SYMPOSIUM BI01

Materials Data Science—Transformations in Interdisciplinary Education
December 2 - December 3, 2019

Symposium Organizers
Raymundo Arroyave, Texas A&M University
Elizabeth Dickey, North Carolina State University
Roger French, Case Western Reserve University
Hiroyuki Fukuyama, Tohoku University

Symposium Support
Bronze
Citrine Informatics

* Invited Paper

SESSION BI01.01: Data Science in Materials Education and Methods Development
Session Chairs: Raymundo Arroyave and Elizabeth Dickey
Monday Afternoon, December 2, 2019
Hynes, Level 2, Room 205

1:30 PM *BI01.01.01
Data Science—The New Critical Capability for Every Materials Scientist Kristen Brosnan; GE Global Research, United States

At GE Research, our mission is to develop innovative technologies and turn those into real products and solutions in the aerospace, power generation, healthcare, additive manufacturing, transportation, and oil and gas industries. Today, we are combining “physics” with artificial intelligence (AI) and machine learning (ML) to invent new materials, revolutionize manufacturing design, processing and inspection across our industrial portfolio. In this talk, I will provide examples of how data science methods are critical to materials discovery, how we are helping to train our work force, and my thoughts on the critical skills needed for today’s Materials Scientist.

2:00 PM *BI01.01.02
Transforming the Science of Materials through the Science of Information—A Pedagogical Perspective Krishna Rajan; University at Buffalo, The State University of New York, United States

This presentation will provide a perspective on how materials informatics can affect how one trains materials scientists and engineers. I will put this in the context of how we have established an entirely new materials department based on building the foundations of materials science through the lens of information science. The pedagogical foundation of MDI is founded on a data intensive perspective of materials science for the study of materials theory, characterization, synthesis, processing and computational and simulation techniques. Our novel pedagogical framework allows students to learn from that data by deriving information that may be outside the models on which they are based, and use this learning process in order to efficiently and robustly explore the information space that cannot be done by existing models

2:30 PM OPEN DISCUSSION

3:00 PM BREAK

3:30 PM *BI01.01.04
Open-Source Tools for Materials Informatics—Atomate, Matminer and Matscholar Anubhav Jain; Lawrence Berkeley National Laboratory, United States

In this talk, I will present our group's work in developing and disseminating three open-source tools for materials informatics: the atomate software (https://atomate.org) for running high-throughput calculations, the matminer software (https://hackingmaterials.github.io/matminer/) for data mining structure-property relationships, and the matscholar software (https://github.com/materialsintelligence/matscholar) for searching and analyzing text data. I will describe usage of these tools and their impact in helping users learn and perform materials informatics studies. For example, atomate makes it possible for users to generate data with high-throughput density functional theory using a high-level software framework. Matminer implements many of the feature extraction routines reported in the materials informatics literature, making it possible for users to rapidly test many different such algorithms for their study, and also collects together sample data sets for testing new algorithms. Matscholar makes it possible for researchers to search for information across millions of published abstracts. Finally, I will discuss usage of these tools with the Materials Project database and their past and potential future role in educational curricula.

4:00 PM BI01.01.05
Materials Software Workshop and Outreach at DOE Materials Genome Innovation for Computational Software (MAGICS) Center Ken-ichi Nomura, Aiichiro Nakano, Priya Vashishta and Rajiv Kalia; University of Southern California, United States

Emerging exascale computing will have a profound impact on materials simulations and machine learning (ML) to enable faster and more targeted material discoveries. This requires a new approach to computational materials science that integrates materials simulations with ML techniques. This interdisciplinary integration, along with the ever-tighter coupling between experiments and simulations, will provide a new platform for ML-enabled materials discovery. Here education and training programs on ML-based methodologies for the materials research community are urgent needs for future scientists and engineers to be competitive in the emerging field.

At the DOE Materials Genome Innovation for Computational Software (MAGICS) Center, we develop open-source materials simulation software, ML tools, training courseware that run on desktops to exascale supercomputers. Center software and databases provide function-property-structure relationships in functional materials to help synthesis and characterization of a wide class of materials. We have provided three hands-on trainings in Center-developed materials software databases so far (106 users from 55 universities, national labs and research institutions), and plan to continue the outreach program at annual MAGICS software workshops. In this talk I will discuss the MAGICS software suite and training courseware, and lessons learned from the software workshops.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607

4:15 PM *BI01.01.06
Incorporating the Principles of Compressed Sensing/Inpainting and Machine Learning into the Implementation of Advanced TEM Methods Nigel Browning¹,²,³, B. Layla Mehdi¹,²,³, Houari Amari¹, Heath Bagshaw¹, Matthew Bilton¹, Andrew Stevens² and Christopher Buurma³; ¹University of Liverpool, United Kingdom; ²Pacific Northwest National Laboratory, United States; ³Sivananthan Laboratories, United States

Transmission electron microscopy (TEM) is a widely used method to observe and quantify the atomic scale structure, composition, chemistry, bonding, electron/phonon distribution and optical properties of nanostructures, interfaces and defects in many materials systems. In addition to observing static structures, in-situ gas and liquid stages now permit dynamic experiments to be performed inside the TEM to observe complex structural and chemical transformations. In all of these cases, the goal in designing and implementing the TEM experiments is to acquire the most information about the sample while the least amount of damaging electron dose is delivered to it—a modern TEM experiment must therefore first determine the “optimal sampling” conditions for the material being studied. In addition, as many TEMs now have direct electron detectors capable of recording 100-1000 images per second or more (resulting in terabytes of data for each experiment), data compression and the use of automated analytics play a key role in interpreting the results of these experiments. The use of compressed sensing and inpainting methods is now being taught as part of the regular senior undergraduate/graduate student course structure.
in advanced TEM methods. In addition, the use of machine learning to improve the analysis of the sub-sampled datasets and data analytics to extract key parameters from a series of images are also key parts of the course. The sub-sampling/inpainting methodology for optimal sensing is hardwired into the acquisition mechanism of the microscopes used for the practical aspects of these microscopy courses, allowing students to directly modify the means by which images are acquired and test its effect on the speed, resolution and precision of the images obtained/reconstructed/analyzed during their training. In this presentation we will discuss the use of TEM images, and in particular obtaining the best TEM image for the lowest dose, to teach the concepts of compressed sensing, inpainting and machine learning as part of a core materials science method. Overall, we have found that the direct atomic scale images of the structure permit students to quickly get a grasp of the main mathematical and data concepts and how to best implement them in their experimental design. Here we will also discuss the application of these same methods onto other materials characterization techniques (and imaging tools in general), the way that users are trained on those methods, and the precision of the results that are obtained.

4:45 PM BI01.01.07
Semantic Exploration of Nanowires Technological Trend and Scientific Advancement  Vasilii Kaliteevskii; Lappeenranta University of Technology, Finland

Within the fast-growing field of nanoscience and nanotechnology, observing and understanding the relation between physical and chemical properties of nanostructures and their potential applications plays a critical role in fueling and channeling future innovations and future perspectives of the field. Nanowires, in particular, have been shown to be excellent object of study to explore new fundamental physical phenomena, yet their integration into working devices has not been progressing at the same rate. The potential commercialization of nanowires could hardly be reliant only on a simple count of growing scientific publication. Therefore, it is necessary to expend the view towards patent publications, with a goal to perform detailed comparative analysis of both technological and scientific knowledge. Patent documents are a superb source of technical information that is not published elsewhere, but at the same time are not peer-reviewed documents. For this reason, separate analysis of knowledge stored in scientific literature or patent databases might lead to an invalid path/picture of current nanowire technology development.

Here, we present possibilities of technologies such as the Natural Language Processing and Machine Learning used in the framework of patent and scientific publications search to support heuristic stage of design of new products and technologies. As a result, the content analysis, together with profiling results can shed a light on the overlap or possible gap between scientific discoveries and technological innovations. Finally, the implementation of heuristic methods such as TRIZ, which are proven to be effective tools for problem solving for classical physics and engineering could inspire combination of different methods, approaches and technologies in the field of nanowires, leading towards inventive solutions in the potential new devices, concepts and technologies, especially at the conceptual design stage.

BI01.02.01
Development of Data Scientists for Interdisciplinary Environments Such as Materials Science  Kazunori D. Yamada¹, Samy Baladram¹, Takuro Nakayama¹, Yinxing Li¹, Roger H. French² and Mitsuyuki Nakao¹; ¹Tohoku University, Japan; ²Case Western Reserve University, United States

Rapid advances in information technology have been drastically changing the world. Informational innovations are affecting people's lives divergently and comprehensively, and data sciences, a foundation to utilize these enormous and diverse data, are of increasing importance. Thus, there is an urgent need for educational institutions to train both experts in data science and to train all types of scientists to have data science skills. Tohoku University has made specific efforts on the education in data science. The “International Joint Graduate Program in Data Science
(GPDS)” and “Data Sciences Program (DSP)” designated for the international students are data science education programs running in Tohoku University. The former targets current students in the university while the latter recruits overseas students and these programs are operated in a coordination. The foundation of data science is undoubtedly statistical analytics and computer science. However, because of the highly-diversified nature of real-world problems, a data scientist cannot be successful with only a focus in a specialized field such as computer science alone. It is expected that data scientists should be easily able to cooperate with experts across many fields in diversified team research projects. In this regard, GPDS and DSP are operated both internationally and interdisciplinarily, in cooperation with overseas universities and other graduate schools in the university.

GPDS and DSP has been focusing on three in important abilities for data scientists. 1) Problem-finding: ability to find a problem from a transdisciplinary perspective and to create a process of solution. 2) Data analysis: ability to analyze the big data to extract the essential information for the problem-solving across diverse fields such as Materials Science and Life Science. 3) Technology architecture: ability to appropriately organize the technological infrastructure necessary for the problem-solving. Based on this direction, GPDS and DSP have been offering lectures, which cover from basic analysis methods to state-of-the-art research topics of data science. Besides the lectures, the educational programs has practical, step-wise training courses. First one is a start-up exercise for beginners of the computer programing, where students learn how to use Linux and Python. Second one is an intensive class based on drills in data analyses, from basic numeric calculation to specialized methods, such as approaches using complex machine learning models. Students successively work out problems, while instructors inspect the answers and codes from each student. By this process, instructors are able to detect weak and strong points of individual students, and to guide a student toward an efficient learning approach. The last one takes project-based learning (PBL) approach. Students are grouped into interdisciplinary teams and each team has heterogeneities in ability in computer programming, fields of specialty and degrees. In the course, students solve realistic problems using real-world data. In previous cases of this PBL training, students with computer skills tended to play a leadership role in a team. For these advanced students, the training course could be an opportunity to fulfill their ability throughout solving complicated real-world problems and to strengthen their expertise by guiding other un-trained team members. Solving a problem in coordination with other team members is definitely an important skill for data scientists and the course give meaningful experience for all students.

In these courses, students deal with various kinds of data from diverse fields, which include material informatics, materials science, natural language processing, plant engineering, blockchain, advertising, biology, bioinformatics and etc. An essential aspect of this learning is the combination of real-world, messy, datasets, and domain scientists, such as Materials Scientists, as critical team members.

B101.02.02
Pathway toward Sustainable Development of Next Generation Photovoltaics Focused on Materials—A Detailed Study on Research Trends through Bibliometrics Jun-Seok Yeo; Korea Institute of Science and Technology, Korea (the Republic of)

The development of sustainable power sources has attracted significant attentions because of the unsustainability of the traditional energies. Among the next-generation power sources, solar energy with photovoltaic (PV) has been considered as a viable alternative. In particular, hybrid organic-inorganic perovskite solar cells (PeSCs) have been intensively explored due to their high performance, high cost-effectiveness, and broader feasibility. In this study, we investigated the research trends and the collaboration networks with the bibliometric methods based on the scientific publications. For the systematic investigations, all the publications were classified by the publication years and the commercialization factors. From publication years of 2009 to 2018, a total of 6,581 documents were investigated. The commercialization factors were categorized by considering the LCOE and the environmental impact of the PeSCs; cost, efficiency, stability, scaling-up, and public acceptability. In addition, multiple bibliometric methods were used in this study: (1) ‘statistical analyses’ of publication output, (2) ‘topic modeling’ based on the publication abstracts, and (3) ‘social network analysis (SNA)’ of co-authorships at institute level. This strategic analysis will provide various aspects of scientific findings, and facilitate further discussion on the direction of the PeSC research.

B101.02.03
Designing Laboratory Activities for Undergraduate Synthetic Materials Chemistry Course Brandon J. Burnett; Weber State University, United States

Creating robust, simple, and safe material synthesis laboratory activities at an undergraduate level is becoming increasingly important as more undergraduate programs are adopting materials chemistry classes and programs. This
presentation will focus on efforts at a PUI to highlight core materials chemistry concepts through hands-on synthetic laboratory activities, including solvothermal syntheses, sol-gel, chemical vapor deposition, powder annealing, synthon design, and computer modeling. We will also discuss opportunities to collaborate with physics departments to incorporate structural and property analyses, for a cross-disciplinary education.

**B101.02.04**
**Developing Selective Absorbers for Solar Water Heating as a Holistic Materials Undergraduate Research Experience** Kristin Rabosky, Corey Collatz and Colin Inglefield; Weber State University, United States

The process of developing new thin film materials can be a rewarding experience as an undergraduate research project exposing students to recipe design for material growth, the intersection of multiple characterization techniques, and incorporating films into useful devices. Additionally, this project is useful in teaching students how to manage and analyze larger data sets garnered from a variety of samples. We are using a series of cermet based selective solar absorbers (SSAs) made with varying ratios of Mo and SiO2 as a platform to teach students about the many pieces in electronic materials development. These SSAs are tested with several characterization techniques to determine film quality and are then incorporated into a prototype water heater to verify optimization of light absorption and heat retention. We have found this project to be a successful platform for teaching students about the iterative cycle of new materials development.

**B101.02.06**
**From Stored Data to Data Stories—Jupyter and R Notebooks for Reproducible Materials Informatics** Paul J. Kowalczyk; Solvay, United States

Literate computing weaves a narrative directly into an interactive computation. Text, code, and results are combined into a narrative that relies equally on textual explanations and computational components. Insights are extracted from data using computational tools. These insights are communicated to an audience in the form of a narrative that resonates with the audience. Literate computing lends itself to the practice of reproducible research. One may re-run the analyses; run the analyses with new data sets; modify the code for other purposes.

This presentation will take one through the steps associated with literate computing: data retrieval; data curation; model construction, evaluation, and selection; and reporting. Particular attention will be paid to reporting, i.e., building a narrative. Examples will be presented demonstrating how one might generate multiple output formats (e.g., HTML pages, presentation slides, PDF documents) starting with the same code base.

As a specific example, a data narrative will be built showing how one might build predictive models for the prediction of band gap energies. Reports will be presented as (1) an HTML file, (2) a PDF document (in a format acceptable for journal submission), and (3) a slide presentation.

The presentation will have three main foci:
1. infrastructure: instantiating the computational environment; loading packages; loading data
2. computation: data curation, transformation, and analysis; model construction and evaluation
3. communication: creating tables, charts, and graphs; weaving all components into data narrative

At the presentation’s conclusion attendees will have walked through exercises that may serve as templates to be used with their data as they build their data narratives.

The R and Python ecosystems will be used throughout. All data, code, and text will be made available.
Graduate education is poised to undergo significant changes as we consider how best to prepare students for a dynamically shifting workforce. Areas of high national need often require scientists and engineers that can work in interdisciplinary/convergent spaces with strong, career-aligned skillsets. This presentation will focus on two National Science Foundation programs within the Division of Graduate Education that support new educational models and approaches. The National Science Foundation Research Traineeship (NRT) program was designed to broaden graduate student career pathways and preparation, foster lasting institutional changes in graduate training, and support interdisciplinary to convergent STEM research. The program currently supports 68 projects across 33 states and territories; each project has a budget of approximately $3,000,000. The Innovations in Graduate Education (IGE) program supports studies to test new approaches and generate the knowledge to identify best practices in graduate education. IGE awards are focused, educational research projects with budgets ranging from $300,000-$500,000. Taken together, these programs are testing new models and approaches that will train inclusive cohorts of STEM graduate students with the appropriate career-aligned skillsets to productively move into diverse career pathways. The presenter is the Lead Program Director for both NRT and IGE. PIs interested in learning more about these funding opportunities are encouraged to attend. Program objectives and exemplary projects will be discussed, and time will be included to answer programmatic questions.

The Materials Genome Initiative (MGI) calls for the acceleration of the materials development cycle through the integration of experiments and simulations within a data-aware/enabling framework. To realize this vision, MGI recognizes the need for the creation of a new kind of workforce capable of creating and/or deploying advanced informatics tools and methods into the materials discovery/development cycle. To meet this need, an interdisciplinary team at Texas A&M University has developed an interdisciplinary program that indeed goes beyond the prescriptions set forth by the MGI as it incorporates the discipline of engineering systems design as an essential component of the new accelerated materials development paradigm.

The Data-Enabled Discovery and Development of Energy Materials (D3EM) program, funded by the NSF Research Traineeship (NRT) program out of the Division of Graduate Education has enabled the creation of an interdisciplinary graduate program at the intersection of materials science, informatics, and design. The program consists of an interdisciplinary curriculum consisting of cross-disciplinary components in the three fields of materials, informatics and design, followed by an interdisciplinary integrative course that has, as its goal, the solution of a real-world materials discovery/development problem motivated by industry or national laboratories. In addition to the technical component of the curriculum, the D3EM program includes a comprehensive professional skill development syllabus that includes career path planning, communication skills, collaboration, leadership as well as an intensive technical writing program based on the POWER method pioneered by the College of Education and Human Development of Texas A&M University.

The D3EM program was created a partnership between TAMUs Center for Teaching Excellence and six departments across the Colleges of Science (Chemistry and Physics) and Engineering (Mechanical Engineering, Chemical Engineering, Electrical Engineering and Materials Science and Engineering) and is at its mid point in its time frame. In this talk I will discuss in detail the pedagogical model underpinning the curriculum as well as different aspects of the program as they relate to fostering interdisciplinarity not only within student participants but also among the entire student cohort and participating faculty.

International Data Corporation predicted that 60% of organization in 2021 will use machine learning approaches for
more extensive data analysis and insights. However, traditional materials engineering education on the undergraduate and graduate levels falls short to address this need. In this talk, I will discuss how NCState response to this shortcoming. For graduate education, we introduced the a graduate certificate which is designed for interdisciplinary graduated education at the intersection of materials science, engineering, and data science with the aim of preparing the next generation of materials engineers given the growing demand for data-science skills and knowledge of the artificial intelligence. The skills and knowledge obtained here will serve as foundation for the understanding of materials informatics and high throughput materials discovery that will improve a student’s career prospects. To address the immediate knowledge gaps in graduate and undergraduate education, we introduced a general hands-on introductory class on Materials Informatics with the aim to introduce the emergent field of materials informatics and current approaches that employ informatics and computational data to accelerate the process of materials optimization, discovery and development. The goal of our efforts was to prepare students to move into career positions that require a basic comprehension of data science techniques as applied to materials science and engineering problems.

9:45 AM BI01.03.04
Challenges and Opportunities in the Development of Data Science Skills in Undergraduate Materials Education—A Perspective from Mexico
Yareli Rojas-Aguirre, Yara C. Almanza-Arjona, Jesús S. Alejandro-Cruz, Lorena Meza-Puente and Marlene Covarrubias-Sánchez; Universidad Nacional Autónoma de México, Mexico

Nowadays, the term nanotechnology is strongly present in many areas of science and engineering. Nanotechnology can be defined as a set of disciplines focused on the study, manipulation, and control of matter at the atomic and molecular level, in order to exploit the properties that it presents in the nanoscale, to generate functional materials with physical and chemical attributes that exceed those we know today. However, after several decades of such research efforts, which are the actual industrial applications of nanomaterials? Which nanomaterials are industrially relevant? What should academic materials nanotechnology research focus on? Which are the main aspects that should be addressed by materials undergraduate students in the field? Despite its popularity in both, academics and the mainstream media, nanotechnology is not sufficiently addressed in the classrooms of Chemical Engineering, Chemistry and other Materials Sciences related undergraduate programs. Materials education and related disciplines have evolved slowly in Mexico because the discipline curriculum remained with no significant changes for almost four decades. One of the primary challenges in current undergraduate materials courses is to incorporate topics, such as Materials Data Science, which are related to several technologies that have enabled the massive production, analyses, and management of scientific data.

The fourth Industrial Revolution (IR4.0) is a technological shift driven by the emergence of robotics, Big Data, Internet of Things (IoT), Smart Manufacturing and Cloud-based Manufacturing. The most important elements of this technological era are machines, devices, sensors, and people, to be in communication with each other through the Internet. Hence, artificial intelligence (AI) and digital-physical frameworks make human-machine interfaces regularly present in our daily life. This new scientific and technological landscape demands a transformation in materials education as new concepts, methods, and technologies not previously taught in college are meant to either substitute or complement the current syllabus. This evolution in materials education is particularly important to learn, discover and design data-driven techniques that will allow future materials scientists and engineers to discover new materials through materials informatics and develop materials by means of machine-learning in order to reduce the time and cost of materials design and deployment.

This work describes the case of study of undergraduate chemical engineering students at the Institute of Materials Research, UNAM, Mexico who engaged in a Technology Intelligence (TI) research project as a learning strategy to analyze the potential applications of nanomaterials at industrial scale through the development of basic Data Science Skills. The objective of the project was to conduct data mining within the cycle of TI in order to collect information, validate and curate data in order to answer the research questions mentioned earlier. The data analysis and visualization enable the students to identify nine areas of the potential application of nanomaterials worldwide at an industrial level in the last 10 years (2009-2019): agriculture, biomedicine, construction, cosmetics and healthcare, electronics, energy, food technology, optics and optoelectronics, and textiles.

By engaging undergraduate students in a data-driven project, students developed basic research and data science skills and transformed their attitude and perception towards the conception of nanotechnology, into a novel and attractive approach by linking fundamental knowledge with state-of-the-art research. Additionally, this educational experience allowed them to acquire other important abilities as decision making, data mining, data curation, data
analyses, data visualization, detection of relevant correlations and communication of results.

10:00 AM BREAK

10:30 AM *BI01.03.05
Data-Driven Materials Design—Educational Needs to Harness Legacy Data for New Materials Development
Jennifer L. Carter; Case Western Reserve University, United States

Data-driven materials design informed by legacy data-sets can enable the education of a new workforce, promote openness of the scientific process in the community, and advance our physical understanding of complex material systems. The performance of structural materials, which are controlled by competing factors of composition, grain size, particle size/distribution, residual strain, cannot be modeled with single-mechanism physics. The design of optimal processing route must account for the coupled nature of the creation of such factors, and requires students to learn machine learning and statistical modeling principles not taught in the conventional undergraduate or graduate level Materials Science and Engineering curricula. Therefore, modified curricula with opportunities for experiential learning are paramount for workforce development. Projects with real-world data provide an opportunity for students to establish fluency in the iterative steps needed to solve relevant scientific and engineering process design questions.

Exploratory data analysis (EDA) coupled with data-driven modeling allows new researchers to quickly orient in a field and gain insight into how and why decisions were historically made. The alloy development in 9-12wt% Cr martensitic steels has been of ongoing for thirty years. EDA quickly highlights the trade-off between short-term strength and long-term creep stability with increasing chromium concentration [1]. Though this knowledge can be gained from careful study of the literature, EDA allows the researcher to gain this institutional knowledge in short order without having to know what or where to look for first in the literature. This reduces the training cycle time and has implications to all R&D sectors facing knowledge transfer challenges as the “Boomer” generation retires.

Data-driven process|structure|performance (P|S|P) modeling provides insights into the oft-competing mechanisms that must be considered and optimized in the design of processing routes for new materials and design performance requirements. P|S|P modeling requires a foundation in statistical principles to assess the significance and quality of the findings. The constraints of different modeling techniques allow researchers to infer different physical qualities from the models [2].

Limitations of legacy data teach students the importance of statistical study protocol development. How to design the next study to mitigate issues of uncertainty and leverage prior knowledge to optimize inference gained from the modeling efforts? This goes hand-in-hand with the development of high-throughput experiments for microstructural characterization and mechanical behavior. For example, the study protocol to deconvolute the time-temperature effects on the kinetics of precipitate formation requires multiple processing steps to extract useful metrics. Next, robust data-science algorithms for analysis of microstructure [3], and mechanical performance [4] are needed to efficiently probe the design space. The approaches are useful for establishing protocols for the procurement of new databases of structure and performance for the process development of alloys from conventional and additive manufacturing.

11:00 AM BI01.03.06
Student Inquiry of Precipitate Morphologies Using an Online GUI for PRISMS-PF Susan Gentry¹, Stephen DeWitt² and Mingwei Zhang¹; ¹University of California, Davis, United States; ²University of Michigan, United States
The morphologies of precipitates in metal alloys can often be complex due to competing mechanisms such as anisotropic interfacial energy and misfit strain energy. For these systems, multiphysics computer simulations can be powerful tools since researchers can artificially “turn off” individual mechanisms while holding all other variables constant. For instance, this approach has been used by investigators to elucidate the effects of misfit strain, interfacial energy, and anisotropic growth rates on experimentally observed precipitate morphologies in magnesium-rare earth alloys. Unfortunately, the inherent complexity of these computer simulations often makes them inaccessible for novice learners.

For educational uses, we have published a tool on nanoHUB that simulates two-dimensional equilibrium morphologies of an isolated precipitate within a matrix. The simulation tool, available at https://nanohub.org/tools/prismspfmisfit, is implemented using a black-box approach with a graphic user interface (GUI). To run a simulation, a user only needs to provide material parameters such as anisotropic interfacial energies, anisotropic misfit strains, elastic moduli, and Poisson’s ratios for the system. Underlying the simple GUI is an application built using PRISMS-PF, an open-source phase field framework that uses the finite element method to solve phase field equations to predict microstructural evolution. The nanoHUB tool launches a finite element simulation for a precipitate in a matrix, which is then evolved until it reaches equilibrium. The equilibrium precipitate morphology is output to the user, along with the dimensions of the precipitate and the volume fraction, for further analysis.

We use this online tool to help materials science and engineering students develop expert knowledge on the fundamentals of precipitate morphology. One trait of a subject-matter expert is the many deep connections between the facts they have learned, such as the interplay between interfacial energy and misfit strain energy. To develop these connections in novice students, we have developed an inquiry-based teaching module. Students are presented with a micrograph of metallic precipitates and are prompted to explain the shape and the aspect ratio based on misfit strain energy and anisotropic interfacial energy. Using the PRISMS-PF tool, students run simulations that vary the misfit strain and anisotropy to build mental models of these effects and ultimately identify the dominant mechanism(s) in the precipitate morphology. Finally, we present an evaluation of metacognitive questions that are used for formative assessment of this activity.

11:15 AM *BI01.03.07
Microstructural Analysis in Python for Materials Data Science Daniela Ushizima¹,², Silvia Miramontes-Lizarraga¹,², Michael Macneil¹ and Dilworth Parkinson¹; ¹Lawrence Berkeley National Laboratory, United States; ²University of California, Berkeley, United States

The growth of X-ray brilliance and extremely quick snapshots allied to advances in machine learning create new opportunities to streamline the description of materials structures as part of the design of new compounds. From industry to national laboratories, X-ray imaging has become fundamental to measure the function and resilience of new materials and for probing dynamic properties. However, the analysis of these rich datasets at scale requires further research in automation that combines computational and experimental methods.

A major challenge is to couple increasing data rate experiments to new data science algorithms in support of quantitative image analysis that can automatically drive the scientific discovery. Our efforts in deep learning applied to image representation and structural fingerprints have made sample sorting and ranking possible, allowing automated identification of special materials configurations from million-sized databases. These complex networks recognize events from data gathered in two regimes: experimentally and by simulation. While such methods successfully bypass hand-engineered features, their full extension to three-dimensional imagery seldom meets standards that are comparable to manual curation. Additionally, labeling large datasets of 3D data is practically impossible.

For example, the inspection of material deformation using X-ray attenuation contrast data from microtomography often generates two thousand cube voxels per volume. The issue is that the creation of millions of labeled volumes means manually handling eight billion voxels per time step for one experimental setting. Therefore, our research efforts also include the creation of the next generation curation tools based on advanced computer vision algorithms addressing fundamental problems, such as multiresolution algorithms for image segmentation (e.g. graph-based
classification and convolutional neural networks), stereological analysis, and enumeration of particles within microtomography imagery.

The contributions of our team include: (a) the development of numerical schemes to analyze data that stem from physical experiments; (b) the construction of new software tools to empower materials scientists and constrain parameter space, particularly given prior knowledge from experimental settings; and (c) the reproducibility of experiments by recognizing the importance of open-source codes and availability of benchmark datasets of scientific images coming from advanced instruments.

This talk will present computational tools for recognition of patterns that occur in scientific images, both coming from synchrotron-based X-ray instruments and simulation through HPC codes. This talk will include scripts for visual analysis and interaction with extracted 3D geometries to be shared with the audience, which will be illustrated on scientific imagery from open-data projects. Use-cases will demonstrate our advancements on inspection of hierarchical materials that consist of many individual strands, bundled within a matrix to achieve high-strength mechanical properties and durability.

11:45 AM BI01.03.08
Nucleation and Growth of AlN—A Case Study of the Challenges in Blending Materials Science and Data Science in an International Collaboration
Masayoshi Adachi¹, Benjamin G. Pierce², Ahmad M. Karimi², Laura G. Wilson², Roger H. French², Jennifer L. Carter² and Hiroyuki Fukuyama¹; ¹Tohoku University, Japan; ²Case Western Reserve University, United States

Aluminum nitride (AIN) is a promising substrate material for AlGaN-based ultra-violet light emitting diodes. In the Fukuyama group at Tohoku University, AIN crystal growth methods have been developed [1] with a recent focus on solution growth using a Ni-Al alloy. In order to design this technique, a fundamental study for the AIN formation on a Ni-Al droplet was undertaken. To understand the growth behavior and design an optimum crystal growth technique, an in-situ observation system for solution growth of AIN crystal using electromagnetic levitation [2] has been developed.

As part of the Tohoku University and Case Western Reserve University collaboration in Data Science for Life Sciences and Materials Science, an international and interdisciplinary research project started, focused on statistical significant quantification of AIN formation behavior, spanning nucleation, growth and coalescence so to design and define an optimum crystal growth technique.

The materials science goal was to profile the nucleation and growth rates of AIN crystals on the spherical liquid Ni-Al droplet. The study protocol, representing the details of how the experiments are to be run, including varying the temperature, the Ni-Al composition ratio, the N₂ gas pressure, and the static magnetic field (which controls the solution flow in the molten droplet). This design space of the crystal growth predictors allowed us to encompass from high to low nucleation rates, and from hundreds of AIN crystalites on the sphere, to controlled single crystal growth. The high speed cameras recorded the droplet from the top and the side simultaneously, and the video images analyzed in this project encompass over 530,000 single frame images. With this large dataset, analysis was done in our distributed and high performance computing environment at CWRU [3]. Image analysis was performed using Python (v2.7) libraries including Matplotlib, Numpy, Scipy, Pandas, Seaborn, Trackpy with Skimage and OpenCV [4-7].

In addition to the technical details, the code development involved graduate and undergraduate students, distributed and high performance computing, data exchanges of large datasets and producing robust codes with a number of students that can be validated and are sufficiently modular so that the pipeline is multi-functional. For code development over a two year period involved 3 undergraduate (UG) and 3 graduate (GS) students who participated sequentially, so proper code styling, commenting, documentation and Git code versioning were essential. In addition, communication between the image analysis students from Materials Science, Mechanical Engineering and Computer Science departments, was enabled by the students all having taken Applied Data Science courses at CWRU, so that the basics of an Open Data Science tool chain, gave them a common framework for both tools and data analysis project structure.

The project goal of the synergistic process may be advanced by French’s teaching Applied Data Science this summer at Tohoku University, with the goal of establishing a “nuclei” of Materials Data Scientists here, which can “grow” into a robust local community of students applying these new and complementary tools to Materials Science problems.
SESSION BI01.04: Novel Experiential Learning and Best Practices in Data-Driven Materials Education

1:30 PM *BI01.04.01  
The Informatics Skunkworks—Undergraduate Research at the Interface of Data Science and Science and Engineering  
Dane Morgan; University of Wisconsin-Madison, United States

Recently there has been an explosion of interest in the application of informatics tools, particularly machine learning, to materials and other domains of science and engineering. A number of features make science and engineering domain specific machine learning applications exceptionally well-suited to undergraduate research. First, relative to many research problems, domain specific machine learning applications are often simple to understand and easy to explore with limited background. Second, research projects in this area develop skills of high-value for future employment or post-graduate education, including technical skills in data science, statistics, programming, and specific domains, as well as broader skills in project management, teamwork, and communication. Third, many problems require only a laptop and free software, or relatively inexpensive computing resources (e.g., a small amount of GPU time). Motivated by the above opportunities I initiated the Informatics Skunkworks. The group has a goal of engaging undergraduates in research dedicated to realizing the potential of informatics for science and engineering, with a focus on materials problems. We have had over a 100 participants since 2015, now with typically over 30 per semester. The projects have had significant impact on students, shown most quantitatively by a strong list of conference presentations, published papers, student awards, and student placement in top graduate programs and companies. Three major challenges we face are (i) how to give students enough information to enable research but not so much that they cannot learn it quickly, (ii) how to allow students to make progress quickly without extensive programming or machine learning expertise, and (iii) how to provide high-quality mentoring given constraints on mentor experience and time. To overcome (i) we have developed a set of modules on key machine learning issues (e.g., machine vision or how to use specific codes) targeted at undergraduates with no background who need to quickly getting a practical working knowledge of the material. To overcome (ii) we have developed the MAterials Simulation Toolkit – Machine Learning (MAST-ML) package, along with useful practice datasets, which allows full machine learning project workflows to be executed from a simple input file with no programming skills and limited machine learning background. To overcome (iii) we are exploring increased program structure and student co-mentoring, but are still far from robust solutions. Our teaching modules and MAST-ML tools allow students to make progress in even just a few hours, supporting not just extended research projects but also class projects and laboratory exercises in this area. In this talk I will describe the mechanics of how we structure the skunkworks, some of the projects we have explored (and their successes and challenges), the resources we have developed to enable this work, and ongoing challenges and opportunities. In particular, I will also discuss our vision for the future and efforts to expand the skunkworks across multiple institutions, and I hope this talk will help start collaborations with others with shared interests to develop integrated efforts going forward.

Final Program 1/13/2020  11
Hackathons Foster Collaboration between Materials and Data Scientists
Brian Reich, Ashleigh Wright, Ralph Smith and Elizabeth C. Dickey; North Carolina State University, United States

Materials science is increasingly turning to data science to extract meaningful inference from large data streams. However, collaborations between researchers within the materials and data-science fields face several challenges including language barriers and domain-specific norms and expectations. In this presentation we discuss our experiences with using a “hackathon” to bridge this gap. We discuss two hackathons models in which participants work intensely for a short time in small groups to develop data-science solutions to authentic materials-science problems. The first hackathon model was implemented in an international workshop with established scientists, while the second model was implemented in a local environment comprised mostly of graduate students. In both cases, we found that short periods of intense interaction resulted in productive interdisciplinary teams. In the talk we discuss the advantages of various formats, approaches that were and were not effective, and offer suggestions for future endeavors and best practices.

Teaching Machine Learning and Artificial Intelligence in Materials through Experiential Learning
Joshua Tappan; Citrine Informatics, United States

Josh Tappan, Citrine Informatics’ head of community, will share Citrine's approach to materials informatics education initiatives. Citrine has successfully run several hands-on, experiential programs with universities across the country.

Josh will share the details of Citrine’s NextGen fellowship, which, over the course of 3 years, has supported 50+ undergraduate students in materials informatics research projects across the United States, as well as the Mines Initiative for Data Driven Materials Innovation (MIDDMI), a partnership with the Colorado School of Mines, which helped 8 student groups incorporate machine learning and materials informatics techniques into their research. Additionally, he will discuss Citrine's approach to education and curriculum development in the industrial materials community.

Audience members will be able to access some of the open educational resources Citrine developed as part of these programs.

SonicAtomic—New Interactive Sonification Interface for Students with Visual Impairment Assisting Multi-Dimensional Scientific Data Analysis
Thomas Watts1, Ahlam Lee2, Roberto Myers3 and Jinwoo Hwang3; 1Cornell University, United States; 2Xavier University, United States; 3The Ohio State University, United States

We present a novel interactive sonification interface that allows people with visual impairments to perceive the multi-dimensional scientific data using their auditory sense. People with disabilities are traditionally underrepresented in science, technology, engineering, and math (STEM) fields. Developing new accommodation technology for them is therefore important to motivate their participation in scientific research and education, which could cultivate a diverse STEM workforce and ultimately meet the nation’s STEM workforce needs. The participation of people with disabilities in STEM fields that typically provide a higher-paying and more secure job will also enable them to join mainstream society and serve as role models for people with disabilities and many other underrepresented groups. In this regard, we focus on the people with visual impairment, whose participation in STEM research and education has been especially low because the majority of scientific data acquisition and analysis processes tend to heavily rely on visual perception. We develop a new digital interface that converts the multi-dimensional scientific data (e.g. electron microscopy images) to sound waves, a process called sonification, which allows individuals to perceive and understand the data using their auditory sense. We opted to develop our sonification software for the 6th generation of the Apple iPad. The first prototype of our iPad application is built to sonify a high-angle annular dark-field image of a β-Ga3O2 lattice. The image is converted to an intensity matrix whose entries are the pixel intensity of the image in 16-bit grayscale. A portion of the iPad’s screen is mapped to points on the image (e.g. entries of the intensity matrix). Based on the location of the user touch on the iPad’s screen, the associated point on the image is converted to sound through one of two modes of functionality. Our first
mode of sonification takes advantage of the human ability for acute pitch discrimination and leverages variations in pitch in order to give the impression of vertical location of the sound source. We elected to associate points of the image of higher pixel intensity to higher frequencies and points of lower intensity to lower frequencies. We conjecture that blind individuals would be able to trace their finger along the iPad’s screen and identify irregularities in the \( \beta\)-Ga_3O_2 lattice (e.g. crystallographic defects) that would appear as a distinct, underrepresented range of frequencies in the sonic space generated by the image. Our second mode of sonification utilizes the perceived loudness of a sound, through variations in amplitude, in order to give the user the impression that the sound, produced based on their touch input, is originating from some point in 3D space. This approach to sonification leverages the fact that blind users are more sensitive to “binaural sound-location cues.” We further conjecture that, through this second mode of functionality, blind users will be able to gain a spatial understanding of the \( \beta\)-Ga_3O_2 lattice and detect variations in the number of Gallium atoms per atomic column. Our hope is that this application will serve as a framework for more advanced sonification techniques may be built upon.

3:00 PM *BI01.04.05
An Overview of Educational Efforts in Materials Data Science at Northwestern
Christopher Wolverton and Peter W. Voorhees; Northwestern University, United States

Data science and data-driven efforts are making substantial impact on the discipline of Materials Science and Engineering. The underlying techniques and research in this area need to be incorporated into educational efforts and curriculum in order to prepare MSE students to use these methods in their materials work. In this talk, I provide an overview of some of the educational efforts in Materials Data Science at Northwestern. There are substantial efforts in this area in faculty members’ research, and these topics naturally have entered the educational curriculum. There are many examples of the incorporation of computational tools into both the undergraduate and graduate curriculum. These are focused on both the tools themselves, but also on the data and databases that result, and the use of these databases in materials design and discovery efforts. In additional, the Center for Hierarchical Materials Design (CHiMaD) is a center of excellence for advanced materials research focusing on developing the next generation of computational tools, databases and experimental techniques in order to enable the accelerated design of novel materials and their integration to industry, one of the primary goals of the U.S. Government's Materials Genome Initiative (MGI). The research within CHiMaD also provides opportunities for educational impact as well. Finally, we discuss the Integrated Computational Materials Engineering (ICME) Master’s program, in which students participate in interdisciplinary courses and seminars where some integrate machine learning methods in materials projects in collaboration with Computer Science faculty.

3:30 PM BI01.04.06
Learnings from Developing a Materials Data Science Curricula for Undergraduates and Graduate Students
Roger H. French; Case Western Reserve University, United States

Data science arises from advances in computing, communication, and data resulting in the ability to develop data-driven models based on large petabyte scale datasets. These distributed computing approaches, complemented by the ease of acquiring large datasets at petabyte scale, is driving the digital transformations of industry, science and technology and society itself. These approaches, complement the “petaflop” computing characteristic of high performance computing, used in materials science such as the materials genome initiative and integrated computational materials engineering research. One challenge for materials data science is that typically materials science datasets have been small and sparse, in comparison to epidemiological studies in the life sciences. Data Science combines advances in statistics, computer science and domain science (such as materials science) to enable new understandings through the application of statistical and machine learning and most recently deep learning. Consider “pure” data scientists as specialists in the academic fields of math and statistics, and computer science. A need arises to develop broader data science skills across the workforce to produce T-shaped graduates, with deep skills in a domain science such as materials science, while at the same time having broad skills in data science[1].

In 2013 we launched a 1 year study to design an applied data science (ADS) undergraduate minor, available to students across our university. These ADS students learn programming, inferential statistics, exploratory data analysis, modeling and prediction and complete a semester long data science project[2]. The ADS minor, started in
2015, and has grown to include 100 undergraduate and graduate students last academic year. The ADS curricula is taught using an open data science tool chain focused on open and reproducible science, based on R/Rstudio, Python, Git, Markdown and LaTeX to produce, compilable data analyses. In R, for example, advances such as the TidyVerse package of pipes and pipelined code and GGPlot2 for the grammar of graphics for data visualization are major steps towards realizing Donald Knuth’s vision of literate programming and are well matched to today’s multi-disciplinary team research [3].

For materials data science, we now offer a data science concentration, focusing the ADS courses on materials problems while addressing the core challenges of integrating data science with the physical and chemical sciences foundations of Materials Science. Essential to adoption of data-driven modeling is demonstrating how they do not replace our physical and chemical theories, models, and experimental experience. Instead they are a new tool, adding statistical power and significance, with improved inference and prediction. And these analyses must be subject to robust validation, using training and testing splits of the data.

Materials data science is not only an educational challenge, but also calls for advancing how we perform our research experiments and acquire data for analysis. A study protocol, encompassing the samples, their exposures and the evaluations performed on them, constitutes the basis of the metadata, the predictors and the responses of the experiment. In many experiments, it is possible to augment the experiment with additional predictors measured in sufficient numbers to provide statistically sound results. Having materials scientists knowledgeable about these data issues is an important to advancing our research methods.

3:45 PM BI01.04.07
Experiences of MIT MechE Faculty Integrating Machine Learning into Teaching Tonio Buonassisi and George Barbastathis; Massachusetts Institute of Technology, United States

The accelerated maturation of data science and machine learning tools has stimulated their integration into university curricula. Herein, we summarize certain efforts within the MIT Department of Mechanical Engineering, including: (1) The design and delivery of in-class and online teaching modules to upskill MIT MechE graduate-student researchers in datasci/ML; (2) project-based learning activities, i.e., learning by doing; and (3) outreach beyond graduate and undergraduate curricula. We evaluate the hypothesis that the artful integration of these tools into curricula enhances students' intuition for problem framing and solving, especially in systems with manifold inputs and outputs. We hope that our sharing sparks dialogue about evolving expectations for university curricula, at the intersection between traditional disciplines and these new tools.

4:00 PM BI01.04.08
Intellectual Community as a Bridge of Interdisciplinary Graduate Education in Materials Data Science Chi-Ning Chang, Clint Patterson, Debra Fowler and Raymundo Arroyave; Texas A&M University, United States

Recognizing materials development was advancing slower than technological needs, the Materials Genome Initiative (MGI) advocated an interdisciplinary approach employing an informatics framework in materials discovery and development. In response, an interdisciplinary graduate program, funded by National Science Foundation, was designed at the intersection of materials science, materials informatics, and engineering design, aiming to equip the next generation scientists and engineers with Material Data Science. The curriculum spans three stages: disciplinary grounding, multidisciplinary courses, and an interdisciplinary course and research. Over a two year period, students work with faculty and students from multiple fields, such as Physics, Chemistry, Materials Science and Engineering, Chemical Engineering, Electrical and Computer Engineering, Mechanical Engineering, Aerospace Engineering, and Industrial and Systems Engineering. Envisioning challenges in this interdisciplinary learning environment, distinctive and blended faculty and student intellectual communities enhance interdisciplinary collaborations and communications.

To connect faculty members from different disciplines, a Faculty Community of Scholars offers a biweekly platform to share an interdisciplinary culture, appreciate and formulate interdisciplinary partnerships and collaboration, and
maintain a communication cadence between members. For students, the program facilitates various intellectual communities. *Student Learning Community* and *Writing Community* meet weekly throughout the first semester of the program. These two intellectual communities not only assist students in the development of transferable skills (interdisciplinary communication and collaboration, critical thinking, ethical behavior, organization and management, and writing), but also devote effort to reduce disciplinary barriers by providing opportunities for students to present their disciplines and research as well as reflect on the gaps among disciplines. Students lacking a solid background in Data Science prior to taking multidisciplinary courses (e.g., materials informatics) and an interdisciplinary course and research (materials design studio), can participate in *Statistics and Python Coding Boot Camp* led by a senior student. Once students begin exposure to Materials Data Science in materials informatics class and materials design studio, a *Peer-Mentoring Group* of senior students help students with statistical issues, disciplinary gaps, and interdisciplinary research. Additionally, a peer and senior student led *Writing Feedback Group* is available to students writing an interdisciplinary research paper. To overcome barriers in the teacher-learner connection, each faculty mentor can facilitate *Coffee Talks* where both faculty and students interact and learn anew. Students generate topics for collegial discussions about career paths, career preparations, academic publication, dissertation writing and defense, funding, teaching, and so on.

In this presentation, we will discuss the implementation of intellectual communities bridging the components of this interdisciplinary graduate program. We will also consider lessons learned from our unique and innovative amalgamation of learning and teaching strategies and ways in which other institutions can implement similar methods.

**4:15 PM BI01.04.09**

*Changes in the Number ofDoctoral Degree Holders inComputational Materials Science in Japan During the Last 50 years—Text Data Mining Analysis on the Difference between Research Universities and Education-Oriented Universities*  
Yayoi Terada and Tetsuo Mohri; Tohoku Univ, Japan

Progress in computational materials science (CMS) has recently accelerated the discovery of advanced and novel materials. However, there have been few quantitative analyses regarding the change in the number of doctoral degree holders (doctors) who support and promote CMS in Japan.

We estimated the change in the number of doctors in CMS in Japan during the last 50 years. We analyzed the subjects of more than 150 thousand doctoral dissertations in science and engineering (SE) found in a Japanese doctoral dissertation database using text data mining techniques. The number of doctors in SE rapidly increased during the 1990s due to a reorganization of the graduate school and peaked at approximately 2000. Then, it rapidly decreased due to the recent birthrate decline. However, we found that the number of doctors in CMS continued to increase until approximately 2010. In addition to that, the decrease rate of those after 2010 has been small. Therefore, the ratio of doctors in CMS to those in SE has continued to increase. This indicates that the importance of researchers in CMS has been constantly enhanced and recognized.

We also analyzed the differences and similarities between doctoral theses in research universities and those in education-oriented universities in Japan. As a result of the analysis, we found that research universities are leading the national trend of the number of doctors in SE and CMS and the ratio of the number of doctors in CMS to those in SE. On the other hand, at the education-oriented universities, new doctoral courses have been established since the 1990s. Change of number of doctors in SE (especially in engineering) in education-oriented universities followed those of research universities and national trend. It has increased rapidly, and then has dropped rapidly as same as research universities. However, the ratio of the number of doctors in the CMS to those in SE in education-oriented universities was almost constant.

We analyzed keywords in the title of theses in both universities. We found that keywords related to application and simulation appear more frequently in theses of education-oriented universities. On the other hand, the keywords related to theory appear more frequently in theses of research universities. This indicates that research universities foster the researchers who orient more fundamental research and education-oriented universities foster the researchers who orient more applied research and practical research.
Metasurfaces are arrays of subwavelength anisotropic light scatters (optical antennas) that can produce abrupt changes in the phase, amplitude, or polarization of light. Within last few years significant progress, design of metasurfaces that refract and focus light, enabling many unique properties and applications such as holograms, optical vortex generation/detection, ultrathin focusing lens, perfect absorber, etc.

This tutorial will cover the fundamental principles, advanced designs and technological applications of optical metasurfaces, particularly focusing on the topics of (I) the development of high performance metasurface components and systems, (II) the advancement of nano-electro-mechanical systems (NEMS) based tunable dielectric metasurfaces, (III) synthetic interfacial optics with metasurfaces and 2D materials, and (IV) the numerical design methods for high performance dielectric metasurfaces.

8:30 AM
**Creating Metasurfaces and Metadevices with Mie Resonators** Mark Brongersma; Stanford University

Semiconductor nanostructures are at the heart of electronic devices and systems. When properly sized and shaped, they can also support optical, Mie-type resonances that are capable of boosting light-matter interaction over bulk materials. By combining their desirable electronic and optical properties, it is possible to create new optoelectronic functionalities. In this tutorial talk, I will start with a discussion of the basic properties of Mie resonators and show how they have been harnessed to create a large variety of passive metasurfaces. One of the key application areas for passive metasurfaces is the realization of flat optical components that can replace more bulky traditional counterparts (e.g. lenses and gratings). One of the next frontiers is to realize active flat optics capable of dynamically shaping optical wavefronts to e.g. tune the focal length of a lens or to actively steer laser beams. I will illustrate different approaches to achieve such active functions. Another area of interest that I will highlight is the development of Mieresonant antennas and metasurfaces that enable real-time measurement of the wavelength, polarization state, angle of incidence and angular momentum of light.

10:00 AM BREAK

10:30 AM
**Synthetic Interfacial Optics with Metasurfaces and Transition Metal Dichalcogenide Monolayer** Cheng-Wei Qiu; National University of Singapore, NUS Suzhou Research Institute (NUSRI)

Metasurfaces and 2D materials have been developing as two important candidates in the interfacial engineering, providing a plethora of new possibilities in novel optoelectronic functions and applications. The synergies between
those two domains hold great promises in manipulating light-matter interaction. In this tutorial talk, I will review and report some of the most recent developments in this field of interfacial engineering, via the artificially constructed hybridized structures of ultrathin thickness compared to the wavelength. In particular, the low-dimension and high-frequency scaling may promise a lot more applications, while the challenges in design principle and fabrication capability will become critical limits. The atomic thickness of 2D monolayers provides many interesting physical properties, while also limits the sufficient interaction with the light. Hence, nano-patterned metasurfaces are deployed with 2D monolayers to modulate and structure novel light behavior. The following advanced functional optical devices, developed by our group, will be discussed: 3D meta-hologram, high-pixelated nanoprinting, dynamic OAM generation, and more interestingly, the 2D-material meta-lens of <1nm thickness, significantly enhanced SHG, PL, and tunable structural colors, by the coordinated hybridization between those two parties. Our work paves a roadmap to design sophisticated and advanced optical devices, with low dimension, miniaturization, randomness, and scaled-up capability.

1:30 PM
High Performance Metasurface Flat Optics: from Components to Systems Federico Capasso; Harvard University

Metasurfaces are leading to the emergence of new optical components that circumvent the limitations of standard refractive and diffractive one by enabling dispersion engineering, which also leads to entirely new functionalities based on the local control of phase amplitude and polarization. The formulation of the generalized Snell’s law for metasurfaces and the use of dispersion engineering has led to the demonstration of metalenses with correction of monochromatic aberrations and to achromatic single lenses across the entire visible spectrum. The planarity of flat optics will lead to the unification of semiconductor manufacturing and lens-making, where the planar technology to manufacture computer chips will be used to make CMOS compatible optical components for a wide range of applications. Instruments based on flat optics will be discussed such as ultracompact spectrometers, endoscopes for the detection of bronchial cancer, polarimeters and polarization sensitive cameras without moving parts and conventional polarization optics.

3:00 PM BREAK

3:30 PM
Nonlinear Optical Metasurfaces: From Enhanced Light-Matter-Interaction to Full Phase Tailoring Thomas Zentgraf; Paderborn University

For efficient nonlinear processes, the engineering of the nonlinear optical properties of media becomes an important task. The most well-known technique for spatially engineering nonlinear optical properties is the quasi-phase matching scheme for second-order processes like second harmonic generation. However, the widely used technique of periodic polling of natural crystals only provides a binary state for the nonlinear material polarization, which is equivalent to a discrete phase change of π of the nonlinear polarization. The continuous tailoring of the phase of the nonlinear susceptibility would greatly enhance flexibility in the design and reduce parasitic effects.

In this tutorial, we will discuss nonlinear metamaterials with a continuously controllable phase of the local effective nonlinear polarizability. We will focus on plasmonic metasurfaces with various designs for the meta-atom geometry together with different polarization states of the light. In particular for circular polarization states, the controllable nonlinearity phase results from the phase accumulation due to the polarization change along the polarization path on the Poincare Sphere (the so-called Pancharatnam-Berry phase) and depends therefore only on the spatial geometry of the metasurface. By using a fixed orientation of the meta-atom, the nonlinear phase can be spatially arbitrarily tailored over the entire range from 0 to 2π. In contrast to the quasi-phase matching scheme, the continuous phase engineering of the effective nonlinear polarizability enables complete control of the propagation of harmonic generation signals, and therefore, it seamlessly combines the generation and manipulation of the harmonic waves for highly compact nonlinear nanophotonic devices.

We will discuss the concepts of enhancing nonlinear processes with simultaneous phase engineering for the manipulation of second- and third-harmonic generation from metasurfaces and the restrictions with respect to
symmetry and geometry of meta-atoms. Nonlinear metamaterials have fundamental significance in nonlinear optics and for tailored nonlinearities, as they provide a further degree of freedom in the design of nonlinear materials.

Dynamic Two-Dimensional Optical Phased Array Metasurfaces—Connecting Nanophotonic and Array Architecture Design Harry A. Atwater; California Institute of Technology, United States

Over the last several years, there has been intensive worldwide effort to explore dynamic and reconfigurable nanophotonics, driven mainly by innovation at the component level. True two-dimensional optical phase array metasurfaces with reconfigurable elements represent a new opportunity for nanophotonics, and here we describe a design approach linking nanophotonic device and array-level architectural design. The results show a surprising ability to achieve near-ideal optical phased array performance for several functions, including beam steering and reconfigurable lens operation, even with the use of highly non-ideal individual nanophotonic devices. We will show experimental results for a ‘universal’ reconfigurable metasurface in which a single dynamically reconfigurable optical phased array aperture can be used to perform multiple functions.

8:45 AM *EL01.01.02
Strong Light-Matter Coupling in Atomically-Thin Semiconductors Deep M. Jariwala; University of Pennsylvania, United States

The isolation of stable atomically thin two-dimensional (2D) materials on arbitrary substrates has led to a revolution in solid state physics and semiconductor device research over the past decade. A variety of other 2D materials (including semiconductors) with varying properties have been isolated raising the prospects for devices assembled by van der Waals forces.1 A fundamental challenge in using 2D materials for opto-electronic devices is enhancing their interaction with light, ultimately responsible for higher performance and efficiency in the devices. In particular, for photovoltaics; inorganic materials (e.g., Si, GaAs and GaInP) can concurrently maximize absorption and carrier
collection. But thin film absorbers have lacked the above ability often due to due to surface and interface recombination effects. In contrast, Van der Waals semiconductors have naturally passivated surfaces with electronically active edges that allows retention of high electronic quality down-to the atomically thin limit. First, I will show our recent work on photovoltaic devices from transition metal dichalcogenides of molybdenum and tungsten such as MoS2, WSe2 etc.\textsuperscript{2,4} as well as more recent work on high open circuit voltage devices. Next we will focus on the subject of strong light-matter coupling in excitonic 2D semiconductors. Visible spectrum band-gaps with strong excitonic absorption makes transition metal dichalcogenides (TMDCs) of molybdenum and tungsten as attractive candidates for investigating light matter interaction and applications as absorbing media in opto-electronics.\textsuperscript{3,5} Further, the excitonic features become more prominent as the layers are thinned down and dominant in the monolayer limit where the TMDCs transition into direct band-gap semiconductors with strong photoluminescence. In addition, TMDCs are known to have very large values of optical constants which allows strong light trapping even in ultrathin samples.\textsuperscript{2} We will present our recent work on the fundamental physics of light trapping in multi-layer TMDCs when coupled to plasmonic substrates. We systematically demonstrate via calculations and matching experiments that the presence of strong excitonic resonances in multilayers (< 20 nm thickness) combined with surface plasmon excitations of the nearby metals can achieve strongly coupled modes with apparent voided crossings in reflectance spectra. Further, we explore additional light confinement by patterning 1D arrays of rectangular resonators of varying widths and periods (100 nm to 500 nm). We observe newer and higher order modes appear with increasing TMDC thicknesses and widths. Simulated field profiles suggest that these modes range from mainly plasmonic to even hybrid nature as well as guided modes for longer wavelengths and thicker TMDCs. Further, the plasmonic mode exhibit strong dependence on 1D array grating period.

10:15 AM *EL01.02.01
\textbf{Meta-Optics—Meta-Lens for Imaging and Sensing} Din-Ping Tsai\textsuperscript{1,2,3}, Mu-Ku Chen\textsuperscript{2,1,3}, Ren Jie Lin\textsuperscript{1,2}, Cheng Hung Chu\textsuperscript{2} and Lin Li\textsuperscript{2}; \textsuperscript{1}National Taiwan Univ, Taiwan; \textsuperscript{2}Academia Sinica, Taiwan; \textsuperscript{3}The Hong Kong Polytechnic University, Hong Kong
Metalenses consist of a large number of optical nanoantennas which are capable of focusing the incoming wavefront of light [1-6]. We use a $60 \times 60$ dielectric achromatic metalens array to capture multidimensional optical information. The highest efficiency can be up to 74% at a wavelength of 420 nm, while the average efficiency is approximately 39% over the whole working bandwidth. The light field images and the depth information of objects can be determined by reorganizing the patches of sub-images and calculating the disparity of neighbor sub-images, respectively. The depth information can be used to optimize the patch sizes to render the all-in-focus images without artifacts. The smallest feature of objects that could be resolved in our system is 1.95 μm under the incoherent white light. Our work provides several advantages associated with light field imaging: elimination of chromatic aberration, polarization selectivity and compatibility of the semiconductor process. Considering the flexibility, the achromatic multiplexed metalens array with integrated functionalities may be promising for multifocusing microscopy, high-dimensional quantum technology, hyperspectral microscopy, micro robotic vision, nomen automobile sensing, virtual and augmented reality (VR and AR), drones, and miniature personal security systems [7].

Color Print and Color Holography Using Single-Layer Silicon Metasurfaces Thomas Zentgraf; Paderborn University, Germany

Metasurfaces possess an outstanding ability to tailor the phase, amplitude and even spectral responses of light with unprecedented ultrahigh spatial resolution, thus have attracted significant interests for several applications in optics. Here, we propose and experimentally demonstrate a novel meta-device that integrates color printing and computer-generated holograms within a single-layer dielectric silicon metasurface by modulating spectral and spatial responses at the subwavelength scale, simultaneously. With our design, such a metasurface appears as a microscopic color image under white light illumination, while encrypting two different holographic images that can be projected to the far field when illuminated with red and green laser beams. The metasurfaces consist of two types of meta-atoms made by amorphous silicon, each of them acts as a color filter under white light and provides a color channel for a specific wavelength to independently manipulate phase distributions by utilizing their orientations angles. Both the phase and spectral responses can be defined at a subwavelength scale simultaneously and independently. For the hologram design, we developed a modified parallel iterative Gerchberg-Saxton algorithm, which obtains holograms for arbitrary shapes to adapt “color-printing” indexed pattern. Such an algorithm is the key to the wavelength multiplexing holograms by utilizing the color filter property (wavelength selectivity) of the two designed meta-atoms. The method can further extend the design freedom of metasurfaces. By exploiting spectral and spatial control at the level of individual pixels formed by the meta-atoms, multiple sets of independent information can be introduced into a single-layer device that requires only a single lithography step. The additional complexity and enlarged information capacity are promising for novel applications such as information security and anti-counterfeiting.

Electrically Reconfigurable Metasurfaces Based on Phase Change Materials Yifei Wang¹, Patrick Landreman¹, Kye Okabe¹, Umberto Celano¹-², H.S. Philip Wong¹ and Mark L. Brongersma¹; ¹Stanford University, United States; ²imec, Belgium

Active tuning of nanophotonic devices has many potential applications. Such tuning can be achieved by changing either the shape or material properties of a structure. Phase-change materials, such as Germanium Antimony Tellurium (GST), are of particular interest as they can exhibit large and non-volatile changes in their refractive index. Pulsed laser illumination has effectively been used to induce phase transitions in GST-based optical devices. Such changes can cause large changes in the optical scattering properties in the near-infrared. However, electrical tuning of GST-based photonic antennas and metamaterials has remained elusive.

Here we present optical antennas and metasurfaces combining phase-change material and plasmonic structures. By
inducing phase-changes electrically in optical antennas, we achieve reversible multi-level tuning of scattered light intensity by more than 30%. Metasurfaces, designed as a perfect absorber, show over a 3-fold enhancement of reflection in the visible wavelength range between phases. This work demonstrates a first GST-based active metasurfaces working in the visible wavelengths, showing the potential to develop randomly-accessible metamaterial platforms in which metamolecules can be individually controlled.

All-Optical Isolation with Nanoscale High-Q Chiral Dielectric Metasurfaces Jefferson Dixon, Mark Lawrence, David R. Barton and Jennifer A. Dionne; Stanford University, United States

Photonic systems promise larger bandwidths, increased speeds, and reduced power consumption compared to their electronic counterparts. An optical diode analogous to an electrical diode represents the most fundamental device needed to realize such photonic platforms. Current optical diodes rely on the relatively weak magneto-optical effect, which requires high magnetic field strengths and long optical path lengths (> 100 µm) to break reciprocity. In order to miniaturize optical nonreciprocity and develop an optical diode that is scalable with current electronics (< 1 µm), we present a scheme based on Stimulated Raman Scattering (SRS) and discuss the design of an intrinsically chiral metasurface that supports diode-like behavior when combined with SRS.

Optical chirality in a dielectric metasurface requires coupled, non-orthogonal electric and magnetic dipole moments. Using full-field electromagnetic simulations, we investigate a dielectric metasurface comprised of cylinders that allow for the individual tuning of electric and magnetic Mie resonances by modifying their diameter and height, respectively. For a Si metasurface with a cylinder height of 600 nm and diameter of 500 nm organized into a square lattice with a period of 1.2 µm, transmission approaches unity at a wavelength of 1830 nm – a result of the overlap of the electric and magnetic dipole moments. Next, we break the orthogonality of electric and magnetic modes by introducing a notch into the center of the cylinder. We sweep notch depths from 50 nm to 300 nm with a notch diameter of 80 nm. The effective electric current loop that defines the magnetic dipole resonance is perturbed by the introduction of the notch, thus resulting in nonorthogonal dipole moments and a resonance in transmission at 1830 nm. By offsetting the notch in different directions in neighboring disks, we break four-fold rotational symmetry for the entire unit cell both geometrically and optically. This geometry exhibits a significant chiral response. For a metasurface array with a lattice period of 1.2 µm, cylinder height of 640 nm, diameter of 500 nm, and optimized notch positions, the difference in transmittance between L-CP and R-CP exceeds three orders of magnitude at a resonant wavelength of 1895.5 nm. This resonance exhibits a Q-factor exceeding 10^4 and can be optimized for even higher Q-factors by shifting the magnetic dipole moment via the height of the cylinders.

Next, we show how this chiral response can enable all-optical isolation through SRS. The probe beam frequency is set to the chiral resonance defined at 1895.5 nm. The pump frequency is Stokes-shifted by the frequency of the optical phonon (15.6 THz in Si) and is set to 1725.3 nm. Importantly, the pump handedness is fixed to L-CP and the probe must also be L-CP to transmit with amplification; a R-CP probe would be orthogonal to the L-CP pump and would not experience amplification. With probe illumination from the backwards direction, a L-CP probe will not experience amplification due to its orthogonality with the rotation of the pump, and a R-CP probe will be reflected by the chirality of the metasurface. This system results in a highly-asymmetric response, where transmission is enhanced for only the L-CP probe in the same direction as the pump illumination, thus resulting in near diode-like behavior for pump powers > 2 MW/cm². For a pump power of 5 MW/cm², the L-CP probe in the forward direction experiences transmittance > 2x more than any other probe handedness and direction. This asymmetry in transmission can be further enhanced by optimizing a geometry that minimizes polarization conversion, approaching values comparable with electronic diodes. This work presents both a general exploration of intrinsic chirality in metamaterials and an entirely new scheme for achieving optical isolation at the nanoscale.

11:45 AM EL01.02.05
Anisotropic Metasurfaces as Tunable SERS Substrates for 2D Materials Vrinda Thareja¹, Pieter G. Kik²,¹, Majid Esfandyarpour¹ and Mark L. Brongersma¹; ¹Stanford University, United States; ²University of Central Florida, United States

The reflection of light from metallic mirrors results in a near-zero electric field at their surface. This precludes strong light-matter interaction between such mirrors and two-dimensional (2D) materials placed in direct contact with them. Patterning of metal surfaces with sub-wavelength grooves can produce anisotropic metasurfaces that...
offer robust enhancements in the magnitude of fields near the surface, and control over their direction. Here, we use this control to analyze the Raman tensor for vibrational modes of atomically-thin graphene.

To study metasurface-enhanced Raman scattering from 2D materials, we pattern sub-wavelength groove arrays into a gold surface by means of focused ion beam milling. Optical reflection measurements show clear absorption resonances associated with gap plasmon modes excited in the grooves, with a resonance wavelength that can be controlled by varying the groove depth. Metasurfaces with groove depths ranging from 30-210 nm were prepared, and monolayer graphene was transferred onto the patterned surfaces. Reference Raman spectra taken on a smooth gold film under 532 nm excitation show a weak Raman signal from the graphene G peak and 2D peak. Spectra taken on the nearby patterned region show clear enhancement of the graphene G peak and 2D peak, with maximum Raman enhancement occurring for a groove depth of 70 nm. Notably, a much larger enhancement factor of ~50 was observed for the 2D peak compared to a factor ~25 for the G peak. We show that this vibrational mode-dependent enhancement can be quantitatively understood by considering the anisotropic nature of the metasurface and the specific tensorial nature of the Raman polarizability of the graphene vibrational modes. Numerical simulations of the enhancement as a function of groove depth show remarkable agreement with the measured data. Our findings demonstrate that anisotropic metasurfaces can be used as reliable and tunable surface enhanced Raman scattering substrates for the investigation of the vibrational modes of 2D materials.

High-Speed Quantum Photonics with Plasmonic Metamaterials Empowered by Machine Learning Simeon I. Bogdanov, Zhaxylyk Kudyshev, Alexander Kildishev, Alexandra Boltasseva and Vladimir M. Shalaev; Purdue University, United States

We outline future directions in the development of a platform for high-speed integrated quantum photonics, the use of plasmonics to outpace quantum decoherence and the application of machine-learning techniques for photonics designs and quantum optical measurements.

2:00 PM EL01.03.02
Propagation and Spectral Sorting of Single Photons in High-Index Dielectric Nanowires Mélodie Humbert1,2, Peter Wiecha2,3, Gérard Colas des Francs4, Aurélie Lecestre1, Guilhem Larrieu1, Christian Girard2, Vincent Paillard2 and Aurélien Cuche2; 1LPCNO, Toulouse University, CNRS, INSA, France; 2CEMES - CNRS, France; 3LAAS - CNRS, France; 4ICB, CNRS, Bourgogne-Franche Comté University, France

We show both experimentally and theoretically that dielectric nanowires made of Silicon (Si-NW) are efficient waveguides allowing the wavelength-dependent transfer of visible photons from broadband quantum emitters. We first study the photodynamics of single NV centers in nanodiamonds positioned in the vicinity of such high index dielectric nanowires. Then, we demonstrate that the 1D propagation of light can be efficiently controlled by the geometry of the wire. These emitter-nanowire hybrid structures might be good candidates as building blocks for the design of CMOS-compatible optical nanodevices operated in the single photon regime.

Discussion: For a couple of decades, nanoscale optics has mainly been driven by plasmonics since noble metal nanostructures sustain strong resonances that can be used to enhance, confine, propagate or redirect visible light. Such properties have led to numerous actual or potential applications in integrated optics, sensors, nonlinear optics, field-enhanced spectroscopies, or photovoltaics. Recently, an alternative to plasmonics emerged with high refractive index dielectric nanostructures, which offer the same range of applications as plasmonics by manipulating waveguide and Mie optical resonances instead of plasmonic ones [1]. These resonances can be efficiently tuned by modifying the size, shape, and material of those nanostructures (e.g. silicon, optical index n=4). Furthermore, high index dielectric nanostructures offer several advantages when
compared to their metallic counterparts: absorption losses are far weaker for wavelengths greater than the direct band gap, access to semiconductor (CMOS) technology for nanostructure fabrication, and presence of intrinsic strong electric and magnetic resonances [2,3].

In the context of quantum nanophotonics, which aims to combine the confinement and propagation of light at the nanoscale along with quantum properties of light, their appealing properties make Si nanostructures an interesting platform to investigate classical to quantum optics transition in coplanar devices. In this work, we first discuss the effect of high index dielectric nanowires on the spontaneous emission of NV colored centers in nanodiamonds. The emission rate of punctual emitters is driven by the presence of the nanostructure which tailors the local density of optical states (LDOS) [4]. With time-resolved photoluminescence acquisitions, we show that the photodynamics of the quantum emitters is modified in the vicinity of the Si wires. The experimental data are systematically compared to simulated decay rates and LDOS computed with the Green Dyadic Method (GDM).

In a second stage, we show that visible photons emitted by the broadband single emitters coupled at one extremity of Si nanowires are efficiently guided up to the second extremity, located several micrometers away. By performing image plane acquisitions on a set of emitter-wire hybrid structures, we observed that the geometrical parameters of the wires, and the related waveguide modes, determine the efficiency of the transfer. The experimental results are in good agreement with numerical experiments.

Subwavelength Raman Molecular Mapping with Electron and Light Induced Stimulated Raman Scattering (ELISR) Amr A. Saleh1,2, Daniel Angell1 and Jennifer A. Dionne1; 1Stanford University, United States; 2Cairo University, Egypt

Many plasmonic processes, from photocatalysis to photothermal therapy, rely on nanoparticle-molecule interactions. Mapping these interactions with high spatial resolution is essential to optimize system efficiency, but can be incredibly challenging due to the molecules’ small size and generally complex microenvironment. Here, we propose a new method capable of identifying and mapping nanoparticle-molecule with sub-10nm spatial resolution. Our method, Electron and Light Stimulated Raman Scattering (ELISR), utilizes in-situ optical spectroscopy within a transmission electron microscope (TEM). Unlike existing correlated optical and electron microscopy techniques, where a sample is first imaged in a fluorescence optical microscope and then sectioned for cryo-electron microscopy, our method enables simultaneous high-resolution microstructure visualization with protein identification through Raman scattering. In particular, our technique uses a laser source as the pump and the electron beam as the broadband Stokes excitation. The electron beam serves as a highly-localized Angstrom-scale source to locally excite the plasmonic resonances of individual nanoparticles whose resonance is red-shifted from the pump laser to resemble Stokes excitation. Accordingly, the Raman scattering is locally enhanced by the electron beam and the spatial resolution is determined by the electron beam spot size and the nanoparticle size. We theoretically model this process using boundary element method (BEM) calculations. Attention is given to gold nanorods (NRs) with plasmonic resonances between 800nm and 900nm; we assume 785nm laser illumination and 80keV electron beam excitation. We investigate the enhancement of the 992cm⁻¹ benzene line, showing that enhancement in the stimulated over spontaneous Raman can be up to six orders of magnitude under electron beam illumination, even with laser pump intensities less than 10mW/µm². Experimentally, we use aberration corrected environmental transmission electron microscope combined with light excitation. The setup uses two parabolic mirrors coupled to two optical fibers. We use one of the optical fibers to couple the 785nm pump laser into the TEM and the other fiber to couple the light scattered from the sample out of the TEM. The scattered light collected from the sample is then coupled into a spectrometer after filtering out the pump laser. To characterize the e-beam stimulated Raman we use a model system of colloidally synthesized gold and silver NRs functionalized with 4-Mercaptobenzoic acid (4-MBA) as a Raman reporter. The lengths and radii of the rods are 105nm and 12nm, respectively, with transverse and longitudinal plasmon resonances at 510nm and 830nm, as confirmed with cathodoluminescence. Upon electron
beam excitation of the NR plasmon modes, we observe a significant increase in the Raman intensity of the 1570 cm\(^{-1}\) line of the 4-MBA. We locally map the stimulated Raman enhancement upon electron-beam excitation as a function of electron beam position and nanorod material and arrangement, including nanorod dimers. Our results demonstrate the promise of Raman spectroscopy with electron microscopy to enable single nanometer resolution molecular mapping, with simultaneous imaging of the nano-to-atomic-scale structure of the sample.

**Excited-States in Nanophotonic Chemistry—First Principles Approaches to Strong Light-Matter Coupling**
Johannes Flick\(^1\), Nicholas Rivera\(^1,2\) and Prineha Narang\(^1\); \(^1\)Harvard University, United States; \(^2\)Massachusetts Institute of Technology, United States

In recent years, research at the interface of chemistry, material science, and quantum optics has opened new possibilities to study strong light-matter interactions for nanophotonic chemistry [1,2]. In this new regime of nanophotonics, correlated electron, nuclear and photon interactions have to be treated on the same quantized footing. Towards this goal, we have introduced a general time-dependent density-functional theory [3] and variational QED framework [4].

In this talk, we demonstrate how these QED-derived frameworks are used to study strong-light matter coupling to change the chemistry of the system. As a concrete example, the effect of strong-coupling on photochemical reaction is studied for Formaldehyde. We construct the polaritonic excited-state potential-energy surfaces (PES) of a CO bond stretching that are modified under strong-light matter coupling [5]. We show how strong coupling can be exploited to alter photochemical reaction pathways by influencing avoided crossings. For CO2 molecules, we study the Rabi splitting and finite temperature effects [3] in vibrational strong coupling. Additionally, we study how strong vibrational coupling influences chemical reactions, recently observed in experiment. By using the variational QED framework, we demonstrate how we can calculate polaritonic observables for a wide range of coupling strengths [4]. Our work opens the important new avenue in introducing ab initio methods to the nascent field of nanophotonic chemistry with strong light-matter interactions and will enable a systematic search for potential new reactions that can be altered by these interactions.

**A Strong Pockels Effect in Optical Devices on Silicon**
Jean Fompeyrine, Felix Eltes and Stefan Abel; IBM Research Zurich, Switzerland

An important building block in integrated optical circuits is an efficient link between the optical and electrical domain. Well-known examples of such links are integrated high-speed modulators to convert electrical signals into optical signals at very high-speed, and low-power tuning elements to compensate for variations in the device operation temperature and for device-to-device variations during fabrication. To enable such electro-optic links, the two most widely used physical effects are the plasma-dispersion effect and Joule heating. Although these effects are attractive to use due to their compatibility with standard photonic fabrication processes, their performance in integrated devices is intrinsically limited by high insertion losses and high-power dissipation.

Over the past decade, we established an alternative electro-optic switching technology by embedding a Pockels
material into silicon-based photonic devices. We reached this goal by developing a process to fabricate ferroelectric barium-titanate (BTO) thin films on silicon substrates using advanced epitaxial deposition techniques and by developing a BTO process technology. We correlated the electro-optical properties of the thin films with their structural properties such as porosity and crystalline symmetry to show guidelines for improving the functional properties [1]. By realizing integrated hybrid BTO/silicon devices, we demonstrated record-high, in-device Pockels coefficients of >900 pm/V [2]. The Pockels effect in BTO-based photonic devices indeed enables extremely fast data modulation at rates beyond >40 Gbps and ultra-low-power electro-optic tuning of silicon and silicon-nitride waveguides. We also show ways of how to integrate and use BTO in plasmonic slot waveguide structures for very compact optical devices. With the development of a wafer-level integration scheme of single-crystalline BTO layers to a 200 mm process, we could demonstrate a viable path to combine the BTO-technology with existing fabrication routes [3].

With major breakthroughs in the past years, BTO has emerged as a strong candidate for a novel generation of electro-optic devices. Major achievements of the BTO technology will be covered in the presentation, ranging from important materials aspects, device development, integration concepts, and novel applications in the area of quantum computing, high-speed communication, and neuromorphic optical computing.

Self-Stabilizing Photonic Levitation and Propulsion of Nanostructured Macroscopic Objects Ognjen Ilic;
University of Minnesota, United States

Light is a powerful tool to manipulate matter, but existing approaches often necessitate focused, high-intensity light that limits the manipulated object's shape, material, and size. Here, we discuss self-stabilizing optical manipulation of macroscopic objects achieved by controlling the anisotropy of light scattering along the object surface. In a scalable design that features silicon resonators on silica substrate, we identify nanophotonic structures that can self-restore when rotated and/or translated relative to the optical axis. Nanoscale control of scattering across a large area creates restoring behaviour by engineering the scattered phase, without needing to focus incident light or excessively constrain the shape, size or material composition of the object. These findings may lead to platforms for manipulating macroscopic objects, with applications ranging from contactless wafer-scale fabrication and assembly, to trajectory control for ultralight spacecraft, and even laser-propelled lightsails for space exploration.

Infrared Pixel Based on Seebeck Nanoantennas Francisco Javier Gonzalez1,2,3 and Robert E. Peale1,2; 1Truventic LLC, United States; 2University of Central Florida, United States; 3Universidad Autonoma de San Luis Potosi, Mexico

Many infrared imagers comprise a focal plane array of thermal detectors that convert incident infrared to heat and
thence to an electrical signal. The thermometric property of the well-established micro-bolometer is a change in resistance of a semiconducting element with temperature. These require a bias voltage and draw a current that consumes power, and the response of sufficiently sensitive bolometers is fairly slow. An opportunity is nano-scale thermocouples connected to planar antennas, which collect the incident infrared and drive a current that Joule heats the thermocouple junction. The antennas are wavelength specific, which has value for spectral sensing. The heated junction of dissimilar materials generates a thermoelectric voltage, which can be detected at the free ends of the thermocouple. The nano-scale junction can change temperature quickly due to small thermal mass, giving faster response than for traditional bolometers. The devices in principle require fewer processing steps and can use low-cost earth-abundant materials, potentially reducing the cost of infrared sensor systems in comparison to microbolometers. The thermoelectric elements generate their own output voltage without external bias, so that the only power required is that needed to operate the read-out circuit. We present results for a Seebeck nano-antenna pixel optimized for 10.6 micron wavelength radiation. Design and performance calculations are presented, together with experimental results for responsivity, noise, noise-equivalent power, detectivity, and time constant.

4:30 PM EL01.04.04
Nanoscale Aluminum Plasmonic Waveguide with Monolithically Integrated Germanium Detector Alois Lugstein1, Maximilian G. Bartmann1, Masiar Sistani1, Hamid Keshmiri1, Sven Barth1, Michael Seifner1, Martien Hertog2 and Minh An Luong3; 1Vienna Univ of Technology, Austria; 2NEEL CNRS/UGA, France; 3Univ. Grenoble Alpes, France

Surface plasmon polaritons have rapidly established themselves as a promising concept for emerging integrated ultra-compact photonic circuits rivaling electronics in both speed and critical feature sizes. Aside of effective sources, detectors and modulators, the overall performance of plasmonic networks critically rely on symmetry broken waveguides enabling the routing of signals within a circuit. We systematically investigated the guiding of plasmonic beams in ultra-thin (<50 nm) monocrystalline Al nanowires enwrapped by a passivating Al2O3 shell. The Al heterostructures were synthetized on 40nm thick Si3N4 membranes by a thermally induced exchange reaction of single-crystalline Ge nanowires and lithographically defined Al contact pads. Due to limited spatial resolution, optical methods are inappropriate to determine the short propagation length in ultra-thin metallic nanowires. Thus, we explored a well-tuned focused grating coupler to launch plasmons in the Al nanowire waveguides. To optimize the focussed grating coupler with respect to plasmon generation and coupling into the c-Al NW, numerical simulations based on the finite-difference time-domain (FDTD) method were performed.

Further we explored and a highly efficient electrical plasmon detector based on a monolithic quasi 1D metal-semiconductor-metal heterostructure device. Based on this system, we experimentally determined a plasmon propagation length of 140 nm for monocrystalline Al plasmon waveguides with diameters of only 40 nm. Further, our monolithic approach of plasmon generation, guiding and sensing enables us to examine bending losses of kinked Al nanowire waveguides.

This particular device allows a clear separation of the contributions of plasmon-induced and photo-excited carriers enabling to separately examine plasmon-induced hot electron injection and photoexcitation. The architecture features further precise control of the injection barrier at the abrupt metal-semiconductor interface, enabling selective probing the hot electron distribution from surface plasmon decay.

These systematic investigations of ultra-thin monocrystalline Al nanowires provide in general a platform for the evaluation of nanoscale metal based waveguides for transmission lines of next generation high-speed ultra-compact on-chip photonic circuits.

High-Speed Phase-Only Spatial Light Modulators with Two-Dimensional Tunable Microcavity Arrays Cheng Peng1, Ryan Hamerly1, Mohammad Soltani2 and Dirk Englund1; 1Massachusetts Institute of Technology, United States; 2Raytheon BBN Technologies, United States

Spatial light modulators (SLMs) are central to numerous applications ranging from high-speed displays to adaptive optics, structured illumination microscopy, and holography. After decades of advances, SLM arrays based on liquid crystals can now reach large pixel counts exceeding 10⁶ with phase-only modulation with a pixel pitch of less than 10 μm and reflectance around 75%. However, the rather slow modulation speed in such SLMs (below hundreds of Hz) presents limitations for many applications. Here we propose an SLM architecture that can achieve high pixel count with high-resolution phase-only modulation at high speed in excess of GHz. The architecture consists of a
tunable two-dimensional array of vertically oriented, one-sided microcavities that are tuned through an electro-optic material such as barium titanate (BTO). We calculate that the optimized microcavity design achieves a π phase shift under an applied bias voltage below 10 V, while maintaining nearly constant reflection amplitude. As two model applications, we consider high-speed 2D beam steering as well as beam forming. The outlined design methodology could also benefit future design of spatial light modulators with other specifications (for example amplitude modulators). This high-speed SLM architecture promises a wide range of new applications ranging from fully tunable metasurfaces to optical computing accelerators, high-speed interconnects, true 2D phased array beam steering, and quantum computing with cold atom arrays.

Gate Tunable Optical Properties in Organolead Halide Perovskite Heterostructures Teng Lam Shen¹, Meng-Ju Yu¹, Mriganka Singh¹, Chih Wei Chu¹ and Yu-Jung Lu¹,²; ¹Academia Sinica, Taiwan; ²National Taiwan University, Taiwan

In the past decade, lead halide perovskite material have received considerable attention to be a promising candidate for solar cells due to its excellent optoelectronic properties. Beyond of the remarkable power conversion efficiency. However, the optical dielectric constants (complex refractive index) are far less discussed, especially the dynamic control of refractive index in lead halide perovskite material has never been reported. Understanding and modulating the material properties could accelerate to the progress of applying perovskite in optoelectronic devices comprehensively. Here, we report electric field modulated dielectric permittivity in CH₃NH₃PbBr₃ film by using ellipsometry measurement. The designed device consists of Silver/Aluminium Oxide/CH₃NH₃PbBr₃/PMMA/Silver and results in a metal-insulator- semiconductor-insulator-metal (MISIM) heterostructures. Under an applied electric field (~10⁶ V/m) crossing the two silver electrodes, 5% change in the refractive index is observed between 440 - 520nm. We believe the results open new avenues for the application of perovskite based optoelectronic devices such as in electro-optic modulator in the visible and active tunable transistor lasers.

EL01.05.02
Manipulating Chiral States of Quantum Emitters via Circular Dichroism Metamaterials Sangsoon Yoon, Young-Bin Kim and Sun-Kyung Kim; Kyung Hee University, Korea (the Republic of)

The properties (e.g., wave vector, polarization, spontaneous emission rate, and so on) of generated electromagnetic waves is inherently dictated by optical density of states that well-ordered structures create. For example, a one-dimensional metal/dielectric subwavelength periodic pattern, which serve as an artificial birefringent film, exhibits a hyperbolic (as opposed to ellipsoidal) material dispersion, thus being capable of generating linearly polarized light into specific direction.

More specifically, when an Al/ITO metal/dielectric metamaterial film designed for a quarter wave plate is evanescently coupled to a quantum emitter, the far-field distribution of radiation is vertically localized for one polarization and horizontally spread for its orthogonal polarization. The contrast of the polarization-selective far-field distribution is the most pronounced when a quantum emitter is positioned at which an interference condition is completely met. As a practical example, such artificial, birefringent films can be applied to organic light-emitting diodes (OLEDs) to attain polarized and vertically directed emitted light; according to electromagnetic simulation result, the maximum extinction polarization ratio is up to approximately 30.

Likewise, circular dichroism materials such as helical reactive mesogen (RM) can be chosen to manipulate the chiral states (e.g., circular polarization) of quantum emitters. A RM embedded film synthesized on a glass substrate shows highly selective reflectance for opposite circular polarization over a particular wavelength range; the wavelength range is readily tuned by the pitch of helical morphology within RM material. Such a circular dichroism layer can help quantum emitters inherently yield circular polarized light. We will discuss the polarization and wavelength
resolved far-field distribution of quantum-dot films when they are integrated with tailored circularly dichroism materials.

EL01.05.03
Dynamic Beamsteering with Nonlinear, High-Quality-Factor Dielectric Metasurfaces
David R. Barton, Mark Lawrence, Jefferson Dixon, Jung-Hwan Song, Jorik Van de Groep, Mark L. Brongersma and Jennifer A. Dionne; Stanford University, United States

Dielectric nanoantennas are capable of sculpting the amplitude and phase of light through resonant modal coupling. Properly designed, these structures promise to transform modern optics by replacing traditional optical components with miniaturized films with curated phase, amplitude, and dispersion relations to generate arbitrary transfer functions for incoming light. The inclusion of nonlinear optical responses into metasurfaces will be crucial for applications spanning optical and neuromorphic computing, optical communications, sensitive detectors and dynamic sensors, but the low nonlinear susceptibility of dielectric materials significantly challenges these applications.

Here, we introduce a route towards efficient nonlinear wavefront shaping and beam-steering using high quality factor (high-Q) resonances in dielectric phase gradient metasurfaces. Typically, metasurfaces operate based on phase pickup from Fabry-Perot-like or Mie-like modes in the propagation direction of interest. In our case, we exploit coupling to in-plane waveguide modes, which interfere with the far-field Fabry-Perot modes to produce extremely high-Q modes, with Q’s exceeding 1000. We use a silicon on sapphire platform and pattern spatially arrayed silicon beams with widths of 200 to 370 nm as metasurface elements. Our beamsteering structures efficiently diffract light to the +1st order with wavelengths between 1300nm and 1500nm. Including small periodic notches, with depths varying from 30nm to 150nm, into one Si beam provides the extra momentum to efficiently couple to a waveguide mode; the interference between the Fabry-Perot mode and waveguide mode leads to a resonant response in the scattered spectrum, which manifests as a resonant decrease in the first diffracted-order scattered intensity. Our experimental quality factors range from 1400-2500 with perturbation periods ranging from 530 nm to 610 nm along a particular Si bar.

The high, experimentally-observed Q factors indicate that the illuminating electric field can locally be enhanced by more than 50 times. We utilize this enhancement to induce nonlinear shifts in the scattered transmission spectrum, using a nanosecond Q-switched laser centered at 1534nm. Here, we exploit the nonlinear Kerr effect to induce modulations to the refractive index of individual silicon bars dependent on the incident laser power. As the incident power increases, the refractive index, and hence the scattered amplitude and phase, of the metasurface elements are modified. Including Silicon’s nonlinear susceptibility in simulation, we show laser powers of 83 uW/um² can shift the resonant feature by greater than a full width half max. Our approach represents a facile route to achieve nonlinear optical phenomena in metasurfaces, and can be readily extended to other common nonlinear schemes, including harmonic generation and parametric wavemixing. Our high-Q scheme is generalizable to almost arbitrary transfer functions and materials, laying a foundation for a range of nonlinear-based technologies in computing, sensing, and communications.

Dynamically-Controlled Nanophotonic Phased-Arrays and Displays with Microfluidic Cavities
Qitong Li, Jorik Van de Groep, Adam White, Jung-Hwan Song, Polly Fordyce, Stephen Quake and Mark L. Brongersma; Stanford University, United States

Ultra-compact, high-resolution, and low energy-consumption tunable phased arrays and displays play a critical role in future’s daily life as they provide an efficient and user-friendly access to information. Nanophotonic devices, made by judiciously engineered optical resonators, are capable of harnessing the amplitude, phase, and spectrum of its scattered light with subwavelength resolution. However, active tuning of these optical resonances is still in its infancy. Active tuning is challenging as the semiconductors and noble metals display a limited tunability due to the generally weak electrorefractive and electroabsorptive effects. Here, we demonstrate the large, fast, and repeatable tuning of optical resonances by tailoring the dielectric environment of silicon (Si) nano-resonators that operate in the visible spectral range. The dramatic tunability results from the strong dispersion and interference of various optical resonances supported by Si nano-resonators when embedded in different refractive-index materials. This working principle is then realized by integrating the nanophotonic device with a microfluidic cavity that can programmably
control the refractive index (n=1-1.7) by flowing different liquid in real time.

Active beam steering, dual-wavelength switchable holography, and wavelength-selective focusing and imaging are all demonstrated to show the power and flexibility of the design principle. We also demonstrate the possible use of these elements in display application by showing both a broadband (~100 nm) amplitude tuning and full-color tuning (from blue to red, reflection peak from 480nm to 580 nm) for individual pixels. This large tunability results from the interference between the symmetric (electric dipole mode, toroidal dipole mode, magnetic quadrupole mode) and anti-symmetric (magnetic dipole mode, electric quadrupole mode) modes supported by Si nanodisk arrays, as their resonant frequencies and bandwidths all depend on the refractive index of surrounding materials. The dielectric environment is programmed up to 20 Hz with microfluidic cavities to show practical multi-color display function.

Altogether, these results demonstrate the unprecedented tunability to control the dielectric optical resonators in practical applications, ranging from active beam steering, real-time holography, to fluorescence microscopy and reflective displays with color-tunable pixels. The successful integration with mature microfluidic cavity technologies further paves the way towards next-generation ultra-compact active optical elements.

Structural Color Systems with the Combinations of Silicon Nanowire Arrays and Ultra-Thin 1D Resonators
Gil Ju Lee¹, Yeong Jae Kim¹, Dong Eun You², Dong-Wook Lee², Il-Suk Kang² and Young Min Song¹; ¹Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); ²Korea Advanced Institute of Science and Technology, Korea (the Democratic People's Republic of)

Structural colors, which can occur by the interaction between visible light and exceptional photonic structures, have rapidly emerged as a key alternative to the traditional dyes or pigments because of their conspicuous advantages as following: 1) outstanding spatial resolution, 2) durability under harsh environments, 3) versatile utilization, 4) compactness, 5) eco-friendly materials, and 6) spectral selectivity. With these strong points, various structural colors including plasmonic nanostructures, metal-dielectric multilayers, and photonic crystals have attempted to substitute with the conventional dyes and pigments. Among them, silicon (Si) nanostructures are considered as the most suitable candidates because of the low-cost/mature fabrication process and excellent optical constants (i.e., high refractive index and low absorption loss compared to metals). Using the aforementioned properties, multicolor generation by Si nanowire arrays (Si NWAs) has been successfully demonstrated for reflective/transmissive structural color filters. However, the restricted color presentation of currently-reported structural colors has hindered the wide spreading of the promising structural color printing.

Here we propose a new class of reflective color filters to enlarge color gamut by attaching a sticker form of Si NWA on ultra-thin one-dimensional resonators which are in nanoscale. To implement the sticker form of Si NWAs, we fabricate transferable Si NWAs (T-SiNAs) embedded in polydimethylsiloxane (PDMS) which is a visibly transparent polymer. The nanoscale structures of each photonic configuration allow an exceptional mechanical softness, hence it enables flexibility and reusability without mechanical failure. First, we design and fabricate the T-SiNAs to possesses optical resonances covering from visible to near-infrared (NIR) ranges (i.e., 400 to 1000 nm). The resonance dip positions are shifted from short to long wavelengths by increasing the diameter of T-SiNAs. The fabricated T-SiNAs have the optimized structural parameters as follows: height = 2 μm, diameter = 50 to 150 nm with 10-nm-step, and period = 1250, 900, and 600 nm. To demonstrate the widening ability in color gamut, we selected metal-insulator-metal (MIM; Ag-SiO₂-Ag) structure as ultra-thin 1D resonator. Generally, MIM structures exhibit subtractive primary colors such as cyan, magenta, and yellow. However, by transferring T-SiNAs on MIMs, we enlarge the pristine color gamut of MIMs and experimentally realize additive primary colors such as red, green, and blue. Furthermore, such intriguing optical and mechanical characteristics facilitate a novel optical anti-counterfeiting sticker.

EL01.05.06
Optical Camouflage—Tunable Coloration Accompanied by Optical Janus Effect
Yong-Sang Ryu, Eui-Sang Yu, Jong-Su Lee and Taehyun Kim; Korea Institute of Science and Technology, Korea (the Republic of)

Reflective asymmetric coloration in a metal–insulator–metal (MIM) structure is proposed to achieve direction selective message encryption through the manipulation of physical characteristic of the top metal and effective refractive index of the dielectric insulator layer. A semicontinuous top metal film with nanoapertures, adopted as a
transreflective layer for MIM resonator, allows to exhibit direction-sensitive optical effect (called Janus effect) as well as to tailor the nanomorphology of a dielectric layer, which plays crucial roles in recognizable color changes when exposed to external liquids. This new concept of direction sensitive distinct colorations, followed by color tuning with respect to liquid exposures were thoroughly analyzed by theoretical simulations and experiments. Our liquid permeable approached in color changes indeed provide dramatic color tunability, a real-time sensing scheme, long-term durability, reproducibility, and most importantly, exhibit direction sensitive message hidings (Optical Camouflage) in a simple and scalable manner.

**Boosting Photoelectrochemical Water Splitting with Large Area Nanophotonic Antenna Arrays** Rambabu Yalavarthi, Stepan Kment, Radek Zboril and Alberto Naldoni; RCPTM, Palacky University in Olomouc, Czechia

Integration of plasmonic metal nanostructures with semiconductor nanomaterials has been proposed as a promising strategy to achieve enhanced light absorption and solar energy conversion efficiencies. In the present work, we report the fabrication of platinum coated Ni pillar arrays integrated with CdS nanoparticle continuous layer (Ni/Pt/CdS pillars) for photoelectrochemical water splitting. We use several Ni/Pt pillar array with varying pitch and diameter to achieve a wide wavelength (visible to near-infrared (NIR)) light harvesting. Compared to CdS coated Ni/Pt planar film, the best Ni/Pt/CdS pillar array shows ~200% photocurrent enhancement. The same is confirmed by an incident photon to current conversion efficiency (IPCE) and electromagnetic simulations. We will discuss the effects enabling the photocurrent enhancement, distinguishing the contribution from increased surface area, photonic and plasmonic light concentration.

**EL01.05.08**
**Design and Fabrication of a Microwave Metasurface Beam-Splitter Reflector** Arben M. Gjonbalaj, Richard Williams and Brian M. Wells; University of Hartford, United States

Metasurfaces have recently gained attention due to their physical compact nature, versatility, and exotic electromagnetic properties in manipulating propagating waves. In this work we present the design, fabrication, and experimental verification of a beam-splitting metasurface reflector with arbitrarily chosen split beam directions. A beam splitter is an integral component in many optical devices such as interferometers and multiplexers. Traditional beam splitters are based on cubes or plates composed of glass and mirrors that are comparatively large and bulky. Being able to fabricate a metasurface beam splitter will prove to be extremely useful for a variety of applications.

The metasurface under investigation was designed to split a normally incident wave into two beams, one directed to 25 degrees and the other directed to 45 degrees, using the Fourier transformation method of array synthesis. This method is used to calculate the necessary metasurface reflection properties and High-Frequency Electromagnetic Solvers (HFSS) simulations are performed to determine the required surface pattern for fabrication. This method can easily be extended to any combination of splitting angles and operating frequency. The beam-splitting metasurface is fabricated using traditional silk printing techniques with conductive ink on selected substrates. For this work conductive nickel ink patches were printed on an aluminum-backed acrylic substrate. Measurements were performed at 10.5 GHz using a single frequency microwave transmitter and receiver, the receiver was scanned through 180 degrees and electric field intensity was measured. These measurements show excellent agreement with the scattering predictions.

**EL01.05.09**
**Novel Diffractive Optical Elements for on Chip Multi-Spectral Imaging and Infrared Spectroscopy** Yuyao Chen, Wesley Britton and Luca Dal Negro; Boston University, United States

The integration of imaging spectrometers with high-sensitivity photodetectors for spectroscopic identification of multi-band infrared (IR) signals is of great potential for a number of applications that range from infrared imaging to environmental monitoring and biochemical detection. In our recent work, we designed, fabricated, and characterize novel diffractive optical elements (DOEs) that integrate imaging and spectroscopic functions on the same silicon chip. In particular, we demonstrate multi-functional focusing gratings and multi-focal lens flat lenses based on the versatile axilens concept with engineered phase modulations over 100µm footprint dimensions. Using electron beam lithography and sequential etching processes we demonstrate a novel four-level multi-functional phase element that combines the phase modulation of a traditional axilens (i.e., a diffractive lens with a large and programmable
focusing depth) with the spatial dispersion behavior characteristic of a compact 2D periodic grating. Furthermore, we demonstrate that the operation spectrum of our designed devices doubles the one of a traditional Fresnel lens. A comprehensive analysis of the operation bandwidth and cross-talk ratio on the detection plane between targeted wavelengths across the long-wavelength IR range (LWIR) is performed demonstrating broad band operation with a 15% cross-talk figure. Device-level simulations are performed using the three-dimensional finite element method and show excellent agreement with predicted device performances based on the rigorous Rayleigh-Sommerfeld diffraction theory.

**EL01.05.10**

**Optical Rectification in a Reconfigurable Metal-Insulator-Metal Diode**

Richard M. Osgood¹, Yassine Ait-El-Aoud¹, Michael Okamoto¹, Sean Dinneen¹, Declan Oller², Gustavo Fernandes², Jin Ho Kim², Sergey Dizhur² and Jimmy Xu²; ¹US Army Combat Capabilities Development Command - Soldier Center, United States; ²Brown University, United States

Optical rectification (OR) is an optoelectronic phenomenon where an illuminating optical field is rectified by a nonlinear material to produce a DC voltage and, in a conductive material, a current which can be a combination of thermionic and tunneling current. OR has been difficult to observe in many systems, due to the need for tunneling junctions with exceedingly small capacitance and surface area.¹,² We report optical rectification in a nanoscopic Metal-Insulator-Metal (MIM) diode’s tunneling junction, which is voltage-reconfigurable via simple resistive switching, thus enabling tunable conductivity. The conductively-tunable resistive switching MIM diode we explore can be tuned, set, and reset via the application of DC electric fields, making it ideal for exploring optical rectification phenomena under different nonlinear conductivity conditions and for dynamically tuning the device’s responsivity. Other nonlinear junctions cannot be so readily set and re-set. The resistive-switching MIM diode that we research also has the advantage of being scalable to large areas, due to its simple fabrication. Using a relatively simple MIM diode consisting of a planar Al electrode (“passive electrode” or PE), a thin Al₂O₃ barrier layer, and an initially planar Ag counter-electrode (“active electrode” or AE), we demonstrate optical rectification. By applying a voltage, a metallic filament, having a cross-section as small as (10 nm)², grows within the dielectric layer, from the PE to the AE, resulting in a nanogap between metals, bridged by a barrier layer, and with tunneling resistance that exponentially depends on the distance between PE and PE, set by a voltage-tunable nanogap. We measure current-voltage curves and the response to a modulated visible laser beam, and compare to our analytical MIM diode model, which was derived for 2D junctions.³ The filament’s separation from the AE is controlled precisely by controlling the junction’s voltage and current. The tunability of this platform opens the possibility for adaptive ultrafast photon detectors, wireless power transmission, and energy harvesting systems, potentially useful for reconfigurable antennas useful for flexible electronics applications, and/or for neuromorphic computing.

**EL01.05.11**

**Employing the Insulator-to-Metal Transition of Vanadium Dioxide for the Use as Switchable Flat Lens in the THz Regime**

Florian Kuhl¹, Janine Lorenz¹, Martin Becker¹, Angelika Polity¹, Teng Wang², Jinwen He³,⁴, Jinying Guo², Xinke Wang², Shengfei Feng², Yan Zhang² and Peter J. Klar¹; ¹Justus Liebig University, Germany; ²Capital Normal University, China; ³Beijing Institute of Satellite Information Engineering, China; ⁴State Key Laboratory of Space-Ground Integrated Information Technology, China

The potential of THz waves for applications has become widely recognized in the last few years and the use of phase transition phenomena for reversibly tuning the properties of functional materials in devices is an attractive research area of materials science. We report on various kinds of designed and microfabricated metasurfaces for actively switching the wavefront of terahertz (THz) radiation based on the well known insulator-to-metal (IMT) phase transition of pure vanadium dioxide (VO₂) and its ternary tungsten (W) doped V₁ₓWₓO₂. The IMT is induced by a temperature change of the structured thin films and occurs at about 68 °C for the undoped bulk VO₂ while doping with W strongly influences the phase transition temperature Tc by about -12.6 K / (at.% of W) . The microstructures, based on metasurfaces of C-shaped slot antennas, are etched into the rf-sputtered thin films on c-sapphire substrates using micro- and nanofabrication methods, i.e. photolithography and ion beam etching. The C-shaped slot antennas are active only when the pure VO₂ or the V₁ₓWₓO₂ is in its metallic phase, i.e. at temperatures
Examples are temperature-switchable THz multi-focus lenses which focus impinging THz radiation into four focal spots or Airy beam generators. Using both materials, VO$_2$ and V$_{1-x}$W$_x$O$_2$, allows us to fabricate stacked lenses that can be switched on and off at different temperatures linked to the critical temperatures $T_c$ of the thin films. We characterized the function of the THz wavefront modulators over a broad frequency range from 0.3 to 1.2 THz. Such thermally switchable THz wavefront modulators with a capability of dynamically steering THz fields will be of great significance for the future development of THz active devices.

**EL01.05.12**

**Optical Metasurfaces by Periodic Gain-Loss Building Blocks Using Colloidal Self-Assembly**

Max J. Schnepf$^{1,2}$, Tobias A. König$^{1,2}$ and Olha Aftenieva$^1$; 1Leibniz Institute for Polymer Research Dresden, Germany; 2TU Dresden, Germany

In conjugated polymers, electronic excitations are coherently spread over the whole conjugated polymer, the individual transition dipole moments interact by dipole-dipole coupling. As this dipole-dipole coupling is a near-field effect, the interaction is limited to a small spatial region, and the participating quantum emitters cannot be addressed and probed individually. With a colloidal approach, we build a larger-scale analogue of a conjugated polymer to study coherent energy transfer. We will couple a small ensemble of quantum emitters with a plasmonic colloidal cavities [1] and a spatially extended hybrid plasmonic lattice mode [2] to study the weak and strong light matter interaction. The fluorescence enhancement (optical gain) is provided by a lattice of silver indium sulphide (AgInS) quantum dots fabricated by confinement assembly. The light annihilation (optical loss) is achieved using a gold particle lattice by soft lithography templates and directed self-assembly.[3] By stacking of those two components, geometrical parameters can be varied, which allows to study the coherent energy transfer systematically by time-correlated scattering and reciprocal space imaging methods. Due to the scalability of both fabrication methods, we can produce substrates with areas larger than 2 cm$^2$, which can be expanded even further. In the end, the stacked structures pave the way to a quantum simulator of the underlying conjugated polymer.

**Scale Law of Far Field Thermal Radiation from Metasurface**

Jiayu Li and Sheng Shen; Carnegie Mellon University, United States

Although the far-field thermal radiation from the single nanoscale thermal emitter is now well-understood under the framework of Quasi-normal mode (QNM) theory and coupled-mode theory (CMT), the collective behavior of a set of closely packed emitters or metasurface is still vague. When the periodicity of the emitter array is large, the optical mode overlapping between adjacent emitters in the near field is negligible. Therefore, it is reasonable and safe to treat the array of sparsely packed emitters in the way of a single emitter. As the packing density keeps decreasing, the interaction between neighbor emitters is no longer negligible. In this scenario, a change of the far-field thermal radiation with respect to the packing density is expected. In this work, we demonstrate a new scale law of the far-field thermal emission by applying QNM to the metasurface consisting of densely packed emitters. The tight binding method is used to approximate the collective resonant mode of the emitter array. The thermal radiation from single emitter inside the array is suppressed by the adjacent emitters. Depending on the resistive and radiative loss of the single emitter, the overall thermal radiation can be either proportional or inversely proportional to the number of emitters coupled. This new scale law of thermal radiation could serve as a general guideline for designing metasurface with desired thermal emission properties.

**Reactive Magnetron Sputtering of Heteroepitaxial Titanium Nitride for Plasmonic and Metamaterial Applications**

Amber N. Reed$^1$, Hadley A. Smith$^1$, Zachary J. Biegler$^{1,2}$, Rachel L. Adams$^1$, Madelyn Hill$^1$, Krishnamurthy Mahalingam$^1$, Kurt G. Eyink$^1$ and Augustine M. Urban$^1$; 1Air Force Research Laboratory, United States; 2University of Dayton, United States
High temperature stability, chemical stability, low surface energy and mechanical robustness, combined with a zero-crossover wavelength in the visible region make titanium nitride (TiN) a promising material for plasmonic and metamaterial applications in harsh environments. In this work we demonstrate the heteroepitaxial growth of TiN on (0001)-Al2O3, (001)-MgO and (0001)-LiNbO3 substrates as well as incorporation of TiN in metal-dielectric stacks. We discuss the differences in growth and crystalline properties based on substrate material and growth conditions. Additionally, we discuss the relationship between TiN crystalline quality and optical properties. Coupled x-ray diffraction (XRD) of our TiN show high quality epitaxial growth on all three substrates, however, further structural characterization reveals differences in crystal defects, strain and surface morphology based on substrate crystal structure and lattice mismatch. Pendellosung fringes on the (111)-TiN diffraction peak for the coupled XRD of TiN on c-plane sapphire and LiNbO3 indicate uniform d-spacing and a pristine interface. 6-fold symmetry for the TiN grown on sapphire is seen in XRD pole figure scans, indicating the presence of stacking faults. These domains, which are further evident in atomic force microscopy (AFM) of the TiN surface, are attributed to different stacking within the TiN domains. XRD of the TiN on MgO show Pendellosung fringes on the (001)-TiN diffraction peak. Cross-hatching features similar to those on the bare MgO substrate are seen in the AFM of the TiN surface. Variable angle spectroscopic ellipsometry (VASE) shows that TiN behaves metallic on all substrates with a zero crossover wavelength between 470 nm and 490 nm. Differences in the real ($\varepsilon_1$) and imaginary ($\varepsilon_2$) permittivity for TiN on the different substrates are also seen in the VASE measurements.

EL01.05.15
Multifunctional Infrared Metasurfaces for Polarization Analysis Joseph Miragliotta, Andrew Strikwerda, David Shrekenhamer, Lance Oh, Luke Currano and Garret Bonnema; JHUAPL, United States

The emergence of metasurface technology and its accompanying design principles are enabling the development of optical components with multiple functionalities, e.g., polarization discrimination and focusing. In this report, we highlight our computational and experimental results associated with the design, fabrication, and experimental characterization of infrared (IR) metasurface optics that were designed for wavelength and polarization-specific analysis of infrared fields in the near and mid-wave IR region of the spectrum. For the former, we developed an all-dielectric metasurface that enabled polarization analysis of a 1.55 micron laser source. For the mid-wave metasurface, a reflective metasurface architecture was observed to exhibit polarization-selective imaging throughout the 4.5 to 5 microns region.

EL01.05.16
Dielectric Loss Compensation for Enhanced Optical Rectenna Conversion Efficiency Ayendra Weerakkody and Garret Moddel; University of Colorado, United States

Frequency-dependent losses associated with dielectrics limit the efficient operation of devices at mid-infrared (IR) wavelengths. These material losses were overlooked in certain research areas such as metal-insulator-insulator-metal (MI2M) diode based optical rectennas for mid-IR energy harvesting, due to the difficulty in measuring/characterizing material properties at these frequencies. Many researchers in this field have focused only on enhancing the rectification efficiency of the diode and the coupling efficiency between the antenna and the diode. In this work, we demonstrate a technique understand the role of dielectric losses at 28.3 THz in our rectennas, and to introduce an innovative solution by taking advantage of combined effects of geometric dependence of losses, high frequency voltage division and resonant tunneling to achieve an improvement in conversion efficiency. First, we measured the frequency dependent complex dielectric constants of the MI2M diode oxide stack, which consisted of NiO and Al2O3, by mid-IR variable angle spectroscopic ellipsometry. After performing physical characterization, we fabricated 6 different wafers of rectennas with varying NiO thicknesses. Then we measured their DC current-voltage (I(V)) characteristics, as well as their optical response under illumination with a CO2 laser. Since the MI2M diode I(V) characteristics vary with frequency [1], we extracted the high-frequency DC resistance of the diodes by considering the ratio of open-circuit voltage to short-circuit current. This resistance, along with the measured complex dielectric constants, is used to model the rectenna as a clamper circuit with shunt-capacitive and conductive losses in parallel with the diode resistance [2]. These material losses were found to depend on the thickness of the diode, with thicker oxides compensating for losses as the losses are inversely proportional to the thickness. Due to compensation of losses in combination with high-frequency voltage division and resonant tunneling, we were able to achieve diodes with a conversion efficiency ten times higher than uncompensated devices.

References:
Light displays a wide range of different possible interactions with naturally-occurring materials. Optical sensing and imaging applications capitalize on this fact to study such materials and structures of interest. Alternatively, it is possible to engineer new, nanostructured materials that only exhibit a strong interaction to light waves with specific properties, e.g. a specific incident angle, wavelengths, or state of polarization. We are interested in using such designer materials to realize new types of specialized photodetectors for angular sensing and spectropolarimetry. To achieve specific sensing functions, one typically combines a conventional photodetector with a set of bulky optical elements capable of filtering light waves with properties of interest. These can include lenses, gratings, apertures, prisms, and polarization filters. This strategy makes dense integration a significant challenge. To overcome this challenge, we proposed the use of different types of high-index semiconductor nanostructures that exhibit an optically resonant interaction with the light waves of interest. These resonances can boost light-matter interaction and enhance absorption and photocarrier generation. This ultimately facilitates the creation of compact, highly integrated photodetectors that do not require additional external elements.

Here, we illustrate our approach with a nanopatterned silicon layer that displays a high differential absorption for left and right-hand circularly polarized light. It achieves this function by engineering both Mie and guided mode resonances in dislocated silicon nanowire patterns. We will present the fabricated photodetector structures and their experimental characterization. The proposed structures could potentially be used in a wide range of applications, for sensing, imaging, and augmented/virtual reality.

Tunable Terahertz Complimentary Metamaterial Enabled by Phase Transition of Vanadium Dioxide
Xiaoguang Zhao¹, Xuefei Wu¹, Jacob Scalch², Guangwu Duan¹, Richard Averitt², Xin Zhang¹ and Chunxu Chen¹; ¹Boston University, United States; ²University of California, San Diego, United States

Metamaterials and metasurfaces have enabled myriad applications by breaking the limitations of natural materials, including negative refraction index, subwavelength imaging, near zero epsilon, metalens, and invisibility cloaking. Tunability in metamaterials has generally been achieved through inclusions of condensed matter systems in which a dynamic response is induced by external excitations. The tunability by this method is both the extension and restriction of the metamaterials capability as the limits of the tuning are defined by the dynamic range of the included material. Overcoming this limitation of tunable materials and achieving better performance in hybrid devices is a challenge that can lead to greater advances in these devices. Vanadium dioxide (VO₂) is a correlated electron material, which has been particularly well studied largely because the insulator-to-metal transition (IMT) occurs above room temperature at around 340K. Upon undergoing the IMT, the resistivity changes by four-orders of magnitude and across a broad spectral range making VO₂ a powerful dynamic material to be combined with metamaterials to introduce nonlinear responses, state switches, and modulators. The physics of the accompanying crystal transformation from monoclinic to rutile state has historically obscured the exact mechanism of the transition.

In this paper, we patterned a complementary metamaterial on a thin layer of vanadium dioxide films by direct laser writing technique and photolithography to explore the tunable terahertz (THz) response. The metamaterial exhibits a transition in THz transmission which is larger than of a pristine VO₂ film. The modulation enhancement of dynamic materials by metamaterial resonators provides a way to enhance the natural utility of VO₂ through metamaterial inclusions while the sensitivity of the complementary resonator provides a straightforward way to investigate the nature of mesoscopic transition phenomena in correlated electron materials. We characterize the phase transition response of the VO₂ film and the tunable metamaterial using THz time-domain spectroscopy. For the complementary metamaterial, the resonance peak occurs at 0.48THz with a peak transmission of 82.8% when the VO₂ is in insulator state at the temperature below 315K. As the temperature increases, the VO₂ thin film transits to the metallic state, thus the resonance peak vanishes. The modulation amplitude of THz transmission at 0.48THz is 68.3%. We measured the dynamic transition as a function of temperature for heating and cooling processes.
transmission of VO$_2$ CSRR during the heating process does not change until the temperature reaches 334K. A dramatic reduction of transmission occurs within a 2K span from 335K to 337K during heating. Upon cooling, the reverse transition occurs albeit at a lower temperature. The rapid onset of this transition coupled with the wide hysteresis presents an attractive feature for applications in THz switches and modulation devices.

**Hybrid Graphene/Metal Antenna Arrays for Terahertz Communications**

Arpit Jaiswal, Arjun Singh, Farah Vandrevala, Josep Jornet and Erik Einarssson; University at Buffalo, United States

There is a critical need for compact antenna arrays capable of transmitting and receiving information in the terahertz band (0.1-10 THz). In order to achieve this goal, control of the array response is essential. Here we report design, fabrication, and experimental characterization of a hybrid graphene/metal antenna array consisting of metallic elements fabricated atop graphene. The antenna design was developed through numerical simulations that were informed by experimentally obtained graphene parameters. Experimental characterization revealed a clear enhancement due to the array, and the presence of the underlying graphene affected the reflected intensity. Graphene’s Fermi energy can easily be tuned by electrostatic gating, which makes this structure promising for active, steerable THz reflectarrays.

**EL01.05.20**

**Unexpected Photonic Band Gaps in 3D Crystal Structures**

Rose Cersonsky, James Antonaglia, Bradley Dice and Sharon C. Glotzer; University of Michigan, United States

Photonic crystals are materials composed of mixed dielectric media that result in the reflection of all electromagnetic waves within a range of wavelengths commensurate with the length scale of the crystal. Such complete photonic band gaps allow for light to be controlled through materials design. Since first theorized in 1987, much effort has been made to define and synthesize photonic crystal structures. In the decades since, many photonic structures have been discovered, often by using naturally occurring crystal structures as templates for design. However, these studies have yet to answer the question: what features of a 3D structure will produce a complete photonic band gap? Here, we present data on over 150,000 potential photonic crystals, and show that complete photonic band gaps are possible for many unexpected structures that have yet to be explored. Our simulations suggest that when designing novel photonic materials, the toolbox of structural templates may be larger and richer than previously thought, widening the field of target crystal structures.

**All-Dielectric Metasurfaces Made of HfO$_2$ Nanopillars for Structural Coloration**

Omid Hemmatyar, Sajjad Abdollahramezani, Yashar Kiarashinejad, Mohammadreza Zandehshahvar and Ali Adibi; Georgia Institute of Technology, United States

We perceive the color of an illuminated object in our surrounding primarily since it selectively reflects certain colors and absorbs the others. Beside these mechanisms, colors can be generated resorting to another mechanism called structural coloration. In structural coloration, the interaction of incident light with nanoscale features in the illuminated object leads to specific resonances in the reflection light each associated to a specific color. In recent years, due to several advantages of structural colors over its counterpart such as resistivity to high-temperature, photobleaching and ultraviolet irradiation on one side, and huge advancement in the fabrication technology on the other side, a significant research has been done to generate artificial structural colors using sub-wavelength nanophotonics structures. To implement these structural colors, both plasmonic and all-dielectric metasurfaces (MSs) have been used due to their capability of manipulating the light-matter interaction at nanoscales. However, the intrinsic dissipative ohmic loss in metals used in plasmonic MSs significantly reduces the quality of generated colors by broadening and weakening the resonance peak of the reflection which leads to small color gamut with low color saturation. To circumvent this issue, all-dielectric MSs using high-index or transparent dielectric materials have been used as an alternative to plasmonic-based structural colors [1]. Here, for the first time to our knowledge, we designed and fabricated an all-dielectric MS comprising of hafnia (HfO$_2$) nanopillars (NPs) to generate colors. These NPs can support both electric dipole (ED) and magnetic dipole (MD) modes due to the low loss of HfO$_2$. The MD mode can be coupled to the reflected light resulting in a sharp Fano-type resonance in the reflection spectrum which is desired for generation of pure and vivid colors. In the design step, we first simulated a set of MSs with different design parameters using finite difference time domain (FDTD) solver in Lumerical. Then, we fed the corresponding
reflection responses as the training data to a pseudo-encoder module [2, 3, 4], within deep learning architecture, and found the periodicity of the unit cell of our MS as the most effective design parameter on the spectral properties of the sharp Fano-type resonances. Based on these results, we again simulated a set of MSs with optimized design parameters to generate colors with high saturation. Finally, the designed MSs were fabricated using atomic layer deposition which enables fabrication of nano-scale features with minimum surface roughness as required in our MSs. The experimental results are in good agreement with those of simulation.

Multipole Resonances in Transdimensional van der Waals Antenna Lattices Viktoriia Babicheva; University of New Mexico, United States

Novel van der Waals materials and their heterostructures are especially promising in an ongoing quest for suitable photonic materials that enable miniaturization of optical components. van der Waals materials possess high optical anisotropy as the strong covalent bonding within a specific layer and weak van der Waals forces between adjacent material layers result in highly anisotropic lattice vibrations along the in- and out-of-plane directions of the layered material. It is proposed to use optical antennas made out of natural hyperbolic material hexagonal boron nitride (hBN) as an alternative way of realizing efficient subwavelength scatterers and overcoming limitations of plasmonic and all-dielectric material platforms [1,2]. Transdimensional designed lattices of resonant hBN antennas in the periodic arrays can serve as functional elements in ultra-thin optical components and photonic applications. In this talk, I will show that the hBN antenna possesses different multipole resonances enabled by the supporting high-k modes and their reflection from the antenna boundaries. An electric quadrupole mode causes a resonant magnetic response of the scatterer because of wave reflections from its boundaries similar to the formation of magnetic resonance in high-refractive-index elements. The full range of the resonances is demonstrated for the hBN cuboid antenna, a decrease of reflection from the array, and highly directional resonant scattering from antennas pairs. Multipole resonances cause the decrease in the reflection from antenna array to zero, which can be ascribed to resonant Kerker effect satisfying generalized zero back-scattering condition for particles in the array [3]. Transdimensional hBN lattices include 3D-engineered nanoantennas supporting multipole resonances in hBN antennas and arranged in the 2D arrays to leverage collective effects in the nanostructure. The effect can be used in designing optical elements and metasurfaces based on hBN scatterers for applications in mid-infrared photonics. The work is supported by AFOSR grant FA9550-19-1-0032.
Oxides exhibiting extremely low thermal conductivity ($\kappa$) are essential for heat management technologies such as thermoelectrics and thermal barrier coatings. Fabricating artificial superlattices is an effective approach to minimize the $\kappa$ of oxides because of the Kapitza resistance (interface between two different phases). However, their practical applications are limited by difficulties and cost of the atomic-scale fabrication. Therefore, materials exhibiting natural superlattice structures are of great value. The $\kappa$ of some natural superlattice In$_M$O$_3$(ZnO)$_m$ ($M = \text{In, Fe, and Ga}$, $m = \text{integer}$) polycrystals have been reported, but it has been very challenging to examine the effect of the Kapitza resistance due to the randomly-oriented grains. Here we fabricated InGaO$_3$(ZnO)$_m$ single crystalline films by the reactive solid-phase epitaxy method and measured the $\kappa$ perpendicular to the natural superlattices. When the superlattice period ($d_{SL}$) was longer than 1.93 nm, the thermal resistivity increased proportionally with the interface density ($d_{SL}^{-1}$), indicating that the ballistic phonon transport was suppressed at the InO$_2$/GaO(ZnO)$_m$ interfaces, which exhibited the Kapitza resistance of 1.64 m$^2$ K GW$^{-1}$. The minimum $\kappa$ was 1.12 W m$^{-1}$ K$^{-1}$ ($m = 5$), which is approximately 1/3 of the polycrystalline ceramics and lower than the amorphous InGaO$_3$(ZnO)$_m$. These results would be useful for advanced heat management technologies.

Controlling Emission of WS$_2$ Monolayer with a Spherical Silicon Mie Resonator

Tatsuki Hinamoto$^{1,2}$, Yan Joe Lee$^2$, Søren Raza$^3$, Hiroshi Sugimoto$^1$, Minoru Fujii$^1$ and Mark L. Brongersma$^2$; $^1$Kobe University, Japan; $^2$Stanford University, United States; $^3$Technical University of Denmark, Denmark

Two-dimensional transition metal dichalcogenides (TMDCs) have emerged as novel quantum emitters. Achieving control of their radiation properties, such as excitation rate, radiation efficiency, and radiation pattern, is of importance for next-generation photonic and optoelectronic devices. Recently all-dielectric nanophotonics has been identified as a promising way to control such radiation properties at the nanoscale by coupling the emitter to Mie resonators. It has been experimentally and theoretically demonstrated that Mie-resonant silicon nanowires (diameter/length $\sim$ 100 nm/40 um) can provide directionality to the emission of monolayer MoS$_2$ emitters due to the interaction between the source dipole and the excited electric and magnetic dipole resonances.[1] In order to further reduce the dimensions of the resonator, we propose a spherical Mie resonator for control over the radiation pattern of monolayer TMDCs.

First, we theoretically analyze the optical coupling of a 100-200 nm silicon nanosphere and a dipole emitter by modifying the classical Mie theory for excitation with a point dipole. As for the case of a silicon nanowire, the interaction of the source dipole and the excited electric and magnetic dipole resonances results in directional emission. To demonstrate this experimentally, we dropcast colloidal silicon nanospheres (100-200 nm in diameter) [2] onto monolayer WS$_2$ coated silica substrates. After Ar$^+$ ion etching of WS$_2$ around the silicon nanospheres to remove uncoupled emitters, we measure the exciton photoluminescence intensity of WS$_2$ under single silicon nanospheres using objectives in the top and bottom direction. By studying the top-to-bottom PL ratio over many nanospheres, we demonstrate 8-fold directionality in emission for selected nanosphere sizes as expected from our theoretical analysis.

Metasurfaces for Augmented and Virtual Reality
Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of nanophotonic metasurfaces has further accelerated the development of flat optical elements through the realization that resonant optical antenna elements can be utilized to facilitate local control over the light scattering amplitude and phase. In this presentation, I will show how metasurfaces can start to impact Augmented and Virtual Reality applications. I will discuss the creation of free space optical beam tapping systems and high-efficiency metasurface-based optical combiners for near-eye displays. The proposed optical elements can be fabricated by scalable fabrication technologies, such as nanoimprint lithography, rolling optical lithography, and direct write optical lithography.

Meta-Optics and Metasurfaces with Mie-Resonant Dielectric Structures
Yuri Kivshar1,2; 1Australian National University, Australia; 2ITMO University, Russian Federation

Metamaterials---artificial electromagnetic media that are structured on the subwavelength scale---were initially suggested for the realization of negative index media, and later they became a paradigm for engineering electromagnetic space and controlling propagation of waves. However, applications of metamaterials in optics are limited due to inherent losses in metals employed for the realisation of artificial optical magnetism. Recently, we observe the emergence of a new field of all-dielectric resonant metaoptics aiming at the manipulation of strong optically-induced electric and magnetic Mie-type resonances in dielectric and semiconductor nanostructures with relatively high refractive index [1]. Unique advantages of dielectric resonant nanostructures over their metallic counterparts are low dissipative losses and the enhancement of both electric and magnetic fields that provide competitive alternatives for plasmonic structures including optical nanoantennas, efficient biosensors, passive and active metasurfaces, and functional metadevices [2, 3]. Here, we aim to summarize the most recent advances in all-dielectric Mie-resonant meta-optics including active nanophotonics as well as the recently emerged fields of topological photonics and nonlinear metasurfaces.

In addition, we also aim to review the physics of bound states in the continuum and their applications in metaoptics and metasurfaces [4]. First, we discuss strong coupling between the modes of a single subwavelength high-index dielectric resonator and analyse the mode transformation and Fano resonances when resonator’s aspect ratio varies [5]. We demonstrate that strong mode coupling results in resonances with high quality factors, which are related to the physics of bound states in the continuum when the radiative losses are nearly suppressed due to the Friedrich–Wintgen scenario of destructive interference. Our theoretical findings are confirmed by microwave and optical experiments for the scattering of high-index subwavelength resonators with a tunable aspect ratio. The proposed mechanism of the strong mode coupling in single subwavelength high-index resonators accompanied by resonances with high-Q factor helps to extend substantially many functionalities of all-dielectric nanophotonics that opens new horizons for active and passive nanoscale metadevices. Next, we discuss how bound states in the continuum can appear in the physics of metasurfaces. We reveal that metasurfaces created by seemingly different lattices of (dielectric or metallic) meta-atoms with broken in-plane symmetry can support sharp high-Q resonances that originate from the physics of bound states in the continuum [6]. We demonstrate a direct link between the bound states in the continuum and Fano resonances, and discuss a general theory of such metasurfaces, suggesting the way for smart engineering of resonances for many applications in nanophotonics and meta-optics.

11:00 AM EL01.07.03
Enhancing the Most Versatile and Time-Tested Radiative Cooling Metamaterial – Challenges and Opportunities with Paints Jyotirmoy Mandal1, Aaswath Raman2, Adam Overvig1, Kamal Krishna Mandal3, Yuan Yang1 and Nanfang Yu1; 1Columbia University, United States; 2University of California, Los Angeles, United States; 3Chittagong Medical College Hospital, Bangladesh

In recent years, research on passive daytime radiative cooling has seen a variety of metamaterial-based innovations, such as structured polymers [1], photonic designs [2-3], and polymer-dielectric composites [4-6]. However, paints, which combine the optical functionalities of pigments, dyes and polymers across the solar to thermal infrared wavelengths, remain a time-tested, versatile and by far the most established radiative cooling 'metamaterial'. With the rapidly rising global demand for cooling necessitating immediate solutions, it is therefore paints on which research advances stand to be most impactful.

In this presentation, we will provide a broad overview of paints as a versatile radiative cooling metamaterial platform with multiple avenues for exploration. We will first discuss how the individual components of paints, e.g. dyes, pigments and polymers, contribute to the solar reflectance and thermal emittance required for radiative cooling. By altering these constituents and their size, as well as the macroscopic morphology of paint coatings, their optical properties can be drastically altered. We will specifically discuss the optimization of reflective pigments to maximize broadband solar reflectance, ways of enhancing the ultraviolet reflectance, tailoring macroscopic morphology to simultaneously achieve color and high near-to-shortwave infrared reflectance, reducing the diffuse glare of white paints, and enabling optical switching. Associated non-optical aspects, like the durability of optical performance, will also be discussed. Commercial state-of-the-art, recent scientific advances, and outstanding questions on paints will be presented as windows for further explorations in this field.

11:15 AM EL01.07.04
Dynamic Flat Lenses with Nonlinear, High-Q Dielectric Metasurfaces Elissa Klopfer, Mark Lawrence, David Barton, Jefferson Dixon and Jennifer A. Dionne; Stanford University, United States

Conventional imaging requires long path lengths and bulky, multi-lens components. For applications including on-chip microscopy, lightweight space probes, LIDAR, and point-of-care diagnostics, metasurfaces promise high-fidelity imaging but in a highly reduced footprint. Metasurfaces, two-dimensional arrays of subwavelength nanostructures, precisely control the amplitude, polarization, and phase of waves in an ultrathin system. However, dynamically controlling their optical output in response to an applied bias remains an outstanding challenge. Here, we present ultrathin imaging metasurface which exploits the nonlinear Kerr effect to locally modulate the refractive index, and hence the focal intensity. Our metasurface lens consists of a series of 25 nanoscale silicon bars, 700 nm in height with a width varying from 100 and 400 nm, separated by 700 nm. The width of each individual bar imparts a phase shift, that in series can be designed to form a parabolically-varying phase profile to focus the incoming light between 4 um and 20 um away. Importantly, Silicon also supports inherent nonlinearities via the optical Kerr effect, which describes a change in a materials refractive index dependent on incident intensity. To achieve efficient
nonlinearities, we introduce periodic notches symmetrically on both sides of the 219 nm wide Si bars, which introduces a high quality factor (high Q) mode via a guided mode resonance near the lens’s designed operating wavelength 1500 nm. Our full-field simulations indicate Q factors spanning 10000 to over 100000 at 1473 nm for symmetric notches spanning in depth from 10 nm to 2 nm with a period of 650 nm in a 100 nm wide Si slab. We then utilize this high-Q lens to modulate the intensity of the focal spot with input power. In the nonlinear regime, as the power increases from 1 kW/cm² to 50 kW/cm², the resonance red-shifts from 1499.4 nm to 1499.7 nm and the normalized power at the focal spot decreases 4-fold. Importantly, this power-limiting meta-lens operates at optical frequencies, utilizes Si in a lossless regime, and can be readily extended for multi-wavelength operation by integrating additional notches into the adjacent Si bars. Our presentation will describe both the design and fabrication of this nonlinear imaging metasurface, as well as applications to dynamic imaging.

11:30 AM EL01.07.05
Inverse Design of Actively Tunable Metasurfaces for Beam Steering Applications Prachi Thureja¹,², Ghazaleh Kafaie Shirmanesh¹, Katherine T. Fountaine³, Meir Grajower¹, Ruzan Sokhoyan¹, Yury S. Tokpanov¹ and Harry A. Atwater¹; ¹California Institute of Technology, United States; ²ETH Zürich, Switzerland; ³Northrop Grumman NG Next, United States

The ability to comprehensively control the constitutive properties of light including wavelength, amplitude, phase and polarization is crucial to the development of novel technologies for sensing, imaging, flat optics and holography. In recent years, metasurfaces have enabled extraordinary advances in light manipulation through precise design of their subwavelength resonant elements. However, the static nature of passive metasurfaces does not allow for post-fabrication modifications to their optical response, which limit their utility. Active metasurfaces overcome this limitation by enabling real-time control of the properties of scattered light. The active control is achieved by applying external stimuli to tune the intrinsic properties of subwavelength antenna elements. While this greatly enhances the versatility of metasurfaces, active metasurfaces typically do not exhibit ideal phase-amplitude response, i.e. constant reflectance and a phase shift of up to 360°. In addition, experimental non-idealities result in discrepancies between desired and measured performance and often generate scattering in undesired directions.

We report an inverse design approach to achieve optimal beam-steering behavior for active metasurfaces that includes experimentally relevant non-idealities, such as limited phase response, non-unity reflectance and correlation of phase and amplitude. By evaluating several multi-parameter global optimization methods, we develop an approach to enable prediction of the amplitude and direction of the scattered light, enabling access to any arbitrary steering angle. Additionally, our approach successfully overcomes the challenge posed by an inherently high dimensional optimization space. The non-intuitive solutions generated by our algorithm show up to an 86% improvement in the directivity of the steered beam compared to previous ‘forward’ designs, which typically assume constant amplitudes and do not account for experimental artefacts.

In previous experiments we have demonstrated wide phase and reflectance tunability via carrier density and refractive index modulation in gated metasurfaces that employ a semiconducting indium tin oxide (ITO) active layer [1]. Our inverse design approach treats each nanostructured antenna as an individual metal-oxide-semiconductor element, by which phase profiles are generated on a flat surface with the goal of creating arrays suitable for applications in beam-steering devices or focusing metalenses [2]. Furthermore, we use these device geometries for experimental validation of the proposed inverse design approach and discuss the role of near-field coupling between nanoantennas and its effects on the far-field radiation pattern. Finally, we explore the capabilities of our algorithm by applying it to other active metasurface functions such as reconfigurable metalens focusing and simultaneous steering in multiple directions.

11:45 AM EL01.07.06
Perfect Absorption in All-Dielectric Photoconductive Metasurfaces for Fast Optoelectronic Switching Thomas Siday¹, Polina Vabishehevich², Lucy Hale¹, Charles T. Harris², Ting Luk², John L. Reno², Oleg Mitrofanov² and Igal Brener¹; ¹University College London, United Kingdom; ²Center for Integrated Nanotechnologies, United States

Perfect absorption at desired wavelengths enables efficient operation of optoelectronic switches. We develop and
demonstrate an all-dielectric metasurface consisting of a network of electrically connected nanoscale semiconductor resonators with perfect absorption at 800 nm. Our metasurface is designed to support two degenerate magnetic dipole modes with their effective magnetic dipole vectors in and out of the metasurface plane. To enable excitation of the latter mode, which is symmetry-protected from coupling to plane waves at normal incidence, we break the resonator symmetry using simple geometrical perturbations. As a result, two modes can be excited simultaneously, leading to perfect absorption at the wavelength of 800 nm. The broken symmetry design implemented in a thin layer of low-temperature grown GaAs allows us to switch the metasurface between conductive and resistive states with extremely high contrast on the time scale of ~1 ps using an unprecedentedly low level of optical excitation. This capability allows us to make fast and more energy efficient optoelectronic detectors with THz bandwidth.

Quasi-2D Plasmons in Optical Coatings—From Emission Engineering to NanoKirigami Nicholas Fang; Massachusetts Institute of Technology, United States

Recently, exciting new physics of plasmonics has inspired a series of key explorations to manipulate, store and control the flow of information and energy at unprecedented dimensions. In this talk I will report our recent efforts on controlling light absorption and emission process in quasi-two dimensional optical coatings. In the first example, we show how the coherent Coulombic interaction between the molecular dipoles within a molecular aggregate can be tuned by surface plasmons in close proximity. We demonstrate experimentally ultrafast quenching of 2D molecular aggregates at picosecond timescale. Our analysis reveals that the metal-mediated dipole-dipole interaction increases the energy dissipation rate by at least five times faster than that predicted by conventional models. Our results can offer novel design pathways to the light-matter interaction in a variety of photon-exciton systems with applications such as high speed visible light communication.

In a second example, I will introduce versatile 3D shape transformations of nanoscale structures by deliberate engineering of the topography-guided stress equilibrium of gold nanostructures. By using the topography-guided stress equilibrium, rich 3D shape transformation such as buckling, rotation, and twisting of nanostructures is precisely achieved, which can be predicted by our mechanical modeling. Benefiting from the nanoscale 3D twisting features, giant optical chirality is achieved in an intuitively designed 3D pinwheel-like structure, in strong contrast to the achiral 2D precursor without nano-kirigami. The demonstrated nano-kirigami, as well as the exotic 3D nanostructures, could be adopted in broad nanofabrication platforms and could open up new possibilities for the exploration of functional micro-/nanophotonic and mechanical devices.

2:00 PM *EL01.08.02
Empowering Bilayer MoS2 by Engineered Plasmonic Nanostructures for Optoelectronic Applications Ta-Jen Yen; NTHU, Taiwan

Recently, extracting hot electrons from plasmonic nanostructures and utilizing them to enhance the optical quantum yield of 2D transition-metal dichalcogenides (TMDs) have been topics of interest in the field of optoelectronic device applications, such as solar cells, light emitting diodes, photodetectors and so on. The coupling of plasmonic nanostructures with nanolayers of TMDs depends on the optical properties of the plasmonic materials, including radiation pattern, resonance strength, and hot electron injection efficiency. Herein, we present three cases of intensifying the light-matter interactions between nano-scale plasmonic structures and a large-scale, transfer-free bilayer MoS2. These methods include 1. unusual quadrupole gap plasmons (QGP) in the tailored nanoantennas, 2. four different morphology-controlled plasmonic nanoparticles, and 3. engineering the bandgap of the bilayer MoS2 with the localized strain from the plasmonic nanostructures. By introducing the plasmonic effects aforementioned into the large-scale, transfer-free bilayer MoS2, our experimental results demonstrate not only excellent optoelectronic response, but also practical applications in hydrogen evolution reaction, photodetection and others.
2:30 PM EL01.08.03
Mid-Infrared Radiative Emission from Bright Hot Plasmons in Graphene Laura Kim1, Seyoon Kim1,2, Pankaj K. Jha1, Victor Brar1,2 and Harry A. Atwater1; 1California Institute of Technology, United States; 2University of Wisconsin–Madison, United States

The decay dynamics of excited carriers in graphene have attracted wide scientific attention, as the gapless Dirac electronic band structure opens up relaxation channels that are not allowed in conventional materials. We report Fermi-level-dependent mid-infrared emission in graphene originating from a previously unobserved decay channel: hot plasmons generated from optically excited carriers. In infrared emission spectroscopy measurements taken under optical excitation with a Ti:Sapphire laser operating at 850 nm with 100-fs pulse duration, we have measured emission for several sample geometries: planar graphene, and non-resonant and resonant gold nanodisks (NDs)-decorated graphene. The Fermi-level dependence of the observed radiation under pulsed laser excitation rules out Planckian light emission mechanisms, and is distinctly different from that observed under CW laser excitation. Our experimental results are consistent with the calculated plasmon emission spectra in photoindverted graphene, which suggest that quasi-equilibrium ‘hot’ carrier distributions in graphene upon ultrafast optical excitation support bright mid-infrared plasmonic excitation. Evidence for bright hot plasmon emission is further supported by a large emission enhancement observed from graphene decorated with gold NDs, which serve as out-coupling scatterers and promote localized plasmon excitation. The spectral flux of spontaneously generated plasmons is found to be several orders of magnitude higher than blackbody emission at a temperature of several thousand Kelvin. In addition, calculations for our experimental conditions indicate that conditions for plasmon gain exist on the sub-100 fs timescale during which stimulated plasmon emission dominates spontaneous plasmon emission. These observations set a framework for exploration of ultrafast and ultrabright mid-infrared stimulated and spontaneous emission processes and bright infrared light sources.

2:45 PM EL01.08.04
Strong Structural Nonlinearity from Plasmonic Nanowire Metamaterials in the Infrared Regime Brian M. Wells1, Anton Bykov2, Giuseppe Marino2,3, Mazhar Nasir2, Anatoly Zayats2 and Viktor Podolskiy4; 1University of Hartford, United States; 2King’s College London, United Kingdom; 3Université Paris Diderot-CNRS, France; 4University of Massachusetts Lowell, United States

Nonlinear optics is essential for information processing, sensing, and optical characterization applications. There are well known strong nonlinear homogeneous materials available at visible frequencies and composite structures that can exhibit a strong nonlinear response already engineered at long-wave-IR frequency ranges, but there are few materials with strong second order nonlinearity that exist within the infrared frequency range. Over the past decade, metamaterials, composites with subwavelength (often, plasmonic) inclusions have emerged as a viable platform for engineering linear optical response. Nonlinear metamaterials, where the structure of the composite used to re-shape local fields and enhance the nonlinear response of the components, have also been proposed.

Recently, we have demonstrated the emergence of structural nonlinearity, where the bulk nonlinear response of the composite results from a nonlinear interaction of nano-shaped light and free-electron plasma in nominally non-second harmonic generation (SHG) active gold. For this work we explore the potential of structural nonlinearity in plasmonic metamaterials for the second harmonic response at infrared frequencies. We demonstrate the emergence of structural response in plasmonic nanowire metamaterials and analyze perspectives of structure-induced plasmonic nonlinearities for the infrared frequency range.

Eigenmode Engineering of Nanolasers Ren-Min Ma; Peking University, China

Nanolasers generate coherent light at the nanoscale. In the past decade, they have attracted intense interest, because they are more compact, faster and more power-efficient than conventional lasers. The eigenmode of a nanolaser can be engineered in a controllable manner for novel inner laser cavity field and/or emission beam synthesis. Furthermore, ensembles of nanolasers operating in unison can provide a macroscopic response that would not be possible in conventional lasers.

4:00 PM E1.01.09.02
Thermal Emission by Nanoscale Transmission Line Resonators Bowen Yu, Jiayu Li and Sheng Shen; Carnegie Mellon University, United States

Thermal radiation with a narrow-band emission spectrum is of great significance in various applications such as infrared sensing, thermophotovoltaics, radiation cooling, and thermal circuits. Although resonant nanophotonic structures such as metamaterials and nanocavities have been demonstrated to achieve the narrow-band thermal emission, tuning their radiation power toward perfect emission still remains challenging. Here, based on the recently developed quasi-normal mode theory, we prove that thermal emission from nanoscale transmission line resonators can always be controlled by tuning the size and geometry of single resonator and the density of the resonator array. By use of nanoscale transmission line resonators as basic building blocks, we experimentally demonstrate a new type of macroscopic perfect and tunable thermal emitters. The transmission line resonator arrays are fabricated by standard E-beam lithography techniques and subsequent lift-off process. The emissivity of the samples is measured by using a FTIR spectrometer combined with an infrared microscope. Our experimental demonstration in conjunction with the general theoretical framework lays the foundation for designing tunable narrowband thermal emitters with applications in thermal infrared light sources, thermal management, and infrared sensing and imaging.

4:15 PM E1.01.09.03
Continuous-Wave Lasing from Single Quantum Dot integrated with Plasmonic Nanocavity Yu-Hung Hsieh1,2, Kang-Ning Peng2, Bo-Wei Hsu1, Hao-Wu Lin1, Ta-Jen Yen1 and Yu-Jung Lu2,3; 1National Tsing Hua University, Taiwan; 2Academia Sinica, Taiwan; 3National Taiwan University, Taiwan

Lead halide perovskites have recently received considerable attention as promising candidates for laser devices due to excellent material properties such as high optical gain coefficient and low non-radiative recombination rate. However, most of the lead halide perovskite lasers were operated in pulsed mode in order to reduce the thermal loss to achieve population inversion, which requires extra efforts to generate the external pulsed excitation source. Here, we demonstrate a continuous wave lasing from single lead halide perovskite (CsPbBr3) quantum dot integrated with plasmonic nanocavity with undetectable threshold (power density lower than 90 mWcm\(^{-2}\)) and ultra-sharp single mode lasing (linewidth of 1.4 nm) under a cryogenic temperature at 4 K. In our design, a silver nanocube was placed on a gold substrate, with a single CsPbBr3 quantum dot placed in between. By finite-difference time-domain simulation method to calculate the electric field distribution of the designed structure, we theoretically observed a strong localized optical confinement, plasmonic gap mode, formed between the silver nanocube and the gold substrate. The plasmonic gap mode acts as plasmonic nanocavity and contributes a large Purcell enhancement (Purcell factor ~200) which can be determined via time-resolved photoluminescence measurement. In order to avoid quenching effect, a 6 nm Al\(_2\)O\(_3\) spacer was used to separate the quantum dot and the gold substrate, and the silver nanocube was covered by 1 nm Polyvinylpyrrolidone to isolate the emitter. In order to measure the lasing threshold, the temperature dependent light-in-light-out curve was performed and we observed a very small lasing threshold (power density lower than 188 mWcm\(^{-2}\)) at 80 K. This work is the first demonstration of continuous wave lasing from single quantum dot integrated with plasmonic nanocavity. In the end, we will discuss the detail working mechanisms as well as the practical applications.

4:30 PM E1.01.09.04
Disordered Anderson Lasing from Plasmonic-Scattering Assisted Perovskite Microparticles Sangyeon Cho1,2, Andreas C. Liapis2 and Seek-Hyun Yun1; 1Massachusetts Institute of Technology, United States; 2Harvard Medical School and Massachusetts General Hospital, United States

The integration of plasmonic nanoparticles and optical gain materials has opened a new avenue in developing micro- and nano-lasers. Lead halide perovskite is as a promising semiconductor gain material with high optical gain and
solution processability. Here, we describe a technique to integrate plasmonic particles into perovskite-based matrices and demonstrate lasing from various micro-structures. In particular, our results suggest that photonic Anderson localization can be achieved owing to the combination of strong light scattering from the embedded plasmonic particles and high optical gain from perovskite nanocrystals. In this work, we used a spin-cast precipitation of perovskite precursors and metallic particles to produce spherical microshells, which comprises a Ruddlesden-Popper phase CsPb$_2$Br$_5$ matrix incorporating CsPbBr$_3$ nanocrystals and silica-coated silver spheres with a diameter of 100 nm. In a coherent-backscattering experiment, we measured the product of wavenumber and disorder length to be 0.7, satisfying the Ioffe-Regel criterion for strong transverse localization. We observed stable multimode Anderson lasing from the hybrid microparticles under nano-seconds optical pumping at room temperature. The smallest Anderson localized laser we observed has an outer diameter of 1.1 μm and a shell thickness of 210 nm containing about 15 silver particles, with a lasing threshold of 4 mJ/cm$^2$.

4:45 PM EL01.09.05
**Plasmon-Enhanced Up-Conversion Fluorescence at Short-Wave Infrared** Shengnan Huang, Ching-Wei Lin and Angela Belcher; Massachusetts Institute of Technology, United States

Optical imaging owns the privilege of high specificity and high sensitivity due to the spectral multiplexing for *in vivo* applications, but is always hampered by the tissue autofluorescence and scattering. One promising approach to preventing tissue autofluorescence for optical imaging is to use up-conversion fluorphores. However, traditional up-conversion nanoparticles emit in the visible range, where the emission signal is heavily absorbed by the tissue, reducing the signal-to-noise ratio. In this work, we developed an autofluorescence-free imaging probe with plasmon-enhanced up-conversion fluorescence in the short-wave infrared window (850-1700 nm). We find the up-conversion enhancement is more than 125 times compared to the free fluorophores. Thermodynamic studies show that the dependence of up-conversion emission intensity on temperature fits the Arrhenius equation. In addition, the up-conversion emission intensity increases linearly with the excitation power. These results reveal that the observed plasmon-enhanced up-conversion is thermally assisted. Moreover, the tunable width of the working optical window for the up-conversion probe is around 200 nm, providing high flexibility for *in vivo* applications. Finally, we find that in a tissue phantom the signal-to-noise ratio of the plasmon-enhanced up-conversion fluorescence is more than 4 times better than the corresponding down-conversion fluorescence. The above results demonstrate that our plasmon-enhanced up-conversion fluorescent probe is a promising candidate for high-contrast *in vivo* imaging at short-wave infrared.

**Self-Assembled Ordered Three-Phase Au-BaTiO$_3$-ZnO Vertically Aligned Nanocomposites Achieved by a Templating Method** Shikhar Misra$^1$, Leigang Li$^1$, Di Zhang$^1$, Jie Jian$^1$, Zhimin Qi$^1$, Meng Fan$^1$, Hou-Tong Chen$^2$, Xinghang Zhang$^1$ and Haiyan Wang$^{1,1}$; $^1$Purdue University, United States; $^2$Los Alamos National Laboratory, United States

Complex multi-phase nanocomposite designs present a great opportunity for developing next generation integrated photonic and electronic devices. In this presentation, we demonstrate a unique three-phase nanostructure combining a ferroelectric BaTiO$_3$, wide band-gap semiconductor ZnO and plasmonic Au metal towards multifunctionalities. By a novel two-step templated growth, a highly ordered Au-BaTiO$_3$-ZnO nanocomposite in a unique “nanoman”-like form, i.e., self-assembled ZnO nanopillars and Au nanopillars in BaTiO$_3$ matrix, has been realized, and is very different from the random three-phase ones with randomly arranged Au nanoparticles and ZnO nanopillars in BaTiO$_3$ matrix. The ordered three-phase “nanoman”-like structure provides unique functionalities such as obvious hyperbolic dispersion in the visible and near infrared regime enabled by the highly anisotropic nanostructures.
compared to other random structures. Such self-assembled and ordered three-phase nanocomposite is obtained through a combination of Vapor-Liquid-Solid (VLS) and two-phase epitaxy growth mechanisms. The study opens up new possibilities in design, growth and application of multi-phase structures and provides a new approach to engineer the growth of complex nanocomposite systems with an increased control over electron-light-matter interaction at the nanoscale. Finally, in-situ Transmission Electron Microscope (TEM) heating studies is presented to determine the thermal stability of the three-phase nanocomposite.

EL01.10.02
Plasmon Driven Synthesis of Single Core@Shell Nanoparticles Rifat Kamarudheen\textsuperscript{1,2} and Andrea Baldi\textsuperscript{1,2}; \textsuperscript{1}Dutch Institute for Fundamental Energy Research, Netherlands; \textsuperscript{2}Technische Universiteit Eindhoven, Netherlands

Under illumination, noble metal nanoparticles such as Au, Ag and Cu can act as efficient sources of heat thanks to the decay of localized surface plasmon resonances, which are light-driven oscillations of their free electrons.\textsuperscript{1} Such heating effect is confined to the immediate surrounding of the particles and could therefore be used to locally activate chemical reactions with nanoscale spatial resolution.\textsuperscript{2,3} Here, we show how we can activate, control, and spectroscopically follow the growth of different semiconducting shells on individual plasmonic nanoparticles under laser irradiation. We first adapted a literature reported temperature-dependent colloidal synthesis of Au@CeO\textsubscript{2} core@shell nanoparticles in the dark\textsuperscript{4} and then perform the same synthesis at the single particle level at room temperature using plasmonic heating. We show that, under plasmon excitation, we can grow conformal metal oxide shells with growth rates that scale with the nanoparticle surface temperature. Furthermore, the shell growth can be monitored in-situ by tracking the photoluminescence spectra of the plasmonic nanoparticle under irradiation. We also demonstrate that such photothermally-driven synthesis of core@shell nanostructures can be extended to grow other semiconductors such as zinc oxide and zinc sulfide, illustrating the universality of our technique. The use of light as a tool to activate and control chemical reactions at the nanoscale can lead to the synthesis of shape- and size-controlled hierarchical nanostructures which are inaccessible with classical colloidal synthetic methods, with potential applications in nanolithography, catalysis, energy conversion, and photonic devices.

Programming Plasmonic Superlattices via Monolithic Assembly of Anisotropic Nanoparticles Yuhyeon Jung\textsuperscript{1}, Yahong Chen\textsuperscript{1,2}, Zhi Zhu\textsuperscript{2}, Chaoyong J. Yang\textsuperscript{2}, Wei Sun\textsuperscript{1}, Lingdong Sun\textsuperscript{1} and Chunhua Yan\textsuperscript{1}; \textsuperscript{1}Peking University, China; \textsuperscript{2}Xiamen University, China

Controllable integration of plasmonic nanomaterials is a key foundation towards diverse applications in enhanced spectrosocopies, sensors and electronic devices. Using top-down lithographical methods, including electron-beam or focused-ion beam lithography, could fabricate metallic nanostructure arrays with prescribed shapes, dimensions, and long-range ordering. However, lithography-defined metal nanostructures are usually polycrystalline in nature, which scatters the electrons and lowers the quality of surface plasmonic resonance. Besides, limited by the lithographic resolution, it is still difficult for scaling the edge-to-edge spacing down to sub-5 nm, further hampering the plasmonic coupling strength.

Alternatively, bottom-up assembly that uses chemical interactions to direct the integration of single-crystalline nanoparticles could provide both atomic-smooth nanoparticle boundaries and sub-1 nm edge-to-edge spacings. Both features promote the surface plasmonic resonance and minimize the energy losses at grain boundaries. Particularly for anisotropic nanoparticles, such as nanorods and cuboids, they exhibit coherent electron oscillations perpendicular and parallel to the long axis (i.e. transverse and longitudinal LSPR). By tuning the chemical recognitions, large-scale assembled nanoparticles display different lattice morphologies, periodicities and compositions. To in silico design and selective prepare prescribed superlattice structures from the anisotropic nanoparticles, it further requires controlling the relative sliding and rotation of the nanoparticles. However, limited by the difficulties for precise calculation and modulation of different assembly modes (i.e. head-to-head or side-by-side), it remains challenging to assemble anisotropic nanoparticles into monolithic superlattices with prescribed plasmonic properties over centimeter scale.
We here report a general framework that could in silico design and selectively prepare monolithic superlattices from anisotropic gold nanoparticles. We discover that precisely designed surface patterns could direct both the surface positions and the assembly modes of anisotropic gold nanoparticles. By designing different surface patterns, anisotropic nanoparticles could be selectively assembled into five prescribed modes, including head-to-head and side-by-side conformations. Epitaxial growth further extends the structural programmability into 3D space. The assembled superlattices exhibit wafer-scale uniform orientations, structural parameters, and assembly morphologies. Complex alphabets, numbers, and polygon shapes could also be constructed using the aligned nanoparticles. Because the minimal edge-to-edge spacing is less than 2 nm, we observed strong plasmonic coupling, as evidenced by the dark-field scattering measurements and FDTD simulations. Additionally, we have revealed that the nanogap induced subwavelength “hot-spots” lead to dramatically enhanced signals for SERS and fluorescence within the superlattices. Using the assembled superlattices, we could further construct sensitive diagnostic platforms that sense multiplex disease markers at single-molecule resolution.

**EL01.10.04**

**Fabrication of THz Rectennas with Metamaterial Selective Emitters** Emily Carlson¹, Minsu Oh¹, Dante DeMeo¹, Corey Shemelya², Nicole Pfiester¹,³ and Thomas Vandervelde¹; ¹Tufts University, United States; ²University of Massachusetts Lowell, United States; ³The Ohio State University, United States

In the United States, 68.5% of energy consumed is lost as waste heat or transmission losses [1]. If we could harness even a small portion of that thermal radiation we could heat and electrify millions of American homes. Rectifying antennas, or rectennas, absorb EM radiation and convert it to a DC voltage using an antenna and a rectifying diode. In a rectenna system with an EM source, the signal is converted into electrical AC signal by the antenna array and AC voltage signal is rectified by the rectifying diode to generate DC. Rectennas with conversion efficiencies greater than 80% are achieved both by using high input power at 915 MHz and 2.45 GHz as in [2] and [3], or by harvesting ambient environment RF from 876 MHz to 2.48 GHz using a multi-band stacked RF rectennas [4]. To move rectennas toward the THz range using infrared radiation sources, we consider the broad-band emission from our sources approximated as a blackbody spectrum. However, a full spectrum IR blackbody source requires high frequency antenna materials. Additionally, using broad-band sources introduces challenges such as needing a broad-band antenna response and a broad-band transmission line. To address these concerns, we add a metamaterial selective-emitter to absorb the radiation from the source and emit a narrow range of photons towards the rectenna.

We designed a metal-insulator-metal (MIM) diode made of Al/Al₂O₃/Au, where the top gold metal consists of our antenna array pattern. The MIM diode was simulated in CST and our Al and Al₂O₃ layers are deposited using the AJA 3-gun Sputtering system at Harvard’s Center for Nanoscale Systems’ Nanofabrication Facility. The antenna pattern is rectangular rows of length 5.4 μm and width 1.2 μm separated by 1.2 μm and connected at one end by a 0.5 μm contact bar. To fabricate the antenna array and selective emitter, we are using the Maskless Aligner MLA150 to expose the pattern directly onto photoresist with a 375 nm laser. Using this tool we can write 1 cm² areas in under 10 minutes, which is significantly faster than writing patterns using electron beam lithography. Although the minimum advertised structure size for the MLA150 is one micron, we have successfully achieved sub-micron resolution by using contrast enhancing material to increase resolution and optical proximity correction to reduce corner rounding [5]. Characterization of the full rectenna device is forthcoming, and samples will be characterized by Vector Network Analyzer in the THz range.

**EL01.10.05**

**Design and Fabrication of Bio-Inspired Nanostructures Exhibiting Structural Coloration** Bianca C. Datta and V. Michael Bove; Massachusetts Institute of Technology, United States

Structural color phenomena exhibited by several organisms produce compelling and vibrant visual displays. These
impressive effects result from interference and diffraction of light incident upon multilayer nanostructures, in which color is broadly tuned based on surface structure and geometry. The wings of the *Morpho* butterfly are a well-studied example of a biological system exhibiting structural coloration and a high degree of wide-angle iridescence due to a non-negligible degree of disorder in the photonic nanostructure. Recent work has demonstrated fabrication of artificial, *Morpho*-inspired nanostructures that exhibit coloration via a variety of fabrication techniques, including multi-step deposition, etching, and assembly processes. However, existing work has largely focused only on replication of specific structures found in nature, with few methods incorporating both color replication and the role of disorder on effects like iridescence. Furthermore, many of the processes used to produce these structures are elaborate or time-consuming. Here we explore methods for generating structures to create desired effects, while proposing new approaches for designing structurally-colored surfaces that are physically producible with rapid prototyping.

We propose methodologies for combined design, simulation, and material fabrication to generate color through new structural surfaces that replicate functional properties of natural systems. We depict a design methodology based around computational inverse design for the formulation of nanostructures exhibiting structural coloration. We furthermore depict example design constraints and study convergence with respect to the design trade space. We use simulation to determine optical properties (such as reflectance, and spectral response) of potential photonic surface structures, and compare different simulation methods on the basis of accuracy, as well as computational complexity and speed.

Such intricate biological systems require advanced fabrication techniques, and replication of nanoscale features of this complexity has been difficult. Thus, our designs are constrained for realizable fabrication using a multitude of processing methods, including direct laser writing techniques such as two-photon polymerization. Such techniques provide amenable platforms for rapid prototyping of simulated optimized structures to test for practical fabrication and implementation that provide a cost- and time-effective alternative to traditional lithographic methods. We then evaluate optical properties such as spectral response, diffraction, and reflectance of fabricated photonic structures. Successful samples will passively produce robust, visible colors with wide angle viewability, and surfaces will be iteratively designed towards the goal of specifically tuned color outputs.

When combined with the design and optimization process presented here, these methods allow for the use of the *Morpho* structure as a baseline for iteration, both to incorporate tailored disorder, and to produce structures with functionality beyond existing systems. In doing so, we present a versatile approach to bio-inspired materials design and provide a platform with applications ranging from light harvesting and steering, to chemical sensing, high performance displays, responsive products and architecture. We aim to compare our simulations to fabricated structures using optical microscopy, scanning electron microscopy, and angular spectrometry to test for quantitative performance. These evaluated and characterized structures could eventually be adapted to roll to roll or imprint-based systems for scale-up and manufacturing on a commercial scale.

**EL01.10.06 Metals and Dielectrics for Transient Photonics**

Thomas Farinha¹², John M. Hoerauf and Marina S. Leite¹²;

¹University of Maryland, United States; ²Institute for Research in Electronics and Applied Physics, United States

Materials that exhibit tunable photonic responses have found widespread application in displays, lasers, sensors, and other optical sources. The combination of inherent material properties and nanostructuring gives fine control of optical transmission, absorption, and reflection in terms of peak wavelengths and intensities. We fabricate thin film and nanostructured designs that apply the transient optical responses of Mg and MgO to produce display pixels that exhibit a color change in response to the chemical reaction between these materials and water [1]. This permanent reaction holds promise for use in data encryption and anticounterfeiting. Color pixels fabricated through both metal-insulator-metal Mg/MgO thin film and Mg nanorod array designs allow for transmission signals corresponding to any color within the sRGB gamut. FDTD simulations are used to verify the accuracy of experimental spectral data and offer new insight into future designs that incorporate both stable and transient elements using spectroscopic ellipsometry data. In order to determine the effects of temperature and deposition method on the transient nature of the optical response, we investigate the etching properties of Mg thin films and nanostructures. Variation of temperature between 10 and 80 °C allows for the tunability of distinct hues, besides the modification of the rate at which color changes for additional device control based on the desired application. Mg and MgO are low cost, earth-abundant, and environmentally friendly materials; and, in turn, ideal candidates for optical components in industrial-
scale devices. Research into their use in conjunction with other metals (e.g. Al, Ag, and Au) opens up a new opportunity for color pixels than can be tuned between multiple signals set through nanostructured geometry, as will be presented.

EL01.10.07

**Additive Manufacturing of Nano-Architected Titanium Dioxide for 3D Dielectric Photonic Crystals**

Andrew Vyatskikh, Ryan C. Ng, Bryce Edwards, Ryan M. Briggs and Julia R. Greer; California Institute of Technology, United States

Probing 3D dielectric photonic crystals in the visible and in the infrared range typically requires fabricating complex 3D architectures with sub-micron features out of low absorption, high refractive index materials. Nano-architecting transparent high refractive index materials in 3D is technically challenging and requires complex experimental procedures, including stacking of individually fabricated 2D layers or double-inversion of a 3D polymer template. We developed a template-free additive manufacturing (AM) process that is capable of producing complex 3D architectures with sub-micron features out of titanium dioxide (TiO₂). We synthesize a hybrid organic-inorganic precursor and use it to formulate a pre-ceramic photoresist that is shaped into a designed 3D structure using two-photon lithography (TPL). This architecture is then pyrolyzed in air at 900°C, which yields a replica of the structure with 70% smaller dimensions. Energy-Dispersive Spectroscopy (EDS) and Raman spectroscopy reveal such processed material to be predominantly rutile titania.

We fabricated titania woodpile structures with a 1.5 μm lateral period that are comprised of 560 nm x 640 nm beams. Transmission Electron Microscopy (TEM) reveals that the microstructure of individual beams is nanocrystalline, with a 110 nm mean grain size and <1% porosity. Fourier Transform Infrared (FTIR) spectroscopy shows a high reflectance and a low transmittance peaks centered at 2.9 μm, which agrees with the position of a full photonic bandgap predicted by Plane Wave Expansion (PWE) simulations. This titania AM process offers a promising pathway to fabricate complex 3D nano-architectures out of high-index materials for 3D dielectric photonic crystals in the visible and the infrared.

EL01.10.08

**Graphene Oxide Si Field Effect Phototransistors with Embedded Nanoscale Vacuum Channel**

Siwapon Srisonphan and Khomsan Ruangwong; Kasetsart University, Thailand

This work presents a hybrid photodetection platform that combines the 2D material graphene, placed on top of well-defined SiO₂/Si nanoscale etched trench structures with simple and cost-effective fabrication processes. The hybrid nanoelectronic devices are consisting of a graphene/Si (Gr/Si) heterojunction in conjunction with graphene/SiO₂/Si (GrOS) field effect structure. Additionally, the suspended graphene naturally placed between two device structure (Graphene/Si and Graphene/SiO₂/Si) enable the nanoscale vacuum electronics formation between two devices, allowing the photoelectron transport and interacting with each other in the quantum regime leading to exceptional characteristics.

In hybrid GrOS based on p-Si substrate, the photo-excited electrons are separated in Si and subsequently transferred to the SiO₂/Si interface to combine with the intrinsic two-dimensional electron gas (2DEG) confined in a quantum well. This will significantly increase the amount of 2DEG. Therefore, the localized 2DEG causes two important phenomena: (1) increasing the localized electric field, leading to carrier multiplication generation in confined 2DEG channels and thus amplifying the photocurrent in the devices and (2) reducing the potential barrier height via strong coulombic repulsion at the edge of the Si, enabling electron emission through the air to complete the electrical current circulation as similar to nanoscale vacuum electronics. The hybrid photodetector device exhibits ballistic transport of photoexcited hot carriers with carrier multiplication gain resulting in high quantum efficiency for photodetection characteristic. Two-dimensional (2D) hybrid nanoelectronic devices based on p-Si and n-Si provide fully and finely tunable sensitivity up to 1.2 and 0.45 A/W, respectively, corresponding to external quantum efficiencies (EQE) of 235% (~350% internal quantum efficiencies (IQE)) and 88% EQE (or ~132% EQE), respectively. The multiplication gain in the proposed hybrid device originates from the impact ionization initiated by photoinduced carrier injection into the self-induced localized electric field (up to ~10⁶ V/cm) distributed in a 2DEG region in Si. The tunable photocurrent was rising with three half-power voltage dependence as a supplied voltage which corresponds to the Child–Langmuir (CL) space charge limited current as electron transport in a vacuum.
Thus, the result suggests that the overall carrier transport associated with the electron emission process from the 2DEG is confined in an inversion layer of the GrOS field-effect structure, allowing the ballistic transport of photoelectrons through a nanoscale vacuum (air) channel within the mean free path distance (<100 nm) to be collected by the graphene electrode.

The ON/OFF ratios of proposed device is in the range of $\sim 10^2$–$10^5$. The hybrid GrOS-based p-Si photodetection has fully tunable responsivity and efficiency that is suitable for imaging applications requiring bright condition adjustments. Therefore, the proposed hybrid photodetection platform is architecturally Si and CMOS-compatible and thus highly promising for ultrafast, low-power, and tunable optoelectronic applications.

**EL01.10.09**

**Electrochemical Growth of InAs Nanoparticle Arrays at Room Temperature—Towards Inexpensive Manufacturing of Optoelectronic Devices**

Marco Valenti, Yorick Blei, Andrea Cordaro, Stefan Tabernig, Albert Polman, Esther Alarcon-Llado and Mark Aarts; AMOLF, Netherlands

III-V nanostructures have shown novel exciting (opto)electronic properties, making them interesting for a wide range of disciplines ranging from bioengineering to quantum information technology and energy conversion. In particular, their optical properties are not only tuned by chemical composition (e.g., in ternary compounds), but also by their size, shape and collective arrangement (e.g., quantum confinement, Mie resonances, collective optical resonances). However, their manufacturing suffers from expensive techniques due extreme operational conditions (e.g., high temperatures and ultra-high vacuum) and has restricted choice on substrate materials.

In this work we explore the combination of electrochemical deposition and soft conformal imprint lithography (SCIL) to grow InAs nanostructure arrays on diverse substrates, including silicon and transparent ITO. We have electrodeposited arsenic from a liquid electrolyte at room temperature onto patterned indium droplets, which spontaneously reacts into InAs. Raman microscopy characterization shows the high crystal quality of the grown InAs nanoparticles by analyzing the lineshape of the longitudinal optical mode. We explain the growth of highly crystalline InAs nanoparticles by a 3D diffusion-reaction model and facile strain release provided by the confined nature of the initial indium particle. We explore the nanophotonic properties of the fabricated InAs nanoparticle arrays, with particular focus on light scattering. By tuning the size and pitch distances we demonstrate the potential of the presented methodology to manipulate the reflection, transmission, absorption and diffraction of light.

While this work represents the first demonstration of crystalline III-V nanostructure growth on a transparent conducting substrate (ITO), combining SCIL and electrochemistry is a promising high-throughput nanofabrication methodology towards inexpensive III-V nanopatterns, with the potential of bringing emerging all dielectric III-V designs to the market.

**EL01.10.10**

**Direct Laser Writing of Polymeric Microcavity with Graphene Oxide**

Cleber Mendonca¹, Nathalia Tomazio¹, Kelly Tasso¹ and Miguel Andres²; ¹University of Sao Paulo, Brazil; ²University of Valencia, Spain

Whispering gallery mode microcavities stand out due to their unique features, such as narrow spectral linewidth, small modal volume and high power density, making them interesting for several applications in photonics. Microcavities made of polymeric materials offer additional advantages, such as the ease of processing and the flexibility for incorporating dopants that bring functionality to the structure. In this direction, femtosecond laser induced two-photon polymerization has proven to be a powerful tool for the microfabrication of 3D polymeric structures. In this technique, spatial confinement of the polymerization is achieved by the nonlinear nature of the two-photon absorption process.

In this work, whispering gallery mode microcavities containing graphene oxide are fabricated via two-photon polymerization on an acrylic-based resin. The produced structure exhibits good structural quality and smooth sidewall surfaces (undoped cavity Q-factor of $1\times10^4$ @ 1550 nm). Raman spectroscopy confirms the presence of graphene oxide in the doped structure. The microresonator modes were characterized by a coupling setup based on evanescent field from a tapered optical fiber, which uses a broadband source centered at 1530 nm as excitation. Light is coupled into the resonator using a 2 µm diameter tapered fiber in the overcoupling regime and the transmitted light is guided to an optical spectral analyzer. The transmitted spectrum exhibits sharp resonances with a free spectral range of 9.3 nm, which is in agreement with the expected value given the structure geometry and index of refraction. Interestingly, we have observed a substantial decrease in the number of modes in the transmission
spectrum for the graphene oxide doped microcavity in comparison to the undoped one, which we believe may be related to some thermal processes since saturable absorption of graphene oxide, whose saturation intensity is on the order of 500 MW/cm², is not expected to occur for the excitation level used here. Therefore, we have been able to demonstrate the use of two-photon polymerization in the fabrication of high performance optical microcavities doped with graphene oxide, which can be exploited for further developments in high performance optical microdevices.

EL01.10.11
Analog Computation Modeling of Memristive Synapse Crossbar for Deep Neural Networks Chanyeol Choi, Jaekang Song, Jaeyong Lee, Beomseok Kang, Subeen Pang, Peng Lin and Jeehwan Kim; Massachusetts Institute of Technology, United States

A memristor-based crossbar is one of promising candidates for in-memory computing since it features nanosecond switching speed, extremely small cell size, low energy consumption for matrix-vector multiplication and weight update, capability of both storage and computing, three-dimensionality, and many analog weight update steps. Although there have been intensive studies on the development of a large-scale memristor crossbar to implement neuromorphic hardware system for deep neural networks, only limited approaches, such as inference task, were suggested due to device and cycle variations and nonlinear/step-limited weight update properties. To handle those issues, a 1T1R (1-transistor/1-memristor) with a closed-loop or spike-based count methods have been used to possess more control on linear weight update. However, to fully exploit memristor-based crossbar in-memory computing without above temporal solutions, it essentially requires (1) linear/symmetric conductance change, (2) multiple-level conductance steps, (3) less spatial and temporal variations for weight values with more analog components involved.

Here, we developed a simulator which estimates the energy consumption and accuracy of inference/online training in multi-crossbar peripheral system to provide an insight on required specifications of memristor device. By introducing analog components, overheads from ADC/DAC are minimized. Also, we partitioned two types of crossbars for fully-functioning in-memory computing: (1) morphable crossbar for computing, (2) memory crossbar for memorizing values used for backpropagation. With our recommended device parameters as guideline, we achieved 97% and 81% accuracy on MNIST and CIFAR-10 datasets, respectively. Also, it performed approximately X 30 and X 12 better than RTX 6000 and TPU in energy savings.

EL01.10.12
Ultrafast Photophysics Dynamics in Phase Transition VO2 Thin Films Pan P. Adhikari1, Shikhar Misra2, Kanishka Kobbekaduwa1, Exian Liu1, Haiyan Wang2 and Jianbo Gao1; 1Clemson University, United States; 2Purdue University, United States

Transition metal oxides are of great research interest over the past decades because of dramatic changes in optical and electrical properties throughout the phase transition processes, which have potential applications in ultrafast transistors, ultrafast electrical switches, gas sensors and thermochromic smart windows. In particular, vanadium dioxide, VO2 is one of the scientifically fascinating and technologically promising transition metal oxides depicting a reversible first-order semiconductor to metal phase transition (SMT) at critical temperature Tc = 68°C (341 K) which is much higher than the ambient room temperature. However, carrier transport mechanism in ultrafast timescale and the effects of dopants on it has yet to be clearly understood.

In this talk, we fabricated VO2 thin films, VO2 doped with Au, and Pt nanoparticles by pulsed laser deposition (PLD). Integrated VO2 films with ultrafast photoconductor device structure, resulted in a sub-40 picosecond response time, we studied the carrier photo-physics dynamics such as carrier photogeneration, recombination, transport, trapping, and de-trapping. In addition to investigate the temperature dependent transport dynamics resulted from the phase transition, we revealed the novel effect of Au and Pt nanoparticles doping. These fundamental understanding paves the pathway to functionalize the VO2, leading to designing nanoelectronics devices.

EL01.10.13
A Three-Dimensional SERS Substrate Fabricated by a Facile Transfer Printing of a Carboxylic-Acid-Functionalized Graphitic Nano-Layer Designed for Protein Analysis Hyung Joon Park and Yeon Sik Jung; KAIST, Korea (the Republic of)
Proteins consisting of one or more polypeptides play vital functional and structural roles in human body. To be used in research involving early diagnosis, drug delivery and clinic therapy, determining structure and concentration of these proteins are extremely important. To date, conventional analysis tools including enzyme-linked immunosorbsent assay (ELISA), X-ray, nuclear magnetic resonance (NMR) and cryogenic electron microscopy (cryo-EM) have contributed significantly to the development of protein research. However, such tools require complex and costly sample preparation procedures as well as skilled experts to analyze the measurement results. SERS (Surface Enhanced Raman Spectroscopy) is considered as a promising alternative for such measurement methods. Raman spectra directly measured from molecular vibrations can provide crucial information on proteins’ conformation and concentration with minimal efforts compared to conventional analysis. However, obtaining reproducible and distinguishable Raman spectra is challenging due to proteins’ extremely small Raman cross section.

To overcome such limitations, and perform conformational studies and quantitative analysis of proteins using Raman spectroscopy, we present a 3D SERS substrate coated with a carboxylic-acid-functionalized graphitic nano-layer (SSCG). The fact that SSCG can perform both structural analysis and concentration determination in a single measurement is a unique advantage over conventional analysis methods and other SERS research reported thus far. SSCG features stacking of gold nanowire sheets, which form 3D nanostructures. Fine and dense gold nanowire arrays generate strong local E-fields, and enable to obtain characteristic Raman spectra of proteins to analyze conformational features. Furthermore, a carboxylic-acid-functionalized graphitic nano-layer is coated on top of the 3D SERS substrate, and used as an immobilization media by forming a peptide bond with analytes. These functional groups enable the analytes to be dip-coated, completely eliminating the coffee ring effect and obtaining a uniform analytes coating, which leads to the possibility of quantitative analysis.

The proteins used in this study are tau protein and beta-amyloid. Both proteins are associated with Alzheimer’s disease (AD), which is a representative illness causing human dementia. These proteins are present in the body fluids and are well-known candidates for AD biomarkers. Accurate identification and quantification of such biomarkers by SERS will enable early diagnosis of the disease, which is critical in delaying disease progression.

**EL01.10.14**

Gallium Arsenide Nanowires for Selective Light Absorption by Lithography-Free Process Gil Ju Lee¹, Kwangwook Park², Gun Wu Ju¹ and Young Min Song¹; ¹Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); ²Korea Advanced Nano Fab Center, Korea (the Republic of); ³Korea Institute of Science and Technology, Korea (the Republic of)

Over the past few years, semiconductor nanowire arrays have been extensively studied for achieving intriguing optical, mechanical, and electrical features. In recent years, the use of nanowires has expanded from the conventional application fields (*i.e.*, electronics and photonics) to medical application such as artificial photoreceptor. This recently-developed nanowire-based artificial photoreceptors interface with blind retinas to restore the vision inability. Their highly ordered structure is more analogous to the architecture of photoreceptors, which allows for proficient photo-absorption and charge separation that is similar in photon-harvesting electronics such as solar cells and photodetectors. Based on these features, the nanowire-based photoreceptors can overcome the representative limitations of predecessors such as requiring an external power supply and low density. They can generate and carry photocurrent to depolarize neurons without an external power supply, and their high/uniform density of photo-responsive units allows an enhanced spatial resolution. However, the reported nanowire-based photoreceptors have not been optically optimized yet, showing a restricted absorption range (*i.e.*, UV range) and low wavelength selectivity and sensitivity.

Here we introduce the approach to the highly selective and sensitive light absorber, like retina, using highly populated III/V nanowire forests fabricated by lithography-free method. Theoretically analyses reveal the diameter-dependent selective photon absorption is allowed even in dense and disordered configuration. Self-catalyzed growth implements the nanowire forest with the high density (*e.g.*, mean nearest inter-distance = 192.4 nm) and high aspect ratio (*e.g.*, mean aspect ratio = 34.3). Also, the averaged diameter of 94 nm with 49 nm-standard deviations sufficiently covers and decomposes visible spectrum. Finally, we observe a selective light-absorbing behavior of the nanowire forests with three monochromatic colors such as red, green, and blue. Weak correlations between each response such as minimally 0.05 and maximally 0.28 demonstrate that the nanowire forest functions like the retina. This work suggests that the nanowire forests could be applied for next-generation optoelectronics and/or bio-compatible light-sensitive material such as retinal prostheses.
Additive manufacturing via two-photon lithography (TPL) has been demonstrated as an effective method to photochemically reduce metal ions to obtain metal structures. Thus far, only a few metals, such as Au and Ag, can be fabricated by TPL, whereas photochemical reduction (PCR) of other metals, such as Ni, Cu, and Ti, remains out of reach. In this work we demonstrate a localized photochemical reduction AM method that is applicable to metallic systems beyond silver and gold using the photoreductant tungsten(0) arylisocyanide, while investigating its reduction mechanism under two-photon excitation. A recent work by Sattler et al has shown that the excited state of tungsten arylisocyanide exhibits a reduction potential of -2.7 V, which can theoretically reduce a wide variety of metal ion species. In this TPL process, we employ an ultra-short pulsed laser that is tightly focused into a voxel, where the tungsten complex absorbs the two photons simultaneously, donates an electron to the metal ion present in the system and reduces it to a metallic atom. We demonstrate a successful reduction of copper in 2D structures, which are characterized by energy dispersive spectroscopy (EDS) to show a uniform distribution of copper. To investigate the reduction mechanism, quenching experiments are performed using time-resolved spectroscopy and an electron transfer rate of 2x10^9 M^-1 s^-1 is determined, which suggests a diffusion-limited process. This method enables direct reduction of metal ions to metal structures and potentially provides gateways to develop new metal composites and to fabricate rare non-native metals for various applications in microelectronics, photonics, medical implants, and microelectro-mechanical systems.

Transparent Conductive Oxides (TCOs) are appealing plasmonic material candidates due to their transparency, refractory character, CMOS compatibility and their ability for dynamically tuning their properties through the application of an electric field. An important additional asset of TCOs is that their optoelectronic properties depend strongly on the precise fabrication techniques and conditions. Specifically, adjustment of the target doping, deposition and post-growth processing conditions causes variations in the stoichiometry, crystallinity and donor states. These result in changes to the carrier transport properties and thus enable one to tailor the optoelectronic properties of TCOs towards specific device requirements. Such modifications of TCOs have been achieved through thermal annealing in controlled ambient compositions to increase the carrier mobility and adjust the carrier concentration by inducing activation of donor states and modulation of the oxygen vacancy concentration. However, thermal annealing of thin films suffers from long dwell times and high thermal budget, making the process expensive, cumbersome and unable to be utilized for cases where the characteristics of the substrate must be preserved (i.e. flexible displays or manufactured chips with heat-sensitive components). Excimer Laser Annealing (ELA) has been demonstrated to be able to overcome these limitations and offer an ultra-fast, scalable and low thermal budget post-growth processing technique to enhance the crystallinity of TCOs. ELA operates through the application of a highly localised heating (in space and time) and offers a significantly increased level of control over the processes by varying the pulse length, pulse frequency, pulse number, fluence, wavelength and environmental temperature, pressure and composition.

In this work, we couple the ability of the local environmental to probe the defect composition with the advantages of laser processing, via ELA of room-temperature sputtered Indium Tin Oxide (ITO), Aluminium-doped Zinc Oxide (AZO), Gallium-doped Oxide (GZO) and Fluorine-doped Tin Oxide (FTO) thin films within a UV-transparent pressurised cell where we can finely control the ambient composition and pressure of the contained gasses. Through the use of a range of reactive gasses which are: oxidising (O_2), reducing (5% H_2 in N_2) or intermediate (0-100% O_2 in N_2 or Ar), we alter the concentration of oxygen vacancies and activated donors within the lattice after processing and relate these laser-induced compositional modifications to changes in the morphological, structural and optoelectronic properties. Ellipsometry in the IR (1.6-40 microns) enables us to directly probe the free-carrier contributions to the permittivity and thus precisely determine the optoelectronic properties of the as-grown and laser processed films.
We report an ambient-dependent modulation of the plasma energy and damping coefficient with laser fluence and ambient composition after laser processing while preserving the amorphous nature of room temperature sputtered ITO and improving the crystallinity of AZO and GZO. Our results present ‘Reactive Ambient - Excimer Laser Annealing (RAELA)’ as a novel and powerful technique to control the optoelectronic properties of key TCO materials. This allows for the creation of recipes to improve the quality of these alternative material candidates as plasmonic components. Due to the fast and localised nature of RAELA, and the utility of IR ellipsometry, we also present the combination of these two techniques as a useful tool in further material science studies into the, still not fully understood, conduction mechanisms of TCOs.

EL01.10.18

Wedge-Shaped Fabry-Perot Cavities for Continuous Variation of the Photonic Environment  
Alvaro Magdaleno1, Nuria Gordillo1, Michel Frising1, Michael Seitz1, Beatriz H. Juarez2, Jose L. Pau1 and Ferry Prins1;  
1Autonomous University of Madrid, Spain; 2IMDEA Nanoscience, Spain

A number of powerful photonic strategies to study the influence of the local density of optical states (LDOS) on the dynamics of light emitters have been developed over the years [1-3]. One of the simplest approaches involves placing the emitters between two reflecting surfaces forming a Fabry-Perot cavity. To vary the LDOS in such a system, the key tuning knob is the cavity length. Typical Fabry-Perot cavities are fabricated as vertical stacks using thin film deposition. However, from a practical point of view, tuning the LDOS in such a vertical Fabry-Perot cavity requires the fabrication of many different geometries [4], thus limiting the ability to efficiently optimize the performance. Obtaining a large range of cavity lengths in a single structure is challenging, though some reports using more complex scanning probe methods have been reported [5-6].

Here, we present a method to produce a wedge-shaped cavity in which the full spectrum of cavity lengths can be obtained [7]. It is fabricated by mechanically clamping together two silver-coated microscope slides using a small spacer on one side. This allows for accurate control over the angle (< 1 degrees) between the two silver surfaces and generates a continuously tunable cavity length along the wedge. The simplicity of this technique provides the quick development of samples which can be analysed with single measurements including the thickness of the cavity as free parameter. This platform allows us to precisely align the cavity mode spectrum with the energy spectrum of the active layer. As a first example, we will present results on the fine-tuning of cavity resonances with excitonic excited states in quantum dot solids, and discuss the influence of the LDOS in modifying the excited state and spatial dynamics of these systems. Second, we will discuss the fine-tuning of strong light-matter coupling between cavity modes and molecular vibrational states [4].

Our simple architecture provides a powerful yet easily implementable strategy for the detailed mapping of LDOS in a variety of materials. This will aid the design of optimized cavity induced photonics.

Large-Area Active 2D Metasurfaces Comprised of Magnetic Nanoparticles  
Guinevere Strack1, Yassine Ait-El-Aoud2, Richard M. Osgood2 and Alkim Akyurtlu1;  
1University of Massachusetts Lowell, United States; 2US Army Combat Capabilities Development Command Soldier Center, United States

In this work, we demonstrate the fabrication and characterization of active, switchable metasurfaces comprised of ordered magnetic nanoparticles (MNP). Metasurfaces can be comprised of periodic scattering structures with dimensions smaller than the operating wavelength. The magnetic and optical properties of MNP arrays are dictated by several factors, including composition, particle size, and spacing. Ferromagnetic particles have high permeability (µ>1) and net magnetic dipole moments in the absence of a magnetic field. Nanoparticles below a critical dimension, can exhibit paramagnetic behavior, i.e., a lack of magnetic moment in the absence of an applied field.
Superparamagnetic nanoparticles are similar to paramagnetic nanoparticles, but exhibit a rapid increase in magnetic moment in the presence of an applied field. MNP arrays that exhibit ferromagnetic ordering have novel applications, for example, switchable metasurfaces and magnetically enhanced antenna arrays. In addition, large-area 2-D MNP arrays on flexible substrates can be integrated onto lightweight platforms that enable multifunctional electronics and optics. Finally, large-area fabrication strategies present a path toward technological development or prototyping. Traditional fabrication approaches for nanoparticle (NP) arrays typically require costly equipment and highly trained personnel. Herein, we employ a scalable fabrication approach for MNPs—nanosphere lithography (NSL). First, a hexagonally-packed monolayer of polystyrene spheres (PS; d≤500 nm) is assembled on a flexible substrate, for example, Willow® Glass. Next, e-beam evaporation or sputter deposition is used to coat the PS layer with Co, Ni, or co-deposited Co and Au. The PS layer template is degraded by exposing the sample to high temperature (for example, 600 °C), leaving behind ordered NPs. The size and spacing of the NPs can be controlled by the size of the PS and the thickness of the deposited metallic film. Another approach is to remove the PS layer using solvent, which produces an ordered, quasi-triangular nanoarray. Total integrated diffuse and spectral scattering are measured using a spectrophotometer with an integrated sphere accessory to account for visible and near-IR scattering characteristics of the nanostructured arrays. The samples are also subjected to sensitive magnetometer measurements, (superconducting quantum Interference device (SQUID)) to establish if the MNP arrays exhibit magnetic properties, and if so, the type of magnetism, e.g., ferromagnetic or superparamagnetic. The optical and magnetic properties of MNP arrays with various sizes and shapes, and materials compositions, are compared. Establishing relationships between materials functionalities and MNP structure and composition can present a path toward developing flexible, lightweight electromagnetic devices, such as textile-based antennas, electromagnetic switches, and optical rectification.

Self-Assembled Monolayers on Gold Nanoparticles for Orientation Control in Surface Enhanced Raman Spectroscopy

Stephen F. Bartolucci1, John Burpo2 and Joshua A. Maurer1; 1U.S. Army CCDC-AC, United States; 2United States Military Academy, United States

Certain metallic nanoparticles display localized surface plasmon resonance (LSPR) when interacting with light. In this study, we synthesize gold nanoparticles with a variety of shapes and sizes, such as spheres, stars and other shapes that display strong LSPR. These particles are then functionalized with self-assembled monolayers for orientation-controlled surface enhanced Raman spectroscopy (SERS). Various SAM molecules with different end groups are used in order to tailor the interaction with molecules of interest for detection using SERS. End groups with partial positive, negative and zwitterionic charges have been attached to the gold nanoparticles and characterized with zeta potential and scanning probe microscopy. Improved proximity and orientation control between the nanoparticle and the molecules being detected could lead to improved SERS response.

EL01.10.21
Chiral Lattice Plasmon Generation from Three-Dimensionally Chiral Helicoid Gold Nanoparticles

Ryeong Myeong Kim, Hyo-Yong Ahn, Hye-Eun Lee, Yoon-Young Lee and Ki Tae Nam; Seoul National University, Korea (the Republic of)

Many researches about plasmonic materials with chirality has been carried out due to their intensive light-manipulating ability1. However, synthesis of plasmonic nanoparticles have difficulties in delicate structure-making. In an effort to solve the problems, we focus on nature materials which have delicate chiral nanostructure and their ability to transfer properties from starting organic material to inorganic material, and vice versa2. Previously, we presented a novel fabrication method for gold helicoid nanoparticles by peptide-assisted method3,4,5 which transfer intrinsic chirality of organic material (peptide) to inorganic achiral gold nanoparticle to manage their morphology and chirality. The synthesized gold helicoid nanoparticles had fine chiral nanostructure in nanoscale level. Based on this structure, they exhibit strong optical activity with Kuhn’s dissymmetry factor 0.2 in visible range under CPL(circularly polarized light). This intense optical activity also can be seen in polarization-sensitive color modulation in far-field transmission of randomly dispersed solution. In an extension of our newly developed synthesis strategy, now, we are doing research about coupling behavior from periodically arrayed Helicoid gold nanoparticles to see enhanced optical properties and apply our nanoparticles to appropriate field. Assembled chiral nanoparticles show collective resonance behavior and strong CD signal which called chiral lattice plasmon resonance. Also, We confirmed their resonance is tunable upon incidence angle of light and periodicity of array. We expect this strategy and template can be new break-through to colloidal chiral nanoparticles for being applied in
various field such as, chiral sensing, wave plate, etc.

Coherent Energy Transfer in an Asymmetric Colloidal Nanostructures Max J. Schnepf1,2, Fabian R. Goßler1,2 and Tobias A. König1,2; 1Leibniz-Institute for Polymer Research, Germany; 2TU Dresden, Germany

We present a film-coupled colloidal building-block, comprising of a plasmonic core surrounded by a dielectric shell containing a fluorophore emitter. Due to the small mode volume and the strong loss rate, fluorescent lifetime of the emitter is significantly reduced and the emission rate is enhanced while the energy of the emitted photons remains unaffected.[1] We systematically study the energy transfer mechanism on the single particle level by employing electron microscopy, scattering spectroscopy, fluorescence life-time imaging (FLIM) and time-correlated single photon counting on the same cavity.[2] Moving from single cavities towards periodically arranged gain and loss materials with periodicities close the optical wavelength range, unique properties result from the energetic coupling of those building blocks. In order to investigate the arising properties on a large scale, we fabricated novel quantum dot lattices and coupled them to periodic plasmonic nanostructures using self-assembly of colloidal particles as fabrication method.[2] By combination of the two lattices with different overlap and at different angles, energy transfer of the coupled structures can be studied comprehensively. This will help to fabricate large scale structures featuring optical band gap structures for unique light matter interactions.

Active and Passive Plasmonic Colloid-to-Film-Coupled Cavities for Tailored Light−Matter Interactions Fabian R. Goßler1,2 and Tobias A. König1,2; 1Leibniz-Institut für Polymerforschung Dresden e.V., Germany; 2Technische Universität Dresden, Germany

For large-scale optical metasurfaces, tailored active and passive subwavelength building blocks are required to modulate the refractive index.[1] Here, we introduce a colloid-to-film-coupled nanocavity whose refractive index can be tailored by various materials, shapes, and cavity volumes. With this colloidal nanocavity setup, the refractive index can be adjusted over a wide visible wavelength range. For many nanophotonic applications, specific values for the extinction coefficient are crucial to achieve optical loss and gain. Recently, we employed bottom-up self-assembly techniques to sandwich optically active ternary metalchalcogenides between a metallic mirror and plasmonic colloids. The spectral overlap between the cavity resonance and the broadband emitter makes it possible to study the tunable radiative properties statistically. For flat cavity geometries of silver nanocubes with sub-10 nm metallic gap, we found a fluorescence enhancement factor beyond 1000 for 100 cavities and a 112 meV Rabi splitting.[2] In addition, we used gold spheres to extend the refractive index range.

EL01.10.24
Metamaterial Device Quality VO2 Thin Films Fabricated by Pulsed Laser Deposition Devanshi Bhardwaj,
Vanadium oxides are the most interesting materials because of its varying oxidation states between V$^{2+}$ and V$^{5+}$, out of which, the most studied compounds being V$_2$O$_5$ and VO$_2$. VO$_2$ has an interesting semiconducting to metal transition (SMT) property where it changes its phase from low-temperature insulating state to high-temperature (T>68°C) metallic state [1]. Because of this, VO$_2$ is explored in the field of the metamaterial. Earlier in our group, tuneable metamaterial has been demonstrated on the VO$_2$ thin films fabricated by UNSPACM [2]. The roughness of the film was found to be ~2.1 nm, thereby making the film inappropriate for metamaterial applications. Thus, the aim was to reduce the roughness of the thin film with a single step synthesis process so that it can be employed as an efficient metamaterial. Pulsed laser deposition (PLD) has been used to fabricate vanadium oxide thin films for several applications. This method has several advantages including easily controllable film composition by deposition parameters, controlled stoichiometry of the target material in the films deposited on the substrate and epitaxial growth of thin films.

We report the synthesis of vanadium oxide thin films by PLD under different parameter conditions on Si/SiO$_2$ substrate using V$_2$O$_5$ target. The microstructure and crystal symmetry of the deposited films were studied with X-ray diffraction, scanning electron microscopy (SEM), and Raman spectroscopy. The film obtained were phase pure as determined from XRD and Raman data. The film roughness and surface morphology were examined by atomic force microscopy. Roughness was reduced to about 4 nm as compared to other synthesis processes used earlier in the group [2, 3]. SMT was studied by I-V measurements on different films where 3-4 orders of resistance change were observed for the best condition. Thus, we were able to successfully synthesize VO$_2$ thin films with reduced roughness making it suitable for metamaterial applications.

EL01.10.25
Hybrid IR Phototransistor with 2D and 0D Nanomaterials Anindita Sahoo$^{1,2}$, Peter Reiss$^{3,2}$, Etienne Quesnel$^{1,2}$, Johan Rothman$^{1,2}$, Eric De Borniol$^{1,2}$, Patrick Demars$^{1,2}$ and Bérangère Hyot$^{1,2}$; 1CEA, LETI, MINATEC Campus, France; 2Univ. Grenoble Alpes, France; 3CEA, IRIG, France

There is a growing demand for IR detectors in the application fields such as building, thermal management or night assistance car driving. To overcome the limitations in sensitivity and cost of existing systems, alternative device architectures and technologies are needed which better match the market requirements in terms of cost/performance ratio in particular. With that respect, graphene has already been established as an interesting 2D material which can operate as a photodetector in a vast range of wavelength covering from ultraviolet to far-infrared and THz regime. However, low light absorption and absence of gain mechanism limit the responsivity of graphene photodetector. Introducing hybrid phototransistor with highly efficient light absorbing 0D quantum dots and 2D materials, opens up the possibility to transfer the photogenerated carriers from 0D materials into the high mobility 2D channel, which dramatically increases the responsivity and gain of the photodetector. In the IR range, this type of low dimensional phototransistor based on graphene/PbS QD hybrid was first proposed in literature in 2012 [1, 2] till the demonstration in 2017 [3] of a high-resolution broadband image sensor sensitive to ultraviolet, visible and infrared light (300–2000 nm).

In this study, the potential of similar phototransistors has been revisited and their underlying photodetection mechanisms were gradually investigated. We initially studied CVD-grown single layer graphene as a phototransistor device. In the NIR region, our device based on a low-doped Si substrate showed a responsivity of about 100 A/W, which is 10$^7$ orders of magnitude higher [4] than graphene phototransistor on conventional SiO$_2$/highly-doped Si substrate [5, 6]. We also observed an unconventional hysteresis in the transfer characteristics of graphene associated with the induced electric field at the interface of SiO$_2$ and low-doped Si substrate. In a second step, we synthesized...
the colloidal QDs absorbing in the NIR region and developed a layer-by-layer dip coating with simultaneous ligand exchange procedure in order to deposit homogeneous PbS QD layers on graphene sheet leading to a well fabricated hybrid phototransistor. The above mentioned hysteresis persists even after the dip coating of graphene with PbS QD layers. However, in the high absorbing IR range of the QDs, the effect of low-doped Si substrate on photoresponse is somehow screened and the measured photoresponsivity of our hybrid devices matches well with the reported one on graphene/PbS QD hybrids with highly doped Si substrate \[2\]. We achieved a significantly high responsivity of 10^5 A/W and a photoconductive gain of about 10^8 at 940 nm with irradiation power of 6.4 µW/cm^2.

EL01.10.26
Enhancement of Photosensing Characteristics for Indium Gallium Zinc Oxide Based Visible Light Phototransistor via Polydimethylsiloxane Residues

Kyungho Park, Jin Hyeok Lee, Jusung Chung, Dongwoo Kim and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

Visible light communication is an emerging area for use in computer optical buses, light fidelity, etc., due to its low cost and high directionality. Recently, phototransistors have attracted attention because they connect objects and users through light. Amorphous oxide semiconductors (AOSs) based thin film transistors (TFTs) are considered as one of many types of promising electrical devices due to outstanding characteristics, such as high mobility, low-off current, high transparency compared to amorphous silicon-based devices. Despite these versatile advantages, AOSs have a serious limitation as visible light sensors because they cannot absorb visible light due to the wide band gap of around or more than 3 eV. Therefore, AOSs cannot be used for an active channel layer of phototransistors for visible light detection. In order to resolve this issue, researchers have tried to apply the additional absorption layer such as quantum dots, 2D materials, or nanowires on the device. However, these studies have a drawback that requires complicated processes.

In this work, we investigated the defect generation method that improves the light absorption characteristics of indium gallium zinc oxide (IGZO) phototransistors by forming polydimethylsiloxane (PDMS) residues on the gate insulator (GI). To fabricate IGZO phototransistors with PDMS residues, we deposited IGZO channel by radiofrequency (RF) magnetron sputtering after forming PDMS residues on silicon dioxide, used as the GI. Thereafter, IGZO channel was annealed at 300°C in the air for 1 h, and aluminum electrode was deposited by RF magnetron sputtering. In this process, we controlled the amount of PDMS residues by optimizing the degree of hardening of PDMS through thermal curing time. PDMS residues could be easily formed by exfoliating cured-PDMS made by heated PDMS on the GI. PDMS residues increase the surface roughness of the GI. Hence, PDMS residues form interface trap sites between the GI and IGZO channel. Additionally, since PDMS has a boiling point at 200°C and consists of (C2H6OSi)n chains, it becomes decomposed during the 300°C annealing of IGZO channel. Therefore, deep states could be formed by hydrogen diffused into IGZO channel. During this process, deep states were formed by diffused hydrogen into IGZO channel. These trap sites could reduce the energy needed for electrons excitation into the conduction band. Also, there were previous researches that showed these trap sites cause formation of subgap states within the band gap of IGZO, and thus light with wavelengths wider than 420 nm could be absorbed by IGZO. We confirmed formation of trap sites through the transfer characteristics that the subthreshold swing increases from 0.37 to 0.50 V/dec and the turn-on voltage was negatively shifted from -1.02 to -6.81 V by forming interface trap sites and deep states, respectively. IGZO phototransistors with PDMS residues showed the light absorption characteristics with the turn-on voltage change from -6.81 to -23.40 V and Iphoto/Idark of 1.79x10^6 under red light irradiation (wavelength of 635 nm, intensity of 5 mW/mm^2). On the other hand, there was almost no change in IGZO phototransistors without PDMS residues at the same condition. Also, photoresponsivity,
photosensitivity, and detectivity were improved compared with IGZO phototransistors without PDMS residues, from 34.78 to 359.08 A/W, from 7.64x10^3 to 4.63x10^7, from 1.58x10^8 to 6.26x10^11 Jones, respectively, under red light irradiation with intensity of 5 mW/mm^2. As a result, this study achieved improved photosensing characteristics of IGZO phototransistors with PDMS residues for visible light above the wavelengths of 420 nm.

EL01.10.27
Defects and Oxygen Vacancies in BaTiO3 Thin Films Resulting from Changes in Growth Conditions Ashley Wissel, Zachary J. Biegler, Madelyn Hill, Kurt Eyink and Shanee Pacley; Air Force Research Laboratory, United States

BaTiO3 (BTO), a perovskite ferroelectric material, has historically been used in capacitors, memory storage devices, and optical devices. At AFRL, we have investigated BTO for use in waveguides for electro-optic modulators. It has been shown that growth conditions used in epitaxial growth have influenced lattice strain in heteroepitaxial thin films resulting in defects. This study investigated how changes in growth parameters affect the types of defects and oxygen vacancies present in BTO films. Tetragonal BTO thin films (a = 3.9945Å, c = 4.0335Å) were grown on cubic SrTiO3 (STO) substrates (a = 3.9046Å) by pulsed laser deposition (PLD) with an excimer laser of wavelength 248nm. The chamber was evacuated to a base pressure of 10^-9 Torr and a 99.99% pure pressed BTO target was used as the source. STO substrates were chosen because it has been demonstrated that STO can be grown as a buffer layer on Si to help with the integration of BTO into current silicon electronic systems. BTO films were grown at oxygen pressures ranging from 10mTorr – 300mTorr, laser energies from 200mJ – 350mJ, and substrate temperatures ranging from 500 - 800°C. Films were characterized by high resolution X-ray diffraction (HRXRD) coupled 2θ-ω scans and rocking curves to examine film quality and lattice spacing. Results from HRXRD show c-axis interplanar spacings around 4.16Å for strained films and 4.08Å for relaxed films. HRXRD showed that decreasing laser energy during growth increased lattice parameter and improved film quality, as evidenced by higher peak intensities and smaller full width at half maximum. Atomic force microscopy showed root-mean-square surface roughness around 330pm over an area of 2x2µm. X-ray photoelectron spectroscopy was used to verify the stoichiometry of the films. Spectroscopic ellipsometry from 1.5 - 4.5eV was used to determine the relevant optical constants and look for defect bands which give evidence of oxygen vacancies. Lastly, Raman spectroscopy from 100-900cm^-1 was used to identify the types of defects present in the films.

EL01.10.28
Multispectral Infrared-Visible Camouflage Surface Utilizing Disordered Silicon Nanowire Array Injoong Chang1, Taehwan Kim2, Namkyu Lee1, Joon-Soo Lim1, Hyung Mo Bae1, Jihyuk Kim1, Juyeong Nam1 and Hyung Hee Cho1; 1Yonsei University, Korea (the Republic of); 2Samsung Electronics Inc., Korea (the Republic of)

Camouflage patterns are focused on the reduction of visibility by confusing the edge of target and background. The development of thermal observation device (TOD) is greatly threatening the survivability of the weapon systems which emit the infrared radiation at their hot parts where the radiation energy is much higher than surroundings such as tank engines or aircraft nozzles. Therefore, infrared thermal camouflage technology has to be applied to these surfaces for military operations. In addition, these surfaces should have visible camouflage performance, thus requiring a surface with multispectral camouflage capabilities of the infrared and visible wavelength range. Silicon nanowires arrays are well-known metamaterials by their high absorption performance in the visible to infrared range. The nanowire arrays made by metal-assisted etching method have highly disordered structures and the nanowire length is controlled by etching time. In this study, we realize the multispectral camouflage by applying the infrared camouflage pattern with the visible camouflage so as to obscure the interface between the energy emitted from the surrounding background and that from the target by patterning the nanowire array structures. Using the CCD Camera and IR camera, the silicon nanowire surface are captured and it shows that the shorter length nanowire array is dark color in visible range and low apparent temperature (low emissive energy) in infrared range, however, the longer length nanowire array is dark yellow color in visible range and high apparent temperature (high emissive energy) in infrared range. We also measure the optical emittance and reflectance of visible and infrared range to analyze the change of color in the visible range and emissive energy of infrared range. It shows that the reflectance in visible range and emittance in the infrared range goes higher with nanowire length longer.

EL01.10.29
A Submicron Perovskite Plexciton Laser Sangyeon Cho1,2, Yi Yang1,1, Marin Soljačić1,1 and Seok-Hyun Yun2,1; 1Massachusetts Institute of Technology, United States; 2Harvard Medical School and Massachusetts General
Surface plasmon polaritons (SPP) with high effective refractive indices offer a new avenue to build sub-wavelength lasers. Here, we present room-temperature plasmonic lasing using CsPbBr$_3$ perovskite crystals on a gold substrate with a 5-nm-thick poly-norepinephine (pNE) dielectric layer. We colloidaly synthesized high-quality CsPbBr$_3$ microcrystals using our recently-developed sonochemical synthesis. The pNE layer was prepared by solution dipping of the gold substrate. The photoluminescence spectra from such structures show distinct double peaks, which indicate strong coupling between electron-hole pairs (excitons) and SPP modes with a vacuum Rabi splitting energy of about 40 meV. Finite-difference time-domain simulation suggests that the SPP hybrid mode is a whispering gallery mode with a Q-factor of 44. The smallest plexciton laser we have observed is 580 nm in width and 270 nm in height, emitting a linewidth of 0.1 nm at 535 nm above the pump threshold at 2 mJ/cm$^2$.

Hybrid Au-NP Dendrimer Plasmonics—Energy and Charge Transfer Systems Rigoberto C. Advincula; Case Western Reserve University, United States

The preparation of new polymers and plasmonic nanomaterials require hierarchical levels of ordering and structuring: from molecular to macroscopic. Au nanoparticle plasmonics phenomena enable demonstration in both localized and propagating plasmons which can be quantified spectroscopically in particles, nanostructures, and thin films. Dendrimers and other hyperbranched polymer systems are of interest for their functionality in catalysis, drug delivery, reactivity, etc. Of high interest are hybrid metal nanoparticle dendrimer functionality in electro-optical applications and photonics. This includes Hybrid NP-dendrimers capable of hierarchical ordering and self-assembly. We highlight the convergent synthesis of a variety of polymer-hybrid dendrimers and their electropolymerizability with electroactive monomer groups. The synthesis of precise dendrons is in the form of modular building blocks for functional dendrimers. Our group has reported a number of these hybrid nanoparticle systems and have reported the step-by-step routes towards structure-property relationships. Energy transfer and charge transfer properties can be observed as well as quenching phenomena. What is also important is the use of surface sensitive spectroscopic and microscopic analytical tools applied rationally to highlight evidence of order and function.

8:15 AM EL01.11.02
Infrared Propagating Electromagnetic Surface Waves Excited by Induction Jonathan Brescia$^1$, Robert E. Peale$^1$, Evan M. Smith$^{2,3}$ and Justin W. Cleary$^2$; $^1$University of Central Florida, United States; $^2$Air Force Research Laboratory, United States; $^3$KBRWyle, United States

Propagating electromagnetic surface waves called surface plasmon polaritons (SPPs) can be excited by free-space beams on corrugated conducting surfaces at resonance angles determined by corrugation period, permittivity, and optical frequency. SPPs are coupled to and co-propagate with surface charges. Electrical isolation of the conducting corrugations blocks charge propagation between them, and excitation resonances of traveling SPPs are absent. However, SPPs can be excited via electric induction if a smooth conducting surface exists below and nearby the insulated corrugations. The dependence of SPP excitation resonances on that separation is investigated here. We find that excitation resonances for traveling SPPs broaden and disappear as the dielectric thickness is increased beyond ~1% of the free-space wavelength. The resonance line shape depends on whether the dielectric SiO$_2$ or TiO$_2$ is used as the separating layer, but this dependence appears uncorrelated with differences in optical constants for SPPs at long-wave infrared frequencies where dispersion is strong.

8:30 AM EL01.11.03
Dynamically-Tunable Plasmonic Devices Based on Phase Transition of Vanadium Dioxide Ruwen Peng$^1$, Yongmin Liu$^2$ and Mu Wang$^1$; $^1$National Laboratory of Solid State Microstructures, Nanjing University, China;
Recently, tunable nanophotonic devices have drawn intense attention with great promise for practical applications. In this work, we have experimentally demonstrated several dynamically-tunable plasmonic devices based on phase transition of vanadium dioxide, which include dynamic plasmonic color generators [1], dynamically switchable polarizers [2], and dynamically tunable bowtie nanoantennas [3]. We have fabricated periodic arrays of silver-nanodisks on a vanadium dioxide film to realize different colors, relying on the excitation of localized and propagating surface plasmons. Based on insulator-metal transition of vanadium dioxide, the plasmonic colors can be actively tuned by varying temperature. This approach of dynamic color generation can easily realize diverse color patterns, which makes it beneficial for display and imaging technology. We have also designed a system consisting of anisotropic plasmonic nanostructures with vanadium dioxide that exhibits distinct reflections subjected to different linearly polarized incidence at room temperature and in the heated state. The composite structure can thus be used to realize a dynamically switchable infrared image, wherein a pattern can be visualized at room temperature, while it disappears above the phase transition temperature. Besides, we have made the dynamically tunable bowtie nanoantennas integrated on a vanadium dioxide thin film. The investigations here can be applied in dynamic digital displays, optical data storage, and imaging sensors.

Dipole-Quadruple Coupling in Plasmonic Honeycomb Lattices Ran Li, Marc Bourgeois, Charles Cherqui, Jun Guan, Danqing Wang, Jingtian Hu, Richard Schaller, George Schatz and Teri W. Odom; Northwestern University, United States

In 2D lattices composed of metal nanoparticles (NPs), the localized surface plasmons (LSPs) of metal NPs couple to the Bragg modes to produce surface lattice resonances (SLRs). By exploiting the intrinsic size and material tunability of these LSP modes, we achieved dipole and quadrupole SLRs from visible to near infrared wavelength range. Our work shows that there is a new mode-mixing scheme, which we call hierarchical hybridization occurring in honeycomb lattices of plasmonic NPs. The non-Bravais nature of honeycomb lattice introduces in-plane quadrupole LSPs mixing with the dipole LSPs to create a sharp and strong SLR. Further, by changing the plasmonic material and engineering the plasmonic NP size, we leveraged the out-of-plane quadrupole and in-plane quadrupole LSP response of plasmonic NPs. Two distinct and simultaneously optimized band-edge states were achieved in a single honeycomb lattice. This work highlights the ubiquity of multipolar LSP coupling in non-Bravais plasmonic lattice systems with different plasmonic materials, which has important implications for the band structure engineering of 2D metamaterials.

9:00 AM EL01.11.05
Substrate-Induced Control of Hyperbolic Polaritons Thomas G. Folland1, Alireza Fali2, Samuel T. White1, Mingze He1, Song Liu1, Neda Aghamiri2, James H. Edgar1, Richard F. Haglund1, Josh Caldwell1 and Yohannes Abate2; 1Vanderbilt University, United States; 2University of Georgia, United States; 3Kansas State University, United States

The current state-of-the-art in materials used for infrared (IR) optical components (e.g. lenses, waveplates or prisms) suffers from significant material limitations, exacerbated by the long free-space wavelengths of light in the IR. Leveraging polariton modes such as surface plasmon polaritons (SPPs), surface phonon polaritons (SPhPs) or hyperbolic phonon polaritons (HPhPs) is one route to overcome these limitations. The class of HPhP modes occurring in anisotropic crystalline materials such as hexagonal boron nitride (hBN), are of particular interest. They
can be supported at extremely high wavevectors, and can shown exhibit phenomena such as hyperlensing. Recent studies show that the substrate plays a critical role in controlling the properties of hyperbolic polaritons, and can designed to produce in-plane refraction within hBN heterostructures on phase-changing materials.

In our work we systematically explore the role that the substrate plays in controlling hyperbolic polariton propagation, using a range of scattering-type scanning near-field optical microscopy (s-SNOM) and nano-Fourier transform infrared (nano-FTIR) spectroscopies. We consider propagation on suspended, dielectric and metallic substrates, reducing the thickness-normalized wavevector by up to a factor of 25 simply by changing the substrate. Moreover, by incorporating the imaginary contribution to the dielectric function in lossy materials, the wavevector can be dynamically controlled by small local variations in loss or charge carrier density, while higher-order modes show reduced sensitivity to substrate-induced losses. Finally, we discuss the potential implications for devices including sensors and refractive optics. Sensing HPhP modes out-perform SPhP modes under certain circumstances, and that the choice of substrate is critical for sensing applications. Furthermore, an optimized substrate produces phenomena such as mode sorting within hBN devices. This demonstrates that the choice of substrate choice is critical in determining the properties of propagating HPhP’s, unlike earlier results on localized HPhP resonators.

Emerging Anisotropic 2D Layered Materials for Photonics, Plasmonics and Polaritonics Koray Aydin;
Northwestern University, United States

Two-dimensional layered materials have recently garnered burgeoning amount of interest due to their unique electronic, optical, thermal, mechanical properties emerging at the mono-to-few layer thicknesses. Over the past decade, we have witnessed significant research activity on the area of two-dimensional materials. Most of research has focused on conventional 2D materials such as graphene and 2D TMDCs, having isotropic electronic and optical properties due to their crystal symmetry. Recently, layered materials such as black phosphorus and hexagonal boron nitride investigated for anisotropic crystal structure. In this talk, I will present theoretical investigations on monolayer borophene plasmons at optical frequencies. Borophene has recently expanded the 2D materials family after its successful deposition on silver substrates. We theoretically investigate the plasmonic properties of nanostructured monolayer borophene using full-field electromagnetic simulations and demonstrate that borophene nanoribbon and nanopatch arrays can support localized plasmon resonances at visible and near-infrared wavelengths. Due to its puckered crystal structure and vacancy distribution in hexagonal lattice, borophene exhibits strong anisotropic in-plane properties which makes it an unconventional plasmonic material. In the second part of my talk, I will introduce α-MoO$_3$ as an anisotropic photonic and polaritonic material. α-MoO$_3$ is a layered material that exhibits both in and out-of-the-plane anisotropic polaritonic response at mid-IR wavelengths. We designed and experimentally demonstrated an anisotropic polaritonic absorber and showed that one can couple to all phonon modes and address them individually either using structural tunability or polarization control of incident infrared radiation. I will also discuss our experimental investigations of the birefringent optical properties of α-MoO$_3$ in visible frequencies. By constructing α-MoO$_3$ based Fabry-Perot resonator, we observed strong polarization-dependent tunability of the Fabry-Perot resonance due to different refractive index of MoO$_3$ for different crystal directions. Anisotropic plasmonic, photonic and polaritonic materials provide additional freedom in controlling polarization dependent properties and could find applications in wide range of fields where polarization control plays important role.

Third Harmonic Generation in Magnesium Near the Metal-to-Insulator Phase Transition Harald Giessen;
University of Stuttgart, Germany
Harmonic generation in plasmonic systems has gained significant interest over the last few years. While the plasmonic near-field enhancement has been studied in great detail, little attention was paid to the origin of the nonlinear signals which in fact lie in the microscopic nonlinearity of the involved plasmonic metals. In order to predict wavelength-dependent nonlinear processes it is therefore crucial to understand these microscopic nonlinearities. Utilizing an optical parametric oscillator as a tunable broadband light source, we study wavelength-dependent third harmonic generation from metallic thin films made of gold, copper, and magnesium.

We find that the linear properties of the metallic films, that is their absorption, strongly influence the third harmonic generation efficiency. Optical transitions between the different bands lead to a resonant enhancement of the third order susceptibilities. Utilizing hydrogen to switch metallic magnesium to dielectric magnesium hydride [2] we can tune the nonlinearity of thin films and observe the metallic-dielectric phase transition in the linear and nonlinear regime. We find complex relations between the linear transmittance and the radiated third harmonic, which provide new insights into the phase transition. Particularly, the first few seconds after switching this metal-to-insulator phase transition show remarkable nonlinear responses. We suspect that the surface roughness could play a substantial role.

Complimentary measurements of magnesium films that are being hydrogenized and investigated with an in-situ s-SNOM setup [3] and a mid-IR laser that is tuned to the magnesium hydride phonons gives additional information about the relationships between local microscopic structure and optical properties.

Our results might be of great relevance for nonlinear sensing [4] and nonlinear hydrogen detection in the future.

High Harmonic Generation with Semiconductor Metasurfaces and Epsilon Near-Zero Materials Igal Brener; Sandia National Laboratories, United States

Metasurfaces created from nonlinear III-V semiconductors and heterostructures used to create resonant optical nonlinearities enable nonlinear optics in a new regime, where many simultaneous nonlinearities lead to harmonics and mixing products of laser beams without the need of phase matching. I will present our latest work on optical mixing and harmonic generation in dielectric metasurfaces made from III-V semiconductors and semiconductor heterostructures.

Similar behavior can be obtained in epsilon near zero materials provided that the mobility of the carriers in the material is high enough; these conditions are met in highly doped CdO where we observe high harmonic generation from the infrared to the ultraviolet, and without the need of any patterning.

Transient Second-Order Nonlinear Media Enabled by Hot-Electron Transfer Mohammad Taghinejad¹, Zihao Xu², Kyu-Tae Lee¹, Tianquan Lian² and Wenshan Cai¹; ¹Georgia Institute of Technology, United States; ²Emory University, United States

Second-order optical effects are essential to the on-demand generation of spectral components as well as active control of light via nonlinear processes such as second-harmonic generation (SHG), sum/difference frequency generation, optical rectification, optical parametric amplification, and Pockels effect. These optical processes rely on the interaction of two optical fields through the second-order dielectric susceptibility $\chi^{(2)}$, of optical materials. The
portfolio of $\chi^{(2)}$ media, however, is rather limited as the inversion symmetry in most optical materials inhibits achieving a nonzero $\chi^{(2)}$ response, under the electric dipole approximation. In such materials, the atomic-scale disordered sites at surfaces and interfaces are limited domains where the termination of the bulk-like crystal structure allows for nonlinear light-matter interactions of second-order type, yet in an inefficient manner. Although the enhancement of the weak surface nonlinearity through the utilization of resonant structures has revealed promising potentials, developing symmetry breaking methods are still necessary to activate $\chi^{(2)}$-based nonlinear effects in the bulk of centrosymmetric media. Towards this goal, exerting external strain and applying direct-current electric fields are among the limited proposed approaches for breaking the inversion symmetry and inducing a notable bulk-like $\chi^{(2)}$ susceptibility. However, the current span of the literature lacks optical symmetry-breaking schemes and initial developments in this area are required. In this work, we present a fundamentally new scheme for breaking the crystal inversion symmetry and enabling $\chi^{(2)}$ processes via the generation and transport of hot electrons. The sub-picosecond kinetics of carriers enables the ultrafast conversion of statically passive dielectrics into transient second-order nonlinear media, immediately expanding the portfolio of $\chi^{(2)}$ media beyond the conventional crystals. The induced nonlinearity is accurately tunable using an optical switch that controls the density of generated hot electrons. As an example, we demonstrate that the transient nature of the induced $\chi^{(2)}$ response enables all optical control of the SHG process, proving the feasibility of dynamically tuning second-order light matter interactions through the optical breaking of the inversion symmetry.

Tuning Second-Harmonic Generation from Silicon Metasurfaces via Electrical Control Kyu-Tae Lee, Mohammad Taghinejad, Jiahao Yan, Andrew S. Kim, Devin K. Brown and Wenshan Cai; Georgia Institute of Technology, United States

The pursuit of chip-scale and compact data processing capacity in a CMOS-compatible fashion has promoted the investigation of silicon-based photonic platforms for active optical functionalities via the nonlinear light-matter interactions. The use of silicon in integrated photonics, however, is primarily focused on passive photonic components such as waveguides, gratings, and resonators, while the investigation of active silicon photonics is largely limited to the exploration of several specific processes like the free-carrier dispersion and the Raman effect. This restriction mainly stems from the absence of the bulk second-order nonlinear susceptibility, $\chi^{(2)}$, under the electric dipole approximation due to the centrosymmetric nature of the crystal structure of silicon. To address such a limitation, here we demonstrate the enhancement and tunability of field-induced optical nonlinearity of the second-order type in silicon metasurfaces, where strong magnetic Mie resonances are leveraged to intensify the nonlinear interaction of light with silicon at a prescribed spectral range. On top of the strengthened surface SHG from the silicon metasurface, as facilitated by the magnetic Mie effect, introducing an electrical signal to our silicon structure provides an additional route to the frequency-doubling of light via the EFISH process. Our experimental characterizations and numerical modeling reveal that the efficiency of the field-induced frequency doubling peaks in the spectral vicinity of magnetic behavior, substantiating the synergic role of Mie resonances on the nonlinear optical generation from the silicon platform. Our finding reveals a generic route towards the dynamic control of second-order nonlinear processes, such as sum/difference frequency generation, optical rectification, and Pockels effect, in electrically active silicon metasurfaces.

Engineered Epsilon-Near-Zero Optical Nonlinearity of Al-Doped Zinc Oxide Thin Films via Atomic Layer Deposition Technique Subhajit Bej1, Sudip Gurung1, Nicholas St. John1, Zhenhuan Yi2 and Ho Wai (Howard) Lee1,2; 1Baylor University, United States; 2Texas A&M University, United States

Strongly enhanced third-order nonlinear optical properties of transparent conducting oxide (TCO) thin films in their epsilon-near-zero (ENZ) region (i.e. the region where the real part of their dielectric permittivity approaches zero), have been reported recently [1-3]. Such giant enhancement can be attributed to the hot electron dynamics resulting from ultrafast laser assisted heating. Upon excitation of leaky ENZ modes, effective nonlinear optical properties of these meta-films can be further boosted. Since the response time of these nonlinear processes can be ~100 fs, the ENZ materials could open distinct functionalities to the path to revolutionary nanoscale nonlinear optics and ultrafast on-chip optical applications.

In this work, we present a method to engineer the nonlinear refraction coefficients ($n_2$) and the nonlinear absorption
coefficients ($\beta$) of Al-doped zinc oxide (AZO) ENZ thin films synthesized by atomic layer deposition (ALD) technique. Nonlinear optical properties of TCO films can be attributed to the free carriers which also contribute to linear absorption of the thin films. Furthermore, third order nonlinear optical signals have cubic dependence on the electric field confined inside the TCO films. Hence, to engineer the nonlinear optical properties, we design the linear absorption and electric field intensity enhancement (FIE) associated with leaky ENZ modes in these AZO nanolayers via control over the ENZ wavelengths and optical losses by ALD deposition parameters such as dopant ratio and the number of macrocycles. The dopant ratio determines the material dispersion and ENZ wavelength whereas the macrocycle regulates the film thickness.

We fabricate AZO films with ENZ wavelengths varying between 1400-1600 nm and their thicknesses ranging from 55 to 216 nm [4]. Nonlinear optical properties of the fabricated films are measured using standard open and close-aperture Z-scan technique using an ultrafast femto-second laser (pulse duration ~70 fs). The peak wavelength ($\lambda_p$) of the fs pulses can be tuned from 1200 to 1600 nm with an optical parametric amplifier unit. Measured $n_2$ and $\beta$ values of the films are evaluated upon fitting the experimental data. Experimental results suggest that nonlinear refraction and nonlinear absorption strengths of these ENZ AZO films can be engineered by controlling the ZnO to Al dopant layer ratios in the deposited AZO films, as well as the film thickness. We also observe an enhancement of the effective nonlinear properties due to excitation of leaky ENZ modes at oblique incidence while illuminating with TM polarized light. Measured values as large as $n_2^{(\text{eff})} \approx 10^{-8}$ mm$^2$/Watt and $\beta_2^{(\text{eff})} \approx -10^{-4}$ mm/Watt are obtained along with approximately an order of magnitude tunability via ALD parameters. Lastly, we present a way to achieve ultrastrong, dispersion-free ENZ nonlinearity which relies on engineering of material dispersion with a multi-layer structure and excitation of a broadband leaky ENZ mode. The giant $n_2$ and $\beta$ values of ALD AZO films in their ENZ region and their controllability will be important for efficient all-optical signal processing.

Polymer-based metamaterials provide a lightweight, flexible and low-cost platform exhibiting new optical, thermal, and electrical multi-functionalities that provide structural coloration, visual and/or thermal camouflage, solar and thermal energy harvesting, and personal cooling/heating. We will discuss several examples of new metamaterials with tunable photon, electron and phonon transport properties achieved by either sculpting the internal structure of polymers or using polymers to sculpt the internal structure of inorganic solids or nanoparticle arrays. These include:

(i) composite organic-inorganic films with a varying degree of crystallinity and mesoscale internal structure fabricated via extrusion and solvent casting followed by polymer chain alignment, which exhibit new tunable transparency, haze, thermal conductivity, and dynamical tunability properties,

(ii) new types of composite organic-inorganic polymer-based network metamaterials grown on low-density porous scaffolds to sculpt their internal structure,

(iii) nanoparticle arrays on stretchable polymer substrates, designed for mechanical tuning and switching functionalities.

This work is supported by the US Army Research Office (via the CCDC Soldier Center and the MIT Institute for Soldier Nanotechnologies), Advanced Functional Fabrics of America (AFFOA), MIT International Science and Technology Initiatives (MISTI), and the UNSW-USA Networks of Excellence. The authors thank Dr. Richard M. Osgood III for useful discussions.

Controlling the Instantaneous Polarization State of Femtosecond Optical Pulses Using Dielectric Metasurfaces

Wenqi Zhu, Lu Chen, Henri Lezec and Amit Agrawal; National Institute of Standards and Technology, United States

Metasurfaces are ultra-thin, planar optical elements composed of sub-wavelength nanostructures, which can be engineered to modify the local characterizations of light. Recently, it has been demonstrated that dielectric metasurfaces can be implemented to simultaneously and independently manipulate of the phase and amplitude for a near-infrared femtosecond pulse having over 200 nm ultra-wide bandwidth while maintaining high spectral resolution of 0.3 nm. Extending the applications of dielectric metasurfaces in ultrafast optics holds great potential for applications ranging from fundamental light-matter interactions to ultrafast communications. In general, the electric field of a femtosecond pulse is a vectoral quantity defined by its phase, amplitude, and polarization. Further controlling the instantaneous polarization state of a single optical pulse as a function of time would largely expand the capability and impact of ultrafast optics.

Here, we offer the experimental demonstration of polarization shaping using dielectric metasurfaces to control the temporal polarization state of femtosecond optical pulses. The pulse shaper consists of a Fourier-transform setup with a dielectric metasurface positioned in the focal plane. Rectangular silicon nanopillars are fabricated on a fused-silica substrate, with the dimensions carefully designed to provide the targeted spectral phase for two orthogonal polarizations – for example, a quadratic phase shift for p-polarized component and a constant phase for s-polarized component. The input pulse is linearly polarized and orientated 45° with respect to the nanopillars, providing two equal polarization components. After passage through the metasurface, the shaped output pulse is characterized by direct electric-field reconstruction using spectral phase interferometry. The measured spectral phase matches with the targeted phase function for both polarizations: the time-domain signal reveals a stretched pulse for p-polarization due to the quadratic dispersion and a narrow pulse for s-polarization due to the constant phase shift. By stacking the polarization ellipses along the time axis, a three-dimensional representation of the femtosecond pulse can be reconstructed. Within a single femtosecond pulse duration, the polarization state evolves between different linear and elliptical polarizations with varying degrees of ellipticity.

In summary, we have demonstrated femtosecond polarization pulse shaping by controlling the spectral phase for two orthogonal polarizations using dielectric metasurfaces. With the large bandwidth, high resolution, and easy compatibility offered by the metasurfaces, such an approach opens up new possibilities in the field of ultrafast
science and technology.

Metaphotonics with 2D and 3D Engineered Optical Materials Andrei Faraon, Philip Camayd-Munoz, Hyonghan Kwon, MohammadSadegh Faraji Dana, Gregory Roberts and Conner Ballew; California Institute of Technology, United States

In the past decade we witnessed the development of optical metasurfaces that enabled diffractive optical elements with new functionalities. However, the number of optical modes in a metasurface is limited, which directly affects the functionality and performance that can be achieved with a single layer metasurface device. In this talk I will present how systems of stacked metasurfaces and fully three-dimensional dielectric structures with more optical modes open up a new optical design space with exciting applications in various imaging modalities, spectrum splitting and other applications.

Light Control with Phase-Cancellation Metasurfaces Amr M. Shaltout, Jorik Van de Groep, Yifei Wang and Mark L. Brongersma; Stanford University, United States

The concept of phase-cancellation metasurfaces is introduced which enables the attenuation of specific optical modes using destructive interference. This concept has been utilized to implement a broadband circular polarizer using dielectric metasurfaces. We design and implement a dielectric metasurface which induces a hybrid phase-shift composed of an accumulation phase component and a geometric phase component. The metasurface is composed of anisotropic Silicon based nanorods in which accumulation phase is controlled by the nanorod thicknesses, and geometric phase is controlled by their orientations. Each unit cell is composed of two sub-units which transmit in-phase left-circularly polarized (LCP) optical component, and out-of-phase right-circularly-polarized (RCP) component. RCP is attenuated as a result of destructive interference, and a broadband circular polarizer with high extinction ratio (>13dB) is achieved using a single metasurface layer. The concept of destructive interference using phase-cancellation metasurfaces can be extended to other applications. It can be utilized in dynamic metasurfaces in which high contrast optical switches is achieved by controlling the condition of phase-cancellation to modulate the action of attenuation between ON and OFF.

Ultraviolet Metasurfaces for Chiral Sensing and Separation Jack Hu, Michelle Solomon, Mark Lawrence and Jennifer A. Dionne; Stanford University, United States

Chiral light-matter interactions are a potentially efficient and versatile method to resolve enantiomers, improving the efficacy of chiral pharmaceuticals and agrochemicals. However, the chiroptical response of small molecules is weak, thus limiting light based detection and separation schemes. Emerging nanophotonic platforms have been shown to increase the interaction between circularly polarized light (CPL) and chiral molecules through a concentration of the local density of optical chirality, \( C \). We have recently shown that tailoring electric and magnetic Mie resonances in dielectric metasurfaces can locally enhance the magnitude of \( C \) over 100-fold compared to CPL in free space. However, both theoretical and experimental demonstrations of enhanced optical chirality have been limited to the infrared and visible, while the chiral absorption features of most industrially relevant small molecules are in the ultraviolet.

In this presentation, we design ultraviolet metasurfaces that overcome this band mismatch, enabling high optical
New plasmonic metasurfaces with high-Q electric and magnetic dipole resonances. Similar to the case of a symmetric metasurface, for the biperiodic lattice we can fix the enhancement of 50-fold. A diameter offset is then introduced which produces high-Q antisymmetric electric and magnetic dipole resonances, producing a maximized ratio allows for spectral overlap of low-Q electric and magnetic dipole resonances, producing a maximized C enhancement of 50-fold. A diameter offset is then introduced which produces high-Q antisymmetric electric and magnetic dipole resonances. Similar to the case of a symmetric metasurface, for the biperiodic lattice we can fix the lattice parameter a=200 nm and disk height h=60 nm, then sweep the center disk diameter from 100 nm to 120 nm to spectrally shift the electric and magnetic resonances in relation to each other. For a metasurface with a 10% offset between neighboring disks, the high Q modes overlap at a center diameter of 107 nm. At this diameter, we calculate a local C enhancement of 1000-fold at an excitation wavelength of 263 nm. Furthermore, the circularly polarized phase of the incident CPL is preserved in the near fields resulting in a C enhancement of a single handedness. Thus, regions of large optical chirality persist above the metasurface, yielding averaged C enhancements exceeding 100-fold in a volume extending 200 nm from the disks. We also show that adjusting the structural asymmetry through the diameter offset allows for tuning of the radiative Q factors and consequently the local C enhancements across four orders of magnitude. Our results demonstrate the first nanophotonic platform that increases C more than three orders of magnitude in the ultraviolet, paving the way for efficient all optical chiral resolution of small molecules.

High-Speed Thermal Photodetection with Plasmonic Metasurfaces Jon Stewart1, Jarrett H. Vella2 and Maiken H. Mikkelsen1; 1Duke University, United States; 2Air Force Research Laboratory, United States

Integration of thermally-sensitive materials with highly-engineered metamaterial absorbers has allowed for the creation spectrally-selective thermal detectors ranging across the MHz-THz frequency bands. However, the fastest detectors possess a millisecond-scale response time limiting their applicability for real-time, high-resolution imaging or time-resolved sensing techniques. Here we demonstrate a high-speed, spectrally-selective thermal photodetector operating at room temperature by integrating a colloidally-fabricated plasmonic metasurface with an aluminum nitride (AlN) pyroelectric film. The subwavelength, absorbing metasurface possesses a picosecond-scale thermal diffusion time, which produces a voltage in the underlying pyroelectric film proportional to its temperature change. Impulse response measurements of the metasurface-pyroelectric detectors show instrument-limited responses down to 500 ps, where finite-element simulations reveal the possibility of achieving 25 ps response times rivaling the carrier-limited response times of photodiodes. These scalable, inexpensive, and large-area devices show potential for realizing uncooled thermal photodetectors with high responsivities and GHz speeds without the spectral limitations of bandgap-reliant detectors.

Tunable Metasurfaces Based on a Hybrid Platform of Dielectric/Phase-Change Materials Sajjad Abdollahramezani, Hossein Taghinejad, Yashar Kiarashinejad, Omid Hemmatyar, Mohammadreza Zandehshahvar, Ali Eftekhar and Ali Adibi; Georgia Institute of Technology, United States

To spectrally, spatially, and/or even temporally manipulating optical wavefronts in the subwavelengthscale, plasmonic metasurfaces consisting of a planar array of patterned metallic nanostructures have gained extensive attention [1]. However, their low coupling efficiency as well as inherent ohmic losses coming with significant heat generation hinder many practical on-demand applications. The advent of all-dielectric metasurfaces, which employ optically induced electric and magnetic Mie resonances of subwavelength high-index nanoparticles, expedited the realization of miniaturized CMOS-compatible metadevices addressing the challenges associated with plasmonic counterparts [2, 3]. Nevertheless, the functionality of the implemented metadevices cannot be tuned postfabrication. To dynamically engineer the amplitude, phase, polarization, and/or dispersion of light for a wider range of applications, exploiting active functional materials is indispensable [4]. Here, we present a non-volatile active platform by hybridizing a high-index metasurface with phase-change alloy Ge2Sb2Te5(GST). The intrinsic high-index and drastic optical contrast of GST (upon conversion from amorphous to the crystalline in multiplestates) make multipolar Mie resonances of all-dielectric nanoresonators optically tunable. As a proof-of-concept, we demonstrate a small footprint, multi-wavelength, and multi-level optical modulator capable of modulating the light with high modulation depth in extreme states of GST. We also experimentally show how the structure takes advantage of the
interplay of electric and magnetic resonance modes, due to the induced intermediate states of GST, leading to a considerable phase shift of the transmitted light necessary for beaming applications. We leverage a new deep learning architecture to effectively design optimized metadevices considering the fabrication imperfections while the underlying physics of light-matter interactions is explained through a sheer mathematical platform [5, 6]. Our findings further substantiate active dielectric metasurfaces as promising candidates for the development of miniaturized energy harvesting modules, optical sensors, phased array antennas, and holograms.

Spectroscopic Optical Imaging at Nanometer Scales Ze Zhang1, Joel Martis1, Brad Takasuka2 and Arun Majumdar3,1; 1Stanford University, United States; 2Silicon Valley Peripherals, United States; 3SLAC National Accelerator Laboratory, United States

Nanometer-resolution optical spectroscopic imaging offers fundamental insights of light-matter interactions that has significant bearing on understanding optoelectronic properties of molecules and inorganic nanostructures, surface chemical reactions, and defect engineering. Optical spectroscopy techniques like Raman, IR spectroscopy and UV-vis-NIR spectroscopy, are widely used for materials characterization. However, their spatial resolution is limited by the wavelength of the light used, which is on the order of hundreds of nanometers to microns. Past attempts to break this diffraction limit include using a scanning probe to locally enhance the interaction between the sample and light, using near field optics to reduce the effective optical spot size, or using super resolution techniques such as PALM, STORM, STED. Electron microscopy, on the other hand, can readily achieve nanometer or even atomic resolution, but surface-sensitive electron spectroscopy of molecules and inorganic nanostructure is difficult due high electron doses and due to the energy mismatch between the high energy (5-300 keV) electron beam and the low energy (5 eV or less) electronic or vibrational states.

We introduce a new imaging technique named PhotoAbsorption Microscopy using ELecron Assays (PAMELA), which combines the high spectroscopic selectivity of photo-excitation with nanometer-scale spatial resolution of electron beams. PAMELA relies on the largely unexplored coupling of light and electron beams within matter that produces unique signatures, which can be utilized for the purpose of nanoscale imaging. This new technique is...
demonstrated by obtaining optical images of inorganic nanostructures at <10 nm spatial resolution that exhibit spectroscopic selectivity based on photoabsorption. PAMELA provides a more general approach for characterizing materials as it relies on the inherent light absorption, without requiring subsequent fluorescence, luminescence or any specific modification of the sample. This will likely open new opportunities in fields such as surface chemistry, biomolecular imaging, and quantum materials.

EL01.15.02
Light Wrangler—Manipulation and Analysis of Molecules with Plasmonic Nanoantennas Michel Frising, Alvaro Magdaleno and Ferry Prins; Universidad Autonoma de Madrid, Spain

Inspired by previous theoretical\(^1\) and experimental work\(^2\) we will show experimental data and simulations of plasmonic nanopore antennas designed to enhance the Raman-scattered signal of molecules. Spectroscopy of single molecules can reveal details about the molecular structure that are inaccessible in ensemble measurements. The most prominent example is the DNA molecule. The knowledge of the exact sequence of the nucleotides in the DNA molecule contains the complete genetic information of an organism. However, the individual base pairs are spaced by only a few hundred picometers, requiring extremely high resolution to distinguish adjacent nucleotides. Recent studies using tip-enhanced Raman scattering (TERS) on single molecules have shown that sub-nanometer resolution can be achieved\(^3–5\). While in these studies the probe is brought to the sample, we are going to bring the sample to the probe to streamline the analysis while maintaining the resolution of the TERS technique. In particular, we are going to present the Raman-scattered signal from different molecules in the hotspot of the plasmonic antennas specifically designed to enhance the intensity of the Raman-scattered signal which can be used to identify different molecules. Further, the plasmonic antennas can be used at the same time to influence the spatial dynamics of the molecules present in the hotspot\(^7,8\), which could be exploited to manipulate the molecule. Such a technique this would pave the way for a lab-on-a-chip system to determine sequences of molecules\(^6\).

Near-Infrared Interband Hot-Carrier Generation with Au-Pd Nanoalloys Sara K. Figueiredo Stofela, Orhan Kizilkaya\(^2\), Tiago R. Leite\(^1\), Mohammad M. Taheri\(^3\), Jason Baxter\(^3\), William A. Shelton\(^1\), Phillip T. Sprunger\(^1,2\), Benjamin T. Diroll\(^4\) and Kevin M. McPeak\(^1\); \(^1\)Louisiana State University, United States; \(^2\)Louisiana State University Center for Advanced Microstructures & Devices, United States; \(^3\)Drexel University, United States; \(^4\)Argonne National Laboratory, United States

The hot-carrier generation in the near-infrared (NIR) in Au nanostructures has recently been explored for applications in photodetection and photocatalysis. While the nonradiative decay of surface plasmons via Landau damping is a pathway to generating hot carriers near the Fermi level, a more efficient mechanism involves direct transitions (interband). However, for Au (and all noble metals) these transitions require at least 2 eV to take place. Therefore, noble metals have a band structure that is not ideal for the generation of hot carriers in the NIR. One possible route to improving the efficiency of hot carrier generation in noble metals at NIR wavelengths, is to shift
their electronic density of states closer to the Fermi level via alloying with a transition metal. In this work, we show how alloying Au with Pd couple the individual metal benefits: an oxidation resistance, a longer carrier lifetime and a favorable band structure for NIR transitions. Grazing incidence x-ray diffraction (GI-XRD) and x-ray photoelectron spectroscopy (XPS) measurements support the formation of single-phase alloy and oxidation resistance in the thin films. While, ultraviolet photoelectron spectroscopy (UPS) data shows how the electron density of states (EDOS) increase near the Fermi level when adding Pd to Au with respect to Au. Ellipsometry measurements show that adding Au to Pd improves the plasmonic properties in the NIR with respect to pure Pd. DFT calculations show that Au-Pd alloys are expected to generate more hot carriers than pure Au under NIR. Using NIR-pump, THz probe transient absorption spectroscopy, we also provide evidence suggesting that alloying Au with Pd results in an increased distribution of hot carriers with respect to Au in the NIR.

EL01.15.04
Super-Resolution Mapping of Plasmon-Enhanced Processes Ruben Hamans1,2, Matteo Parente1,2, Gabriel Castellanos3, Mohammad Ramezani1,3, Jaime Gómez Rivas1,3 and Andrea Baldi1,2; 1Dutch Institute for Fundamental Energy Research (DIFFER), Netherlands; 2Institute for Complex Molecular Systems, Eindhoven University of Technology, Netherlands; 3Institute for Photonic Integration, Department of Applied Physics, Eindhoven University of Technology, Netherlands

Plasmonic and photonic structures have dimensions that are typically smaller than the diffraction limit. Here, we use super-resolution microscopy to map the coupling between fluorescent molecules and metal nanoparticle arrays and to study catalysis on individual Au nanostructures.

First, we investigate the coupling between fluorescent molecules and a periodic array of metallic nanoparticles. Due to their ability to support surface lattice resonances, these arrays can enhance the emissive properties of fluorescent molecules across the whole unit cell of the array, instead of just in the vicinity of a nanostructure. By combining super-resolution microscopy with finite-difference time-domain simulations, we find that collective resonances have minimal influence on the spontaneous decay rate of an emitter, but instead can be exploited to enhance the directivity of the emission. Our approach of experimentally mapping emission enhancement with sub-diffraction resolution and numerically disentangling the underlying contributions can inform the rational design of optical devices based on plasmonic particle arrays [1].

Second, we study the effect of the decay of localized surface plasmon resonances on the catalytic properties of metal nanoparticles. As a test reaction we use the nanoparticle-catalyzed reduction of the weakly fluorescent molecule resazurin to the strongly fluorescent molecule resorufin. By using catalysts with a plasmon resonance spectrally separated from the absorption and emission of the reaction products and by controlling the polarization of the incident fields, we can study the different contributions to the total catalytic rate of plasmonic hot electrons, electromagnetic hot spots, and photo-thermal effects. Understanding the underlying mechanisms of plasmon-enhanced catalysis is fundamental for the development of a next generation of photo-catalysts that can efficiently harvest light to drive chemical reactions.

Overcoming Quantum Decoherence at Telecom Bands with Plasmonic Nanocavities Yue Luo1,2, Xiaowei He1, Younghee Kim3, Jeffrey L. Blackburn4, Stephen K. Doorn3, Han Htoon3 and Stefan Strauf1; 1Stevens Institute of Technology, United States; 2Harvard University, United States; 3Los Alamos National Laboratory, United States; 4National Renewable Energy Laboratory, United States

Indistinguishable single photon generation at telecom wavelengths from solid-state quantum emitters remains a significant challenge to scalable quantum information processing. Here we demonstrate efficient generation of indistinguishable single photons directly in the telecom O-band from aryl-functionalized carbon nanotubes by overcoming the quantum decoherence with plasmonic nanocavities. With an unprecedented single-photon
spontaneous emission time down to 10 ps (from initially 0.7 ns) in the coupling scheme, we show a two-photon interference visibility at 4 K up to 0.79 without post selection. Cavity-enhanced quantum yields up to 74% and Purcell factors up to 415 are achieved with single-photon purities up to 99%. Our results establish the capability to fabricate fiber-based photonic devices for quantum information technology with coherent properties that can enable quantum logic.

**EL01.15.07**  
**Propagating Dirac Plasmon Polaritons in Topological Insulators** Yong Wang and Stephanie Law; University of Delaware, United States

The properties of topological insulators (TIs) have been widely explored due to their unique band structure. The energy states at the TI surfaces exhibit linear dispersion and spin-momentum locking. Carriers occupying these states are therefore two-dimensional, massless, and spin-polarized. Dirac plasmons comprising these carriers can be excited in TI thin films. Because most TI films are much thinner than the wavelength of light, plasmons excited on the top and bottom surfaces couple, resulting in an acoustic and an optical plasmon mode. Due to the spin-momentum locking characteristics of the TI surfaces, the optical mode is predicted to be spin-polarized. Before the spin properties of TI plasmons can be measured, propagating plasmons must first be excited. There are a variety of ways to excite plasmons in TI thin films. The most common way is to etch the film into an array of stripes to create localized plasmons. Although this technique has been highly effective, these localized modes cannot easily be used to understand the spin properties of TI plasmons. To excite propagating plasmons, we instead choose to use a grating coupler fabricated on the surface of the TI film.

We first grew a series of 50nm Bi₂Se₃ films using a molecular beam epitaxy (MBE) system. The TI films had the following structures: a layer of 5nm BiInSe₃ (BIS) on the top, 50nm Bi₂Se₃ TI in the middle, and 50nm BIS between the TI and the Al₂O₃(0001) substrate. The BIS layer on the top serves as a protection layer to prevent surface degradation and charge redistribution caused by the grating metals. The BIS layer on the bottom serves as a buffer layer to optimize the quality of the TI growth. After growth, 100nm gold/10nm titanium gratings with different grating periodicity are lifted off of the surface of the film. The periodicity of the gratings ranges from 100nm to 700nm. TM polarized transmission spectra are then taken in a Fourier Transform Infrared Spectroscopy (FTIR) system. From the extinction spectra, we observe a series of absorbing peaks that shift with the grating periodicity. We have ruled out any source other than the plasmons that could have possibly caused the peaks to show up in the range. TM transmission spectra were taken on a bare sapphire substrate, a single layer TI film directly grown on sapphire, a single layer BIS film grown on sapphire, and a sapphire substrate with gratings on top. None of the spectra shows the same peaks as those we see in TI films with top gratings. Hence, we have successfully demonstrated the existence of the propagating Dirac plasmons in the TI Bi₂Se₃ and the tunability of the plasmon frequency with grating period.

The next steps will be to launch the plasmon and detect the spin wave dynamically. TIs are the only known single-material system where such spin-polarized plasmons can be observed. The observation of propagating Dirac plasmons in TI is significant not only because it proves the theoretical predictions of TI Dirac plasmons, but also creates possibilities in developing future technology. A frequency-tunable propagating spin-density wave could be feasible for better memory or computing systems.

**Surface-Plasmon-Polariton-Driven Narrow Linewidth Magneto-Optics in Ni Nanodisk Arrays** Francisco Freire Fernández⁵, Mikko Kataja⁶ and Sebastiaan van Dijken¹; ¹Aalto University, Finland; ²Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Spain

The integration of plasmonics and magneto-optics has led to the emergence of a new research field known as magnetoplasmonics. The main goal of magnetoplasmonic is twofold. First, the use of magnetic materials in plasmonic structures enables active light manipulation at the nanoscale via field-controlled breaking of time-reversal symmetry [1,2]. Second, the excitation of surface plasmons in magnetic materials can be used to resonantly enhance and spectrally tailor their magneto-optical response [3-7]. Despite its promise, magnetoplasmonics faces a challenge of overcoming optical losses. This holds particularly true for nanostructures containing ferromagnetic metals, whose losses are significantly larger compared to noble metals. Here we exploit surface plasmon polaritons (SPPs) excited at the interface of a SiO₂/Au bilayer to induce strong magneto-optical responses on the Ni nanodisks of a periodic
array. Using a reference system made of Au nanodisks, we show that optical losses in Ni do not broaden the linewidth of the SPP-driven magneto-optical signals. Loss mitigation is attained because the free electrons in the Ni nanodisks are driven into forced oscillations away from their plasmon resonance. By varying the SiO2 layer thickness and lattice constant of the array, we demonstrate tailoring of intense magneto-optical Kerr effects with a spectral linewidth down to ~25 nm. Our results provide important hints on how to circumvent losses in magnetoplasmonics via the design of off-resonance driving mechanisms.

Chiral Light-Matter Interactions in a Plasmonic Nanocavity for Chiral Organic Optoelectronics
Hyungchae Kim, Kyung Ryoul Park and Changsoon Kim; Seoul National University, Korea (the Republic of)

In recent years, circularly polarized light (CPL) detectors and CPL emitters based on chiroptical effects arising from chiral molecules have attracted much attention as building blocks of advanced information technology. Their performances, however, have been shown to be severely limited by the trade-off between the external quantum efficiency ($\eta_E$) and the dissymmetry factor ($g$) that characterizes their asymmetric optical behaviors depending on the helicity of CPL. One way to overcome this is to utilize the supramolecular chirality, which translates a molecular chirality into a supramolecular system whose size is comparable to or larger than the wavelength of light. Although this approach can increase $g$ without necessarily decreasing $\eta_E$, it is not applicable to optoelectronic devices whose vertical (with respect to the substrate) dimension is smaller than the wavelength, such as organic light-emitting devices and photodetectors.

Here, we numerically demonstrate that a nanophotonic platform consisting of a chirally patterned metal layer–insulator layer–metal layer (cp-M/I/M) structure can induce a strong chiroptical response of organic molecules positioned inside the insulator layer, and that a CPL-sensitive organic photodetector with both high $g$ and $\eta_E$ can be realized using this platform. In this nanophotonic structure, plasmonic hot spots are excited at an optical frequency only for a helicity of the incident CPL matched to the twisted direction of the chiral nanopattern, which is attributed to a selective excitation of a mode arising from the hybridization of a plasmonic mode near the top electrode and that near the bottom electrode. For full utilization of the plasmonic hot spots possessing high photonic densities of states, we examine the dependence of $\eta_E$ and $g_A$ on the molecular orientations. A CPL-sensitive photodetector incorporating in the cp-M/I/M structure vertically-oriented molecules, i.e., molecules whose transition dipole moment is normal to the substrate, features $\eta_E = 24\%$ and $|g_A| = 1.6$, which are respectively 24 (or 240) and 1.7 (or 1) times larger than $\eta_E$ and $|g_A|$ of Schottky photodiodes using Z-shaped chiral nanostructures [1] (or helicene based photodetectors [2]).

The Effect of Magnetic Fields on Plasmon Resonance Frequencies of Metal Nanostructures
Peter Novello1, Yael Gutiérrez2, Siyuan Zhu1, Fernando Moreno2, Pani Varanasi1,1 and Jie Liu1; 1Duke University, United States; 2University of Cantabria, Spain; 3U.S. Army Research Office—Materials Science Division, United States

The interaction of a magnetic field and the field generated by a localized plasmon resonance on Au nanorods is shown to be a measurable effect. Previously, the magneto-optical Kerr and Faraday polarization dependent effects have been observed on hybrid magnetic-plasmonic structures, and it has been theoretically demonstrated that under
high magnetic field strength (>10T) a splitting of the plasmon absorption band occurs with circularly polarized light. Here the surface plasmon absorption of Au nanorods is measured utilizing a magnetoo-spectrometer with a magnetic field force up to 1.5T and non-polarized light. It is found that as the magnetic field strength increases, the energy and the lifetime of the plasmon resonance are altered. Coupled with theoretical work, our findings suggest either the Lorentz force is acting on the electrons under a magnetic field effectively amplified by the localized plasmon resonance, or an alternative mechanism exists.

Atomic Layer Engineering of Epsilon-Near-Zero Ultrathin Films with Controllable Zero Index Field Enhancement Sudip Gurung1, Aleksei Anopchenko1, Subhajit Bej1 and Ho Wai (Howard) Lee1,2; 1Baylor University, United States; 2Texas A&M University, United States

Enhanced and controlled light absorption as well as field confinement in an optically thin material are pivotal for energy efficient optoelectronics and nonlinear optical devices. Highly doped transparent conducting oxide (TCO) thin films with near-zero permittivities, in their so-called epsilon near zero (ENZ) frequency regions, can support ENZ modes which may lead to perfect light absorption and ultra-strong electric field intensity enhancement (FIE) within the films. To achieve full control over optical absorption and FIE, one must be able to tune the ENZ material properties as well as the film geometries. Here, we report a nano-engineering of ultra-smooth aluminum doped zinc oxide (AZO) films with tunable ENZ wavelength (1500-1725 nm), low optical losses, and thickness as small as 22 nm by using atomic layer deposition (ALD) technique. The ENZ properties of the AZO thin films are controlled by deposition conditions such as dopant ratio, deposition temperature, and number of macro-cycles. We experimentally demonstrate engineered absorption and FIE of AZO thin films via control on their ENZ wavelengths, optical losses, and film thicknesses. Furthermore, we introduce a simple mathematical formula for quick and accurate estimation of FIE when ENZ modes are excited in classical Kretschmann-Raether configuration. Finally, we demonstrate that under ENZ mode excitation, though the absorption and FIE are inherently related, the film thickness required for observing maximum absorption differs significantly from that for maximum FIE. This systematic study on engineering ENZ materials related enhancement properties by optimization of ALD deposition process will be beneficial for the design and development of next generation tunable photonic devices based on flat zero-index optics.

EL01.15.12
Approaching Ultra-Strong Polaritonic Coupling within CdO Bilayers Joshua R. Nolen1, Evan Runnerstrom2, Kyle P. Kelley3, Thomas G. Folland1, Angela Cleri4, Joshua Nordlander4, Edward Sachet2, Christopher Shelton2, Alyssa Livingood3, Jon-Paul Maria4 and Josh Caldwell1; 1Vanderbilt University, United States; 2North Carolina State University, United States; 3Oak Ridge National Laboratory, United States; 4The Pennsylvania State University, United States; 5University of Kentucky, United States

Epsilon-near-zero (ENZ) modes are supported in films of polaritonic materials with vanishing permittivity values and deeply sub-wavelength thicknesses. These novel optical excitations are associated with extreme electric field confinement, enabling control over light-matter interactions such as resonant perfect absorption and strong nonlinear interactions. Recent studies have demonstrated ENZ phenomena in doped transparent conducting oxides (TCOs). Unlike traditional metals that are not tunable in the IR and THz due to fixed, high carrier densities, TCOs allow for tuning of both carrier density and electronic mobility. One highly promising TCO is highly-doped CdO, which has been shown to achieve electron mobilities extending upwards to 500 cm²/V-s with carrier densities ranging from 10¹⁹ to 10²⁰ cm⁻³. Unique to this material is a range of carrier densities where increasing values result in increasing mobilities.
ENZ modes are unique for their strong absorption/emission and narrow resonant linewidths that can be achieved without the need for nanostructuring. This behavior has been utilized to achieve perfect absorption in thin films as well as thermal emissivity control. These modes are attributed with a nearly-flat spectral dispersion that consequently results in low group velocities and short propagation lengths, diminishing their utility. However, these limitations may be mitigated through hybridization with other polaritonic modes, such as surface plasmon polaritons (SPPs) which are also supported in doped CdO films. Unlike ENZ modes, SPP modes propagate at a much higher group velocity but are hindered by carrier scattering losses and highly sensitive to surface morphology. Careful control over the carrier concentration during film growth has opened the door to achieving multilayer CdO films. Here we show that epitaxially-grown bilayer stacks of CdO, with bottom and top layers supporting SPP and ENZ modes respectively, exhibit cavity-free strong coupling between the ENZ and SPP modes and overcome the deficiencies of each constituent mode. The combined ENZ-SPP dispersion of these bilayer films displays a prominent anti-crossing with a separation that is on the order of the mode frequency, giving clear evidence of strong coupling. The degree to which these modes are strongly coupled together is dependent on both the spectral and spatial overlap of the modes. By carefully controlling the plasma frequency of the two individual CdO layers, this spectral overlap and thus the ENZ-SPP dispersion, can be tuned. We also show that tuning the oscillator strength of the individual modes is another approach towards manipulating the ENZ-SPP dispersion. This is controlled geometrically, by tuning the ENZ layer thickness.

In more recent work we have extended our focus to other geometries, such as CdO films where the SPP and ENZ films are spatially separated by a dielectric spacer layer. The dielectric layer thickness modifies the spatial overlap of the constituent electric fields as well as alters the effective index of the region above the SPP layer, providing additional tuning to the ENZ-SPP dispersion. We also examine the hybridization between localized SPP modes and an ENZ layer imbedded within a perfect absorber structure to monitor the impact of nanostructuring upon this strong coupling phenomena and how this can be used as independent knobs for tuning the resonant absorption, and alternatively thermal emission, of the structures. By fabricating such hybrid materials into nanostructure arrays, direct control of the emission polarization, spatial coherence and divergence is also engineered through careful design of nanostructure geometry and periodicity. This approach may lead to the realization of spectrally tunable thermal emitters for narrow-band, polarized and spatially coherent IR sources.

**Probing Hot Carrier Dynamics in Alternative Plasmonic Materials** Ping-Hsien Ou\(^1\), Meng-Ju Yu\(^1\), Hye-Young Ahn\(^2\) and Yu-Jung Lu\(^1,3\), \(^1\)Academic Sinica, Taiwan; \(^2\)National Chiao Tung University, Taiwan; \(^3\)National Taiwan University, Taiwan

Transition metal nitrides have been considered as promising plasmonic materials due to the high thermal stability and tunable optical properties to replace noble metals. In this work, we used pump probe transient absorption measurements to study the ultrafast carrier relaxation processes in gold film (standard plasmonic materials) and alternative plasmonic materials, including sputtered titanium nitride, zirconium nitride, hafnium nitride and niobium nitride. The long lifetime of hot carrier in alternative plasmonic materials make it more beneficial than that in gold to cross the Schottky barrier between semiconductor and plasmonic materials, and further enhance the performance of plasmonic device. Here, we demonstrated that transition metal nitrides are possible to be utilized in efficient hot carrier extraction. With femtosecond Ti:Sapphire pulsed laser, we are capable of distinguishing various carrier dynamics within a nanosecond. Two relaxation mechanisms take place during the period hot electrons relax probing at photon energy of 2.58 eV. One is the combination of electron-electron and electron-phonon interactions which occurs at femtoseconds to several picoseconds, and slow phonon-phonon relaxation with a hundreds of picosecond comes after the first short relaxation. Moreover, we not only confirmed that the relaxation process in transition metal nitrides are one order magnitude slower than that in gold, but also proved that niobium nitride has the longest first fast decay time. The more slowly the carriers relax, the more possibly they are captured. In addition, the relaxation time could be tuned with respect to quality of materials, thickness and substrate. Besides, we theoretically calculated the band structure of transition metal nitrides by first principles in order to study the carrier relaxation time. We conclude that the slow carrier relaxation time strikes an opportunity for hot carriers in transition metal nitrides to be efficiently transferred to semiconductor as hot carrier donor due to the long hot carrier lifetime. Thus, we believe the results pave the way for the applications of high performance optoelectronic devices with high efficient hot carrier extraction.

**Electric-Field Tunable Magnetoplasmonic Gratings** Mikko Kataja\(^1\), Rafael Cichelero\(^2\) and Gervasi Herranz\(^1\);

Final Program 1/13/2020 74
With the advent of integrated photonics, grating couplers offer a solution towards integrated optical isolation by coupling optic fibers to on-chip waveguides. In this context, we study the interplay between electro-optical and magneto-optical effects. The magneto-optical effect breaks the time-reversal symmetry and induces frequency shifts in the energy and angular spectra of plasmon resonances. As a result of these shifts, exceptionally large magneto-optic responses are can be achieved [1]. In optoelectronic devices modulation and switching capabilities can be accomplished by electric control of the amplitude and phase of electromagnetic waves, using architectures based either on Mach-Zehnder interferometers or micro-ring resonators. Combining the properties of the two aforementioned materials could enable the control of the properties of magneto-optically active devices by electric fields which is an attractive prospect for development of novel nanophotonic devices. Facing this challenge, we study a magneto-optically active Au/Co multilayer grating coupler fabricated on top of an electro-optically active substrate (BaTiO3) as the basic device to uncover how these two active properties influence each other. We used Fourier optics microscopy to obtain the plasmonic band structures of our gratings [2]. The Fourier spectroscopy approach can be adapted to the study of magnetoplasmonic gratings by reducing the beam spot size in the objective back aperture, so that diffracted modes can be analyzed independently, enabling the exploration of the interplay between plasmonic resonances and diffracted light. We used this approach to study selectively surface plasmon polaritons propagating along backward or forward directions, enabling us to easily assess their non-reciprocal magnetic modulation. To assess the magneto-optic response, we measured the transverse magneto-optic Kerr effect (TMOKE) amplitude of Au/Co magnetoplasmonic gratings, measured from the ARR maps, obtained through the expression \( TMOKE = \frac{I(H_+)-I(H_-)}{I(H_{avg})} \), where \( I(H_+), I(H_-) \) are the reflected or diffracted intensity detected at opposite saturated magnetizations of Co (taken at \( H_- \approx 150 \text{ Oe} \)), and \( I(H_{avg}) \) is defined as the average of the absolute value of \( I(H_+) \) and \( I(H_-) \). To find out how the electro-optical effects influence plasmon propagation and magneto-optic responses, we measured ARR maps under applied electric fields. In line with our previous results, large magneto-optic signals – two orders of magnitude larger than intrinsic responses– arise from the SPP excitation. We show that, due to the presence of the ferroelectric layer, plasmon propagation can be modulated by electric fields enabling reversing the sign of magneto-optics signals. Thus, the combined integration of magneto-optical and ferroelectric materials enables control over non-reciprocal device properties by application of external electric fields, rather than magnetic fields, which could greatly simplify their integration into multifunctional nanophotonic devices.

Influence of Plasmonic Metasurfaces on the Optical and Electronic Properties of Organic Semiconductor Thin Films
Zhongkai Cheng and Deirdre O’Carroll; Rutgers, The State University of New Jersey, United States

Organic semiconductors have attracted considerable research interest owing to their ease of processing and unique physical properties, such as compatibility with plastic substances, low temperature processing, large area coverage, mechanical flexibility and low embodied energy. Plasmonic metasurfaces, which are nanostructured metallic films capable of supporting and directing surface plasmons at visible wavelengths, have been shown to improve the performance of organic optoelectronic devices by, for example, enhancing light absorption in or emission from the active layer. However, large-area, low energy fabrication processes are required for plasmonic metasurfaces to be compatible with organic semiconductor device processing.

In this work, we describe a straight-forward fabrication process for Ag plasmonic metasurfaces based on thermally dewetting thin Ag films. We study the integration of plasmonic metasurfaces with the organic semiconducting polymer, poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT), and the impact on the optical and electrical characteristics of the semiconductor thin film. F8BT is a fluorene-based conjugated polymer, that is widely employed as an active material in organic optoelectronic devices, especially organic photovoltaics and organic light-emitting diodes, because of its high quantum and power conversion efficiencies. By varying the size of the Ag nanoparticles (AgNPs) on the plasmonic metasurfaces from 20 nm to 150 nm in diameter, we observe pronounced increases in the scattering, absorption and photoluminescence spectra from F8BT film coatings. From the optical images, the light scattering intensity of metasurfaces with 150 nm diameter AgNPs is highest because of the high albedo (ratio of scattering to total extinction) of the large AgNPs. The extinction spectra are attributed to absorption and scattering by the localized surface plasmon resonances of the AgNPs. From the UV-visible extinction spectra,
the extinction peaks of 20 nm- and 80 nm-diameter AgNP metasurfaces occur at a wavelength of 500 nm and the extinction peak of the 150 nm-diameter AgNP metasurface is around 550 nm. The red-shifted extinction of the larger AgNPs is due to their more extended and distributed dipole response to incident light which causes a lowering in the energy of the surface plasmon resonance. Similarly, the 150 nm-diameter AgNP metasurface caused the greatest enhancement in photoluminescence emission from F8BT film coatings because of the high albedo of the large AgNPs. In addition, using integrating sphere absorption measurements we find stronger absorption enhancement and red-shifted F8BT absorption spectra on metasurfaces with increasing AgNP diameter. Finally, we investigate the effects of plasmonic metasurface electrodes on electrical properties of F8BT hole-only devices. We demonstrate working F8BT hole-only devices with plasmonic metasurface electrodes containing a wide range of Ag nanostructure sizes in an inverted device geometry.

Enhanced Subwavelength Coupling and Nanofocusing with Fiber-Plasmonic Hybrid Probe Khant Minn¹, Ho Wai (Howard) Lee¹² and Zhenrong Zhang¹; ¹Baylor University, United States; ²The Institute for Quantum Science and Engineering, Texas A&M University, United States

For studies of molecular interaction with light such as tip-enhanced Raman spectroscopy (TERS), it is imperative that light be confined to a small space in the order of nanometers which can be achieved by means of localized surface plasmons.¹ In conventional TERS, which has seen dramatic advancements in recent years such as chemical mapping with atomic resolution,² surface plasmons are excited on the metallic probe by directly focusing the laser beam in free space in the vicinity of tip apex. Such excitation scheme has to overcome the inherent spatial mismatch between diffraction-limited, micrometer-sized focal spot and nano-scale tip-sample interaction volume, leading to low mode coupling efficiency and high background scattering in the detected field.³ Recently, studies have shown that optical fiber-incorporated plasmonic probes can be a platform for transporting electromagnetic energy in nanoscale with high efficiency.⁴ However, these devices rely on the higher order radial vector mode for coupling of photonic to plasmonic modes which requires a special type of fiber that maintains radial polarization and expensive radial polarizer in the excitation path.

In this work, we propose a fiber-plasmonic hybrid probe that efficiently couples linearly polarized fiber core mode to radial plasmons on gold tip for nano-scale confinement of light. Using finite difference time domain 3D simulations, we show that linearly polarized light can be utilized to create hot-spot at the apex of the tip by selectively exciting plasmons at only one side of the tip base from the optical fiber. The coupled plasmonic mode then propagates to the narrow apex where it gets localized and strongly focused. Then we discuss the polarization selectiveness of our excitation scheme by comparing two orthogonal source polarizations. We show that the enhanced field at the apex is due to the spiraling plasmons excited by the end-fire coupling of light from fiber core at the tip base. We also demonstrate the cavity-like resonant response of the device by spectrally mapping the field enhancement for varying tip sizes. The focusing efficiency of 900 nm long tip at resonant wavelength is 1.3%. In the collection mode, the radiated power from a dipole emitter is probed by the 800 nm long tip and 5.1% of the dipole radiation is transmitted through the fiber. The proposed device is highly desirable for a plethora of applications including medical procedures, biomedical imaging and near-field spectroscopy.

Plasmonic Coupling in Topological Insulator/Band Insulator Layered Structure Zhengtianye Wang, Vishnuvardhan Mambakkam, Theresa P. Ginley, Greeshma Chandan and Stephanie Law; University of Delaware, United States

Topological insulators (TIs) are semiconductor materials, exhibiting topologically protected surface states that arise...
from strong spin-orbit coupling. These surface states form a Dirac cone band structure at Γ point, which exhibits linear dispersion. Electrons occupying these states travel at relativistic velocity and behave as massless Dirac fermions. In addition, these states demonstrate spin-momentum locking, which limits scattering from nonmagnetic perturbations. When perturbed with a sinuosoidal electromagnetic field, these surface states can house two-dimensional Dirac plasmons at room temperature. The Dirac plasmons in TIs are predicted to be topologically protected and spin polarized, which means spin of electrons can be optically manipulated.

Instead of the normal bulk plasmon mode that arises in three-dimensional films, electrostatic coupling between the top and bottom surface states of a single layer of TI thin film causes an optical plasmon mode and an acoustic plasmon mode [1]. However, only the optical mode can be observed by optical methods due to its non-zero optical dipole [2,3]. Interestingly, the frequency of the optical mode lies in the untapped terahertz (THz) range. A superlattice structure of TIs and normal band insulators (BIs) is expected to bring coupling of multiple surface states, generating multiple optical modes in the THz. These modes are tunable by changing the layer structure of the superlattice, which is easy to do with molecular beam epitaxy (MBE). In our system, Bi$_2$Se$_3$ and (Bi$_0.5$In$_0.5$)$_2$Se$_3$ (BIS) were used as the TI and BI materials, respectively. BIS is a topologically trivial alloy material of Bi$_2$Se$_3$ and β-In$_2$Se$_3$, both of which belong to the group and share close lattice constants: 2.866nm and 2.823nm, respectively. It was shown that by using BIS as a buffer layer between a sapphire substrate and the Bi$_2$Se$_3$ film, the carrier mobility increased and the overall carrier density was reduced by a factor of at least two, indicating a reduction in trivial carriers and a Fermi energy closer to the Dirac point. Using BIS, indium diffusion into the TI layers is less of a concern than it would be with pure β-In$_2$Se$_3$ as the BI layers [5]. In this talk, we will demonstrate the experimental evidence of Dirac plasmon coupling in BIS /Bi$_2$Se$_3$/BIS/Bi$_2$Se$_3$/BIS stacked layers grown on sapphire (0001). The film was patterned into nanoribbon arrays with varying widths to excite localized plasmon modes. Fano-shape extinction spectra containing two distinct plasmon modes were observed with all samples in the range of 1.5THz-8THz through Fourier-transformed Infrared (FTIR) spectroscopy measurements. A three-oscillator, double-Fano-resonance model was adopted to extract parameters of the high/low frequency plasmon modes and to explain the quantum interference between the plasmons and the bulk phonon (α phonon=2.01THz). A blueshift in frequency was observed for both the high/low frequency modes as the nanoribbon width narrows, similar to what has been observed in the single plasmon mode in a single layer Bi$_2$Se$_3$ [2,3]. Understanding plasmon coupling in a multilayer TI/BI structure will provide a deep insight to the many-body interaction in low-dimensional strong spin-orbit coupling systems. It also lays the cornerstone for future tunable THz devices for detection, security screening and advanced communication.

Use and Limitations of Titanium Nitride Thin Films for Next Generation Optoelectronic and Plasmonic Devices Ryan Bower$^1$, Daniel Loch$^2$, Qiaomu Yao$^1$, Papken Hovsepian$^2$, Arutiu Ehiasarian$^2$ and Peter K. Petrov$^1$; $^1$Imperial College London, United Kingdom; $^2$Sheffield Hallam University, United Kingdom

Titanium nitride has emerged as an alternative material to the noble metals gold and silver for optoelectronic and plasmonic applications due to its increased mechanical stability, thermal stability and spectral tunability. As the number of TiN-based optoelectronic devices increases it is necessary to develop an understanding of the applicability of TiN within a range of operating environments. Key factors to consider include temperature stability and compatibility with application specific materials.

In this work, we investigate the applicability of TiN in conjunction with a range of materials commonly used within plasmonic and optical devices. TiN thin films were deposited by radio frequency (RF) and High-power impulse (HiPIMS) magnetron sputtering onto a variety of semiconductor- and industrial standard substrates including Si, MgO, glass and steel. Optical properties were measured using spectroscopic ellipsometry and correlated with the crystalline structure and surface morphology of the TiN thin films. Additionally, the spectral tunability of these materials was investigated with respect to lattice-mismatch-induced strain and film texture. This work also reveals
the temperature range of applicability of the TiN based optoelectronic devices.

**Plasmonic Aluminum Nanohole Arrays as Transparent Conducting Electrodes for Organic Ultraviolet Photodetectors with Bias-Dependent Photoresponse**

Qiuming Yu, Monica R. Esopi and Shin-Ya Chen; University of Washington, United States

Metallic nanostructured films incorporated into optoelectronic devices such as photodetectors have attracted attention for their ability to support localized surface plasmon polaritons (LSPPs), which can enhance optical absorbance, internal electric field, and ultimately device performance. Metallic nanostructured films can also act as a device electrode, making them a cost-effective, flexible, high-performance alternative to the commonly used indium tin oxide (ITO), which is expensive and brittle. Photodetectors that are sensitive to UV illumination are important in a variety of applications including environmental monitoring, scientific research, imaging, and flame and missile detection. Despite their applicability, extension of plasmonic enhancement mechanisms to UV-selective devices has been relatively slow, because the common plasmonic metals of Ag and Au cannot support surface plasmon polaritons (SPPs) when illuminated by light with wavelengths shorter than about 350 nm. Al is well-suited to support and tune SPPs in the UV spectral range due to its carrier concentration and dielectric function, although oxide formation on the Al surface can interfere with and cause a redshift in its plasmonic properties. In addition, Al provides an attractive material option for UV photodetectors due to its relative abundance and low cost compared to Ag and Au.

In this work, Al nanohole arrays (Al-NHAs) were utilized as transparent conducting electrodes to optimize the UV-selectivity and response tunability of photodetectors having a conventional photodiode structure with organic active materials, which provide a low-cost, flexible alternative to inorganic materials. UV-selectivity was ensured through the material selection of Al, for plasmonic activity within the UV spectral range, and the polymer donor of poly(9,9-diocetylfluorene-alt-bithiophene) (F8T2), for strong UV absorption with a cut-off around 515 nm. The active layer was a 350 nm film consisting of F8T2 and the fullerene-derivative electron acceptor PC71BM, combined in a weight ratio of 100:4 based on previous reports. PEDOT:PSS and LiF were used as hole and electron transport layers, respectively, for an overall device structure of Al-NHA/PEDOT:PSS/F8T2:PC71BM/LiF/Al. 3-dimensional finite-difference time-domain (3D-FDTD) electromagnetic simulations were conducted to design the Al-NHA to produce strong UV absorption in the active layer and enhanced internal electric field intensity. Al-NHA electrodes were successfully fabricated using nanosphere lithography and incorporated into photodetectors, which produced two narrow photoresponse peaks with specific detectivity (D*) values of 4.0x10^9 and 4.6x10^9 Jones under 340 and 515 nm illumination, respectively, and -2 V bias, and one broad photoresponse peak with a peak D* of 8.8x10^9 Jones under 450 nm illumination and 2 V bias. Compared to control ITO-based devices, Al-NHA-based devices had similar response under reverse bias and superior response under forward bias, as ITO-based devices became unstable under forward bias. The bias-dependent photoresponse switching is believed to benefit from plasmonic enhanced internal electric field that increases the driving force for hole diffusion. The mechanism was further confirmed by the investigation of conventional devices with planar Al electrodes and hole-only devices with both planar Al and Al-NHA electrodes. This response switching improves the applicability of UV photodetectors through the incorporation of cost-effective, flexible, and performance-enhancing plasmonic Al-NHA transparent conducting electrodes.

**Observation of Atomic-Like Transition in Sapphire Crystal by a Deep UV Photoluminescence Spectroscopy**

Nikesh Maharjan and Mim Nakarmi; Brooklyn College and The Graduate Center of the CUNY, United States

Deep UV Photoluminescence (PL) Spectroscopy was employed to study optical properties of sapphire crystal. The sample was excited by the third harmonic of a Ti:sapphire pulse laser at wavelength ~ 266 nm which is a below bandgap photoexcitation. In the low temperature (12 K) PL measurements, we observed two sharp atomic-like peaks at 368.8 and 374 nm with line-width of 0.85 and 3.30 nm, respectively in the PL spectra. We also performed
temperature and power dependent PL measurements. We will present the properties of the atomic-like transitions observed in sapphire at different conditions. The origin of these emission lines could be due to the point defects or incorporation of rare-earth elements. We will also discuss our exploration on the origin of atomic-like electronic states in sapphire crystal. Atomic-like emission in the sapphire could have potential applications in quantum information technologies for the development of solid state single photon source in UV region.

Atomic-Like Transition in Hexagonal Boron Nitride Probed by a Deep UV Photoluminescence Spectroscopy
Nikesh Maharjan1, Neelam Khan2, James H. Edgar3, Eli Janzen3 and Mim Nakarmi1; 1Brooklyn College and The Graduate Center of the CUNY, United States; 2George Gwinnett College, United States; 3Kansas State University, United States

Bulk single crystal hexagonal boron nitride (h-BN) flakes were characterized by deep UV photoluminescence spectroscopy. We performed a comparative study of oxidized and unoxidized h-BN flakes at low and room temperatures. In the low temperature (15 K) PL of h-BN flakes, we observed strong phonon assisted band edge emission peaks at 5.451 and 5.755 eV. The sample was oxidized at 900 °C for 1 hour. The PL measurements of the sample after oxidation, in addition to the phonon assisted band edge emissions, we also observed a sharp atomic-like emission line at 4.082 eV along with its photon replicas at 3.88 and 3.68 eV which were not present in the unoxidized samples. The origin of the sharp atomic-like transition could be related to the incorporation of defect or impurity during the oxidation process. We will discuss the properties of these atomic-like transitions and its possible origins in the h-BN flakes. Our results could have potential applications in the solid state single photon source for quantum information technologies.

Extracting Fundamental Physics of Nanoscale Light-Matter Interactions Using Deep Learning
Yashar Kiarashinejad, Sajjad Abdollahramezani, Mohammadreza Zandelshahvar, Omid Hemmatyar and Ali Adibi; Georgia Institute of Technology, United States

In this paper, we introduce a new approach based on deep learning (DL) for understanding the fundamental phenomena of nanoscale electromagnetic (EM) waves and matter interactions. This method builds on the dimensionality reduction (DR) technique in which autoencoders are leveraged to reduce the dimensionality of a light-matter interaction problem with the minimal imposed error by using the strong correlation among its different features [1]. The DR approach highlights the most important features (e.g., design parameters, material state) of any linear or nonlinear EM structure that affects its functionality. This method provides priceless information about the role of nanostructure parameters responding to incident EM waves for a given functionality. Moreover, along with providing the analytical formulas, the DR technique converts a large-size problem into a smaller space which can significantly facilitate and reduce the computation of brute-force optimization and design techniques. To show the applicability of the proposed approach, here we consider two sophisticated design problems for implementation of a reconfigurable multifunctional metadevice enabling dual-band and triple-band absorption in the telecommunication window [2,3]. The metadevice consists of an array of supercells, where each supercell has 4 design parameters (i.e., height, widths, pitches, and crystallization levels of the phase-change material), so that the total number of design parameters become 10. The simulation and experimental results are in a good agreement justifying the effectiveness of our proposed approach in predicting the most critical design parameters in the design problem.

Graphene-Mediated Surface Enhanced Raman Spectroscopy for Detection of Biomolecules and Monitoring DNA Hybridization Sanju Gupta and Alexander Banaszak; Western Kentucky University, United States

In this work, we prepared graphene-mediated surface-enhanced Raman scattering (G-SERS) substrates comprising few-layer graphene nanosheets decorated gold and silver nanoparticles for bio-nanotechnology. Raman spectroscopy is a surface-sensitive and nondestructive inelastic light scattering technique. SERS, a specialized form, is useful for rapid and precise identification of biological molecules, industrially relevant chemical dyes at ultralow concentration and monitoring DNA hybridization. This phenomenon is due to the enhanced Raman signals by several orders of magnitude on SERS-active surfaces. While the key point of SERS technology is the nanoscale metal particles, which generates localized surface plasmon resonances in response to laser excitation, the resulting electromagnetic enhancement of > 10^4, controlled diameter and interparticle gap of metal nanoparticles on graphene supports offer an advance toward sensitive G-SERS substrates via localized hybridization at graphene-metal interfaces. We have used thermal reduction technique to produce functionalized graphene and wet chemistry for size tunable gold and silver nanoparticles as cost-effective facile synthesis approaches for strategic G-SERS platforms. Simple and high-throughput arrays (‘biochips’) are developed by decorating graphene nanosheets with gold and silver nanoparticles as well as sandwiching gold and silver nanoparticle and few-layer graphene for cascaded signal amplification to differentiate among nucleotide bases (adenine; A, thymine; T, cytosine; C, guanine; G), DNA hybridization through complementary and probe single-stranded DNA and to detect beta-carotene and malachite green chemical dye.

EL01.15.26
Real Space Imaging of Hyperbolic Phonon Polaritons in Boron Isotopically Enriched Hexagonal Boron Nitride via Photothermal Induced Resonance Georges Pavlidis1, Jeffrey J. Schwartz2,1, Joseph Matson3, Thomas G. Folland3, Song Liu4, James H. Edgar4, Josh Caldwell3 and Andrea Centrone1; 1National Institute of Standards and Technology, United States; 2University of Maryland, United States; 3Vanderbilt University, United States; 4Kansas State University, United States

Hyperbolic phonon polaritons (PhPs) demonstrate great promise for the advancement of nanophotonics in applications such as subdiffraction focusing and flat optics. Due to the large optical anisotropy of hexagonal boron nitride (hBN), PhPs are intrinsically hyperbolic, meaning that they propagate with very large wavevectors, well below the optical diffraction limit. In comparison to plasmons, another class of propagating modes in metals, hyperbolic PhPs enable tighter confinement and experience lower losses in the mid-infrared regime. Isotopic enrichment of the polaritonic medium (e.g., hBN) has been shown recently to be an effective strategy to increase the propagation lengths and lifetimes of PhPs.

Photothermal induced resonance (PTIR) is a scanning probe-based technique that yields nanoscale IR absorption spectra and maps by transducing the light-induced thermal expansion of the sample with the probe tip. In this study, a novel tapping-mode PTIR measurement paradigm with heterodyne detection is implemented to measure PhP propagation and to determine the spectral dispersion in large flakes (up to 120 μm × 250 μm) of isotopically enriched hBN (10B). The high signal-to-noise ratio afforded by this measurement scheme enables imaging PhPs in real space over distances up to 40 μm. Such measurements, coupled with reciprocal space analyses, enables accurate evaluation of PhP propagation lengths, lifetimes, and in-plane wavevectors. Our results confirm for first time, experimentally, that isotopic enrichment provides over a eight-fold improvement in PhP propagation lengths and lifetimes, as predicted by theory. We believe that the measurement scheme developed here and the isotopic enrichment strategy will further foster the engineering and development of high performance PhP-based nanophotonic devices.

EL01.15.27
Graphene-Metal Optical Modulators Using Interband Transition Ziqiang Cai and Yongmin Liu; Northeastern University, United States

Graphene is a well-known 2D material, and its optical property can be tuned by changing its Fermi level [1]. This tunable property makes graphene useful to build novel optical devices, such as modulators. However, due to its atomically thin thickness, the interaction between pristine graphene and light is low, impeding its practical applications. To solve this problem, people have demonstrated that by combining graphene with plasmonic nanostructures, the interaction between light and graphene can be greatly enhanced, which significantly increases the tunability and efficiency of graphene-based optical devices. For photon energy larger or smaller than twice the
Fermi Level, the absorption of light in graphene falls into interband or intraband interaction. Up to now, most of graphene-based modulators utilize intraband transition, corresponding to mid-infrared or terahertz operating wavelengths (e.g. [2]). In contrast, few works reported graphene modulators based on interband transition, corresponding to near-infrared and visible wavelengths. Although in the interband region, graphene plasmons cannot be excited, and surface conductivity is much lower compared with intraband region, the interband interaction has its advantages of insensitivity to graphene quality and step-like change of its surface conductivity, offering the potential to push the working wavelength of graphene modulators into the near-infrared or even visible range. Based on the idea proposed above, we have fabricated a graphene-based modulator, in which graphene is hybridized with metal-insulator-metal (MIM) structures to confine the light intensity around graphene. The resonant wavelength is at 1.5 μm and theoretical modulation depth is 50%. The measured modulation depth is close to 15%, higher than the reported modulation depth of graphene modulator using CVD graphene at the near-infrared wavelength ([3], [4]). By further optimizing the structure design as well as fabrication process, we believe that our device can provide a practical platform for near-infrared tunable optical devices.

EL01.15.28
Exciton Dynamics in Monolayer MoS2 Synthesized by Metal Sulfurization Hsu-Sheng Tsai1, Yung-Hung Huang1, Po-Cheng Tsai1, Zong-Yi Chiao2, Yi-Jia Chen3, Hye-Young Ahn4, Shih-Yen Lin1 and Yu-Jung Lu4; 1Research Center of Applied Sciences, Academia Sinica, Taiwan; 2National Taiwan University, Taiwan; 3National Dong Hwa University, Taiwan; 4National Chiao Tung University, Taiwan

The exciton dynamics in layered transition metal dichalcogenides, pioneering the new family of 2D materials beyond graphene, has been attracting a great attention for several years. Actually, the as-photoexcited carriers in monolayer MoS2 are distributed non-thermally in the electronic bands, and then undergo the thermalization and cooling processes before the formation of excitons. Many works concerning this topic have been done, the MoS2 used in these studies were all obtained by either exfoliation from bulk or chemical vapor deposition (CVD). However, the thickness and area of exfoliated MoS2 cannot be precisely controlled. The optical microscope (OM) and/or atomic force microscope (AFM) images of MoS2 triangular flakes obtained by CVD growth indicate that the MoS2 films are non-continuous even if the dimension is larger than 100 μm. These non-continuous films totally limit the real applications for semiconductor industry. In this study, we report the exciton dynamics in monolayer MoS2 synthesized by novel metal sulfurization method, in which the measured carrier relaxation time is comparable to the exciton dynamics in exfoliated monolayer MoS2 or by CVD growth. The carrier dynamics of A/B excitons were studied by using pump-probe transient absorption spectroscopy with broadband white-light probe beam. It is important to note that the sulfurization growth method can achieve large-scale (1.5 cm x 1.5 cm), continuous, and uniform MoS2 thin films with controllable number of layers. We performed PL measurement, Raman spectroscopy and UV-Vis absorption spectroscopy to study the layer number dependent optical properties. The transient absorption pump-probe spectra of monolayer MoS2 varying with pump energy density and delay time will be discussed. Finally, we conclude the dominant processes of carrier relaxation in monolayer MoS2 are the exciton-exciton annihilation, the trapping of the excitons by surface states, and the interband carrier-phonon scattering. The carrier lifetimes of A/B excitons of the three relaxation processes mentioned above are around 600 fs, 8.7 ps, and 45 ps, respectively.

EL01.15.29
Tunable Exciton-Plasmon Coupling with Strained 2D Semiconductors Yan Joe Lee1, Colin Yule1, Ozgur Burak Aslan1, Yifei Yu2, Linyou Cao2 and Mark L. Brongersma1; 1Stanford University, United States; 2North Carolina State University, United States

Two-dimensional transition metal dichalcogenides (2D TMDCs) are a promising materials platform to integrate with nanophotonic structures due to their strong optical response in the visible spectral range. In particular, their strong
Exciton resonances are stable even at room temperature and allow facile coupling with resonant semiconductor and plasmonic nanostructures. Furthermore, the optical properties of 2D TMDCs are very susceptible to external stimuli because they are atomically thin. Their exciton resonance location (and hence the optical permittivity) can be controlled by methods such as electrical gating, dielectric screening, and strain. This paves the way towards the realization of practical and tunable nanophotonic devices.

In this work, we demonstrate a novel approach to tune the coupling of excitons in 2D TMDCs with plasmonic nanostructures using strain. By straining the monolayer TMDC, we can detune the exciton resonance location from the localized surface plasmon resonance. This then allows us to actively control the coupling between the two resonances and the resulting scattering spectra of the nanostructure. We study the spectral evolution and mode splitting of the coupled plasmonic-TMDC structure. Since we can control the scattering amplitude and/or phase of this coupled system, they act as building blocks for tunable nanophotonic devices and metasurfaces.

Plasmonic-Assisted Photo-Catalysis—Nothing More Than a Classical Thermal Effect Yonatan Sivan, Ieng-Wai Un and Yonatan Dubi; Ben-Gurion University of the Negev, Israel

Recent experimental studies demonstrated that chemical reactions can be accelerated by adding plasmonic metal nanoparticles to the chemical reactants and illuminate them at their plasmon resonance. It was claimed that the enhanced reaction rate occurs via the reduction in the activation energy driven by the plasmon-induced non-thermal ("hot") electrons [Brongersm, et al, Nature Nanotech (2015)].

In this breaking news, we show that these claims are extremely unlikely to be correct, and that instead, the faster chemical reactions are likely the result of mere heating. To do that, we derive a self-consistent theory of the electron distribution in metal nanostructures under continuous wave illumination [Dubi & Sivan, Light: Science & Application (2019)]. We show that only about one billionth of the energy provided by the illumination goes to creating non-thermal ("hot") electrons, and the rest goes to heating. Quite different from previous theoretical studies, we took account of the heat transfer from the illuminated nanoparticle to the environment via phonon-phonon coupling and ensured energy conservation in the electron-phonon-environment system (rather than just in the electron sub-system). This approach not only allows us to distinguish between the generation of high energy non-thermal ("hot") electrons and the regular heating of the nanoparticles, but also enables the determination of electron and phonon temperatures in a unique and unambiguous way. The theory is then used to compute the rate and energy distribution of electrons that tunnel out of the metal and can participate in a chemical reaction or enable photodetection [Sivan et al, Faraday Discussion (2019)].

Further, we develop a simple model based on the Fermi golden rule and the Arrhenius Law, which shows that the enhanced chemical reactions observed experimentally are highly unlikely to result from the generation of non-thermal non-thermal ("hot") electrons in the metal; instead, it is more likely originate from a purely photo-thermal effect [Sivan et al, Science (2019), Sivan et al, arXiv (2019)]. Specifically, we focus on a few of the seminal papers on this field and identify experimental errors in the temperature measurements that led the authors of these papers to underestimate the photo-thermal effect. Then, we show that the alternative theory of illumination-induced heating can explain the experimental data to remarkable agreement, with minimal to no fit parameters. Comprehensive thermal calculations (whereby we sum properly the heat generated by all particles in the system) confirm the temperature extracted from the experimental data, thus, showing that any claim in these papers related with "hot" electron action is not supported by the data.

Finally, we show that for sufficiently high temperature and/or illumination intensity, it is necessary to account for the thermo-optical nonlinearity due to the temperature dependence of the optical and thermal properties of the...
system [Sivan et al, arXiv (2019)]. We discuss the dominant contributions to the nonlinearity and the sensitivity to the various parameters of the sample and illumination. Our results provide the first ever comprehensive theory of plasmon-assisted photocatalysis and should become the basis for analysis of future experiments; it also reveals various routes for optimization of the chemical reaction acceleration. Our theory is also instrumental in quantifying experiments aimed to enable efficient photodetection.

Nanomechanical Plasmon Spectroscopy—Optomechanics as a New Plasmonic Transducer Daniel Ramos, Oscar Malvar, Javier Tamayo and Montserrat Calleja; CSIC, Spain

We experimentally demonstrate the effect of the localized surface plasmon resonance (LSPR) of a single gold nanoparticle (AuNP) of 100nm in diameter on the mechanical resonance frequency of a free-standing silicon nitride membrane by means of optomechanical transduction. The key effect to explain the coupling in these systems is the extinction cross-section enhancement due to the excitation of the LSPR at selected wavelengths. In order to validate this coupling, we have developed an interferometric readout system with an integrated tunable laser source, which allows us to perform the first experimental demonstration of nanomechanical spectroscopy of deposited AuNPs onto the membrane, discerning in between single particles and small clusters by the frequency shift and polarization sensitivity.

The use of plasmonic structures as sensors is widely spread in recent scientific literature; thus, during the last years we have been witnessing a rising interest in the research on increasing the sensitivity of devices. The most widely used sensor type is based on the concept of surface plasmon resonance (SPR) which is especially sensitive to refractive index changes of the medium surrounding the metal structure, eventually detecting changes in the refractive index of 10⁻⁷. Despite the low-quality factor exhibited by the broad optical resonances, plasmomechanical systems represent an attractive alternative when compared with other optical cavities in literature because the SPR are easily excited by free-space light beams. This issue is of crucial importance because the free-space optomechanical coupling largely decays when the size of the mechanical system is below the wavelength[1,2], which, is needed to achieve high mechanical frequency regime.

We demonstrate the optomechanical coupling that emerges in the plasmonic cavity formed by a AuNP onto a free-standing SiN membrane by means of the excitation of the LSPR, which is related with an enhancement in the extinction cross section of the nanoparticle at a selected wavelength. The extinction is the combination of the absorption and the scattering of the particle; therefore, it becomes a hot-spot on the membrane consequently tuning the mechanical resonance frequency through thermomechanical effects. The LSPR can be tuned by changing the particle diameter or by clustering the particles, which allows the harnessing of the collective plasmonic modes. This cluster coupling usually vanishes when the separation between the particles exceeds the exponentially decreasing distance in which the evanescent field expands, which usually is in the order of few nanometers. However, we demonstrate the use of a membrane to efficiently extend the range of applicability of the coupling between nanoparticles to hundreds of nanometers[3].

We calculated the temperature profile by FEM simulations for different absorption powers from 10nW to 10uW. This temperature profile is translated into a frequency shift by means of the non-released stress generated in the structure due to the thermal expansion and the temperature-dependency of the material Young’s modulus. For integration times of about 3s, we have an Allan variance of 1.1x10⁻⁸, which means that the noise of our fundamental mechanical resonance at 8.6MHz is of 95mHz, which implies that the minimum detectable power is 72pW. On the other hand, the minimum power detectable by the state-of-the-art photodetectors is 2.2nW. Therefore, the proposed optomechanical device is two orders of magnitude more sensitive than a commercially available photodetector.

Magneto-Optical Surface Plasmon Resonance Biosensors with Uni-Axial Magnetic Anisotropy

Mathias Dolci, Xiaokun Ding, Yannick Dusch, Sabine Szunerits, Rabah Boukherroub, Philippe Pernod and Nicolas Tiercelin; Université de Lille, CNRS, Centrale Lille, ISEN, Université de Valenciennes, UMR8520, France

Surface plasmon resonance (SPR) is a surface-sensitive analytical technique used in a variety of biological sensors. The main problem with classical SPR technology is associated with the existence of a lower physical limit of detection (LOD) with respect to fluorescence. Various approaches have been proposed to overcome this limitation by developing different sensing concepts including phase-sensitive detection schemes, use of metallic nanostructures, line gratings and others. More recently, the addition of active functionalities to the SPR based devices have been proposed to enhance the intrinsic sensitivity of the SPR system. A magneto-optical (MO) SPR sensor, based on a magneto-plasmonic modulation technique produced in multilayers of noble and ferromagnetic metals has been lately proposed.

The use of a trilayered thin film structure (e.g. Au/Ferro/Au) allows to provide a transverse magneto-optical Kerr effect(TMOKE) of the p-polarized light. This TMOKE signal exhibits an improved physical sensitivity over classic SPR measurements thanks to the non-reciprocal modification of the surface plasmon wave vector induced by the magnetization in the ferromagnetic layer which is controlled by the applied magnetic field. Beyond sensing techniques, this modulation of the surface plasmon wave vector in this kind of architecture allows for applications in active plasmonics such as optical switches.

Here, we propose a novel combination of metals based on exchange coupled ferrimagnetic multilayer thin films composed of TbCo2 stacked with FeCo providing a well-defined in-plane and uniaxial magnetic anisotropy thus giving rise to an easy and a hard magnetization axis in the layer. This specific structure adds a new behavior to exploit the active control of surface plasmon resonance. Simulationsof the Magneto-Optic SPR effect in our structures were performed using a finite element software. The dielectric tensor, including magneto-optical constants of the TbCo2/FeCo multilayers was measured by ellipsometry, whereas standard parameters were used for the noble metal. Experimental studies were made by coupling our architecture with a modified-SPR commercial setup equipped with an external magnetic field and controlled by a Labview program. Measurements show a significant increase of sensitivity when used in a magneto-plasmonic configuration. Moreover, the measured plasmonic properties perfectly reflect the magnetization characteristics along the easy and hard axes allowing an indirect local measurements of the magnetic properties of the sample, and confirm the performed simulations. Methods, simulations and measurements will be shown and discussed at the conference. The interest of this novel sensing device for the detection of cardiac biomarkers such as troponin I will also be shown.

suffers from a low absolute optical absorption of ~1-2% depending on the substrate. [1] This significantly limits its efficiency as surface-incident photonic devices. Here we demonstrate a semimetal-dielectric-metal (SMDM) cavity structure that synergistically integrates near-field absorption enhancement with a Fabry-Perot cavity to address this challenge. The SMDM cavity structure consists of self-assembled, close-packed ultrahigh refractive index semimetal Sn nanodots (n=8~9 at λ=1600–5000 nm [1]) on a SLG/SiO2/Al stack. The nanogaps (~10 nm) between Sn nanodots effectively funnel the incident light into the underlying SLG regions with >100x electromagnetic field enhancement, and scatter the incident light into oblique angles. SLG absolute absorption has already achieved 5-15% over the visible and near infrared light regimes without a SiO2/Al stack. Reflection by the backside Al layer and coupling into the SLG (high index and a 2D Dirac semimetal at room temperature)/SiO2/Al cavity further enhances the SLG absorption to up to 25% in a broad spectral regime of λ=500-2500 nm. The enhanced SLG absorption has also been confirmed by field-enhanced Raman scattering and significantly increased photo-conductivities. This is much advantageous over the conventional plasmonic approach which uses costly materials (typically Au or Ag) and has a narrow resonant peak, as well as the nanophotonic design which requires a complicated and precise lithography in nanoscale. [2, 3] Further tuning the thickness of SiO2 dielectric optical medium and the size/gap of Sn nanodots, our design even shows an optimal SLG absorption of 40-45% at λ=1500-2500 nm. This work offers a new approach for high efficiency, broad-band, nanoscale photon management in 2D photonics, which is also compatible with nano-fabrication foundries in terms of scaling up photonic device fabrication.

9:00 AM EL01.16.05
Tunable Hybrid Metal-Nitride Metamaterial Framework towards Plasmonic Sensing and Nanophotonic Device Integration **Xuejing Wang**1, Haiyan Wang1, Xinghang Zhang1, Lia Stanciu1, Ping Lu1, Xuedan Ma1 and Deirdre O’Carroll1; 1Purdue University, United States; 2Sandia National Laboratories, United States; 3Argonne National Laboratory, United States; 4Rutgers University, United States

The advance on hybrid metamaterial design using bottom-up fabrication technique brings multiple advantages towards sensing and large-scale nanophotonic device integration. In our work, a novel two-phase plasmonic framework with Au nanoantenna arrays being embedded inside a titanium nitride (TiN) matrix was demonstrated, with easy access of controlling the packing density or aspect ratio. Advantages include sub-10 nm nanoantenna arrays, high crystalline quality, inch-scale fabrication as well as high durability. Such geometrical flexibility brings tunable resonance frequency and anisotropic dielectric dispersion at optical regime. We demonstrate effective molecular sensing affected by the surface-enhanced plasmonic substrate with built-in Au antenna array. Our functional hybrid thin film template, as a first step, can be applied to many three-dimensional metamaterial designs, we will show some of our latest research progresses on nanostructures and applications using such hybrid template.

9:15 AM EL01.16.06
Direct and Simultaneous Absorption and Scattering Measurements of Single Plasmonic Particles Using Integrating Sphere Microscopy **Eitan Oksenberg**1, Andrea Baldi2 and Erik Garnett1; 1FOM Institute AMOLF, Netherlands; 2Differ - Dutch Institute for Fundamental Energy Research, Netherlands

The spectral behavior of localized surface plasmon resonances is often studied using ensemble spectroscopy techniques, which provide average values of resonance energies and broadened line-widths due to varying sizes and shapes of the nanostructures. Single particle measurements can offer a sharp and distinct spectral fingerprint of plasmonic nanostructures but they often probe only the scattering profile or a mixture of multiple light-matter processes. Here we introduce integrating sphere microscopy as a method to probe directly and simultaneously the scattering and absorption behavior of single plasmonic nanostructures. We use this technique to quantitatively characterize the energy, line-width and extinction cross-section of the localized surface plasmons of single nanostructures. Our measurements are compared with theory and used to trace hot-electron chemical reactions on the surface nanostructures. The realization of a direct measurement of the scattering and absorption of a single plasmonic entity allows to probe with superior resolution physical and chemical processes that are induced by localized surface plasmon resonances.

Metal Hydrides as a Platform for Reconfigurable Photonic and Plasmonic Elements Kevin Palm1 and Jeremy N. Munday1,2; 1University of Maryland, United States; 2University of California, Davis, United States

The ability to control the optical properties of photonic materials on demand is essential for the operation of a variety of devices ranging from active color filters and routers to switchable mirrors and sensors. Here we will present our latest work on actively controllable photonic devices using metal hydrides. We have developed an apparatus for in situ measurements of hydrogen content and optical and mechanical response. Using this apparatus, we will show the dynamically tunable optical properties of several metals and alloys over a broad spectral range (250 - 1690 nm) and discuss a number of devices including structures that have five orders of magnitude change in reflectivity, as well planar systems for physical encryption and counterfeit detection. Finally, we investigate the hydrogen-loading amounts for several metal alloys and find higher loading amounts when compared to previous measurements for alloys with low atomic percent Pd, resulting from film stress and microstructuring. These results have led to new insights in the dynamic behavior of metal-hydrides and will help in the design of next-generation hydrogen sensors and tunable photonic devices.

10:30 AM EL01.17.02
Unidirectional Excitation of Surface Plasmon Polaritons via a Meta-Grating with Parity-Time Symmetry Yihao Xu, Lin Li and Yongmin Liu; Northeastern University, United States

Over the past years, there has been rapidly growing interest in non-Hermitian photonic systems. In 2003, Bender et al. proved that a Hamiltonian is not necessarily Hermitian to have a real spectrum. For instance, a Hamiltonian with Parity-Time (PT) symmetry can show real spectrum below a certain threshold, known as the exceptional point, accompanied with novel phenomena above the EP. Thanks to the equivalence in mathematical forms between the Schrödinger equation in quantum mechanics and the paraxial wave equation in optics, we can conveniently explore unique phenomena and properties of PT systems in optics, which will accelerate the development of novel optical devices.

Here we propose a plasmonic meta-grating with PT symmetry to excite unidirectional surface plasmon polaritons (SPPs). The basic principle is based on the behavior of the PT system around the exceptional point, where only directional propagation mode of SPPs is allowed. We have designed realistic grating array consisting of passive gratings (i.e., without gain materials), which can significantly reduce the challenges in fabrication and optical experiments. In addition, instead of using ideal sinusoidal permittivity modulation in simulation in former paper, here we demonstrate in both simulation and experiment that using discrete grating array can also achieve excellent contrast between SPPs in opposite directions at the working wavelength around 1150nm.

In addition to the unidirectional excitation of SPPs, we have designed PT symmetric meta-gratings to realize other intriguing functionalities, such as a unidirectional plasmonic distributed Bragg reflector, that is, a plasmonic diode, that shows selective reflection/transmission for SPPs with high contrast. To achieve this function, we need to modify the 2nd order Fourier coefficient for permittivity modulation, which is proportional to the reflectance of SPPs incident from the left and right.

In summary, we have demonstrated a sub-wavelength plasmonic grating structure with PT symmetry for unidirectional excitation and transport of SPPs. These results can be potentially employed as a new approach to designing transformative nanoscale optical devices, such as low-loss plasmonic routers and isolators for efficient optical computation, communication, and information processing.

**Excitation of Epsilon-Near-Zero Mode in Optical Fiber Coated with Ultrathin Aluminum-Doped Zinc Oxide Film**

*Jingyi Yang*¹, Khant Minn¹, Aleksei Anopchenko¹, Sudip Gurung¹ and Ho Wai (Howard) Lee¹;² ¹Baylor University, United States; ²Texas A&M University, United States

Near-zero refractive index systems, i.e., with vanishing permittivity and permeability values, have been shown to exhibit unique and extreme optical properties. Ultrathin epsilon-near-zero (ENZ) layer can support plasmon polariton mode with enhanced and highly-confined optical field [1]. Recent studies on ultrathin transparent conducting oxide (TCO) ENZ film have proposed various optical applications such as broadband perfect absorber [2], enhanced ENZ nonlinearity [3] and electrically tunable meta-devices [4, 5], etc. However, most of the recent studies on ENZ materials are limited in planar structures or metasurfaces with a relatively short length of light-matter interaction and operation, which restricts the excitation platform for developing novel optical devices with advanced functionalities.

In this work, we report the first experimental demonstration of ENZ mode excitation in D-shaped optical fiber nano-coated with aluminum-doped zinc oxide (AZO) layer via atomic layer deposition (ALD) [6]. The ultrathin AZO layer possesses ENZ property (real part of permittivity crosses zero at a wavelength of 1546 nm) in near-infrared wavelength regime. The evanescent optical field of the guided core mode of D-shaped fiber interacts with the ultrathin AZO ENZ layer on the side-polished portion to excite the ENZ mode. Highly polarization- and wavelength-dependent transmission with on and off ENZ resonance difference of ~20 dB at a wavelength of ~1600 nm in ENZ regime is observed in a 1.7 cm-long ENZ-optical fiber with a 30 nm-thick AZO layer. The measurements show a good agreement with full-wave numerical simulation and phase matching condition between fundamental core mode of D-shaped fiber and ENZ mode supported by ultrathin AZO layer. Compared to the excitation of ENZ mode on the planar substrates, the hybrid ENZ mode on the optical fiber exhibits much lower loss and relatively long light-matter interaction length of a few centimeters. The hybrid ENZ-optical fibers provide a novel platform for zero-index photonic applications, for instance, studying enhanced ENZ nonlinearity in fiber, quantum emission in ENZ media, and subwavelength mode enhanced in-fiber optical- and bio-sensing.

This work was supported in part by the Young Faculty Award Program from Defense Advanced Research Projects Agency (grant number N66001-17-1-4047), Robert A. Welch Foundation (award number: AA-1956-20180324), and the Vice Provost for Research at Baylor University.

**IR Plasmonic Thermopile via Epsilon-Near-Zero Plasmons Using Y:CdO/Au Junctions**

*Joshua Nordlander*¹, Angela Cleri¹, Kyle P. Kelley², Evan Runnerstrom³, Patrick E. Hopkins⁴, Brian Foley¹ and Jon-Paul Maria¹;² ¹The Pennsylvania State University, United States; ²Oak Ridge National Laboratory, United States; ³U.S. Army Research Office—Materials Science Division, United States; ⁴University of Virginia, United States

CdO thin films have generated interest due to high electron mobilities with tunable carrier concentrations via substitutional doping with Y (Y:CdO). This combination of mobility and carrier concentrations have been used to support plasmonics in the mid-infrared spectrum spanning from 2.5 µm to 8 µm in wavelength. As the thickness of a film is reduced far below the skin depth of the material, a plasmonic mode known as an epsilon-near zero (ENZ) mode becomes active. This plasmonic mode is highly absorbing and highly confining of the incident electric field. One can create a Y:CdO/Au thin film junction, where the work function difference results in a small EMF. Illuminating this structure with IR light at ωIR=ωENZ produces strong absorption and an increased Tε in Y:CdO. As
electrons equilibrate with the lattice, the Y: CdO temperature increases thus changing the junction EMF. Y: CdO films were fabricated via HiPIMS sputtering, and junctions were created via photolithography techniques. The thermopile output voltage increases with increasing incident laser power, and is linear with the number of thermopile junctions. 30 µV were measured between 10 junctions with an incident laser power of 350 mW without optimization of the illumination area.

Osgood1, Paulo Jarschel2,3, Jin Ho Kim2, Hao Peng2, Sean Dinneen1, Yassine Ait-El-Aoud1, Yassine Ait-El-Aoud1, Jimmy Xu2 and Bruno Granddidier2; 1Combat Capabilities Development Command - Soldier Center, United States; 2Brown University, United States; 3"Gleb Wataghin" Physics Institute, Brazil; 4Univ. Lille, CNRS, Centrale Lille, ISEN, Univ. Valenciennes, UMR-8520-IEMN, France

The field of plasmonics and metasurfaces has advanced by leaps and bounds in the last 10-15 years, but ohmic losses continue to slow technological advances and scientific understanding. There is a need for plasmonic metasurfaces with tunable conductivity, instead of relying on fixed conductivity of ohmic metals. Here, we explore a novel material – a crystalline PbS/InP heterojunction – that is voltage-tunable, exhibits single-electron tunneling (SET), and has possible applications to neuromorphic computing. A neuromorphic computing architecture would go beyond traditional von Neumann linear architecture to a bio-inspired (neural) network of non-linear devices and weighting elements responsible for data processing, allowing much faster computation [1,2]. We report on tip-based tunneling measurements and analysis of SET in self-formed oxide interfaces between the two materials, which exhibit single-electron Coulomb-blockade staircases along with memory and memory-fading behaviors. This gives rise to both short-term and long-term (seconds and hundreds of seconds, respectively) plasticities as well as a convenient non-linear response, making this structure attractive for neuromorphic computing applications. We predict typical behaviors relevant to the field, obtained by an extrapolation of experimental data in the SET framework. The estimated minimum energy required for a synaptic operation is in the order of 1 fJ, while the maximum frequency of operation can reach the MHz range. Comparatively, the human brain synapses consume more energy (~pJ) and operate at a slower rate (1 ms or 1 kHz) [3], which demonstrates the potential of the proposed structure for such applications.

Plasmon-Enhanced Energy Transfer via Nanostructures
Alireza Rahimi Rashed, Mohsin Habib, Nekhel Das and Humeyra Caglayan; Tampere University, Finland

In this work, we have designed and fabricated an array of plasmonic nano-ellipses that interacts with different types of quantum emitters (QEs) in the visible range of wavelength. The proper geometry of our design provides such absorption-reflection properties which spectrally overlap with emission spectrum of the QE. Alongside such spectral overlap, a thin layer of the dielectric layer between the plasmonic structures and a gain medium provides the possibility of spatial overlap. The interaction between the strong subwavelength localized field at the edges of the gold nano-ellipses and QEs, enhances Purcell factor towards the modification of the fluorescence and decay time of QEs. This approach allows enhanced emission from different emitters embedded in hybrid quantum systems. In this work, we study the energy transfer between the fluorescent dye molecules and CdSe/ZnS hydrophobic QDs with the array of plasmonic nano-ellipses.

Visualizing Conformational Changes of Biomolecules Using Optical Force Microscopy In Situ Yang Zhao¹, Yun-Sheng Chen¹, Jack Hu², David R. Barton², Michelle Solomon², John Abendroth², Keino Davis², Lisa Poulakos², Katherine Sytwu² and Jennifer A. Dionne²; ¹University of Illinois Urbana Champaign, United States; ²Stanford University, United States

Many biological processes are associated with conformational changes of macromolecules such as enzymes, proteins, and DNAs. Currently, these dynamic processes can be observed indirectly through techniques such as optical tweezers, Förster resonance energy transfer (FRET), and optical beacon or directly with ultra-high frequency atomic force microscopy (AFM). While the last example points to the promises using AFM to directly visualize the molecules of interest, it only limits to certain processes where the speed is slower or comparable with the mechanical scanning of AFM. In this talk, I will discuss a new approach to visualize the conformational changes of biomolecules in situ. We constructed the technique based on the force exerted by polarized light on biomolecules. To enhance the light-molecular interactions, we created a plasmonic cavity formed between the plasmonic AFM tip and a plasmonic nano-aperture. We have shown that the plasmonic nano-aperture can exert differential optical forces down to piconewton ranges when illuminated with circularly polarized light of opposite handedness. Here, instead of a nano-structured AFM tip, we functionalize DNA molecules on the plasmonic AFM tip with a controlled density. We investigate both single strand and double strand DNAs at 20-base pair length with various densities. We are able to measure the difference in optical forces with a sensitivity of ~2.1pN/100uW/um². This sensitivity is associated with the optical forces exerted on single strand and double strand DNA molecules embedded between the plasmonic cavity. In addition, by introducing denaturing agent to the solution, we observed in-situ dynamic conformational changes of the double-strand DNA molecules, directly measured with the optical force microscopy technique.

2:00 PM EL01.18.02
Energy-Tunable Hot Carrier Photocatalysis with Surface Plasmon Polaritons Wonmi Ahn¹, Igor Vurgaftman¹, Jeremy J. Pietron², Pehr Pehrsson² and Blake S. Simpkins²; ¹Excet Inc., United States; ²U.S. Naval Research Laboratory, United States

The decay of surface plasmons generates hot carriers that can be injected into semiconductors or molecular systems, opening a new pathway to drive photo-induced chemical reactions. Recent studies demonstrate that by tuning plasmon resonance of metal nanoparticles hot carriers may be injected into specific anti-bonding orbitals of an adsorbed molecule and therefore the product selectivity can be achieved. In this talk, we will demonstrate surface plasmon polariton (SPP)-induced hot carrier generation that has a potential for energy-tunable photocatalysis. Unlike metal nanoparticles that suffer from resonance inhomogeneity and limited spectral tunability, metal films support SPPs that are homogeneous in-plane and accessible by simply tuning an illumination angle in a broad spectral range. We measured electrochemical responses of a metal/semiconductor heterofilm (Ag/TiO₂) and a bare metal film (Au) that were contacted with a mixed solution of sodium hydroxide and methanol. A strong photon energy dependence in the photon-to-carrier conversion efficiency was obtained from the heterofilm and this was further confirmed by the hole injection efficiency calculated using a Schottky transport model. Hot carriers generated in the bare metal film were energetically positioned near the metal's Fermi level, and therefore, chemical reactions were controlled by tuning electrode potential or solution pH. Both of these results have important implications for plasmon-induced photocatalysis, especially for energy-tunable chemical reactions.

2:15 PM EL01.18.03
Hyperbolic Meta-Antennas—Arbitrary Control of Light Scattering and Absorption towards Thermo-Plasmonic Bio-Medical Applications Nicolo Maccaferri¹,², Yingqi Zhao², Tommi Isoniemi², Marzia Iarossi², Antonietta Parracino², Giuseppe Strangi² and Francesco de Angelis²; ¹University of Luxembourg, Luxembourg;
Besides its fundamental importance, manipulation of light at the nanoscale is of great interest for the prospect of real-life applications, such as energy harvesting and photovoltaics, wave-guiding and lasing, optoelectronics, biochemistry and medicine. Novel optical designs and architectures that modify the optical power flow through plasmonic nanostructures represent another crucial step towards a nanoscale manipulation of light-matter interactions. In this framework hyperbolic metamaterials (HMMs) have received great attention due to their unusual properties at optical frequencies that are rarely or never observed in nature [1-2].

Here, we report about unconventional optical properties of metal-dielectric meta-antennas supporting type II hyperbolic dispersion, which enable almost pure and spectrally separated absorption and scattering channels in the visible/near-infrared spectral range [3]. We demonstrate that the physical mechanism responsible for the control of scattering and absorption lies in the different nature of the plasmonic modes excited within the hyperbolic meta-antennas. We also show that scattering is the dominating electromagnetic decay channel, when an electric super-radiant dipolar mode is induced in the system, whereas strong light absorption occurs when a magnetic sub-radiant dipole is excited. Importantly, both modes can be excited directly by coupling with far-field radiation, thereby making the proposed architecture suitable for practical applications. In this framework, we demonstrate also that HMM meta-antennas could find promising applications in photo-thermal therapy. Our findings open the pathway towards novel routes for exploiting light to energy conversion channels beyond what is offered by current plasmon-based architectures, possibly enabling applications including thermal emission manipulation, thermoplasmonics-based theragnostic nano-devices, novel nano-antenna designs and plasmon-enabled enhanced molecular spectroscopy.

2:30 PM EL01.18.04
Visualizing Plasmon Photocatalysis on Individual Bimetallic AgPd Nanoparticles with Concurrent Optical and Electron Spectroscopy Daniel Angell, Briley Bourgeois, Michal Vadai and Jennifer A. Dionne; Stanford University, United States

Bimetallic nanoparticles have emerged as a promising class of photocatalysts for chemical processing, energy harvesting, and environmental remediation. By alloying multiple metals together within a nanoparticle, significant improvements in reactivity as well as product selectivity have been realized. However, to date, most measurements are conducted on particle ensembles, where limited spatial resolution and averaging effects conceal important details about the photocatalytic mechanisms and optical properties of individual nanoparticles. To improve the efficiency of bimetallic photocatalysts, it is crucial to understand how their nanoscale properties such as shape, size, crystallinity and composition, affect performance.

Here, we investigate the photocatalytic efficiency of individual bimetallic nanoparticles, focusing on the light-driven dehydrogenation of AgPd single crystalline prisms. The particles are synthesized through the reduction of palladium and silver salts by formaldehyde, resulting in monodisperse prisms with edge lengths of approximately 35nm. We systematically vary the concentration of Ag in the nanoparticle from 0% to 2%, 5%, 10%, 20%, 30%, and finally 40%. The particles are dispersed onto a SiO2 grid, and a combination of electron imaging, diffraction, and electron energy loss spectroscopy (EELS) are used to follow the photocatalytic transformation. First, using monochromated EELS, we determine how the Ag concentration affects the plasmonic modes in individual AgPd triangular prisms. For the corner, edge, and bulk plasmon modes, we see dramatic shifts in the plasmon resonance energies with increasing Ag composition: 7.5eV to 6eV for the bulk, 5.8eV to 4.1eV for the edge, and finally 3eV to 1.9eV for the corner mode, for a composition change of 0% to 30% Ag. Although resonance shifts are observed, we see minimal change in comparative extinction cross-sections. Next, we illuminate the particles on their plasmon resonances and follow the dehydrogenation of these individual nanoparticles in an environmental TEM. Our TEM setup consists of an optical fiber coupled to a parabolic mirror for in-situ sample illumination, while concurrently allowing gas flow to the sample. We introduce H2 gas at pressures of ~20Pa - 40Pa and observe the light-driven transformation of individual AgPd nanoparticles from the H-rich phase to H-poor phase. Using both direct imaging of the propagating grain boundary defect, as well as the change in bulk plasmon resonance via low-loss EELS, we show that the phase transformation progresses to minimize the planar defect area at the phase boundary. While the dark-
state kinetics decrease with increasing Ag concentration, illumination on resonance can lead to an order-of-magnitude increase in reaction kinetics. Importantly, the transition speed is linear in time and is therefore not limited by hydrogen diffusion but rather by surface-reaction-rates. Furthermore, the speed is correlated with excitation of the edge plasmon mode. We discuss how the transformation kinetics and mechanism vary with illumination wavelength and power, and we can correlate these changes with an individual nanoparticle’s specific plasmonic modes and chemical composition. Our results help elucidate the combined roles of electronic and chemical contributions to bimetallic catalysis, informing optimized alloy concentration and nanostructure for record efficiency.

Highly Frequency-Selective Light Redirection for Optical Eye Tracking in Rainbow-Free Guided-Mode Resonance Diffractive Optical Elements with Near-Unity Transmission Jung-Hwan Song, Jorik Van de Groep and Mark L. Brongersma; Stanford University, United States

Augmented Reality (AR) is a technology which superimposes information or optical images onto the real-world environment of an observer. It is challenging to create optical elements that can seamlessly overlay images on top of a real scene and offering high transparency across the visible spectrum. Typically, bulky optical systems are required, but recent advances in holographic diffractive optical elements (DOE) have precipitated new approaches to realize high-performance AR displays. Unfortunately, high-diffraction-efficiency DOEs tend to produce undesired rainbows and image distortions. Many of the same opportunities and challenges hold true for eye-tracking systems. Here, we demonstrate an ultracompact, near-unity transmission, and rainbow-free optical eye tracking DOE based on a guided-mode resonance structure. To realize this optical element, we first prepare an anti-reflection coating on a quartz substrate by depositing a 200-nm-thick Si₃N₄ slab capped with a 100-nm-thick SiO₂ layer. This dielectric stack affords high transmission (~90%) over the entire visible spectrum. The nitride layer also serves as a waveguide that support a single transverse electric and transverse magnetic mode in the frequency range of interest. For this reason, this system can be turned into a guided-mode resonator by placing 3-nm-thick Si gratings between the Si₃N₄ and SiO₂ layers with 1-μm-long periodicity. Upon the planewave incidence, the scattered light from the Si grating elements can couple light into quasi-guided modes supported by the nitride layer. This guided light is primarily absorbed or diffracted, depending on the frequency of the incident light. We observe a high quality (Q~1000) guided-mode resonance at 870 nm wavelength and rigorously characterize the dispersion properties with a home-built angle-resolved confocal spectroscopy microscope. The spectrally sharp (<1 nm) resonant diffraction with a high peak diffraction efficiency (≈13%) to first-order diffracted beams is also directly measured under the normal incidence illumination. In contrast, across the visible spectrum the guided-mode resonance is dampened severely due to light absorption by the Si grating. This achieves the successful suppression of visible rainbows and diffraction efficiencies into the diffracted-orders are below 0.1% across the visible spectrum.

As a prototype eye tracking device, we fabricate a 2-cm-wide guided-mode resonance glass and attach it to a regular eyeglass frame. A small 870 nm light-emitting diode (LED) suspended on the eyeglass frame illuminates an artificial eye in front of the glasses. The scattered light from the eye is redirected by the optical element into a 1.6-mm-wide endoscopic camera located at the temple arm of the frame. The images formed by the diffracted rays allow the endoscopic camera to capture the full front-view of the eye even viewing at an oblique angle (60°). We also mathematically formulate all the relevant physics of the image formation with this element. We anticipate that our guided-mode resonance platform opens a promising route to realize new types of AR optical devices and elements for three-dimensional holography.

Durable Meta-Optics for Powerful Lasers Applications Eyal Feigenbaum; Lawrence Livermore National
The field of optical meta-surfaces is rapidly growing due to its great potential to enable thin optics implementation with relatively complex and flexible functions. In particular, high power laser systems could benefit from meta-optics that could implement beam shaping, e.g., for wave-front aberration correction, but with the advantages of smaller accumulation of nonlinearity and lighter weight. Additionally, meta-surface technology could enhance laser optics with improved anti-reflective layer designs.

Current meta-surface technology is limited with respect to high power laser optics, which requires both scalability and laser intensity durability. The principal challenge arises from the necessity of patterning sub-wavelength features (to control the local optical properties by modifying geometrical properties) while being able to modify the structural parameters on the large optics scale used in high power laser systems (e.g., National Ignition Facility, Laser MegaJoule). The current patterning methods are either limited in scalability (e.g., FIB, e-beam lithography) or limited in robustness due to the usage of soft-materials (e.g., nanoimprint).

We are developing novel technology capable of generating robust and scalable all-dielectric based meta-surfaces. In this talk we will describe the method, show results of fabricated meta-surfaces, and discuss the various levels of control that we have with this process. This method extends the current application field of interest for meta-surfaces to high power lasers, with the potential to stimulate meta-surface utilization in additional fields requiring large and robust optics.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-CONF-777421.

TiO$_{2-x}$ Enhanced IR Hot Carrier Based Photodetection in Metal Thin-Film-Si Junctions

Nicholas A. Güsken$^1$, Alberto Lauri$^1$, Yi Li$^{1,2}$, Takayuki Matsui$^1$, Brock Doiron$^1$, Ryan Bower$^1$, Anna Regoutz$^2$, Andrei Mihai$^1$, Peter K. Petrov$^1$, Rupert Oulton$^1$, Lesley Cohen$^1$ and Stefan A. Maier$^{1,2}$; $^1$Imperial College London, United Kingdom; $^2$Ludwig-Maximilians-Universität München, Germany

The extraction of hot carriers at a Schottky barrier interface has attracted enormous attention for example due to the possibility to create a photovoltage in a semiconductor/metal junction without being limited by the semiconductor bandgap energy. In particular the use of hot holes for these types of devices has not yet been studied extensively while recent studies predict an increase in extraction efficiency compared to their hot electron counterparts$^1$.

Here$^2$, we perform hot hole photodetection measurements on a simple p-Si/metal thin film junction using various metals such as Ti, Au and Titanium nitride (TiN). TiN is of particular interest as it constitutes a refractory alternative to other materials used for plasmonic applications where high field intensities exceeding the melting point of commonly used metals can occur. Resonantly excited plasmonic structures lead to strong fields in the vicinity to the metal surface which has been demonstrated to give rise to energetic and large hot carrier distributions.

We show that a backside illuminated p-Si/TiN system can be used for efficient hot hole extraction allowing for a responsivity of 1 mA/W at an excitation wavelength of 1250 nm and at zero bias. Our results unambiguously demonstrate that a few nanometer thin TiO$_{2-x}$ interfacial layer forming during growth at the Si/TiN interface allows for an increase in photoresponsivity of about one order of magnitude compared to a clean p-Si/metal interface. The direct comparison between a p-Si/Au and p-Si/TiO$_{2-x}$/Au further underpins this observation and additionally shows that the photoresponse dispersion relation of a TiO$_{2-x}$ thin film containing system deviates clearly from the response of a p-Si/metal system and thus from the commonly used Fowler description. Despite the fact that based on a bandgap energy of about 3.2 eV, TiO$_{2-x}$ is expected to act as a hole blocking layer, our results show a strong photoresponse. Thus, we propose a trap state mediated carrier transfer mechanism which is further supported by results obtained via electrical transport measurements.

Quantum Dot Lasing from Plasmon-Based Nanocavities

Jun Guan$^1$, Laxmi Kishore Sagar$^2$, Ran Li$^1$, Danqing
Plasmonic nanolasers are important for fundamental studies of light-matter interactions and applications in on-chip photonic integration. Metal nanoparticle arrays supporting surface lattice resonances (SLRs) can provide optical feedback for directional lasing emission at room temperature. However, current SLR lasers rely on organic dye molecules as the gain media and show limited photostability. Colloidal quantum dots are promising gain materials because of their long-term stability, bright photoluminescence, convenient solution processing, and size-controlled spectral tunability. Here we show quantum dot lasing from SLR-based nanocavities. Our quantum dot-plasmon lasers exhibit low thresholds and engineered far-field properties. In addition, we demonstrated the energy transfer between excitons and plasmons by investigating the lasing dynamics.

Anisotropic Thermal Magnetoresistance in Radiative Heat Transfer
Antonio Garcia-Martin; Inst. de Micro y Nanotecnologia - CSIC, Spain

The possibility to create and manipulate nanostructured materials encouraged the exploration of new strategies to control the electromagnetic properties without the need to modify its physical structure, i.e. by means of an external agent. An approach is the combination of magneto-optically active and resonant materials (e.g. plasmonic modes), where it is feasible to control the optical properties with magnetic fields in connection to the excitation of resonances [1] (magnetoplasmonics). It has been shown that these nanostructures can be employed to modulate the propagation wavevector of SPPs [2], which allows the development of label free sensors with enhanced capabilities [3-5] or to enhance the magneto-optical response in isolated entities as well as films, in connection with a strong localization of the electromagnetic field [6-8].

Here we will show that they also play a crucial role in the active control of thermal emission and the radiative heat transfer (RHT) [9-11]. In particular Near Field RHT between two MO particles can be efficiently controlled by changing the direction of the magnetic field, in the spirit of the Anisotropic Magneto Resistance in spintronics [11]. This phenomenon, which we term anisotropic thermal magnetoresistance (ATMR), stems from the anisotropy of the photon tunneling induced by the magnetic field. We discuss this effect through the analysis of the radiative heat exchange between two InSb particles, and show that the ATMR can reach amplitudes of 100% for fields on the order of 1 T and up to 1000% for a magnetic field of 6 T. These values are several orders of magnitude larger than in standard spintronic devices. More importantly, this thermomagnetic effect paves the way for exploring heat transfer physics at pico- and even subpicosecond time scales, which are even shorter than the relaxation time of heat carriers. Moreover, we show that the heat flux is very sensitive to the magnetic field direction, which makes this effect very promising for the development of a new generation of thermal and magnetic sensors.

Lead Halide Perovskite Based Plasmonic Upconversion Nanolaser
Yu-Jung Lu1,2,3, Teng Lam Shen1, Wen-Hui Cheng1, Chih Wei Chu1, Tsung-Fang Guo1 and Harry A. Atwater3; 1Academia Sinica, Taiwan; 2National Taiwan University, Taiwan; 3California Institute of Technology, United States; 4National Cheng Kung University, Taiwan
Organo-lead halide perovskite materials have recently received considerable attention for achieving an economic and tunable diode laser, owing to the use of solution-processable materials and the exceptional optical attributes of long carrier lifetimes and diffusion lengths, high fluorescence quantum yields, wavelength tenability, high optical gain coefficients, and promising two-photon absorption properties. However, reducing the volume of such lasers to the nanoscale is the challenge nanophotonics, with potential applications in arrays of ultra-compact lasers on a chip. Nanoplasmonic devices facilitate strong light-matter interactions at nanoscales, thus providing unique opportunities to control and manipulate radiative emission. Here, we report a novel plasmonic enhanced upconversion nanolaser consisting of a subwavelength organo-lead-halide perovskite nanocrystal on a 5-nm Al₂O₃ film on top of a plasmonic TiN film. A pump-probe transient absorption spectroscopy was used to study the photon-recycling-effect of perovskite nanocrystals as excellent optical gain media. Hence, we experimentally and theoretically demonstrated the localized strong optical filed enhanced single-mode lasing emission through two-photon absorption process in single perovskite nanocrystal coupled with plasmonic cavity. With the plasmonic cavity, the measured upconversion lasing threshold (200 nJ/cm²) was reduced by more than two orders of magnitude. Finally, we will discuss the outlook for upconversion plasmonic nanolasers in applications including, on-chip coherent light sources for bio-imaging, optical communication applications.

Seeded Growth Synthesis of Uniform Gold-Silver Alloy Nanoparticle and its Etching Study
Xingming Situ, Serene Bayram and Amy Blum; McGill University, Canada

Noble metal nanoparticles are one of the most interesting and well-studied nanomaterials because of their versatile preparation and their attractive electrical and optical properties. Alloyed noble metal nanoparticles have opened up new possibilities in applications such as in heterogeneous catalysis, electro-catalysis, imaging and surface enhancement Raman spectroscopy due to their tunable plasmonic properties. This tunability can come from controlling both the composition and the size in the synthesis of nanoalloys. Herein, we introduce a seeded growth synthesis of gold-silver alloy nanoparticles by chemical co-reduction in aqueous solution. Using gold acetate or gold chloroauric acid and silver nitrate as precursors and sodium citrate as the main reductant and stabilizer, we successfully synthesize stable gold-silver nanoalloys with diameters from 15 nm to 80 nm. The size of alloy nanoparticles can be controlled by the number of growth steps and the amount of precursor ions, which also determines the elemental composition of alloy nanoparticle. In addition, bis(p-sulfonatophenyl) phenylphosphane (BSPP) is utilized to etch the nanoalloys to obtain novel nanostructures, where smaller nanoparticles surround a larger "mother" nanoparticles of different composition. These novel nanostructures might be of significance in SERS since the periphery mainly contain silver on EDX-mapping.

Thermal Effects—Alternative Mechanism for Plasmonic-Assisted Photo-Catalysis
Ieng-Wai Un1,2, Yonatan Dubi1 and Yonatan Sivan1,1; 1Ben-Gurion University of the Negev, Israel; 2National Tsing Hua University, Taiwan

Recent experimental studies demonstrated that chemical reactions can be accelerated by adding plasmonic metal nanoparticles to the chemical reactants and illuminate them at their plasmon resonance. It was claimed that the enhanced reaction rate occurs via the reduction in the activation energy driven by the plasmon-induced non-thermal ("hot") electrons.
In this contribution, we show that these claims are extremely unlikely to be correct, and that instead, the faster chemical reactions are likely the result of mere heating. To do that, we derive a self-consistent theory of the electron distribution in metal nanostructures under continuous wave illumination. We show that only about one billionth of the energy provided by the illumination goes to creating non-thermal ("hot") electrons, and the rest goes to heating. Quite different from previous theoretical studies, we took account of the heat transfer from the illuminated nanoparticle to the environment via phonon-phonon coupling and ensured energy conservation in the electron-phonon-environment system (rather than just in the electron sub-system). This approach not only allow us to distinguish between the generation of high energy non-thermal ("hot") electrons and the regular heating of the nanoparticles, but also enables the determination of electron and phonon temperatures in a unique and unambiguous way. The theory is then used to compute the rate and energy distribution of electrons that tunnel out of the metal and can participate in a chemical reaction or enable photodetection.

Further, we develop a simple model based on the Fermi golden rule and the Arrhenius Law, which show that the enhanced chemical reactions observed experimentally are highly unlikely to result from the generation of non-thermal non-thermal ("hot") electrons in the metal; instead, it is more likely originate from a purely photo-thermal effect. Specifically, we focus on a few of the seminal papers on this field and identify experimental errors in the temperature measurements that led the authors of these papers to underestimate the photo-thermal effect. Then, we show that the alternative theory of illumination-induced heating can explain the experimental data to remarkable agreement, with minimal to no fit parameters. Comprehensive thermal calculations (whereby we sum properly the heat generated by all particles in the system) confirm the temperature extracted from the experimental data, thus, showing that any claim in these papers related with "hot" electron action is not supported by the data.

Finally, we show that for sufficiently high temperature and/or illumination intensity, it is necessary to account for the thermo-optical nonlinearity due to the temperature dependence of the optical and thermal properties of the system. We discuss the dominant contributions to the nonlinearity and the sensitivity to the various parameters of the sample and illumination. Our results provide the first ever comprehensive theory of plasmon-assisted photocatalysis and should become the basis for analysis of future experiments; it also reveals various routes for optimization of the chemical reaction acceleration. Our theory is also instrumental in quantifying experiments aimed to enable efficient photodetection.

EL01.20.03
Three-Dimensional Plasmonic Nano-Composites Fabrication by Two-Photon Lithography Based 3D Printing
Qin Hu, Yaan Liu, Derek Irvine, Christopher Tuck, Richard Hague and Ricky Wildman; University of Nottingham, United Kingdom

Metal-containing nano-composites have numerous advanced optical, mechanical, electrical and photovoltaic properties. Thus, recent advancement in the diverse fields of plasmonics, metamaterials, flexible electronics, biosensors, artificial implants and solar cells have generated a significant demand for the fabrication of novel metallic nanoparticle containing nano-composites. However, the traditional techniques for the production of such nano-composites are either inherently limited to two-dimensional (2D) processing and/or involve multiple, time- and cost-intensive synthetic steps. Two-photon lithography based 3D printing technology has been shown to overcome these limitations and can fabricate arbitrary 3D micro/nano structures with resolution in the region of 100 nm. In this work, we report our progress in fabricating complex 3D gold-/silver-/copper-containing nano-composite structures by simultaneous two-photon polymerisation and photoreduction. The success of the two-photon induced (a) polymerisation is verified by Scanning Electron Microscopy (SEM) and Raman spectroscopy, and (b) metal salt reduction is verified using Transmission Electron Microscopy (TEM). This confirmed the presence of small metallic nanoparticles (diameter of gold nanoparticles: 4.3 ± 2.8 nm; diameter of silver nanoparticles: 5.8 ± 1.5 nm) embedded within the polymeric matrix. UV-vis spectroscopy defined that they exhibit the property of localised surface plasmon resonance (LSPR), whilst X-ray Photoelectron Spectroscopy (XPS) confirmed that they exist in the zero valent oxidation state. The capability demonstrated in this study opens up new avenues for a range of applications, including plasmonics, metamaterials, flexible electronics and biosensors.

EL01.20.04
Intermediate Coupling between Organic-Inorganic Perovskite Multi-Quantum Wells and Single Plasmonic Silver Nanoparticles
Franziska E. Muckel, Kathryn N. Guye, Yun Liu, Shaun Gallagher and David S. Ginger; University of Washington, United States
In quantum optics, different types of light-matter interactions are studied through the coupling of optical emitters to microcavities with the aim of developing high performance optoelectronic devices. In the weak coupling regime, when the coupling strength is less than the damping rate of emitter or cavity, the spontaneous emission rate of the emitter is enhanced, known as the Purcell effect. With increasing coupling strength, the scattered light of the systems starts exhibiting a Fano-like, coupling-induced transparency-dip in scattering, which grows into a vacuum Rabi splitting in the strong coupling regime, when energy transfer between the cavity and the emitter is reversible.

While plasmonic particles coupled to single emitters like dyes or quantum wells represent auspicious candidates for single photonic sources, systems with multiple emitters like quantum wells promise high coupling strengths, as the coupling strength scales with the number of emitters. Two-dimensional organic-inorganic perovskites, which grow naturally in multi-quantum well structures, combine large oscillator strengths with large exciton binding energies (> 250 meV), distinguishing them as promising emitters for use in cavity coupled systems. Two-dimensional perovskite have been successfully integrated into dielectric Bragg reflector cavities, but have not yet been integrated with plasmonic particles.

Here we study the coupling between solution processed, two-dimensional butylammonium lead iodide perovskite (BAPI) and individual silver nanoprisms. Consisting of defined layers of PbI$_4$ separated by organic spacers, the thin layer n=1 BAPI multi-quantum wells feature narrow excitonic absorption and emission linewidths (ca. 100 meV). Through sequential spin coating of nanoprisms and two-dimensional perovskite emitter, we are able to combine individual silver nanoprisms with BAPI multi-quantum wells. The area around individual nanoprisms exhibit an enhancement of the emission intensity in photoluminescence. Using single particle dark field scattering spectroscopy, we observed a suppressed scattering in the single nanoprism spectra corresponding to the excitonic feature of the BAPI, indicating a coupling between the cavity and emitter. The observed transparency dip induced a peak splitting of approximately 300 meV, approaching the strong coupling limit.

Additionally, by placing the BAPI layer between a gold mirror and the silver nanoprisms, we explored the effect of different geometries on the plasmon-perovskite coupling, further modifying the coupling interaction between the plasmonic cavity and the emitters.

**Accordion-Like Plasmonic High Density Silver Nanorod Array for Multiple Electromagnetic Responses**
**Mooseong Kim, Jungho Mun and Jin Kon Kim; POSTECH, Korea (the Republic of)**

We realized a high-density array of “accordion-like” plasmonic silver nanorods over a large area (~cm$^2$) exhibiting multiple electromagnetic responses in visible and near-infrared (NIR) wavelengths. This array of “accordion-like” silver nanorods was fabricated by confining lamellar-forming polystyrene-block-poly (methyl methacrylate) copolymer (PS-b-PMMA) inside cylindrical pores of aluminum oxide (AAO) template grafted by thin neutral brush layers. PS and PMMA lamellar nanodomains with the sizes of ~15 nm were alternatively stacked along the nanorod direction. After the AAO template was removed, a 5 nm thick layer of silver was thermally deposited on only PS nanodomains. Due to the multiple resonances exhibited in the visible and NIR regimes, the array could be used for multi-analyte detection. Furthermore, this concept of fabricating sophisticated nanoscale architectures by utilizing block copolymer self-assembly and incorporating plasmonic metals into one nanodomains could be applied to realize large-scale metamaterials working at visible and NIR wavelengths.

**Ultrathin Dielectric Shell Radiative Coolers on Semiconductor Substrates**
**Jin-Woo Cho¹, Sung-Jun Park¹, Soo-Gyeong Chang¹, Dukkyu Bae², Kyung-Jun Lee¹, Youngsuk Nam¹ and Sun-Kyung Kim¹; ¹Kyung Hee University, Korea (the Republic of); ²Hexa Solution, Korea (the Republic of)**

Thermal engineering in the pursuit of attaining radiative coolers, thermophotovoltaics, optical clocks as well as classical incandescent lamps is currently being studied intensively. An appropriate radiation spectrum must be engineered fitted for specific applications. In this study, we established a passive cooling strategy which tunes a spectral irradiance of objects in mid-infrared wavelengths (e.g., $\lambda = 2.5 – 30 \mu m$). For solar photovoltaics, the device temperature is much higher than an atmospheres temperature under direct sun light in daytime, which deteriorates the power conversion efficiency (e.g., 0.042%/K [1]). Therefore, a passive radiative cooling strategy without consuming external energy is considered a highly promising approach as a new environmentally friendly
technology.
For thermal radiation cooling, dielectric materials (e.g., SiO$_2$, HfO$_2$, Si$_3$N$_4$, Al$_2$O$_3$) are widely used due to the existence of phonon-polariton resonance at specific mid-infrared wavelengths. According to Kirchhoff’s radiation law, one needs to design a structure having large absorptivity over broadband mid-infrared wavelengths. Thus, we tailored a dielectric structure which is absorptive in considered mid-infrared wavelengths and also visibly transparent (e.g., $\lambda = 0.4 – 0.8 \mu m$).
We fabricated a two-dimensional array of micron optical cavities covered with dielectric shells on Si substrates using standard photolithography, in which hollow voids were conformally covered with thin dielectric layers. The dielectric shells were composed of 300-nm-thick Al$_2$O$_3$ and 500-nm-thick SiO$_2$ layers. Fourier-transform infrared spectroscopy equipped with an integrating sphere showed greatly enhanced, broadband absorptivity, although the total thickness of the dielectric shells is far below than the center wavelength of radiation (e.g., $\lambda \sim 10 \mu m$). We evaluated the thermal capability of developed radiative coolers through outdoor experiment in daytime and nighttime. Then, we observed a temperature drop of 8 K (daytime) and 5 K (nighttime) on a Si substrate.

EL01.20.07
Asymmetric Control of Scattering Behavior for Plasmonic Nanoparticle Assemblages Jonathon Mitchell; RCVA, Japan

In transparent or translucent films, similar transmissions in wavelengths are generally observed, however, plasmonic scattering of metal nanoparticles is known to alter the transmitted light. Likewise, nanospherical particles have been demonstrated to exhibit the same properties without the inclusion of metallised particles. Here we propose a design methodology for films which can exhibit asymmetric scattering behaviour via directed self-assembly. The results of two polymorphic approaches for nanospheres are reported, molecular-induced asymmetry and topological asymmetry.

In both cases we embedded the nanospheres within an ultra-thin a-Si:H or a-SiC:H layer, coated with TiO$_2$ thin film to match polarisation between samples. On one surface either a molecular-altered nanosphere or topological nanosphere was selected for front incidence, with either selected for rear incidence. To date we have experimentally prepared a series of different samples that scatter light of different wavelengths and to different degrees from the front and rear surfaces.

EL01.20.08
Development of Terahertz MEMS Imaging Sensor for Fast Measurement at Room Temperature Jonathon Mitchell; RCVA, Japan

The detection and measurement of THz radiation presents an ongoing challenge in many potential applications mainly due to the difficulty in building devices suited to detection within the THz region. In many devices some level of cryogenic cooling is required in order to obtain sufficient signal/noise ratio, or alternatively resolution is sacrificed by the use of a GaAs antenna. Given that most materials have properties in the THz range different to their properties in the visible range, THz-detection and imaging potentially opens up a vast range of applications. Therefore, development of a new micromechanical devices suitable for detection of terahertz radiation at or close to room temperature while offering significantly faster measurements than conventional thermal sensors is worthwhile.
In this study, a unique bridge design, adapted from our MEMS e-sensors, detects and measures the incident THz radiation by analysing the fluctuations in the mechanical resonance frequency of the bridge which result from thermal expansion under incident THz radiation. Three thin-layer coatings were tested on the bridges, Nickel-Chromium (NiCr), Silicon-Gold (Si-Au), and Silicon-Titanium (SiTi), for their distinct sensitivity to THz radiation and ease of fabrication. Standard semiconductor fabrication process are used to produce our MEMS e-sensors, as well as form the thin layer coating on the bridges. Our devices demonstrated high THz–induced thermal sensitivity, with electrical noise approximately 110pW/√Hz.
A hierarchical neural network was utilised to fingerprint spectra based on the variations in resonance for single bridge configurations and between parallel bridge configurations. Although at an early stage, this new approach has advantages over current alternatives for THz radiation detection and measurement. The thermomechanical sensor in this work operates uncooled while remaining sensitive to THz, ideally suited for real-world applications, for example real-time, non-destructive integrity testing of electrical wiring and electronic trace-lines.
EL01.20.10
Studying Hot-Electron Injection in a Gold-Nanoparticle Graphene Hybrid Structure by Raman Spectroscopy
Marcel Weinhold, Sangam Chatterjee and Peter J. Klar; Justus Liebig University, Germany

Plasmonic nanostructures provide enhanced light-matter interaction due to the excitation of collective free-carrier oscillations, so-called localized surface plasmons (LSPs). LSPs cause enormous electric-field enhancements in the near-field. They also may decay into energy-rich electron-hole pairs due to Landau-damping. These ‘hot-carriers’ are exploited in various applications including photocatalysis, photovoltaics, and optoelectronics in general. Consequently, combining such plasmonic nanostructures with two-dimensional layered materials that are discussed for next generation (opto)-electronic devices should drastically enhance their capabilities: such hybrid-materials could offer the unique and extraordinary properties known from 2D materials like graphene and benefit from the enhanced light focusing, large absorption cross sections, and hot-carrier generation provided by the plasmonic nanostructure. For instance, ‘hot carriers’ in graphene-based semiconductor-devices reportedly generate photocurrents or locally increase the electron density leading, for example, to the formation of pn-junctions. However, those plasmonic effects strongly depend on the particle’s dielectric environment and geometry mandating the investigation of individual structures. Here, we study the injection of hot-electrons that arise from non-radiative localized surface plasmon decay in a model system, i.e., a single gold nanoparticle, on a monolayer graphene substrate. We reveal the intricate interplay between hot-electrons injected from plasmonic nanoparticles into graphene and show how this induces a quantifiable altering of graphene's phonon dispersion relation. Spatially resolved micro-Raman spectroscopy is a virtually ideal tool for this study as the generation of hot-electrons due to the excitation laser and the detection of the corresponding Raman-spectra occur simultaneously. Furthermore, micro-Raman spectroscopy provides easy access to single particle measurements, which is desirable since the plasmonic properties of such particles vary drastically with the particle’s size and shape. In addition, we present an analysis procedure yielding further information on occurring temperature and strain distributions solely from the captured Raman shift maps. Raman-mappings on single spherical nanoparticles, either consisting of pristine gold or encapsulated by silica which are positioned on single-layer graphene on quartz substrates with different excitation wavelengths and under variation of the incident laser power have been carried out and will be compared in terms of hot-carrier injection and heating effects.

EL01.20.11
Hydrogenated Amorphous Silicon for Integrated Photonic Waveguides Juan E. Villegas¹, Boulos Alfakes² and Mahmoud Rasras¹; 1NYU Abu Dhabi, United Arab Emirates; 2Khalifa University, United Arab Emirates

The fabrication of thin dielectric layers is essential in the development of micro-photonic devices. The disposition of the layered materials is based on their refractive index contrast. This allows determined architectures (waveguides) to confine light and selectively transfer specific wavelengths through different types of on chip optical devices. Furthermore, future planar photonic platforms need the ability to construct stacked layers of such photonic devices. However, this has been proven to be economically restricted by the current methods of transferring crystalline Silicon layers. Therefore, it opens opportunities for other materials such as Silicon Nitrate (SiN) and amorphous Silicon (a-Si) to be deposited through standard CMOS processes.

In this work we present the fabrication of low loss hydrogenated amorphous silicon that can be used to build planar photonic devices. Thin films of a-Si were deposited through low temperature Plasma Enhanced Chemical Vapor Deposition (PECVD). Different levels of hydrogenation were used to passivate the deposited layers and both undoped and n-doped (with phosphorous) films were studied. Additionally, the films were optically and electrically characterized, their surface topology was analyzed through AFM, and their vibrational modes studied through Raman spectroscopy. Simple micro-ring resonators (with 15 µm in radius) were also fabricated in these films using e-beam lithography and Deep Reactive Reactive Ion Etching (DRIE) and used to study their propagation losses. We attained an optical loss of 15.88 dB/cm at 1537 nm for single mode waveguides with width and thickness of 500 nm and 200 nm, respectively.

EL01.20.13
Alumina-Based 2D Random Photonic Nanomaterials Mikhail Pashchanka and Jörg J. Schneider; Technical Univ-Darmstadt, Germany

Many researchers have extensively studied optical properties of porous anodic alumina in recent years. Apart from
the interference colors appearance due to the multiple reflection of the vertical and skew incident light.[1] Photonic
effects due to the light scattering and propagation into lateral directions have also gained much interest.[2] Although
considerable research has been devoted to the well-ordered porous alumina photonic crystal structures, rather less
attention has been paid to the systems with deliberately introduced tailored disorder. Such planar random photonic
alumina films, however, have numerous potential applications ranging from structural coloration, light entrapping,
to lasing and diverse optical devices. In any realistic experimental situation, anodic alumina will always naturally
contain intrinsic defects in nanopore layout. The challenge in preparation of alumina-based 2D random photonic
nanomaterials is, however, to introduce different predetermined degrees of disorder into highly ordered photonic
crystal by a controlled manner, gradually varying the experimental parameters. A number of approaches have been
developed in attempts to tune the nanopore and cell sizes and the degree of pore ordering independently, such as
imprint and electron beam lithography.[3] Such methods commonly rely on the artificial creation of pore nucleation
sites on aluminum and yield only limited nanochannel length due to the spontaneous rearrangement of pores during
the long-term growth. Here, we demonstrate the feasibility of preparation of mechanically stable and transparent 2D
photonic waveguides with predetermined degree of disorder introduced into alumina by pulse anodization method.
The resulting nanochannels have invariable diameters, length up to 166 µm, as well as clearly controllable and
predetermined randomness in their arrangement.

High Performance Perovskite Photodetector Based on Nanopatterned Monocry stalline Thin Film Jinshuai
Zhang and Lei Su; Queen Mary University of London, United Kingdom

A new class of semiconductor materials, MAPbX₃ (where MA=CH₃NH₃⁺, X = I⁻, Br⁻ or Cl⁻), perovskites, has
emerged as a promising candidate for high-performance photovoltaic and optoelectronic devices, exhibiting a range
of excellent properties including strong light absorption, direct bandgaps, long carrier lifetime, high balanced hole
and electron mobilities, and long electron-hole diffusion lengths. Patterning has been proposed to form periodic
structures on the surface of perovskites, for applications such as improving the power conversion efficiency for solar
cells, enhancing photodetector performances, fabricating photonic crystals and distributed feedback lasers. Here we
report high-performance nanoscale surface patterned perovskite monocrystalline thin film photodetectors. The
nanopatterned metal-semiconductor-metal photodetectors demonstrate significantly improved performance
compared to the nonpatterned monocrystalline thin-film devices.

EL01.20.15
UV Plasmonic Behavior of Fluoride Thin Films with Metal Nanoparticles Fabricated by Pulsed Laser
Deposition and Evaporation Jan Lancok, Tomas Zikmund, Sergei Chertopalov, Jiri Bulir and Michal Novotny;
Institute of Physics CAS, Czechia

Fluorides exhibit unique optical features, such as low phonon energy and high transparency in UV region. Fluoride
doped by rare-earth (RE) makes them excellent for optoelectronics and photonics applications. Nano-structured
materials, where the metallic nano-particles (NPs) are distributed in a dielectric matrix, represent new type of
material with unique optical properties such as local surface plasmon resonance LSPR. Most of the plasmonic
research has so far focused on “classical” materials Ag and Au. However, other less used metals could bring
significantly new functionalities. For example Al NPs yield an LSPR within the deep UV optical range and by
tuning the size of NPs the resonance frequency could be shifted up visible spectral range. Despite potential and low
cost of Al, the exploitation of its plasmonics is very recent and still facing both scientific and technical challenges.
One of the crucial problems is the degradation of plasmonic properties induced by rapid oxidation. This problem
could be solved by using fluorides matrices, which will embed the Al NPs. In our work we demonstrated
successfully fabrication of Ag, Al as well as Rh and Bi NPs embedded by CaF2 and Eu⁺:CaF2 films fabricated by
Pulsed Laser Deposition techniques (NPs) with auxiliary Electron Beam Evaporation (fluoride) at UHV conditions.
By alternating of PLD and evaporation the photonic crystals consist of multilayers of metals nanoparticles and fluoride dielectric were fabricated. The fabrication of metallic NPs in UHV conditions embedded in fluoride matrix prevent the oxidisation, which could degrade of plasmonic properties of NPs. The size of the NPs was controlled by the number of the laser pulses focused on the metallic target and varied between 5 and 20 nm. The distance between them in perpendicular direction is easily controlled by laser triggering. The analysis of the measured date revealed an absorption band in the range from 200nm up to 450 nm corresponds to LSPR of incorporated metallic NPs depending on the metals and size, respectively. Results were compared and discussed with the results of analysis structural properties performed by SEM, TEM, AFM and XRD. The calculated absorption cross absorption effective cross-section will be compared with experimental results. The plasmonic behaviour of metal NPs will be compared with those presented for metal oxides nanocomposites. The effect of NPs on luminescence and down conversion properties of Eu3+:CaF2 films will be presented as a function of their structural properties.

Scalable Plasmonic Gain and Loss Lattices by Laser Interference Lithography Templates and Colloidal Self-Assembly  
Fabian R. Goßler1,2 and Tobias A. König1,2; 1Leibnizinstitut für Polymerforschung Dresden e.V., Germany; 2Technische Universität Dresden, Germany

The emerging field of noble metal nanostructures has gained a lot of interest in the recent years. Their ability to induce localized surface plasmon resonances (LSPR) when excited by incident light shows much potential for various applications reaching from biomedical technologies over sensing to optical circuits. Plasmonic structures interacting with optically active materials like quantum emitters or J-aggregates can lead to light-matter interactions like strong coupling and fluorescence enhancement. [1] If such plasmonic systems are arranged in a periodic manner, coupling between the grid resonances and the LSPR can lead to coherent energy transfer and Surface Lattice Resonance (SLR) modes of high optical quality. Their properties can be tuned over a large spectral bandwidth by varying parameters like periodicity, composition and lattice structure. There was significant progress in both, manufacturing and tailored properties of such plasmonic nanosystems lately. Nevertheless, it still remains challenging to develop efficient and scalable ways to produce such devices. In this work, we show a procedure to generate plasmonic grids on transparent and flexible materials by using Laser Interference Lithography (LIL). This enables us to fabricate a square lattice of gold nanodiscs in a highly time- and cost-efficient way whose properties can be easily adjusted to meet the desired demands. The SLR of these periodic arrays can be coupled to gain materials to induce phenomena like coherent energy coupling on macroscopic scale. With this scalable approach based on LIL, nanophotonic devices can be moved closer to implementation in future optoelectronic devices.

Thermally Induced Changes in Plasmonic Colors Based on Solid State Dewetting of Gold on a Paper Surface  
Nobuko Fukuda and Sakae Manaka; National Institute of Advanced Industrial Science and Technology (AIST), Japan

We have observed solid state dewetting [1-3] of gold formed by vacuum vapor deposition onto a paper substrate. Solid state dewetting occurs resulting in minimization of total free energy of the gold-air, gold-paper, and paper-air interfaces. We previously reported plasmonic color changes with solid state dewetting of gold nanoparticles on a coated paper surface [4]. In the case that the isolated gold nanoparticles are formed all over the paper surface just after deposition, coalescence of the nanoparticles proceeds even though ambient condition at room temperature. In the case that the gold nanolayer with defects is formed all over the paper surface, growth of the defects proceeds and finally the gold particles are formed. The shape changes of gold due to solid state dewetting bring about dynamic color changes.

In this study, we investigated the relationship between gold coverage on the coated paper surface and dynamics of solid state dewetting. A gold nanolayer with a metallic color was deposited on the coated paper with 1.0 Å/s for 10 nm. The gold coverage is about 90% on the paper surface according to analysis on the image collected with a scanning electron microscope. Heating of it at 40°C induces growth of the defects, resulting in formation of particles after 72 h. The surface color changes to magenta after 72 h. The growth of defects and the color change at 40°C proceed faster than at 80°C. We guess that the speed of the growth of defects might be determined by losing the
One of the most critical challenges to high-performance nanowire (NW) photodetectors is the detectability of weak signals that noise obscures. Cloaking is a proposed method to reduce the noise generated due to the probed field being disturbed by light scattered by the photodetector itself. Here we study and compare theoretically a traditional plasmonic material gold (Au) with an emerging plasmonic material zirconium nitride (ZrN) as a plasmonic cloak for silicon nanowire photodetectors, using Mie formalism for scattering and absorption efficiency and near-field contours of the electric field. Compared to Au, ZrN has real permittivity values similar in magnitude to common dielectric components, an ideal condition for generating a polarization vector in the shell that is antiparallel to that in the core, resulting in cloaking, and the cheaper availability of raw materials makes it a good replacement for the noble metal. We have predicted the performances across the entire visible spectrum, and have shown that though ZrN cloaks produce a significant decreasing the scattering, greater than 10 times compared to a bare nanowire, and twice as better compared to Au in the wavelength region of 400-500 nm, their performances become comparable at 550 nm, with Au providing twice as good a scattering cancellation as compared to ZrN over the wavelength region of 600-700 nm. By taking the absorption efficiency into account, we have defined a figure of merit (FOM) to determine the overall performance of the cloaked Si photodetector, and show that a ZrN cloak provides up to 3 times enhancement over the performance of a bare Si NW and a 60% improvement over a Au cloaked NW, in the wavelength region of 400-500 nm, while a cloaked Au NW shows up to 30 times improvement in the wavelength region of 600-700 nm over bare Si NW and up to a 4 time improvement over a ZrN-cloaked NW. We have also predicted the optimal dimensions for the cloaked NWs at various wavelengths between 400-700 nm.

**Controlled Dewetting and Regrowth of Composite ErAs NP –GaAs(001) Interfaces** Kurt Eyink, Yuanchang Zhang, Madelyn Hill, Brittany Urwin and Krishnamurthy Mahalingam; Air Force Research Laboratory, United States

ErAs is a semimetallic rare earth monopnictide which has a plasmonic response in the IR-region. ErAs has a rock salt crystal structure and is known to grow epitaxially in zinc-blende GaAs. This ability has led to numerous potential application such as thermoelectrics, plasmonics, and photonics. In the case of plasmonics, patterning the ErAs is required in order to design particular resonances in a metasurface. However, Er oxidizes extremely easily in air which has prevented ErAs use in these application. Due to the difference in crystal structure of ErAs and GaAs, a high energy interface exists between ErAs and GaAs. ErAs nanoparticles form on the GaAs As surface via an embedded growth mode in which the ErAs NP are partially buried in the GaAs surface. We recently observed a dewetting of GaAs films from the ErAs NP-GaAs composite interface. In this presentation we study this phenomena as a vehicle for the formation of tunable plasmonic structures. Previously we have shown that the dewetting process depends on several variable such as ErAs NP concentration, the dewetting temperature, dewetting time, and the thickness of the GaAs cap. We explore the ability to form a patterned surface by controlling the thickness of the GaAs. Specifically we produce a cap covering an ErAs NP growth (0.5 monolayers) which is sufficiently thick to prevent the surface from dewetting. By ex-situ etching we thinned the GaAs cap back to a thickness between 2 and 5nm which will allow dewetting. We then perform in-situ cleaning followed by dewetting of the structure in an MBE chamber. We dewet at a temperature greater than 550°C for at least 15 min. We show that we can form dewetted regions of exposed ErAs NPs. Using a low flux growth process, we control the ErAs growth to only the exposed region and produce large areas with continuous ErAs. This demonstration is a first step in producing definable resonances in a metasurface composed of ErAs using this approach.

EL01.20.21
**Optical Properties of Individual and Ensemble Metamaterial Building Blocks—Rings of Plasmonic Nanoparticles** Dan Petrescu¹, Morgan Thinel¹, Amy Blum¹ and Klas Lindfors²; ¹McGill University, Canada; ²University of Cologne, Germany

Metamaterials interact with electromagnetic radiation to produce exotic resonant optical responses that arise as a result of meta-building block geometry and arrangement, rather than chemical composition alone. Such exotic optical responses include near-zero permittivity, negative permeability, and negative refractive index, which find applications in high resolution super flat-lenses, perfect absorbing super-flat antennae, and cloaking materials, among many others. In order for resonances to occur, the size of the meta-building blocks and the spacing between them need to be significantly smaller than the target radiation wavelength. Optical metamaterials therefore require the synthesis of highly uniform nano-sized building blocks as well as their 2D or 3D nano-scale arrangement. Currently, the large-scale synthesis of uniform nano-sized objects faces difficulties due to the costly and time-consuming nature of high-resolution lithographic techniques. Furthermore, the periodic arrangement of these nano-sized objects in 3D over extended length-scales presents yet another challenge. To address these challenges, we employed viral proteins that self-assemble into robust supramolecular scaffolds which can host a variety of plasmonic metallic nanoparticles for the preparation of nano-sized and uniform meta-building blocks. These building blocks were further assembled in 3D in a polyelectrolyte multilayer (PEM) system, using a layer-by-layer deposition technique.

One particular meta-building block, an annular ring composed of discrete plasmonic metallic nanoparticles, has previously been predicted to display a dominant magnetic dipole moment at optical frequencies. Once assembled in a 3D square lattice, these rings collectively displayed effective negative permeability resonances. Most excitingly, this material produced a negative refractive index at frequencies where the negative permeability and negative permittivity resonances overlapped. The permeability resonance frequency exhibited tunability across the entire visible regime, as a function of the number of nanoparticles in the ring. Our study investigated the optical properties.
of in-house fabricated rings as a function of the number of nanoparticles. Optical scattering spectra of individual rings were correlated with ring morphology and nanoparticle number via transmission electron microscopy (TEM)-correlated hyperspectral dark-field microscopy. In order to compare single-ring with ring-ensemble properties, polarization-dependent absorption measurements were investigated for solutions of rings as well as 3D ring assemblies in a PEM system. Finally, to probe the putative magnetic dipole moment of individual rings, Lanthanide complexes were chemically conjugated onto rings and employed as fluorescent magnetic moment reporters. Individual and ensemble measurements were also compared for fluorescence studies, using both TEM-correlated hyperspectral dark-field microscopy and solution-phase fluorescence.

Infrared Reflecting/Transmitting Smart Glass for Energy Efficient Windows

Mark C. Altwerger, Harry Efstathiadis and Yashashvini Andugula; SUNY Polytechnic Institute CNSE, United States

Low-emissivity (low-e) glass innovation is intended to decrease the loss of infra-red radiation produced from articles at the inside of a structure with an ambient temperature of 300 K. Consequently, the reflection characteristic for the low-e glass is appropriate to reflect ~72% of the radiation from around 3.5 μm and up to ~9.7 μm. However, claiming the reflectivity characteristic drops at wavelengths below 10 μm, about 28% of the radiation discharged is yet lost to the exterior. In addition, this glass covering isn't appropriate at all to reflect sun oriented NIR radiation. Practically 49% of sun-based vitality is appropriated in the range from 0.7-2.5μm for which the low-e glass-sheet reflectivity is beneath 10%. Along these lines, the advancement of a robust film that can reflect close infrared and infrared warmth radiation in the range 0.7-10 μm while transmitting over 90% of the obvious light power is highly desirable.

Metal oxides have been utilized to deal with the light reflectance over a constrained wavelength extend. In such materials, electron plasma recurrence characterizes the beginning of the high reflectivity routine. To move the plasma recurrence to higher energies (shorter wavelengths), the doping convergence of the metal oxide must be expanded over the dimension of 1x1021 cm-3. At these focuses, in any case, the dopant particles have been appeared to create transporters with heavier powerful mass, diminished portability, and more profound benefactor expresses that fundamentally decline the transmittance.

The metamaterial proposed circumvents the need for excessive dopant incorporation through field-enhancement of the electron concentration at the interface of the moderately doped ZnO thin film with SiO2. To achieve this, a structure was designed that alternates insulating and conducting layers that, when voltage biased, produces a 2-dimensional electron accumulation in a field-enhancement device (FED). The device structure deposited by magnetron sputtering may also find application in a variety of optoelectronic applications.

**EL01.20.23**

Monitoring the Release Process of Gold Nanoparticles from Gold-Incorporated Mesoporous Silica

Anthony Stender; Ohio University, United States

Because silica nanoparticles scatter but do not absorb light in the visible wavelength range, their spectral profile gradually increases in intensity with a decrease in illumination wavelength. Upon adding small gold nanoparticles (5-10 nm diameter) to a much larger mesoporous silica particle (100s nm in diameter), the latter gradually takes on enhanced optical properties that reveal the presence of the gold. In a series of experiments, the degree of gold loading into mesoporous silica was gradually increased, in order to characterize the optical effects. Two methods of gold loading were employed with slightly different end results. In the first method, gold was directly plated into the silica structure. In the alternative technique, gold nanoparticles were attached to the silica structure through molecular linkers. In an additional series of experiments, the optical signals of mesoporous silica particles were monitored in real time as molecularly-linked gold nanoparticles were removed from their surface. This was performed through the use of chemical cleaving agents in two different settings: a controlled experiment within a microchannel and naturally within an A549 cancer cell. All data were captured by means of filtered imaging via differential interference contrast (DIC) microscopy. These findings demonstrate that these dual-nanoparticle systems provide a valuable method for monitoring activities within dynamic environments.

**EL01.20.24**

Three-Dimensional Graphene Nanomaterials for Plasmonic Optofluidic Sensing

Kriti Agarwal, Chunhui Dai
Three-dimensional graphene architectures namely, graphene-based polyhedral pyramids, cubes, and hollow cylindrical tube, and cubes have recently been realized using a surface-tension self-folding mechanism. The spatial coverage of the plasmon-enhanced electric-field in two-dimensional graphene ribbons needs to be extended into the bulk space through volumetric enhancements to overcome the surface and edge-limited efficiencies induced in 2D nanoribbons currently used for conventional plasmonic devices. Unlike patterned 2D graphene where the conventional and coupled enhancement modes are isolated only to the edges of the materials, the self-assembled multi-faced polyhedral graphene exhibits hybrid plasmon modes caused by multi-dimensional coupling between the graphene vertices, edges, and surfaces over an extra spatial degree of freedom. While 2D graphene can only demonstrate bi-directional coupling through the two edges; the 3D nanomaterials benefit from fully-symmetric 360° coupling at the apex of pyramidal graphene, orthogonal four-directional coupling in cubic graphene, and uniform cross-sectional radial coupling in tubular graphene. Each of these coupling mechanisms exhibits a corresponding plasmonic enhancement mode with unique optical features and advantages. Here, we discuss the fabrication and characteristics of each 3D graphene nanomaterial and the corresponding advantage for plasmonic sensing mechanisms. 3D graphene nanomaterials induce bounded volumetric field that senses minute quantities of targeted substances even away from the graphene surface with almost a 60% shift in resonant frequency that is far superior to the 10% change exhibited by 2D graphene ribbons. The ease of incorporation of the 3D nanomaterials with microfluidic channels has the capability of delivering optofluidic sensing mechanisms that far exceed the performance constraints faced by current plasmonic sensors.

Chiroptical Kirigami Modulators for Terahertz Circular Dichroism Wonjin Choi, Gong Cheng, Theodore Norris and Nicholas A. Kotov; University of Michigan - Ann Arbor, United States

Circular dichroism (CD) is a spectroscopy method based on the differential absorption of left and right circularly polarized light, which enable identification and quantification of structures at molecular and nanometer scales. Until now, however, available spectral range for CD is physically limited by the development of dynamic polarization modulators. Among not yet fully explored region, of particular interest is the far infrared or terahertz (THz) region of the electromagnetic spectrum. This is because terahertz circular dichroism (TCD) could offer multifaceted spectroscopic capabilities for understanding mesoscale chiral architecture and low-energy molecular vibrations. Here we show that reconfigurable optical modulators fabricated from patterned sheets with periodic kirigami cuts enabled dynamic range of polarization rotation modulation in the THz region over thousands of cycles. Under mechanical application, the plasmonic stripes transformed into a topologically equivalent helix structure. We measured TCD spectra of several representative biological samples using kirigami modulators and found distinctive TCD peaks. Kirigami modulators will also play an indispensible role for other applications, such as polarization resolved THz imaging and phase-encrypted THz telecommunication.

**EL01.20.27**

Towards Applications of Plasma-Synthesized Plasmonic TiN Nanoparticles Alejandro Alvarez Barragan, Carla Berrospe Rodriguez, Giorgio Nava, Stephen Exarhos, Lorenzo Mangolini and Joseph Schwan; University of California Riverside, United States

The appealing capacity of plasmonic nanoparticles to efficiently harvest, scatter and emit light has recently garnered attention for application of these materials in plasmon-based photocatalysts, solar cells and thermo emitters. Gold and silver have been extensively used to successfully drive hydrogen dissociation and CO oxidation reactions by injecting hot electrons into molecules adsorbed to their surface. However, due to the low thermal stability and the high cost of both metals, the necessity of studying alternative plasmonic materials, that potentially will expand the field towards more ambitious and cost-effective applications, has been growing in the last years. Titanium nitride (TiN) is a conductive ceramic with high hardness and bulk melting point (2930 °C). Its plasmon resonance located in the visible-NIR region, low cost (relative to gold and silver), and the well-understood properties as a thin film in the semiconductor industry, make it a strong alternative to precious plasmonic metals.

The present work encompasses a comprehensive study of the plasma-based synthesis of TiN nanocrystals and highlights the potential for their in plasmonic-driven catalysis and as a high-temperature-resistant photothermal absorber.
TiN particles were synthesized via a scalable, modular, non-thermal plasma method. Titanium and nitrogen precursors were transported into a RF frequency plasma where TiN particles nucleate and grow. Platinum nanoparticles were subsequently deposited on the TiN by photo-induced reduction of an aqueous solution of chlorplatinic acid (H₂PtCl₆). The reduction of the precursor metal was driven by electron hole pair generation via plasmon decay. The addition of methanol as a hole scavenger increased the electron lifetime, obtaining metallic platinum. This reaction occurred at temperatures below 40°C under visible light illumination.

In addition, a novel TiN@SiOₓNy core-shell structure was produced by taking advantage of the modular capabilities of the non-thermal plasma synthesis method. The synthesized core-shell particles displayed a 60% higher plasmon peak in the extinction coefficient with respect to the uncoated TiN particles. To probe the potential of these heterostructures, core-shell and uncoated TiN particles were deposited on SiOₓ substrates by coupling the plasma reactor with a nozzle. This simple modification enables to deposit a thin film by jet impaction method. The emissivity (absorptivity) of both samples were measured under vacuum conditions, demonstrating the high temperature resistance of TiN@SiOₓNy core-shell films, as their optical properties at 700 °C remained stable. This simple experiment demonstrates the stark promise of this material to generate a tunable-band-like emission for applications in thermo photovoltaic systems.

This work strengthens the case for alternative plasmonic materials in fields dominated by precious metals, and heavily driven by materials cost.

**EL01.20.28**

*Nanofabrication of Improved Titanium Nitride Plasmonic Surfaces via Nanosphere Lithography*  
Spyridon Kassavetis¹, Stavros Panos¹, Despina Tselekidou¹ and Panos A. Patsalas²; ¹Aristotle University of Thessaloniki, Greece; ²Aristotle University, Greece

Plasmonic materials and devices have attracted enormous and multidisciplinary interest and efforts over the last decade. However there are few examples of plasmonic devices mainly due to materials issues, since gold and silver, the "traditional" plasmonic materials, are expensive, with limited possibilities to tune their plasmonic response across the spectra and low melting point, which makes them incompatible with CMOS growth and processing for application in microelectronics.

Transition metal nitrides (TMN) emerge as alternative plasmonic materials and principal candidates for plasmonic applications. The TMN are conductive ceramics with exceptional properties such as substantial electronic conductivity, high melting point (>3000 K) and tunable work function values. Consequently, they are particularly stable in hostile chemical environments, high temperatures, and strong electric fields, such as in lasers. These traits make them suitable for a wide range of applications from microelectronics to photonics and medicine. Among them, titanium nitride (TiN) is recently emerging as significant candidate for plasmonic applications (biosensors, catalysis and photochemistry, solar energy harvesting, photo-detection, and optical storage of information). In this work, TiN nanostructures with controlled spacing and tunable dimensions were fabricated using Nanosphere Lithography (NSL) and DC magnetron sputtering (MS) for the growth of TiN nanostructures. NL appears as a very promising approach, due to its rapid implementation and compatibility with wafer-scale processes. NSL combines the advantages of both top-down and bottom-up approaches and includes: (a) preparation of the nanospheres colloidal mask and (2) the deposition of the desired material in the empty space between the spheres. The mask is then removed and the layer keeps the ordered patterning of the mask interstices. Specifically, a suspension of monodisperse polystyrene nanospheres (diameter, d=552 nm) was spin coated onto the Si (001) substrate to form the mask. Subsequently, the selective growth of TiN was made by: (i) rf biased DC MS in Ar/N atmosphere by varying the TiN thickness from 10 to 30 nm. The arrays of ordered TiN nanostructures appear after the lift-off of the nanospheres mask. Atomic Force Microscopy showed the fabrication of relatively large scale (> 40X40 μm) and well-ordered plasmonic surfaces, where the TiN nanostructures with thickness lower than 20 nm form a honeycomb template over the Si (001). The optical response of the TiN plasmonic surface was examined by Optical Spectroscopy and Spectroscopic Ellipsometry.

Dopant Selection Strategy for High Quality Factor LSPR from Doped Metal Oxide Nanocrystals Bharat Tandon1,2, Sandeep Ghosh1 and Delia J. Milliron1; 1The University of Texas at Austin, United States; 2Indian Institute of Science Education and Research, Pune, India

Thin films of degenerately doped metal oxides such as those of Sn-doped In2O3 (Sn:In2O3) are commercially significant for their broad utilization as transparent conducting electrodes in optoelectronic devices. Over the last decade, nanocrystals (NCs) of Sn:In2O3 and other doped metal oxides have also attracted interest for localized surface plasmon resonance (LSPR) that occurs in the near to mid-infrared region. The suitability of this LSPR for some applications depends on its capacity to concentrate light in small regions of space, known as near-field hot spots. This efficiency to create near-field hot spots can be judged through an LSPR figure-of-merit such as Quality factor (Q-factor), defined as the ratio of LSPR peak energy to its linewidth. The free electron density determines the LSPR peak energy while the extent of electron scattering controls the LSPR linewidth and hence these factors together essentially dictate the value of the Q-factor. Here, we describe the properties of aliovalent cationic dopants that allow both high LSPR energy and low LSPR linewidth and, subsequently, high LSPR Q-factor. In this context, we identify Zr4+ as a model aliovalent dopant for high LSPR Q-factor in the In2O3 lattice. The resulting Zr-doped In2O3 NCs exhibit one of the highest LSPR Q-factors reported in the mid-infrared region while also performing equivalently to the recognized materials for either high dopant activation (Sn:In2O3 NCs) or low LSPR linewidth (Ce-doped In2O3 NCs), simultaneously.

EL01.20.30
Design of ZrB2 Patterns for Emissivity Enhancement with Adjoint Method Ali M. Kecebas1, Lina Irez1 and Ibrahim Sendur1,2; 1Sabanci University, Turkey; 2Center of Excellence for Functional Surfaces and Interfaces, Turkey

ZrB2, which belongs to family of ultra-high temperature ceramics (UHTC), is known in the literature by its high melting point, oxidation and ablation resistance, chemical reactivity and erosion resistance. These properties make ZrB2 a great candidate for applications in extreme environments, such as aeronautics and astronautics. In such applications, device temperatures can reach up to elevated temperature, therefore an effective cooling approach is required. Due to the unavailability of the conduction and convection heat transfer, task of controlling the radiative heat transfer becomes crucial. To improve the radiative heat transfer rate from the surface, effects of mixing and doping on the emissivity of the ZrB2 have been widely investigated. Improved emissivity is reported in these studies, by which heat transfer from the surface is increased.

As an alternative to mixing and doping, we investigated the effect of patterning of ZrB2 on the emissivity of it in 0.5 – 1.5 μm spectrum interval. As a starting point, we considered grating structures which are heavily utilized for coupling between incident waves and the surfaces. We found out that by arranging the periodicity of the patterns on the surface, emissivity is improved due to the increased coupling. Two resonant behaviors are observed as well as the broadband emissivity enhancement in the 0.5 -1.5 μm spectrum interval. Parametric analysis is carried out to optimize the emittance of the surface in broadband spectrum. Underlying physical mechanisms are investigated and source of broadband enhancement is explored. Initial findings yield that one distinct peak stems from the surface geometry and other one occurs due to dielectric function of ZrB2, which approaches to zero around the second peak wavelength.

After the parametric analysis, an initial design is determined. To further improve the emittance of that structure, we used adjoint method to optimize the topology it. In recent years, adjoint method is adapted to field of electromagnetics and utilized to design superior structures via computationally efficient topology optimization. When adjoint method is applied, final structure’s emissivity approaches to 1 around peak wavelengths and reaches up to 85 % in 0.5-1.5 μm spectrum interval. These findings show that emissivity of the pure ZrB2 can be improved by patterning. When parametric analysis is combined with adjoint method, very high emittance is obtained. Such high emittance demonstrates the possibility of an alternative approach for emittance enhancement, thus thermal management.

Tunable Graphene Plasmonic Devices Driven by Ferroelectric Domains Junxiong Guo1, Yu Liu2, Yuan Lin1, Wen Huang1, Xiaosheng Zhang1 and Jinxing Zhang2; 1University of Electronic Science and Technology of China, China; 2Tsinghua University, China; 3Beijing Normal University, China

Tunable Graphene Plasmonic Devices Driven by Ferroelectric Domains Junxiong Guo1, Yu Liu2, Yuan Lin1, Wen Huang1, Xiaosheng Zhang1 and Jinxing Zhang2; 1University of Electronic Science and Technology of China, China; 2Tsinghua University, China; 3Beijing Normal University, China
Graphene and related two-dimensional materials have attracted intensive attention for electronic and photonic applications due to their unique structures and band energy aligns over a wide wavelength range, despite being atomically thin. However, most of the existing active graphene devices suffer from low light-matter interactions, resulting in either slow responsivity or limited detectivity. Integrating graphene with the intelligent substrate to excite graphene surface plasmons offers a promising approach for improving the photoelectric performances of graphene-based devices.

Here, we demonstrated the graphene carriers can be easily modulated by ferroelectric domains and firstly proposed its potentials for tunable infrared photodetector and micro-spectrometer applications. Compared with the silicon-based graphene plasmonic devices using a complex process of micro-nano fabrication, our proposed devices provide the advantages of more convenient and controllable technique without the need of patterning graphene, and lower energy consumption due to nonvolatile properties of the ferroelectrics free of additional contact electrode. The simulated results show the photodetector features a tunable absorption peak, modulated by periodically polarized ferroelectric domains at nanoscale, with an ultra-high responsivity up to $6.72 \times 10^6 \text{ A W}^{-1}$ in the wavelengths ranging from 5 to 20 μm at room temperature. The potential mechanism for the prominent performances of the proposed photodetector can be attributed to the highly confined graphene surface plasmons excited by the local electrical field across the interface of graphene and ferroelectric layer resonant to the incident wavelength, which could be easily controlled by the features of the ferroelectric domains. The tunable spectral response and the ultra-high responsivity make the photodetector based on graphene plasmon tuned by the ferroelectric domains promising in practical applications of micro-spectrometer and other light sensing devices.

**A Plasmonic Platform with Lattice Manipulation of Metal Nanopatterns for Enhanced Upconversion Luminescence**

Byunghoon Kim and Doo-Hyun Ko; Kyunghee University, Korea (the Republic of)

Rare-earth activated upconverting nanoparticles (UCNPs) have been studied due to their energy conversion property based on multi-photon absorption process. Often, these nanoparticles are combined with plasmonic nanostructures to overcome the intrinsic limit, especially, low internal quantum efficiency. However, recent plasmonic structures suffer from complicated process and restricted resonance region. In this study, we demonstrated a novel plasmonic platform to manipulate resonance wavelength via lattice control method using sequential metal-contact nanolithography. The platform employed metal nanostructure-UCNPs embedded insulator-metal reflector (MIM), which exhibited various optical characteristics including confinement of near-infrared (NIR) light, and facile extraction of converted visible light through plasmonic resonance excitement. Consequently, we observed over 200-folded enhancement for upconverted luminescence. Unlike the previous research, which tends to enhance specific wavelength, the lattice-controllable plasmonic platform shows broadband enhanced upconversion luminescence providing a convenient and versatile application for photo-isomerization reaction.

**EL01.20.33**

**Giant Third-Harmonic Optical Generation from Topological Insulator Interfaces**

Yinxiao Xiang, Chenhui Yan, Fan Shi, Prakash Gajurel, Lian Li and Cheng Cen; West Virginia University, United States

Efficient nonlinear optical materials are rare yet critical platforms to enable photon coupling. Here, we report an anomalous third harmonic generation (THG) effect universally found in the epitaxial films of a family of V-VI chalcogenide topological insulators (TIs) with drastically different optical density of states. Unlike the regular scaling behavior and without any optical resonances, THG generated from these films decays exponentially as the film becomes thicker. At the minimum thickness required for the topological states at the top and bottom surfaces to remain decoupled, the THG intensity reaches its maximum which is almost four orders of magnitude stronger than current leading materials. We attribute this unusual effect to the topological bands with nonlinear dispersion velocities and nontrivial Berry connections. This discovery provides new insights into the connection between band topology and optical nonlinearity and also a unique venue for realizing strong nonlinear optical performances on chip.

**Direct Deposition of Plasmonic Nanoparticles via Sputtering Performed in Open Air for Easy Manufacturing of Plasmonic Nanocomposite Film**

Yoshiki Shimizu, Kazuto Hatakeyama and Yukiya Hakuta; National Institute of Advanced Industrial Science and Technology, Japan

---

Final Program 1/13/2020  107
Nanocomposite film composed of plasmonic nanoparticles and matrix of metal-oxide semi-conductor is promising materials in future application for conversion of solar light into chemical energy with high efficiency. This background motivates the research on fabrication of noble-metal (Au, Pt, Ag, Pd) nanoparticles/semi-conductor metal oxide (TiO2, ZnO) nanocomposite film. Generally, the fabrication process employs one of the following conventional coating method; sol-gel, sputtering, vacuum evaporation. In these, sputtering and vacuum evaporation have an advantage of chemical wastewater free, while these require costly high-vacuum vessel. In this paper, we present the novel method based on sputtering performed in open air, which is expected to be alternative to the conventional sputtering and evaporation method. The method has the following features; 1. Non-use of harmful source for operation in open air, 2. Synthesis of nanoparticles of noble-metal with narrow size distribution, 3. Direct deposition of the synthesized nanoparticles on film surface. We have investigated its potential as a method for easy manufacturing of plasmonic nanocomposite film. Recently, we confirmed that the fabricated nanocomposite film reveals high photocatalytic activity for pollutant degradation under sunlight exposure. The detail of the developed method and the performance of the nanocomposite film will be presented in our presentation.

**EL01.20.35**

**All-Graphene-Electrode Electrically Driven Microdisk LEDs**

Ja-Hyun Ku, Sun-Wook Park and You-Shin No; Konkuk University, Korea (the Republic of)

Integrating micro-scale light sources with passive components in a single chip has been one of critical challenges in photonics and optoelectronics. In addition, driving the active optical elements by direct current injection has been a long-standing goal since it’s been great challenge to inject current into micro-sized optical devices without affecting the important optical characteristics. In this work, we use epitaxially grown III-V semiconductor compounds (AlGaInP) with vertical p-i-n junction including multi-quantum wells (MQWs) structures with central emission wavelength of ~680 nm, and successfully fabricate an individually transferrable microdisk (MD) array with diameters of 5 and 7 µm, respectively, which can serve as micro-scale light sources at visible frequency. In addition, we utilize the CVD-grown multilayer graphene (MLG) that shows high charge transmission and optical transparency at the given frequencies as the transparent electrodes to electrically pump the device. In fabrication, we first transferred the CVD-grown MLG on a Si3N4 device substrate using wet transfer method. Then we exploited PDMS micro-tip transfer technique to pick up the pre-fabricated MDs from the semiconductor wafer and transferred them onto the pre-transferred MLG on Si3N4 substrate. We used the electron-beam (E-beam) lithography and O2 plasma etching to pattern top- and bottom-MLG electrodes that are directly in contact with p-doped top and n-doped bottom layers of the MDs. A final metallization carried out on these MLG electrodes completed the fabrication of the electrically driven MD devices. We performed the electroluminescence (EL) experiment by applying pulsed currents with a repetition rate of 1MHz and duration of 19.5 ns. A clear EL emission from the device was captured by the charge-coupled device (CCD), and subsequently observed in the measured spectrum. We believe that our device can be essential building blocks for the compact integrated optical circuits.

**Generating Vibrant and High Contrast Structural Colors from Lossy Metals on Dielectric Gratings**

Youngji Kim¹, Kyungmin Jung¹, Jiung Cho² and Jerome Hyun¹; ¹Ewha Womans University, Korea (the Republic of); ²Korea Basic Science Institute, Korea (the Republic of)

Despite their unique properties including CMOS-process-compatibility, high chemical stability, catalytic activity, etc, lossy metals are generally shunned from use in structural colors because their damping loses compromise the color vibrancy. In this work, we demonstrate a strategy to create highly vibrant and high contrast color pixels from lossy metals (e.g., Pt and W). Our pixel is of the reflective type and consists of a metal substrate supporting a near-wavelength dielectric grating oriented 45 degrees to the input polarization. This allows the incident light to be decomposed into s-polarized (s-pol) and p-polarized (p-pol) light with equal strengths. The reflected signal is filtered by a cross-polarizer, cancelling the background signal and keeping the pixel contrast high. Each s-pol and p-pol component excites a resonance at different wavelengths through the coupled waveguide-array modes in the grating [1,2]. At each resonance, a phase difference between the s-pol and p-pol light arises, abruptly rotating the total polarization vector by π/2 over the wavelength. As a result, the cross-polarized filter transmits two spectrally distinct and sharp signals from the two resonances. We find that the metal loss severely degrades the p-pol resonance (i.e., surface plasmon polariton) due to the spatial overlap of the resonant field with the metal interface whereas its effect on the s-pol resonance, located between the grating and air interface, is relatively small. By measuring the cross-polarized reflection from gratings on lossy metals, we obtain spectrally pure and sharp signals.
translating to a high color vibrancy and large gamut range, as only the spectrally sharp s-pol resonance contributes to the reflected spectrum. In fact, W which is one of the lossiest metals, provides a larger gamut coverage than that of Ag. These results offer intriguing routes for realizing high-contrast structural colors from an expanded range of metals that host interesting chemical and physical properties [3].

Zeeman-Like Splitting of the Plasmonic Response of InSb Nanoparticles Raul Esquivel-Sirvent and Alonso Márquez-Hernández; Universidad Nacional Autonoma de Mexico, Mexico

We show that the plasmonic response of InSb spherical nanoparticles splits into two resonances when an external magnetic field is applied. This splitting is akin to a Zeeman splitting with the frequency separation of the satellite resonances depending on the magnitude of the applied magnetic field. InSb has a homogeneous dielectric function, and the extinction of the nanoparticle shows a resonance in the frequency range of THz. The application of the external magnetic field induces an anisotropy in the dielectric function. To understand the splitting of the plasmonic resonance, we show that the anisotropic sphere is topological equivalent to a spheroid with an isotropic dielectric function. The shifting of the plasmonic peaks is equivalent to having a spheroid of varying eccentricity. The plasmonic response and peak splitting also depends on the direction of the applied magnetic field. Finally, applications to active plasmonics will be discussed.

EL01.20.38
Ultimate Light Trapping in a Free-Form Plasmonic Waveguide Juho Park1, Sanmun Kim2, Joongwon Lee3, Sangjun Han1, Ju Young Kim1, Junhyeong Kim1, Sergey Menabde1 and Min Seok Jang1; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2University of Cambridge, United Kingdom; 3Cornell University, United States

Slow light enables spatiotemporal manipulation of electromagnetic waves at the nanoscale and allows access to a plethora of nonlinear optical phenomena. Although the guided waves in plasmonic waveguides are known to inherently possess a slow energy velocity, their ultimate light-trapping performance remains unknown as the effect of the waveguide’s shape alteration has not been considered systematically so far. In this work, we search for the optimal geometry of a free-form metal-insulator-metal (MIM) plasmonic waveguide for light trapping, and reveal its unique properties that are significantly different from the conventional linear taper structures. We optimize the waveguide geometry by using three different numerical optimization algorithms combined with the transfer matrix method, and confirm the results with full-wave simulations based on the finite element method (FEM). The optimized light trapping structure possesses a dramatically enhanced quality factor, almost reaching the theoretical limit imposed by the material loss. Interestingly, it also exhibits a distinctive mode dynamics and a unique dependence on the material loss, both being fundamentally different from those of the conventional linear taper structures. Unlike linearly tapered waveguides, whose characteristic length (minimum necessary length to reach half of the maximum quality factor) is inversely proportional to the material loss, the quality factor of the optimized structure saturates at much shorter length, and its characteristic length scales logarithmically to the inverse material loss. Further, in order to demonstrate the feasibility of proposed design approach, we analyze the optimization results obtained with realistic materials at visible and mid-IR frequencies.
PLASMONICS ENHANCED PHOTODETECTORS HAVE BEEN WELL EXPLORATED IN VISIBLE TO THZ SPECTRUM. SEVERAL PLASMONICS MATERIALS HAVE BEEN GIVEN PROMISED RESULTS IN VISIBLE TO THZ REGIME, SILVER AND GOLD ARE THE MOST EXTENSIVELY USED NOBLE METALS FOR PLASMONICS APPLICATIONS. A WIDE RANGE OF ULTRAVIOLET SPECTRUM IS LESS DISCOVERED DUE TO THE LIMITATION OF THE INTRINSIC BEHAVIOUR OF THESE METALS. WHERE SILVER SUFFERS FROM RAPID OXIDATION AND POOR QUALITY FACTOR OF SURFACE PLASMON RESONANCE (SPR) AND LOCALIZED SURFACE PLASMON RESONANCE (LSPR) BELOW 350 NM BESIDES GOLD HAS AN INTERBAND TRANSITION AROUND 500 NM. TO EXPLORE THE PLASMONIC PROPERTIES IN ULTRAVIOLET (UV) REGIME, ALUMINUM HAS ENORMOUS POTENTIAL AND HIGH QUALITY FACTOR TO OPERATE IN THE DEEP UV TO NEAR UV SPECTRUM, SO WE PRESENT LOCALIZED SURFACE PLASMON RESONANCE DRIVEN UV PHOTODETECTION THROUGH ALUMINUM METASURFACE ON GALLIUM NITRIDE (GAN) SUBSTRATE. FOR THE GENERATION OF UV RANGE LSPR AND FORMATION OF SCHOTTKY CONTACT AT THE SURFACE OF GAN, THE SINGLE CRYSTALLINE ALUMINUM FILM IS GROWN BY PLASMA ASSISTED MOLECULAR BEAM EPITAXY (PA-MBE) METHOD ON UNDOPED GAN/AL2O3 SUBSTRATE. AS A METASURFACE, PERIODIC NANOHOLES WERE DESIGNED. CMOS COMPATIBLE TECHNIQUES ARE USED TO MAKE SUBWAVELENGTH METASURFACE AND SCHOTTKY DIODE. FURTHERMORE, FDTD SIMULATION AND MICRO UV REFLECTANCE MEASUREMENT WERE PERFORMED TO REALIZE THE BEHAVIOUR OF THESE PERIODIC NANOHOLES. THE HOT ELECTRONS GENERATED BY THE DECAY OF LSPR IN THESE PERIODIC SUBWAVELENGTH NANOHOLES AND ATOMICALLY SMOOTH METAL SEMICONDUCTOR INTERFACE CONTRIBUTE TO ENHANCE PHOTOEMISSION EFFICIENCY AND WIDE UV SPECTRAL ENHANCEMENT COVERAGE. THE ULTRAHIGH RESPONSIVITY (670 AMP/WATT) AND DETECTIVITY (1.48 × 1015 CM Hz-1/2 W-1) ARE OBSERVED AT 355 NM. THIS CMOS COMPATIBLE PLASMONICS BASED ULTRAVIOLET PHOTODETECTOR CAN REPLACE THE TRADITIONALLY GAN-BASED PHOTODETECTOR AND OPEN A NEW ERA IN ULTRAVIOLET DETECTION REGIME.

DIFFRACTION CONTROL WITH HIGH Q PHASE GRADIENT METASURFACES FOR NONLINEAR FREESPACE OPTICS

PHOTONIC MICRO-STRUCTURES, INCLUDING MICRONING RESONATORS, PHOTONIC CRYSTAL DEFECT CAVITIES, AND WHISPERING GALLERY RESONATORS, HAVE BEEN BY FAR THE MOST SUCCESSFUL PLATFORMS FOR BOOSTING LIGHT MATTER COUPLING, WHICH IS LARGELY THANKS TO THEIR HUGE QUALITY (Q) FACTORS, SPANNING THOUSANDS TO MILLIONS. THE ASSOCIATED LONG PHOTON RESIDENCE TIMES AND ENORMOUS AMPLIFICATION OF THE LOCAL LIGHT INTENSITY HAS LED TO HIGH-EFFICIENT LASING[1], FREQUENCY COMB GENERATION[2], OPTICAL SIGNAL MODULATION[3], OPTICAL ISOLATION[4], QUANTUM GENERATION[5], AND SINGLE MOLECULE BIOSENSING[6]. AT THE SAME TIME, NANOANTENNAS PROVIDE AN UNPRECEDEDENT LEVEL OF CONTROL OVER THE SCATTERING OF FREESPACE OPTICAL SIGNALS, ESPECIALLY WHEN ARRANGED INTO METASURFACE ARRAYS, ENABLING FLAT OPTICAL ELEMENTS SUCH AS BEAM STEERERS, LENSES, AND HOLOGRAMS[7]. HOWEVER, RESEARCHERS TYPICALLY FACE A TRADE-OFF BETWEEN ANTENNA SIZE IN RELATION TO WAVELENGTH AND RESONANT LIFETIME, WITH SUBWAVELENGTH STRUCTURES LIMITED TO QUALITY FACTORS (Q) LESS THAN 100, KEEPING MORE EXOTIC NONLINEAR PHENOMENA OUT OF REACH WITHOUT THE USE OF EXTREMELY HIGH POWER FEMTOSECOND LASERS.

BY UTILISING MIE AND GUIDED MODE RESONANCE (GMR) TO CONTROL THE SCATTERING PROFILE OF HIGH Q, Q>1000, RESONANT NANOARCHITECTURES, HERE, WE DEMONSTRATE EXPERIMENTALLY THAT THIS TRADE-OFF IS NOT IN FACT FUNDAMENTAL. WE SHOW THAT GMR IN ULTRATHIN DIELECTRIC METASURFACES CAN BE EMPLOYED TO BRING STRONG FIELD AMPLIFICATION TO A WIDE CLASS OF FREESPACE NANOPHOTONIC SYSTEMS, PRODUCING EFFICIENT OPTICAL NONLINEARITIES IN A NANOSCALE FOOTPRINT. COMBINING WAVEFRONT SHAPING WITH SUBTLE STRUCTURAL SYMMETRY BREAKING, ARBITRARY FREESPACE SCATTERING CAN BE ACHIEVED ALONGSIDE GMRS WITH LIFETIMES THAT CAN BE INCREASED ALMOST INDEFINITELY. AS A PROOF OF PRINCIPLE, WE PROVIDE THE FIRST THEORETICAL AND EXPERIMENTAL DEMONSTRATION OF TWO HIGH Q PHASE GRADIENT METASURFACE FUNCTIONS, ONE CAPABLE OF EFFICIENTLY STEERING AN INFRARED PLANE WAVE TO A PREDETERMINED ANGLE AND ANOTHER SPLITTING A PLANE WAVE INTO TWO BEAMS, WITH BOTH DEVICES SUPPORTING GMR Q FACTORS GREATER THAN 1000.

THE METASURFACES WERE PATTERED INTO A SILICON ON SAPPHIRE WAFER WITH A 600NM SILICON LAYER, USING ELECTRON BEAM
lithography followed by reactive ion etching. To realize the different metasurface phase profiles, nanowires of varying widths were arranged within a 2121nm supercell. Subwavelength periodic notches were also etched into particular nanowires, giving rise to GMRs with Q factors controlled via notch depth. Using a home built angle resolved microscope coupled to a grating spectrometer, we report efficient beam steering and beam splitting between 1350-1500nm, accompanied by GMRs with Q factors as high as 2500. To the best of our knowledge, this is the highest Q factor observed to date in a phase gradient device. We have numerically confirmed that the huge electric fields associated with these resonances can excite efficient nonlinearities, including the Kerr effect and stimulated Raman scattering, opening the possibility for novel functionalities such as subwavelength nonreciprocity. While our proof of principle demonstrations involve beam steering and beam splitting, the design principle we present could easily be extending to other types of wavefront shaping applications, such as lensing.

**Programmable Multiplex Optical Bandpass Filter via Laser Reshaping of Gold Nanostructure** Kyoungweon Park1,2, Jake Fontana3, Jason K. Streit1,2, Jamie Gengler1,2, Carl Liebig1 and Richard A. Vaia1; 1Air Force Research Laboratory, United States; 2UES, Inc., United States; 3U.S. Naval Research Laboratory, United States

Optical bandpass filters allow or reject the light within a specific wavelength range to prevent damage from unfiltered light or to utilize the quarantined light. The terrestrial atmosphere or complex biological fluids are among the examples which provide either broad or narrow transmission windows to accomplish certain functions. Metallic nanorods and their assemblies are a promising platform for optical bandpass filter due to their intense light-matter interactions with tunable optical cross-section greater than the particle volume. With our innovative synthetic strategy, we achieve to fabricate optical filters with independently tunable center wavelength and a variable bandwidth by carefully selecting the aspect ratio of a collection of AuNRs with narrow resonances that allow to create ideal flat top profile for targeted absorption and a sharp roll-off at the filter edges. Laser irradiation can be a simple tool to transcribe a transmission window at desired wavelength by reshaping a population in resonance with the LSPR. It is possible to write a single or multiple transmission window using polydisperse nanorods or nanowires with dense broadband spectral distribution over visible to mid-IR. We examine the impact of laser irradiation conditions on the spectral position, depth, and width of the transmission window and validate the results with theoretical study. The rational design can be achieved in various systems including solutions and nanocomposites to fabricate complex optical materials with properties not found in natural media.

Broadband Light-Trapping Layers for Thin Si Solar Cells Based on Dense Arrays of Silicon Mic Resonators
Nayeun Lee, Muyu Xue, Jiho Hong, Jorik Van de Groep and Mark L. Brongersma; Stanford University, United States

The high reflectivity of typical semiconductor is a major factor in deteriorating the efficiency of solar cells. The conventional approach to minimize these losses is to add a quarter-wavelength-thick antireflection coating with an optimized refractive index. However, this technique has limitations as single-layer antireflection coatings are relatively narrow band and do not trap light in the cell by redirecting it into the plane of the cell. New high-performance photon management approaches are required to achieve high-efficiencies with optically-thin and low-cost cells.

In this research, we propose and experimentally test the performance of broadband light-trapping layers for few-micron-thick Si cells using dense arrays of Si nanostructures. Light reflected from Si substrate can be canceled out by the scattered light from the array of Si nanostructures. While dense arrays of nanostructure can be viewed as homogeneous medium with a broad Fabry-Perot resonance, each individual nanostructure can also support Mie resonances of destructively interfering with the reflected light from the substrate. By judiciously optimizing the structure parameter of the Si nanostructures in an array, both broadband antireflection and light trapping can be achieved. The increased absorption of light is demonstrated experimentally with a 3 um thick solar cell. A 10.3% power conversion efficiency is achieved, representing a boost in the current density as well as enhancing cell’s efficiency over 48% compared to a reference cell without an antireflection coating.

Nanophotonic Refrigeration by Controlling the Chemical Potential of Photons Linxiao Zhu, Anthony Fiorino, Dakotah Thompson, Rohith Mittapally, Edgar Meyhofer and Pramod Sangi Reddy; University of Michigan, United States

Photonic cooling using coherent laser radiation has enabled reaching temperatures close to absolute zero, which plays a key role in identifying new states of matter, and led to novel strategies for solid-state refrigeration. The low entropy of laser radiation makes these cooling processes thermodynamically feasible. Recent theoretical studies have suggested the possibility of photonic cooling using incoherent light from semiconductor diodes. However, such photonic cooling using incoherent light has not been experimentally achieved. In this talk we will describe a first demonstration of photonic refrigeration by controlling the chemical potential of photons. Leveraging the large heat-transfer rates of near-field radiation and sensitive, high-resolution nano-calorimetry, we were able to experimentally observe net cooling of a planar object when it was separated from a reverse-biased photodiode by a nanoscale gap. Such cooling arises from a combination of a suppression of thermal radiation from photodiode at reverse bias, and an enhancement of photon emission from the planar device due to near-field tunneling. We will also describe the dependence of cooling power on gap distance and voltage bias. Finally, the competing effects of negative luminescence and radiative heating will be considered. Our study points to the new and promising direction of combining nanophotonics and optoelectronic devices for achieving solid-state refrigeration.

Integration of Magnetooptical Materials for Photonic Devices Caroline A. Ross; Massachusetts Institute of Technology, United States

Thin film magnetooptical materials are enablers for integrated non-reciprocal photonic devices such as isolators and circulators, as well as magnetoplasmonic and magnetooptical heterostructures. Iron garnets, A12FeO12 where the A-site includes Y, Bi and Ce or a rare earth, offer particularly good magnetooptical figure of merit (Faraday rotation
(FR)/optical absorption) in the near-IR communications wavelengths, with FR and absorption both increasing at visible wavelengths. We describe the growth and magnetooptical properties of films of polycrystalline bismuth-, cerium and terbium-substituted yttrium iron garnet (BiYIG, CeYIG, and Tb,Bi,CeYIG), deposited on silicon substrates and waveguide devices using pulsed laser deposition. These materials were incorporated as cladding materials on Si or SiN waveguides to make integrated isolators based on both ring resonators and on Mach-Zehnder interferometers (MZIs). For TM-mode devices, isolation ratios and insertion losses are up to 40 dB and 3 dB respectively for a ring resonator and up to 30 dB and 6 dB for an MZI, with the latter having a significantly higher bandwidth of 20 dB isolation ratio over a 2 nm wavelength range. TE-mode devices, which require growth of the magnetooptical material on the sidewall of the waveguide, were also fabricated and tested. Garnet films are also useful in active photonic or magnonic devices based on the propagation of spin waves, and programmable spin wave logic devices have been demonstrated in YIG films. In BiYIG films capped with Pt, spin-orbit torque has been used to translate domain walls at velocities exceeding 4 km/s, enabling rapid magnetic switching or transmission of data. The potential of these complex oxides in enabling new types of photonic devices and structures will be assessed.

Surface Fermi Level Pinning and Surface Conduction in CdO Thin Films Angela Cleri¹, Joshua Nordlander¹, Evan Runnerstrom², Joshua R. Nolen³, Josh Caldwell³, John A. Tomko⁴, Patrick E. Hopkins⁴ and Jon-Paul Maria¹; ¹The Pennsylvania State University, United States; ²North Carolina State University, United States; ³Vanderbilt University, United States; ⁴University of Virginia, United States

Cadmium oxide (CdO) is one of the most promising candidates for low-loss mid-infrared plasmonics to date, as it demonstrates a tunable range of carrier concentrations (from $10^{18} - 10^{21}$ cm$^{-3}$), while maintaining mobilities between 300 cm$^2$/vs and 500 cm$^2$/vs over the entire range. These high mobility values lead to plasmonic structures with very low loss and very narrow frequency bands. Fully accessing the spectrum of plasmonic applications, including surface plasmon oscillations, epsilon-near-zero (ENZ) modes, and strong coupling phenomena requires that one maintains these appealing transport properties over a film thickness range spanning a few tens to a few thousands of nanometers.

Extensive CdO fabrication experiments using high-power impulse magnetron sputtering reveal a strong dependence of carrier density and mobility on film thickness, particularly when thickness values drop below 100 nm, a particularly interesting and important range for ENZ modes. For unintentionally doped material in this thinness range, mobilities fall and carrier concentrations rise, both of which can be attributed to surface donors. There is a widely reported surface accumulation phenomenon in CdO thin films that accounts for this phenomenon. Conversely, if CdO is donor doped to values where the Fermi energy is above the surface donor energy this effect can be reversed. In this case, as film thickness falls below 100 nm, carrier concentration drops due to surface depletion.

In this presentation, we demonstrate the reversal between surface accumulation and depletion in CdO by comparing thickness series sets of intrinsic CdO and In-doped material. Transport properties from this sample collection reveals a carrier concentration at which the thickness-dependence relationship is no longer present. At this carrier density, the bulk Fermi energy aligns with the surface defect energy so as to eliminate accumulation or depletion zones. Finally, we show how optical properties, i.e., perfect absorber ENZ layers are affected by these surface effects, and how they can be eliminated by sandwiching doped CdO layers between intrinsic (and lower doped layers), or by capping CdO surfaces to change the surface defect formation energies.

While surface accumulation has been reported in CdO thin films, this is the first demonstration of the reversal between surface accumulation and depletion at varying dopant levels, allowing for tunability of surface charge. This offers potential for tunable quasi-2-dimensional electron gas (Q2DEG) behavior at CdO surfaces.

Two-Photon Direct Laser Writing of Inverse-Designed Free-Space Near-Infrared Polarization Beamsplitter Wisnu Hadibrata, Heming Wei, Francois Callewaert, Vesselin Velev, Zizhuo Liu, Prem Kumar, Sridhar Krishnaswamy and Koray Aydin; Northwestern University, United States

Owing to high sub-diffraction limit resolution (~100 nm) and a true three-dimensional printing, two-photon polymerization (2PP) direct laser writing has opened the possibility of fabricating near-infrared complex 3D optical
components such as micro-lenses, micro-ring resonators and others. In this work, by combining 2PP direct laser writing and inverse design optimization methods, we have been able to demonstrate a compact, thin and broadband free-space polarization beam splitter working in infra-red range. We have optimized a 2λ-thick (in the direction of propagation) device capable of splitting parallelly and perpendicularly polarized light to be directed to the left by +θ° and right by -θ°, respectively. From our simulations, we observe a relatively large bandwidth operation ranging from 1.3 μm to 1.7 μm for the beam splitting behavior. In the experimental demonstration, we successfully fabricated the device using a commercial 3D direct laser lithography system based on a femtosecond laser at 780 nm. We have also performed optical characterizations for the fabricated device operating at 1.3 μm and 1.55 μm. The device exhibits good polarization splitting while also maintaining low transmission loss of 2 dB (1.3 μm) and 2 dB (1.55 μm).

11:15 AM EL01.22.04
Metal Oxide Perovskites—A Viable Platform for Mid to Far Infrared Nanophotonics? Ioannis Vangelidis1, James A. Hillier2, Elefterios Lidorikis1 and Nikolaos Kalfagiannis2; 1University of Ioannina, Greece; 2Nottingham Trent University, United Kingdom

In order to fulfil the promise of plasmonics, it has been viewed that one of the most disruptive technologies will be the “all dielectric plasmonics”. This, by itself, contradicts the definition of plasmonics (interaction of light with collective charge oscillations at metallic nanostructures). However, some interesting approaches can be exploited. In that respect, polar dielectrics can be used to couple an electromagnetic field to collective lattice oscillations, namely optical phonons. Those polar crystals can support optical modes that are confined either to the surface of the material or can be highly confined within or in the vicinity of sub-wavelength geometries, resulting in strong field enhancement. Similar to their metallic counterparts these oscillations are only supported when the real permittivity is negative and in the case of the polar dielectrics, this happens at the so-called Reststrahlen band. Naturally, the extent of this band defines the spectral range of operation.

In this work, we focus our attention to a family of very important technological materials; that of metal oxide perovskites. Metal oxide perovskites have been investigated for many years due to their excellent dielectric, piezoelectric, ferroelectric and optoelectronic properties. When a small number of electrons are introduced in the lattice (e.g. in oxygen-deficient samples or doped with metals, such as Fe or Nb) many other attractive properties arise such as superconductivity, ferromagnetism, high thermoelectric coefficient, blue and green light emission as well as accommodation of a two-dimensional electron gas. We present their exceptional capabilities, in terms of their bulk optical constants, which we have measured with an IR Spectroscopic Ellipsometer and which we compare with the most prominent polar dielectrics (h-BN, Sapphire, InP, GaN and GaP) and metals (such as Au) in an effort to establish a baseline for their performance. A particular focus is given to SrTiO3 which demonstrates a unique capability to maintain negative real permittivity for an extended spectral range due to an effective overall between two Reststrahlen bands and could throw it directly into centre stage for future infrared nanophotonic applications. We then calculate the localised modes on subwavelength structures and we: (i) clarify the fundamental nature of the modes, (ii) demonstrate an extraordinary tunability that SrTiO3 offers in the mid and far infrared wavelengths and (iii) we present a practical example of IR photodetection based on this material.

11:30 AM EL01.22.05
Nanoscale Manipulation of Carbon Nanotube Structure with Light-Matter Interaction Pingping Chen, Shuting Lei and Suprem R. Das; Kansas State University, United States

Carbon Nanotubes have been extensively studied in more than two decades for their physical and chemical properties, and more recently in their industrial applications, including wafer scale nano-electronic devices and nanocomposite structures. The interest in carbon nanomaterials has been greatly enhanced by the rise of graphene, the two dimensional analog of the one-dimensional tubes. Due to their extreme scaled-down geometry, particularly the diameter, a small perturbation in their structure could induce large changes in their electronic properties. However, such control of their structure is difficult to achieve due to processing complexity in a growth reactor. In this work, we use a fast, scalable and room temperature process to alter the nanotube structure by exploiting the light-matter interactions from a femto-second laser radiation. Multi-wall carbon nanotubes are irradiated with pulsed laser beam to modify the tube structures into ribbon-like geometry that may lead to unique electronic and photonic properties. In this work, we use scanning electron microscopy, atomic force microscopy and Raman spectroscopy to study the structural properties of these carbon nanomaterials that may be suitable for coupling with photons.
Controlling the micro- and nanostructure of metals offers the opportunity to investigate and engineer the properties of metal nanotechnologies, which are essential components in advanced optical and electronic systems. The electronic, optical, and thermal properties of these systems are closely related to the presence of strain, defects, and grain boundaries in the metal. Carrier transport, band structure, electromagnetic field enhancements, and thermoelectric properties are all dependent on crystal quality, but there is still an incomplete understanding of the role that individual crystal defects play.

Here, we report a study of the thermoelectric properties of thin-film gold single crystals and bicrystals on amorphous insulating substrates. The crystalline gold microstructures are created via rapid melt growth, which supports the high-yield, high throughput growth of thousands of single crystals and bicrystals on the wafer-scale [1,2]. Using the crystalline gold microstructures as a model system, we can enable systematic studies that reveal the relationship between the micro- and nanostructure of gold and its properties. We studied the spatial variation of the photothermoelectric voltage across the gold stripes using a focused scanning laser probe, which locally heats the metal via direct absorption and excitation of a plasmon resonance. In the bicrystals that each possess a single grain boundary, we observe a thermoelectric voltage distribution where the local Seebeck coefficient varies at the grain boundary, indicating strong carrier interaction with the boundary. Furthermore, variations in Seebeck coefficient along the length of the single crystal gold grains suggest that other crystal defects and strain play a role in determining the thermoelectric properties.

applications. GeOI based photonic components could have better performance than silicon-on-insulator (SOI) counterparts at this new spectral window, due to the superior optical properties of Ge over Si. High performance GeSn photo detector has been demonstrated on this platform. Ge has also been considered as a promising channel material to replace Si for high performance logics applications. This platform also enables the potential of integrating photonics devices with Ge CMOS devices.

2:00 PM EL01.23.02
Vertically Stacked Suspended SiGe Nanowire Meta-Photodetector for Visible Light with Active Tunability of Optical Coupling Junkyo Suh, Qitong Li, Jorik Van de Groep, Fenghao Xu, Krishna C. Saraswat and Mark L. Brongersma; Stanford University, United States

The ability to tune the optical spectra of nanostructures such as nanowires (NWs) through optical coupling is valuable for optoelectronic applications. The optical coupling of two Si NWs horizontally placed without active tunability has been studied. In this case, a part of optical resonant modes (symmetric mode) is only excited under top plane wave illumination. However, the optical coupling of vertically stacked suspended NWs has not yet been explored due to its difficulty to reliably fabricate the system. This configuration is particularly advantageous in that both symmetric and asymmetric modes can be simultaneously excited when illuminated because they naturally receive different phase information. Moreover, the active tuning of the system to engineer the strength of optical coupling has not been demonstrated. In this study, we demonstrate a novel method to fabricate vertically stacked (3D stacking) suspended SiGe NWs. Furthermore, photodetectors are realized with active tunability by electrostatic force applied between the two suspended NWs.

High quality pseudomorphic SiGe (30% Ge)/Si multilayers are epitaxially grown on Si substrate by chemical vapor deposition (CVD) and patterned by e-beam lithography. Then, the SiGe nanobeams are released by tetramethylammonium hydroxide (TMAH), followed by electrode formation on the SiGe NWs. Here, Ge composition in NWs can be increased by high temperature oxidation of the NWs. Electrostatic force applied between the SiGe NWs is used to modulate the spacing in between them. Spectral changes in both scattering and absorption through photocurrent measurement are monitored with various spacings ranging from 200nm to 50nm. As a result, the proposed meta-photodetectors with the active tunability pave a new way for the next generation CMOS compatible on-chip optoelectronic devices that can be monolithically integrated with nanoelectronics.

2:15 PM EL01.23.03
Guided-Mode Resonator Devices for Phase-Contrast Imaging Anqi Ji, Jung-Hwan Song, Qitong Li, David Miller and Mark L. Brongersma; Stanford University, United States

Phase-contrast imaging is an optical method which visualizes the optical phase differences that light acquires as it traverses structures with similar transparency. The inventor of phase-contrast microscopy, Frits Zernike, demonstrated successful imaging of unstained cells. The underlying key principle of this technique is to interfere the scattered light by a specimen with the high spatial-frequency content with an attenuated, 0.5π phase-retarded illumination containing the low spatial frequencies (i.e. DC component). This maximizes the intensity contrast in the interference images. Conventionally, this requires a set of bulky Fourier optics components for filtering and selective phase retarding elements, limiting its use in certain applications.

Here, we propose ultracompact phase-contrast Fourier optics elements with unprecedented high angular accuracy by using a planar guided-mode resonance structure. We designed 40-nm-thick, 160-nm-wide Si3N4 gratings on a 130-nm-thick Si3N4 slab waveguide with a lattice constant of 370 nm. The structure can be used to perform phase-contrast microscopy by interfacing the normally incident plane wave to the guided-mode resonance at a 645 nm illumination wavelength. This facilitates 90% amplitude reduction and 0.5π phase pickup for the DC incident illumination while leaving the scattered, non-DC Fourier components from a specimen passing through with near unity transmission. We deposit the Si3N4 waveguide on a quartz substrate by low-pressure chemical vapor deposition (LPCVD) and fabricate the grating with electron beam lithography and reactive ion etching (RIE). We also characterize the optical dispersion properties of the fabricated samples in a home-built angle-resolved-spectroscopy setup and observe the high quality guided-mode resonances (Q~100). This Q corresponds to ~0.5° angular accuracy in selecting the Fourier components for amplitude reduction and phase retardation. Our guided-mode resonance structures can be used in a conventional optical microscopes and we expect this opens a promising avenue for compact, flexible, and high-quality phase-contrast microscopy.

Photonic Materials for Deep Space Exploration Artur Davoyan; University of California Los Angeles, United States

In this talk we give an overview of our work on solar and laser sailing for deep-space travel in our solar systems and beyond. We will show that with the use of novel materials and lightweight photonic designs, radiation pressure forces may be harnessed to enable ultrafast maneuvering and travel. We will show that both solar and laser sailing may be used to enable revolutionary in-space propulsion. Hence, we will discuss conceptually new solar sail designs that making use of solar gravity assist and can be propelled to unprecedented >30 AU/year velocities. These sails maybe ideally fitted for interstellar probe missions. The close solar approach requires design of novel photonic materials capable of withstanding high solar flux. Laser sailing, on the other hand, may pave the way to near speed of light (20% of the speed of light with a ~100 GW laser) space travel enabling exploration of interstellar space and neighboring stars. We will highlight the conditions needed, discuss sail materials challenges, and provide a brief overview of problems such a mission might face. We will than show that with a smart photonic design many of the challenges facing laser propulsion may be alleviated.

3:30 PM EL01.24.02
Self-Assembly of Soft Matter in Porous Solids—From Multiscale Physics to Designing Metamaterials Kathrin Sentker, Manuel Brinker, Mark Busch and Patrick Huber; Hamburg University of Technology, Germany

Self-organized multiscale porosity in terms of precise pore size, shape, and orientation has been achieved in many base materials. Here we exemplify that in combination with self-assembly of soft fillings in pore space this provides particularly versatile pathways for the engineering of functional materials [1]. First, we present a nanoporous semiconductor/polymer hybrid with tunable electro-strain and will relate the macroscopic deformation to meso- and nanoscale electroactuation. Second, we show that embedding liquid crystals in nanoporous solids provides novel opportunities for subwavelength control of light-matter interactions on the single-pore scale and thus to fine-tune the optics of these materials. To that end we present reciprocal space mappings employing synchrotron-based 2D X-ray diffraction in combination with high-resolution birefringence experiments on disk- and chiral rod-like molecules confined in monolithic nanoporous silicon, silica and alumina. As a function of pore hydrophilicity and thus distinct molecular anchoring at the pore walls we observe a remarkably rich self-assembly behavior, unknown from the bulk state, such as a quantized formation of concentric discotic rings [2], a transition from axial to radial aligned discotic columns and the formation of pore-axis aligned supemolecular helices [3]. Intimately related with this surprising self-organization at the nanoscale the soft-hard hybrid materials exhibit novel metaphotonic functionalities encompassing optical anisotropy step-wise changing with temperature [2], enhanced light rotation and extremely fast electro-optically active Goldstone excitations typical of para-to-ferroelectric phase transitions [3]. Self-assembly of radial aligned rings and axial aligned columns of disk-like molecules in cylindrical alumina nanopores as evidenced by X–ray diffraction. This results in an either prolate or oblate ellipsoid of refractive indices (indicatrix) aligned to the pore axis direction. Thus, linear polarized light is split up by a parallel array of such pores into two beams with perpendicular polarizations and distinct propagation speeds. Their relative phase shift (retardation R) after passing the birefringent pore array is positive or negative, respectively, and vanishes upon heating to the isotropic liquid state.

Beyond Solubility—Hyperdoped Silicon for Near-Infrared Plasmonics

Jura Rensberg\textsuperscript{1}, Kevin Wolf\textsuperscript{1}, Martin Hafermann\textsuperscript{1}, Sebastian Geburt\textsuperscript{2} and Carsten Ronning\textsuperscript{1}; \textsuperscript{1}Friedrich Schiller University, Germany; \textsuperscript{2}INNOVAVENT Laser Optics, Germany

The free charge carrier concentration of semiconductors, such as in silicon, is tunable over several orders of magnitude. Thus, the plasma wavelength of these materials can be adjusted over a wide spectral range by controlling the doping concentration. Comparable to noble metals in the ultraviolet/visible spectral region, highly doped semiconductors possess 'metal-like' optical properties but typically limited to the mid infrared region due to the solubility limit of dopants.

We demonstrate that the range of accessible plasma wavelengths can be extended far into the near-infrared region reaching the telecommunication wavelength by hyperdoping of silicon – doping beyond the solubility limit - using two non-equilibrium processes: high fluence ion beam doping and subsequent pulsed laser annealing. Laser annealing using high intensities over very short time scales leads to surface layer melting followed by rapid resolidification, which allows exceeding the solubility limit.

Further, we demonstrate how area selective activation of dopants by focused laser annealing can be used as a fabrication-friendly platform for flat optical and plasmonic devices. Detailed characterization of the optical properties of silicon is performed at various doping levels, and diffractive optical elements and plasmonic surfaces that operate in the near-to-mid infrared regime are presented. Our resulting devices are monolithic, flat, resilient to thermal and physical damage, and can be easily integrated into other silicon-based platforms.

Dynamic Nano-Optics Enabled by Stimuli-Responsive Polymers

Irina Zubritskaya\textsuperscript{1}, Alexandre Dmitriev\textsuperscript{2}, Sara Nocentini\textsuperscript{3}, Daniele Martella\textsuperscript{3}, Diederik Wiersma\textsuperscript{3} and Mark L. Brongersma\textsuperscript{1}; \textsuperscript{1}Stanford University, United States; \textsuperscript{2}University of Gothenburg, Sweden; \textsuperscript{3}University of Florence, Italy

Planar nano-optical elements beyond the diffraction limit are envisioned to replace the conventional refractive optics and are already providing needed functionalities to build lenses, beam deflectors, holograms and polarizing interfaces [1]. Their key elements are the nanoantennas that operate via plasmon or Mie-type optical resonances and are able to confine light on the nanoscale and modify its fundamental properties such as scattering, directionality, polarization and phase. However, a significant demand exists for the real-time steering of light in such optics. Here, we combine for the first time Mie-resonant and plasmonic nanoantennas and the light-responsive elastomers to create a fundamentally new dynamic / real-time tunable optical platform for reflected or transmitted light control.

We build a tunable optical platform based on nanoantennas and stimuli-responsive polymers, already well known to the fields of haptics and soft robotics, and also as artificial muscles, due to their strong yet soft actuation properties. For that, we employ liquid crystalline elastomers (LCEs) that are a special type of elastic polymers with self-organization and the ability to reversibly change their microscopic shape in response to the external stimuli such as temperature, irradiation with light or the electric fields (via resistive heating or piezo-like response) [2]. We further functionalize the LCE with photoswitchable molecules (azo-derivatives) incorporated to the molecular network, which makes elastomers light-responsive and capable of producing large mechanical strains upon illumination. By spacing the nanoantenna’s elements with LCE we change their mutual positioning upon actuation, thus providing the change in scattered light’s propagation, polarization and phase. We also demonstrate that the desired photomechanical strains and modified optical response can be programmed by careful chemical engineering of the molecular network. For that, we employ lithographic techniques such as direct laser writing (DLW) to produce high-resolution three-dimensional (3D) nano- and micro-scale structures and add the nano-mechanical functionality to optically resonant nanoantennas [3].

Phonon Polaritons and Biphasotropy in α-MoO₃
Sina Abedini Dereshgi, Xianglian Song, Akshay A. Murthy, Vinayak Dravid and Koray Aydin; Northwestern University, United States

Since successful demonstration of graphene as a monolayer 2D material, scientific community significantly expanded layered van der Waals materials family with different electronic, optical, mechanical and thermal properties which are pivotal in the quest for miniaturized photonics. Here, we investigate the optical properties of α-MoO₃ both theoretically and experimentally. Due to strong anisotropy of α-MoO₃ in all 3 dimensions, it is expected to show three distinct Reststrahlen (RS) bands in mid-IR wavelengths which can give rise to the excitation of phonon polaritons within these RS bands. Phonon polaritons have significant implications for optical device design due to their unique properties such as wavelength shrinking and low loss. The optical properties of α-MoO₃ can adequately be described using the phenomenological Lorentz oscillator model with parameters estimated in literature. Applying this relation, the complex dielectric constant of α-MoO₃ is calculated which is in turn used to obtain the dispersion relation of α-MoO₃ in x, y and z directions. After confirming our optical model, we propose a thin film multi-layer structure in order to experimentally examine the traces of the mentioned three RS bands through enhanced absorption as a result of phonon polariton excitation. The proposed structure, from bottom to top, is composed of thick Au, Ge and transferred α-MoO₃. In particular, two samples with two different thicknesses of Ge (400 nm and 800 nm) are fabricated. The reflectance (R) versus wavenumber measurements are carried out using FTIR to obtain the total absorption (A). Since the thick Au suppresses any transmission, the total absorption can easily be calculated using the R data. The FTIR results illustrate absorption peaks around 800 cm⁻¹ (12 μm) and 550 cm⁻¹ (18 μm) which represent the x and y direction (in-plane) phonons respectively. Furthermore, polarized incident light measurements in FTIR emphasize polarization-dependent absorption in α-MoO₃ which is an explicit outcome of perpendicular x and y phonons, where one of the in-plane resonance peaks is maximized only when the other one disappears. In order to explain the observed results in further depth, simulations are carried out using TMM and FDTD methods which are in agreement with the experiments. In order to have accurate simulation results, the thickness of α-MoO₃ flakes are measured by AFM and introduced to simulation. Our simulation results show Fabry-Perot (FP) effect in the Au/Ge/α-MoO₃ structure which enhances the absorption. Specifically, for the sample with 800 nm thick Ge, the FP resonance is intentionally designed to occur in the vicinity of the x-phonon peak. Therefore, the x-phonon peak is intensified which further supports our discussion. Since our measurement method relies on normal incidence measurement, there is no electric field component in z-direction. As a result, excitation of z-phonons is not viable. In order to circumvent this issue, we have designed and fabricated a new structure. A patterned layer of periodic Au nanodisks is added to the top of α-MoO₃ in Au/Ge/α-MoO₃ structure. When illuminated, the nanodisks diffract light and facilitate the coupling of radiation to the z-phonons of α-MoO₃. The absorption peak near 10 cm⁻¹ (10 μm) can be spotted in both experiments and simulations which justifies the observation of z-phonon polariton excitation. The electric field simulations are in line with the expected enhancement of z-component of the electric field. The outstanding anisotropy of α-MoO₃ in three directions can open new paths for mid-IR optics and it can provide unprecedented opportunities to engineer low-loss optical devices for the crucial mid-IR atmospheric window (8 – 12 μm).

Kerker-Conditioned Dynamic Nanoprints for Cryptographic Application
Jaehyuck Jang and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Metasurfaces are 2D metamaterials; they have exciting optical behaviors and interesting applications as ultrathin optical devices for nanoscale-resolution imaging, sensing, holograms and nanodisplay. Plasmonic metasurfaces, studied so far have inherent metallic-loss in the visible regime, so they have poor color saturation. Instead of plasmonic coloring, all-dielectric metasurfaces such as silicon metasurfaces offer an alternative way to generate colors by exploiting Mie resonances [1,2]. Nevertheless, for the next step toward real-life applications, the metasurface coloration demand a broad color spectrum as well as dynamic/tunable functionality which many of research are dealing with recently [3]. Therefore, we should consider three main aspects: material selection, structural design and the dynamic colour mechanism. All-dielectric materials are preferred to avoid optical losses that exist in conventional metals. The metasurfaces should be designed based on deep physical understanding of the
nanoantenna’s scattering behavior to achieve vivid and bright colours. Lastly, the dynamic colour mechanism requires a fast response and the compatibility to work with electrically driven devices. Here, we would like to introduce our significant effort which realize cryptographic nanoprints by metasurface coloration and thus will achieve a substantial step forward towards enhanced security printing applications [4].

1) Our hydrogenated amorphous silicon (a-Si:H) metasurfaces achieve diverse colours due to high refractive index and near-zero extinction coefficient of a-Si:H. 2) We deploy nanocuboid-antennas which is designed based on Kerker’s condition for tunable functionality. Unidirectional scattering tuned by the asymmetric nanoantenna’s spatial dimensions and polarization state enable a wide colour gamut and modulation range. 3) We design and experimentally demonstrate cryptographic nanoprints that contain encrypted optical information under unpolarized light, where the hidden information can be decoded under polarized light of a specific angle. This dual optical data storage enables doubly-secured QR codes as cryptography and microprints as steganography, respectively. We success to scan those QR codes with smartphone scanner. Consequently, we were able to connect nano planar optics with smartphone technology spread out all over the world. This research hastens the date when the meta-prints technology will be deployed on a commercial use.

Developing Ferroelectric Materials to Generate Giant Electrocaloric Effect Qiming Zhang; The Pennsylvania State University, United States

Electrocaloric effect (ECE) is the ability of a dielectric to change its temperature and entropy as an electric field is applied and released. ECE provides an effective means to realize solid-state cooling that is environmentally benign
and potentially highly energy efficient. During past several years, we have been investigating approaches in developing ferroelectrics which can generate giant electrocaloric effect over a broad temperature range. This talk will present these progress, especially, on how to generate a large ECE under low electric fields.

9:00 AM EL02.01.02
Reversible and Irreversible Pyroelectricity—Thermal Expansion and Ferroelectric Imprinting in P(VDF-TrFE) Christian Peter and Herbert Kliem; Electrical Engineering Physics, Germany

We investigate and discuss the pyroelectric response of poled and unpoled thin films of the ferroelectric co-polymer P(VDF-TrFE) at a composition 70/30 mol%. Having the films prepared in a low humidity environment reduces the dark current yielding polarization versus temperature hysteresis loops in unprecedented resolution. The loops are recorded between the glass transition temperature and the melting temperature. Poled and unpoled films are presented to exhibit clear first order Curie transitions. In poled samples we monitor a current in close vicinity to the Curie transition, which is assigned to detrapped charges released from the crystal-amorphous interface.

In the later sections of this work we show, that below the Curie transition, the pyroelectric response in poled films can be divided in reversible and irreversible contributions. The reversible contributions are a result of the thermal expansion of the non-ferroelectric amorphous phase in association with rigid ferroelectric crystallites. The irreversible contributions can be assigned to imprinting. Imprinting is an aging mechanism: Stray fields generated by the ferroelectric polarization in the ferroelectric crystallites, force the dipoles outside the ferroelectric crystallites to reorient anti-parallel to the ferroelectric polarization vector. According to that, the irreversible pyroelectric response is a current caused by dipole reorientation processes in the polymer due to internal fields. A consecutive annealing procedure below the Curie transition is used to experimentally separate the reversible from the irreversible pyroelectric response. Then, with the aid of numerical calculations, we model the current flow due to irreversible pyroelectricity. We show that above a certain temperature (Ta=45°C), the relaxation processes associated to imprinting / irreversible pyroelectricity stop being Arrhenius-like and start following a compensation law. We think that these relaxation processes take place at the surface of ferroelectric crystallites, in the so called defect-ferroelectric (DFE) phase. The DFE phase is postulated to be located at the boundary crystal-amorphous, so to say enveloping the ferroelectric crystallites. The conjecture that the relaxation processes associated to imprinting / irreversible pyroelectricity are located in the DFE phase is founded on two facts: First, the temperature Ta coincides with the onset-temperature at which the cell parameters of the DFE phase start to continuously expand with increasing temperature due to inclusion of defects. Besides, the DFE phase with fast changing cell parameters seems suitable to host non-Arrhenius-like relaxation processes. Second, both, the compensation law and the DFE phase depend substantially on the Curie Temperature. We conclude with the hypothesis, that there is an interphase at the crystal-amorphous interface, which hosts relaxation processes associated to imprinting.

LIMM Analysis and Geometry Depending Characterization of Novel Lead-Free Pyroelectric Materials for IR Array Detectors Sebastian Bette1, Stefan Tappertzhofer1, Simon Fichtner2, Thorsten Schmitz-Kempfen1, Bernhard Wagner2, Norman Laske3, Carl Van Buggenhout4 and Stephan Tiedke1; 1aixACCT Systems GmbH, Germany; 2Institute of Material Science, Christian-Albrechts-Universität, Germany; 3Fraunhofer Institute for Silicon Technology, Germany; 4Melexis Technologies NV, Belgium

New non-toxic biocompatible materials with piezoelectric and pyroelectric properties are developed for biomedical applications. Lead-free pyroelectric thin films are promising candidates for CMOS compatible and environmental-friendly miniaturized infrared sensors. Piezo responsivity of pyroelectric materials due to mechanical clamping makes the electrical response to transient thermal changes depended of geometrical properties of the pyroelectric material and its mounting. In this study, we report on the characterization of micro structured pyroelectric thin films. By measurement of the transverse effective piezoelectric coefficient, pseudo pyroelectrical contribution due to piezoelectric clamping can be separated from real pyroelectricity. Our novel IR-laser-based measurement setup is designed to record frequency dependent electrical response to spot wise intensity modulated IR irradiation of the sample surface and provides 2D responsivity maps. 3D information of the pyroelectric properties is extracted by LIMM (Laser Intensity Modulation Method). Therefore, the modulation of the IR source is swept up to high-frequencies while recording the sample’s electrical response (including absolute value and phase angle) by a lock-in amplifier. Thermal distribution inside the pyroelectric material is simulated to extract the material’s polarization distribution distribution out of the LIMM data. These results are complemented by microscopic techniques for fundamental
thermal analysis below the microscale. Our novel laser-based measurement setup is an essential step forward for precise material characterization with high spatial resolution for research and can be easily adapted for quality control on industrial scales to enable pyroelectric IR sensor arrays for mass-manufacturing.

9:30 AM EL02.01.04
Development of Functional Piezoelectric Polymers Based on Controlling Flexible Structure Takashi Nakajima1,2, Yoichiro Hashizume1, Takeo Furukawa3,1 and Soichiro Okamura1; 1Tokyo University of Science, Japan; 2Japan Science and Technology Agency, Japan; 3Kobayasi Institute of Physical Research, Japan

Vibrational energy harvesting using piezoelectric materials has been an emerging topic of a renewable energy technology. The technology has a possibility to establish a self-powering device for IoT system that do not depend on conventional power supplies such as batteries, which can deliver electric power only for limited-duration operations. Therefore, the technology is expected to apply to novel sensors for health care and intelligent buildings [1]. The inorganic piezoelectric materials such as Pb(Zr, Ti)O3 have been a promising material which shows highly efficient energy conversion owing to their high electromechanical coupling coefficients. From another point of view, power generation using piezoelectric polymers such as polyvinylidene fluoride (PVDF) are also attractive because of their prospective features of the robustness, flexibility and large scale production. Note that piezoelectric polymers are expected to generate high electric power under large deformation. For example, we designed the power generating systems which enable PVDF to induce large strain by applying a lever structure. The power generating floor generated 7 mW by human stamping [2], which is relatively large output using a piezoelectric material. However, the variety of the piezoelectric polymer is still limited. Thus, we have focused on developing the novel piezoelectric polymers which are more flexible, easy to install everywhere and eco-friendly. Firstly, we report on the self-polarization phenomenon observed in melt-crystallization process of VDF copolymer thin films. Ferroelectric polarization was spontaneously formed when Pt was used as the bottom electrode [3]. Thus, the poling process can be omitted by controlling the crystallization process, which has the advantage to avoid the breakdown. In addition, we also report on the recent progress of VDCN/VAc copolymer. VDCN/VAc is known as an amorphous polymer with great dielectric property and relatively large piezoelectric property. However, the mechanism of the piezoelectricity has not been understood yet. We have revealed that VDCN/VAc has nanoscale domains observed by scanning probe microscopy. Based on controlling the hierarchical structure of the polymer, we challenge to improve the energy conversion efficiency and formability for the fabricating process of the vibration energy harvesting devices.

Nanoscale Switching Behavior of Molecular and Polymer Ferroelectrics Alexei L. Gruverman; University of Nebraska-Lincoln, United States

Piezoresponse Force Microscopy (PFM) has been used to investigate the switching behavior in ultrathin films of PVDF-TrFE. The mechanism of polarization reversal has been investigated via sub-10 nm real space imaging of domain pattern evolution under an applied electric field. The domain switching behavior revealed in PVDF-TrFE nanomesas is drastically different from that observed in inorganic solid-state crystalline ferroelectrics. The
nanoscale features of the switching process include remote domain nucleation and spatially nonuniform wall velocity. Local switching spectroscopy and domain dynamics studies relate the observed switching features to a random-bond type disorder associated with defects in conformation and molecular packing. The PFM approach has been also used for investigation of the static and dynamic behavior of ferroelectric domains in diisopropylammonium bromide (DIPA-B) microcrystals. It is shown that stable head-to-head or tail-to-tail domain configurations can be realized in DIPA-B. In-plane alignment of polarization allows investigation of the forward domain growth along the polar axis - a process that is difficult to attain in conventional ferroelectric switching studies. Using this sample geometry, we have directly measured anisotropy of the domain wall velocity for the forward and lateral growth and demonstrate the effect of the forming charged domain walls on morphology of the growing domains.

Mapping the Microscopic Electric Fields of a Self-Assembled Anti-Ferroelectric Material with Vibrational Spectroscopy Aaron Rury, Sydney Lavan, Cathleen Saraza, Adedayo Sanni and Kanwar Bhullar; Wayne State University, United States

The bulk polarizability of self-assembled anti-ferroelectric materials is central to the energy storage capabilities of these molecular solids. This polarizability critically depends on poorly understood electric fields on length scales smaller than constituent molecular units. In this study we use vibrational spectroscopy of single crystals of the anti-ferroelectric material 2-trifluoromethylbenzimidazole (TFMBI) to directly analyze these fields and how they change with temperature. Experimentally, we find cooling the material causes red-shifts of Raman-active peaks near 3100 cm\(^{-1}\) and blue-shifts of peaks between 900 cm\(^{-1}\) and 1600 cm\(^{-1}\). Density functional theory calculations provide assignments of these reporter vibrations. By comparing solid-state spectra to those acquired from molecules dissolved in different solvents, we are able characterize the direction and magnitude of changes to microscopic electric fields in TFMBI. We discuss how to relate the measured changes in the microscopic electrostatic structure of the material to temperature-dependent changes to its macroscopic dielectric properties. These results indicate vibrational spectroscopy may be a critical tool in assessing the microscopic electric fields central to the application of self-assembled materials in energy storage applications.

Correlation Microanalysis of Nanoscale Mechanical Property and Molecular Orientation of PVDF Based Copolymer Using Dynamic and Infrared Atomic Force Microscopy Wen Qian, Shuo Sun, Charles Nguyen, Stephen Ducharme and Joseph A. Turner; University of Nebraska-Lincoln, United States

Electrically active materials, such as Poly(vinylidene fluoride) (PVDF) and its copolymers, have the ability to harvest mechanical energy through mechanical vibrations and structural flexing. The ferroelectric phase of PVDF consist of long chains of the dipolar VDF (–CF\(_2\)-CH\(_2\)) monomer that crystallize in a quasi-hexagonal close-packed “β-phase” structure with the molecular dipoles aligned perpendicular to the chain axis, producing a switchable spontaneous polarization and consequently, a significant piezoelectric response. Due to the inherent nanoscale dependency of PVDF’s molecular structure, quantitative methods for nanoscale molecular structure and mechanical analysis are limited. In this presentation, we demonstrate the methods for investigating the local mechanical properties quantitatively. These properties include the elastic modulus and damping which are measured using contact resonance atomic force microscopy (CR-AFM). In addition, we have used nanoscale infrared (nanoR) spectroscopy with chemical mapping to probe the correlation between localized molecular structure and orientation on the nanoscale. The thin PVDF nanomesa studied here were made from a copolymer of 70% vinylidene fluoride and 30% trifluoroethylene, P(VDF-TrFe) using the horizontal Langmuir-Blodgett transfer technique. This nanomesa film was formed on a substrate of a p-type silicon wafer by a drying and fine annealing procedure. For CR-AFM, the height image, frequency map, and Q factor map are collected, which allows for the investigation of the local mechanical properties associated with the in plane and out of plane structure. In general, higher frequency value means stiffer and higher Q value reflects less energy dissipation. The orientation of PVDF’s molecular structure dependency was investigated by rotation of the sample stage. The distribution of the polymer chain axes was determined from the asymmetric frequency mapping -- which is attributed to the local stiffness of in-plane structure. The results demonstrate that CR-AFM can aid in the understanding of the fabrication process, to achieve high crystallinity and orientation with good mechanical properties. The nanoR mapping data were used to determine the crystalline orientation of an individual nanocrystal. By fixing the wavelength at 1078 cm\(^{-1}\) the C-C antisymmetric stretching absorption band can be mapped for the nanomesa crystal. In this way, we identified higher
signals when the IR laser was aligned with the C-C-C chain and lower signals were found when the IR laser was not aligned. A similar approach was used to determine molecular orientation, where the IR laser direction is changed to investigate the orientation dependency within the nanomesa structure -- which is consistent with the stage rotation done for the CR-AFM measurements. Through combination of CR-AFM and nanoIR, we are able to correlate the molecular structure and localized mechanical properties, to optimize the electroactive polymer organization. This approach can guide the design and fabrication of high-performance, flexible, energy-harvesting devices. [Research supported by the Nebraska Center for Energy Sciences Research].

Effect of Local Polar Environment and Phase Morphology on Organic Optoelectronics Aditi Khirbat1, Ilaria Bargigia1, Artem Levitsky2, Mark D. Losego1, Carlos Silva1, Gitti L. Frey3, Lee Richter3 and Natalie Stingelin1;
1Georgia Institute of Technology, United States; 2Technion - Israel Institute of Technology, Israel; 3National Institute of Standards and Technology, United States

Combining semiconducting and ferroelectric functions in a given architecture has been a long-time goal in the electronics community. Various approaches have been used1,2 to blend semiconductor and ferroelectric polymers for micro- and opto-electronic applications. Here we discuss model systems based on the archetypal semiconducting polymer poly(3-hexylthiophene) (P3HT) blended with the ferroelectric commodity polymer poly(vinylidene difluoride) (PVDF), to provide insights on the effect of the local environment and phase morphology, manipulated by the addition of PVDF, on the optoelectronic properties of P3HT. Unlike the phase separated structure generally reported in these blends1,3 we present signs of intermixing, with varying P3HT domain purity and crystallinity as a function of PVDF. We show strong influence of these structural effects, along with the blending induced effects of the ferroelectric β phase of PVDF, on the photo-physical processes of the semiconductor. We illustrate variations in the photoluminescence and charge dynamics of photo-induced absorption with blend compositions, suggesting localized enhancements of the polar, dielectric environment in the blend. Finally, a correlation between structure and relevant dielectric and semiconducting features is demonstrated, opening pathways to design new multicomponent material systems with multifunctional architectures for optoelectronic applications.

1:30 PM *EL02.03.01
Highly Ordered Molecular Organic Ferroelectric Films by Soft Lithography Techniques Ilaria Bergenti1, Giampiero Ruani1, Silvia Milita2, Fabiola Liscio2, Franco Dinelli3, Xiaofeng Xu4, Indre Urbanaviciute5, Martijn Kemerink6 and Massimiliano Cavallini1; 1ISMN CNR, Italy; 2IMM CNR, Italy; 3INO CNR, Italy; 4Chalmers University of Technology, Sweden; 5Linkoping University, Sweden

Ferroelectric molecular compounds present great advantages for application in electronics because they combine the high polarization values, comparable with those of inorganic materials, with the flexibility and low cost properties of organic ones. However, some limitations to their applicability are related to the high crystallinity required for deploying the ferroelectricity. Highly ordered ferroelectric patterned thin films of disopropylammonium bromide have been successfully fabricated by lithographically controlled wetting technique. Confinement favors the self organization of ferroelectric crystals, avoiding the formation of polymorphs and promoting long range orientation of crystallographic axes. Patterned structures present high stability and polarization can be switched to be arranged in stable domain pattern for application in devices. The versatility of this methods allows to extend the results to the class of molecular ferroelectric materials.
Deuteration can be used as an effective probe for dynamic and structural properties of ferroelectric materials, especially those based on hydrogen-bond ordering, such as potassium dihydrogen phosphate (KDP) [1]. The diisopropylammonium halide (DIPA-X, X = Cl, Br, I) system is a ferroelectric material of interest due to its high room-temperature polarization, low coercive field, and low material cost [2]. The three DIPA halides all share similar structures and ferroelectric properties. In particular, on heating, the ferroelectric P21 phase gains a mirror plane to become the paraelectric P21/m phase. While the DIPA halides aren’t strictly hydrogen-bond-ordered ferroelectrics, they do contain NH–X hydrogen bonds, which form a continuous chain along the polarization axis. This hydrogen-bond chain plays an important role in crystal structure and may also influence the properties of the ferroelectric phase. The purpose of this report, therefore, is to address the role of deuteration on the properties of DIPA-X ferroelectric materials. We found that deuteration of the amine hydrogens in DIPA-X is easily carried out by recrystallization from heavy water. Like KDP, DIPA-Br exhibits a negligible change in lattice spacing on deuteration. Deuteration also lowered the temperature of the peak low-frequency dielectric constant associated with the ferroelectric-to-paraelectric transition by approximately 0.5 K in DIPA-Br. Further study with differential scanning calorimetry (DSC) revealed deuteration lowered the ferroelectric–paraelectric transition temperature and decreased the associated temperature hysteresis for all three DIPA halides. DIPA-I exhibited the largest shift with a decrease in transition temperature of 2.9 ± 0.4 degrees to its phase transition temperature, and DIPA-Cl the lowest with decrease of 0.5 ± 0.1 degrees. The temperature shift is downward, rather than upward, as is observed with most hydrogen-ordered ferroelectrics. For example, deuteration of KDP increases the transition temperature by 91 K [1]. The enthalpy of the transition, which ranged from 3.6 ± 0.1 J/kg for DIPA-Br to 4.2 ± 1 J/kg for DIPA-I, exhibited negligible change on deuteration.

This work was supported by the National Science Foundation (NSF) through the Nebraska Materials Research Science and Engineering Center (MRSEC) (DMR-1420645).

Therefore, the crystals transformed from the non-polar phase to the ferroelectric phase occurs without changing morphology or exhibiting significant internal stress, suggesting that the transition is continuous. This hypothesis is further supported by the relatively low enthalpy of the transition (1.3 J/g), and the small (1%) change in density [1]. The elastic modulus of approximately 10 GPa is the same in both phases (<10%) change in the elastic modulus, which is approximately 10 GPa for both phases, although the loss modulus of the ferroelectric phase, at 1 GPa, is approximately twice that of the non-polar phase. This work was supported by the National Science Foundation (NSF) through the Nebraska Materials Research Science and Engineering Center (MRSEC) (DMR-1420645) and by the Nebraska Center for Energy Sciences Research.

Molecular Organic Piezo- and Ferroelectric Coatings and Fibbers for Biodegradable and Biocompatible Platforms for Tissue Engineering Paula Maria Vilarinho, Nathalie Barroca, Ana Marote, Sandra Vieira, Maria Helena Fernandes, Odete Silva, Paula Marinho, Marisa Costa and Ana Gil; Univ de Aveiro, Portugal

Creating new tissues and organs and promoting the regeneration of damaged or diseased tissues and organs are the objectives of tissue engineering and/or regenerative medicine. In spite of the complexity of regenerating tissues major advances have been achieved. The potential of piezoelectricity-stimulated cell migration and growth unveils appealing opportunities in tissue engineering, as the use of devices allowing surface charges to be controlled in real time by simply applying a mechanical stimulus.

Poly (l-lactic) acid (PLLA) is an FDA approved biodegradable and piezoelectric polymer that has been object of extensive research, namely as a scaffolding material and drug delivery system. Here, we exploit the feasibility of using electrical polarization in PLLA coatings and aligned nanofibers and investigate the biological outcome of these electrically-induced poled PLLA platforms on neuronal relevant in vitro models. In addition we have carried out a metabolomics study of the effects of PLLA (either non-poled or negatively poled) on the metabolism of osteoblastic HOb cells, aiming at unveiling the metabolic cell adaptations to PLLA and its poled state. The presence of PLLA seems to trigger cell catabolism and anti-oxidative protective mechanisms in HOb cells, while directing them towards cellular growth. A qualitative tendency for negatively-poled PLLA to be more effective in sustaining cell growth than non-poled PLLA was suggested. Finally, the concept of a biological BioMEMs platform composed of piezoelectric PLLA and 316L stainless steel is proposed as an alternative to be used in the implant technology.

Molecular Ferroelectrics with Perovskite Structures Yu-Meng You; Southeast University, China

Molecular ferroelectrics with cheap, light-weight, flexible, wearable, and environmentally benign characteristics have been an attractive research topic in the past decades due to the potential applications in data storages, piezoelectric sensors, actuators, and nonlinear optical devices. Their intrinsic structure-property flexibility attracted particular interest for molecular design towards new materials with good ferroelectric performance at room temperature. Nevertheless, developing a reliable method to form polar structures and further tune the ferroelectricity is an imminent ongoing challenge.

In this talk, we present our recent achievements on molecular ferroelectrics in perovskite structures with new design strategies of selection of molecular building blocks and several new molecular ferroelectrics with exciting ferroelectric, optical and piezoelectric properties.

Alternating Current Sensors, Memories and Displays with Ferroelectric Polymer Driven Sound Cheolmin Park and Jong Sung Kim; Yonsei University, Korea (the Republic of)

Visualization of human senses has been of great interest for developing an emerging interactive display that can artificially stimulate synesthesia with numerous unprecedented applications. Especially, visualization of various daily sound and music, which are much more complicated than human touch, in a form of flexible thin film devices can be a great challenge. In this presentation, we first present flexible artificial synesthesia devices that visualize continuous and complicated sounds. The device is made of a thin composite film of a piezoelectric polymer for sound generation and inorganic electroluminescence (EL) microparticles for direct visualization of input sound signals. Field-induced alternating current (AC) EL of the microparticles in the device depends upon the source sound wave, making their EL synchronized with sound arising from the piezoelectric actuation. Our device showed extreme mechanical tolerance that can be repeatedly folded and crumpled with visible sound, allowing a variety of unexplored applications including synchronous sound-lightings and wearable, on-body sound-vision systems to facilitate emotional interaction of human being with sound in a human-friendly form. We also demonstrate that piezo and ferroelectric sound is capable of sensing, monitoring, and storing the information of various liquids. Our platform utilises sound arising from liquid-interactive ferroelectric actuation, which is dependent upon the polarity of the liquid. Liquid-interactive ferroelectric sound (LIFS) is successfully developed when a liquid droplet is placed on a ferroelectric polymer layer across two in-plane electrodes underneath the ferroelectric layer under an external in-plane AC field. An AC field built up vertically between one of the electrodes and the liquid results in ferroelectric vibration of the device, leading to sound. The sound pressure level (SPL) of the device depends upon the polarity of the liquid, allowing for facile liquid sensing and identification. More importantly, as the SPL arising from LIFS of a liquid is correlated with non-volatile remnant polarisation of the ferroelectric layer, the information of a liquid is readily stored and retrieved even after the liquid is removed, resulting in a sensing memory of the liquid. By programming different LIFSs on a thin film pad, we can also identify the 2D position of a liquid droplet on the pad. Moreover, our device successfully monitored the flow of a human serum liquid passing through channels with their diameters ranging from millimetres to tens of microns and determined its velocity. Mechanically flexible and optically transparent tube-type LIFS AC devices allow for in situ analysis of the flow of a liquid in terms of SPL.

4:00 PM EL02.04.02
Fabrication of Piezoelectric Rubber Materials with Flexibility Tatsuya Ota and Shogo Mamada; Railway Technical Research Institute, Japan

Piezoelectric Rubbers prepared with mixing piezoelectric-ceramic particles and an elastic material have potential applications such as sensor and actuator due to the piezoelectricity and flexibility. In our previous study, in order to enhance the piezoelectricity, aligned-type piezoelectric rubbers in which piezoelectric particles were aligned in the direction parallel to the thickness by an electric field were fabricated. Since the piezoelectric rubbers previously fabricated had thinner shapes and large spring constants, it has not had the flexibility sufficient to use as vibration-isolating materials.

In this study, in order to lower the spring constants, the aligned-type piezoelectric rubbers with a thickness of more than 5 mm were prepared. For the thinner conventional aligned-type piezoelectric rubbers, piezoelectric particles precipitated in a molding were easily aligned by an electric field due to the thin shapes. On the other hand, it was difficult to align piezoelectric particles only by an electric field in the case of thicker rubbers because the piezoelectric particles used were submillimeter in size and they tended to precipitate to the bottom of the molding by gravity. Hence, in order to prepare the thicker aligned-type piezoelectric rubbers, a novel process in which the molding was inverted before applying an electric field was introduced. In the process, a precipitation layer of piezoelectric particles was set to the top of the molding before applying an electric field. The piezoelectric particles
gradually precipitated in an uncured rubber medium by gravity, which supported to align piezoelectric particles by an electric field.

To confirm the formation of particle alignments, numerical simulations on the process in which the molding was inverted before applying an electric field were carried out. As the results of the simulation study, piezoelectric particles were aligned from the top to the bottom in the molding even if the piezoelectric rubbers had more than 5 mm of thickness. Thus, the numerical simulations clarified that the particle alignments were affected by particle position before applying an electric field. Furthermore, in the experimental study, considering the case that piezoelectric particles comparably fast precipitated after inverting the molding due to the low viscosity of a medium, the viscosity of a medium was controlled by changing the period from starting to heat an uncured medium to inverting a molding and applying an electric field, which led to adjusting the speed of particle precipitation. Based on the actual experiments, the aligned-type piezoelectric rubbers with thicknesses of 5 mm and 10 mm were successfully fabricated for the piezoelectric particle volume of 10–30%.

The piezoelectric performance of the piezoelectric rubbers obtained in this study was comparable to previous ones. For the piezoelectric rubbers with a thickness of 10 mm, the spring constants as small as approximately 1/30 of the conventional piezoelectric rubbers were obtained. The thicker aligned-type piezoelectric rubbers newly fabricated have potential uses as anti-vibrating and sensing materials.

Polymer Based Micromachined Ultrasound Transducers for Display-Like Applications David Cheyns; imec, Belgium

Traditional microphone units focus on human perceptible sound waves (between 20 Hz and 20 kHz). Acoustic development also includes the ultrasound region, compromising the frequencies above the detection limit of the human ear (from 20 kHz to several GHz). These sound waves can be used for a wide variety of applications, including medical imaging, therapeutic treatment, non-destructive testing, fingerprint detection, gesture recognition and mid-air haptic feedback. Nowadays, the ultrasonic transducer and sensor technology is largely based on rigid bulk piezoelectric ceramic materials, such as lead zirconate titanate or barium titanate. Classical techniques to grow such ceramic materials require high process temperature and dedicated substrates. Although this is a mature technology for discrete passive components, offering a reasonably wide bandwidth and sensitivity, it is not amenable to machine large two-dimensional (2D) transducer arrays. Monolithic integration with other electronic components such as signal processing electronics is hardly possible. For this, a display like process technology is required. During this presentation, I will give an overview of the recent developments at imec to use polymer based piezoelectric materials processed on glass substrates for large arrays of ultrasound transducers. Several challenges specific to organic material processing are tackled or under investigation: uniformity over larger substrate size, photo-lithographic based patterning, integration of the ultrasound elements with thin-film circuitry. Larger arrays of up to 64x64 elements are developed, which can be used to either emit ultrasound or to detect reflected acoustic waves. Using beam-forming techniques, the acoustic pressure can be focused on a single point in 3D space, which enables future application such as mid-air haptic feedback or local wound healing.

8:30 AM *EL02.05.01
Chain Dynamics Governing Phase Transition and Polarization Switching in Ferroelectric VDF-Based Polymers Takeo Furukawa¹, Hidekazu Kodama¹ and Takashi Nakajima²; ¹Kobayasi Institute of Physical Research, Japan; ²Tokyo University of Science, Japan

Ferroelectric vinylidene fluoride (VDF)-based polymers are overviewed with special interest on the chain dynamics governing phase transition and polarization switching phenomena. Their ferroelectricity originates in the large dipole moment of CH2CF2 unit. All-trans conformation and parallel packing induce alignment of all molecular dipoles to generate spontaneous polarization P_s that is switchable by action of high external electric field. The copolymer with trifluoroethylene (TrFE) containing 50-80mo% VDF exhibits Curie point T_c associated with...
transition into the paraelectric phase. As the VDF content exceeds 80 mol%, $T_c$ is overtaken by melting. For TrFE-rich copolymers, the paraelectric phase is preceded by the anti-ferroelectric phase consisting of randomly packed all-trans chains. Thus the phase behavior in VDF-based polymers is related to successive loss of intermolecular, intramolecular and crystalline dipolar order.

In the molten phase, VDF-based polymers assume a random mixture of three conformational states (TT, TG, TG’) and gain the conformational entropy of $R\ln 3$. That in the paraelectric phase is calculated to be $R\ln 1.6$. These values are consistent with the observed heat of transition at $T_m$ and $T_c$. Chain dynamics comprising such conformational disorder can be characterized by dielectric spectroscopy. One particular relaxation process has been found to exist near 1MHz at room temperature and to move toward higher frequency side to reach 1GHz on melting. Although the relaxation time shows down near $T_c$ in accord with dielectric anomaly, essentially the same chain dynamics govern the dielectric relaxation process. Below room temperature, the relaxation spectra split into two components. One is of VTF-type characteristic of segmental motion and the other is of Arrhenius type referred to a local mode. The latter is important because it lies on a linear extension to the molten phase with activation energy of 50kJ/mol. This is a clear demonstration of an elementary molecular motion governing the ferroelectric, paraelectric and molten phases.

The time domain measurements of polarization reversal using a step-wise electric field reveal another chain dynamics associated with 180-degree rotation of all-trans molecules about their chain axis. We have consistently examined the switching characteristics of VDF-based polymers from highly crystalline-thick to ultra-thin films. One of the common features is that the switching time obeys an exponential law that is transferred to a power law above 300MV/m. The fastest switching time was found to be limited to 1 ns at 800 MV/m. The time-resolved PFM confirmed that polarization reversal progressed via. nucleation-growth mechanism in respective crystalline grains filling VDF/TrFE thin film. The effect of high electric field in VDF-based polymers is not limited to polarization switching. It has been already established that extremely high fields lead to conversion among crystalline polymorphs of PVDF from nonpolar form II to ferroelectric form I via form IV and III. Another example is related to the observation that the VDF/TrFE films as prepared exhibit much reduction of dielectric constant after poling. This result is consistent with the reduction of lattice spacing and crystalline disorder. In the presence of dc field, $T_c$ moves to higher temperature side. Disorder induced by bulky TrFE in VDF sequence is a key factor for the appearance of $T_c$. Even if fully poled, there remains disorder inherent to ferroelectric instability. In VDF-based polymers, the elementary process observed dielectrically from molten phase to glassy state provides further information about such disorder.

9:00 AM EL02.05.02
Discovery of the Morphotropic Phase Boundary in Ferroelectric Polymers Yang Liu1, Haibibu Aziguli1, Bing Zhang2, Wenhan Xu1, Wenchang Lu2, J. Bernholc2 and Qing Wang1; 1The Penn State University, United States; 2North Carolina State University, United States

Significantly enhanced electromechanical responses are inherent to the piezoelectric materials at morphotropic phase boundary (MPB). However, this well-established physical concept has never been realized in organic materials. This work demonstrates the stereochemically-induced MPB in the ferroelectric copolymers. We reveal that compositionally tailored tacticity can lead to intramolecular order-disorder evolution in the crystalline phase and thus an intermediate MPB region allowing for simultaneous occurrence of competing ferroelectric and relaxor properties. Our first-principles calculations confirm the crucial role of chain tacticity in driving the formation of MPB via structural competition between trans-planar and 3/1-helical phases. The copolymer with the morphotropic composition exhibits significantly enhanced piezoelectric responses, approximately two times the state-of-the-art piezoelectric polymers. This finding (Y. Liu et al, Nature 562, 96 (2018)) not only enables the investigation of the mechanisms of MPB from a completely new perspective but also offers unprecedented opportunities for the development of scalable high-performance piezoelectric polymers that are promising for flexible, wearable and biocompatible applications.

9:15 AM EL02.05.03
Dipolar Doping of Organic Semiconductors to Enhance Carrier Injection Alexander J. Hofmann1, Simon Züfe2,3, Kohei Shimizu4, Markus Schmid1, Vivien Wessels1, Lars Jäger1, Stéphane Altazin1, Keitaro Ikegami2, Motiur R. Khan1, Dieter Neher1, Hisao Ishii4,4,4, Beat Ruhstaller2,3 and Wolfgang Bruetting1; 1Universität Augsburg, Germany; 2ZHAW Zürcher Hochschule für Angewandte Wissenschaften, Switzerland; 3Fluxim AG, Switzerland; 4Chiba University, Japan; 4Universität Potsdam, Germany
The strong dipole moment of polar organic semiconductor materials like tris-(8-hydroxyquinolate)aluminum (Alq3), if not oriented perfectly isotropic, will lead to the buildup of a giant surface potential (GSP), and thus to a macroscopic dielectric polarization of the organic film. Despite this being a known fact [1], the implications of such high potentials on charge transport and injection within and into an organic layer stack have only been studied recently. For example, we could explain and reproduce in silico the dependence of electron current in organic light emitting diodes (OLEDs) depending on the sign of the GSP of the electron transport layer (ETL)[2].

In this contribution, we will discuss the influence of the GSP of the hole transport layer (HTL) on hole injection into organic layers. Unfortunately, most hole conducting materials are either non-polar or show an isotropic orientation, hence we resort to the new concept of dipolar doping to tune the GSP of a hole conducting layer. Therefore, we chose the prototypical organic materials N,N’-Di(1-naphthyl)-N,N’-diphenyl-(1,1’-biphenyl)-4,4’-diamine (NPB) as host and Alq3 as dopant and varied the doping ratios to tune the GSP in the HTL of a prototypical OLED.

The mixtures are investigated in single-layer, monopolar devices with only the HTL as well as bilayer OLEDs with Alq3-doped NPB as HTL and neat Alq3 as ETL, respectively. The latter are treated as metal insulator semiconductor (MIS) structures following and applying our recently published method of charge extraction by linearly increasing voltage (CELIV) on polar OLEDs[3, 4].

Characterization is then done electrically using current-voltage characteristics, impedance spectroscopy, CELIV and time of flight, as well as optically with ultraviolet photoelectron spectroscopy. For all device types, we find an optimum in device performance and carrier injection for moderate doping concentrations of about 5%. By comparing all different methods with a focus on charge injection barriers, we reveal a complex relationship of carrier transport, substrate workfunction, modified injection and the effect of polarization, effectively manipulating charge carrier injection across the metal-organic interface and transport in the device.

9:30 AM EL02.05.04
Bulk and Interfacial Conductivity Switching in Organic Semiconducting Ferroelectrics Tim Cornelissen¹, Indre Urbanaviciute¹, Nicolas M. Casellas², Julia Guilleme², Tomas Torres², Miguel Garcia-Iglesias² and Martijn Kemerink¹; ¹Linköping University, Sweden; ²Universidad Autónoma de Madrid, Spain

Combining semiconductors and ferroelectrics is a promising strategy to realize novel non-volatile organic memories. While this has been demonstrated by blending ferroelectric and semiconducting polymers, we show that the same functionality can be incorporated in a single supramolecular material, solving amongst others phase separation and scaling issues. This unprecedented class of materials has a disc-like semiconducting core to which dipolar side groups are attached, making the materials both semiconducting as well as ferroelectric.

The ferroelectric and semiconducting properties are found to couple: the conductivity switches between a high and a low state when the ferroelectric polarization reverses. We show that there are two different switching mechanisms at play: bulk conductivity switching or injection barrier modulation. Depending on the material and the energy level alignment with the contacts, one of the two mechanisms will be dominant. Both mechanisms are rectifying, allowing for implementation in high-density, low-cost crossbar memory arrays.
Injection barrier modulation is the working mechanism behind the ferroelectric/semiconductor blends, and functions through a lowering of the injection barrier by the ferroelectric dipoles at the interface. The conductivity will switch from the low to the high state upon polarization reversal. This mechanism will be dominant when there is an injection barrier present.

In contrast, the bulk conductivity switching mechanism occurs when the energy levels of the material and the contact are well-aligned. Here the conductivity will switch from the high to the low state upon polarization reversal. Using a modified Marcus hopping model, we show that the asymmetric potential caused by the ferroelectric dipoles is responsible for the conductivity switching. Fitting the JV-curves to a combination of Ohmic and Space-Charge Limited current provides further proof for the conductivity switching being a bulk effect. This bulk conductivity switching is unique as in general conductivity switching mechanisms are caused by interface effects.

We have thus introduced a new class of materials that are both semiconducting and ferroelectric. The interplay of these two properties leads to rectifying and switchable conductivity. This makes these materials an excellent candidate for printable non-volatile memories.

Polymer Ferroelectric Non-Volatile Memories—Beyond the Single Bit Gerwin Gelinck1,2; 1TNO-Holst Centre, Netherlands; 2Technical University of Eindhoven, Netherlands

P(VDF-TrFE) based thin-film transistors and diodes have emerged as a promising storage technology for low-cost microelectronic applications on substrates such as plastic and paper. Items where today integration of a silicon chip is not economical, such as toys, cards, labels, badges, value paper, medical disposables, could be imagined to be equipped with electronics – with embedded memory functionality.

In this presentation, some of the higher-order integration aspects are discussed, as in almost all foreseeable applications, multiple memory devices are needed to store a multiple number of bits. An attractive architecture for exploiting the strengths of ferroelectric diodes for memory and logic is the cross-point array, without the need for transistors or other electronic components. In the context of memory, the memory cells are defined by patterning the top electrode into columns and the bottom electrodes into rows. The memory state is changed by addressing the corresponding row and column and applying a bias that will provide the desired ferroelectric polarization. To program all memory elements, each row is sequentially addressed. Large-size memory arrays – up to 1 kbit – will be demonstrated.

Other achievements reported here include multi-bit memory elements, via innovative schemes in fabrication as well as electric driving schemes; integration with relatively complex thin-film transistor addressing circuitry; and finally the combination with OLED pixels, resulting in non-volatile pixels.

Flexible Robust and High-Density FeRAM from Array of Organic Ferroelectric Nano-Lamellae by Self-Assembly Mengfan Guo, Yang Shen and Ce Wen Nan; Tsinghua University, China

Ferroelectric memories are endowed with high data storage density by nanostructure designing, while the robustness is also impaired. For organic ferroelectrics favored by flexible memories, low Curie transition temperature limits their thermal stability. Herein, we demonstrate a ferroelectric random access memory (FeRAM) based on an array of P(VDF-TrFE) lamellae by self-assembly. Written data shows enhanced thermal endurance up to 90 °C and
undergoes 12 thermal cycles between 30 and 80 °C with little volatilization. The promoted thermal stability is attributed to pinning effect at interfaces between grain boundaries and lamellae, where charged domain walls and charged defects are coupled. These results provide a novel strategy for improving robustness of organic flexible FeRAMs, and reveal an attracting coupling effect between different phases of ferroelectric polymer.

11:00 AM EL02.06.03
Ferroelectric Field-Modulation Imaging for Proton-Transfer-Type Organic Ferroelectric Thin Films Yohei Uemura1, Shunto Arai1, Jun’ya Tsutsumi2, Satoshi Matsuoka1, Hiroyuki Yamada2, Reiji Kumai3, Sachio Horiuchi2, Akihito Sawa2 and Tatsuo Haségawa1; 1The University of Tokyo, Japan; 2National Institute of Advanced Industrial Science and Technology (AIST), Japan; 3High Energy Accelerator Research Organization (KEK), Japan

The proton-transfer-type organic ferroelectrics are a novel class of ferroelectric materials composed of π-conjugated molecules that are linked by hydrogen bonding. The spontaneous polarization originates from the cooperative transfer of protons within the crystals as well as from the electric dipoles of π-conjugated organic molecules [1]. Many of the materials present room-temperature ferroelectricity with a much lower coercive field (10 – 20 kV/cm) than that of ferroelectric polymers (> 500 kV/cm). The soluble, lead-free, and rare-metals-free characteristics of the organic ferroelectrics allow us to expect that they could become useful components for printed electronics devices operating at low voltages [2]. Nonetheless, the appearance and dynamics of ferroelectric domains and domain walls in such a weak lattice-polarization coupling system are still unclear, although they primarily determine the ferroelectric switching characteristics.

Here we show that the variation in electro-optic response of π-conjugated organic molecules enables visualization of the ferroelectric domains and domain walls in organic ferroelectric thin films [3]. For this purpose, we adopt difference optical image sensing between the forward and reverse field applications with use of CMOS image sensor. We successfully demonstrate that highly sensitive and rapid visualization becomes possible by this technique which we call “ferroelectrics field modulation imaging (FFMI).” Based on the FFMI, we show that the unique optical-probe nature reveals the existence of two types of domain walls showing different three-dimensional orientations within the ferroelectric single-crystal films of Hdpzz-Hca: one type of domain wall is roughly perpendicular to the film plane, whereas the other is considerably tilted from the normal to the plane. We consider that both of the domain walls are neutral ones that are stabilized to generate substantial neutrality by being directed parallel to the direction of spontaneous polarization. We discuss and suggest that the FFMI technique opens a route for exploring the three-dimensional topological nature of domain walls in ferroelectric materials.

crystalline phases. In P(VDF-TrFE)-based polymers, nanoactuation is realized by the twisted-to-all trans conformation transformation. In polyamide-based polymers, nanoactuation is realized by the trans-to-twisted conformation transformation. This understanding will help us design new electroactive polymers for large electrostriction in practical applications.

Assessing the Individual Contributions of Dipolar, Trapped and Triboelectric Charges to Electrospun PVDF’s Electrical Response Valerie Rennoll, Ugur Erturun and James E. West; Johns Hopkins University, United States

Electrospun polyvinylidene fluoride (PVDF) has been widely investigated for energy harvesting and sensing applications due to its high sensitivity and flexibility. The electrical response of electrospun PVDF is largely attributed to the piezoelectricity of the polymer when poled and stretched to promote the β-phase. In this phase, dipolar charges are generated in the material when a force is applied due to the separation of hydrogen and fluorine atoms. However, when an air gap is present between the PVDF nanofibers and an electrode, the material can demonstrate an electrostatic response in addition to the piezoelectric response. This electrostatic response is created by surface and space charges that are trapped in the material during electrosprining, as well as triboelectric charges that are transferred between the electrode and material when in contact. The individual contributions of dipolar, trapped, and triboelectric charges in PVDF with an air gap present between the electrode and material remain unclear. In this work, each of these charge contributions is quantified and determined as a function of distance between the electrode and material, electrode material type, and duration, frequency, and load amplitude of the applied force. It is demonstrated that under certain conditions the piezoelectric response of electrospun PVDF is overwhelmed by the electrostatic response caused by trapped and triboelectric charges.

2:15 PM EL02.07.03
Unraveling the Electroactive Properties of Electrospun Silk Fibroin Vitor Sencadas1,1,2, Christopher J. Garvey3, Stephen Mudie4 and Gwenaël Gouadec5; 1University of Wollongong, Australia; 2Illawarra Health and Medical Research Institute, Australia; 3Australian Nuclear Science and Technology Organization (ANSTO, Australia; 4Australian Synchrotron, Australia; 5Sorbonne Université, France

Silk obtained from the formation of the cocoon during the larval stage of the Bombyx mori moth has been used in the textile industry for more than 5,000 years. This natural resource has found a wide range of applications, e.g. textiles, air cleaning filters, drug delivery, and tissue engineering [1, 2].
Silk fibroin (SF) is a copolymer made from heavy, light chains and a glycoprotein (P25) with a molecular weight of approximately 350, 26 and 36 kDa [1, 3, 4], respectively, linked together by a disulfide bridge [3]. While the heavy chain is predominantly made of alternating hydrophobic oligopeptides, the light chains are mainly hydrophilic and contain a high concentration of glutamic and aspartic acid residues [1, 2].
SF is known to have five different molecular structures: the metastable α-helix, also known as silk I; the trans-planar beta-sheets parallel to the fiber axis (silk II) with alternate amino acids chains projected to opposite sides of the sheet; turns and bends, beta strands and the polyglycine II, where the amino acids adopt a right-handed helix with three amino acids per turn [5].
SF presents a crystalline dimorphism, where the silk II crystals have a monoclinic unit cell [6, 7], while silk I crystallizes in an orthorhombic one [6]. The lack of center of symmetry on both crystalline units suggests that silk fibroin is piezoelectric, independently of the crystalline polymorphism present in the protein. Furthermore, the first quantitative measurements of silk piezoelectricity were made by Fukada [7] and reported a piezoelectric response of ≈1 pC.N⁻¹, similar to the piezoelectric constant of quartz crystal (≈2 pC.N⁻¹) [1, 7].
Here we will present our last findings in the understanding of the origin of silk piezoelectric properties. Silk fibroin processed by electrospinning has a high degree of orientation and is readily electrically poled. The electroactive properties of the protein were assessed by piezo-force microscopy (PFM) and correlated with its crystalline structure. A simple and cost-effective structure was fabricated to demonstrate the remarkable electroactive properties of this protein for energy scavenging and harvesting. The wearable nano-harvester device shows potential to be used in real-time monitoring of human physiological signals. Moreover, this work opens up new opportunities to explore silk fibroin materials as self-powered materials for biomedical and tissue engineering applications.

Charge Accumulation and Polarization in Electrospun Piezoelectric Nanofibres Tobias Cramer1, Francesco Calavalle2, Oliviero Bocchi1, Davide Fabiani1 and Beatrice Fraboni1; 1University of Bologna, Italy; 2CIC nanoGUNE, Spain

Electrospinning is a versatile processing technology that offers a promising route to achieve large quantities of oriented nanostructured piezo- and ferroelectric materials. The processing conditions during electrospinning open the opportunity to impact on material morphology and to improve electromechanical material properties. As a consequence electrospun piezo- and ferroelectric materials have been employed in ferroelectric memory, strain and pressure sensors as well as energy harvesters. Despite this interest, the detailed mechanism of how nano-confinement and high electric fields during electrospinning impact on material properties is yet to be discovered. Here we prepare PVDF-TRFE nano-fibres at different electrospinning conditions. We compare macroscopic electromechanical response of fibre mats with microscopic analysis performed by PFM switching spectroscopy and electrostatic force microscopy on single fibres.1 Our results show that while electrospinning favors the formation of the piezoelectric b-phase in the polymer, the electric field is not strong enough to achieve piezoelectric domain polarization. Instead we observe accumulation of space charge in the polymer that explains the more electret like macroscopic electromechanical response.

Ultrahigh β-Phase Content PVDF with Relaxor-Like Ferroelectricity for High Energy Density Capacitors Nan Meng, Xintong Ren, Giovanni Santagiuliana, Haixue Yan, Mike Reece and Emiliano Bilotti; Queen Mary University of London, United Kingdom

Poly(vinylidene fluoride) (PVDF)-based dielectric materials are prospective candidates for electric high power density energy storage applications because of their ferroelectric nature, high dielectric breakdown strength and superior processability. However, obtaining a polar phase with relaxor-like behavior in PVDF, as required for high energy storage density, is a major challenge. To date, this has been achieved using complex and expensive synthesis of copolymers and terpolymers or via irradiation with high-energy electron-beam or γ-ray radiations. Herein, a facile process of pressing-and-folding (P&F) is proposed to produce ferroelectric β-PVDF with relaxor-like behavior, without the need of any hazardous gases, solvents, electrical or chemical treatments. This simple and scalable processing route generates unprecedentedly high β-phase content (~98%) and relaxor-like behavior in PVDF with
high molecular weights ($M_w$) (>534 kg mol$^{-1}$). An ultra-high energy density (35 J cm$^{-3}$) with a high efficiency (74%) is achieved in a P&F PVDF ($M_w$: 670-700 kg mol$^{-1}$), which is the highest value ever reported for a polymer-based dielectric capacitor.

Flexible Hybrid Electronics Audio System David E. Schwartz, Robert Street, Ping Mei, Brent Krusor, Rene Lujan, Elif Karatay, Adrien Pierre, Siv Kor and Steve Ready; PARC, United States

Integration of piezoelectric materials into flexible electronics systems can enable enhanced functionalities in sensing and actuation. An example of this is the use of ferroelectric polymers to form flexible audio speakers. This talk will discuss the development of a flexible hybrid electronics (FHE) technology platform that combines printed interconnect, printed passive components, and discrete silicon chips with a bimorph PVDF-based speaker. The bimorph configuration is shown to produce increased sound pressure levels (SPL) over a single-layer device. The audio system has been demonstrated using two flexible circuits that include ink-jet-printed resistors developed for long-term reliability. One circuit amplifies the output of a portable music player and feeds it to the speaker. The second is a record-and-playback circuit designed around a dedicated audio integrated circuit. In both cases, the audio is clearly intelligible.

Roll-to-Roll Production of High Performance, Flexible and Transparent Piezoelectric Pressure Sensors and Loudspeakers Armen Yildirim, Rahim Rahimi and Mukerrem Cakmak; Purdue University, United States

The introduction of IoT (Internet of Things) has created an unprecedented demand toward the development of self-powered and high-performance sensors, among which piezoelectric materials are of great use in various important fields due to their unique properties such as high sensitivity, mechanical stability, energy harvesting and fast response time. Despite recent advances, the current state-of-the art solutions are still primarily based on brittle ceramic materials and hence cannot be easily incorporated into existing flexible electronic devices. In addition, the large-area processing of the modern advanced materials still poses a challenge.

Here, we report the roll-to-roll production of dual-functional high-performance piezoelectric pressure sensors and loudspeakers via electric field alignment of PZT (Lead Zirconate Titanate) and Graphene Nanoplatelets (GNPs) in a silicone-based polymer matrix. The alignment of particles in the thickness direction (“Z” direction) has not only shown to dramatically increase the piezoelectric performance, but also improves the transparency of the system by creating depletion zones where light can travel with less scattering. The ultra-sensitivity of the system has been demonstrated by the detection of a small bird feather (1.4 mg) dropped from a certain distance. The material can also generate up to 8.2 V signal when the pressure is applied by the touch of a fingertip.

Apart from its outstanding sensing capabilities and response time, the exact same system can also be used as a transparent, flexible and thin film loudspeaker when a voltage is applied across the material. To better understand the material’s performance and capabilities, sound pressure level (SPL) of the loudspeaker has been characterized across the entire range of human hearing (20 Hz-20 kHz) along with the sound directivity measurements at certain angles in an anechoic chamber. The potential applications of this system can range from built-in speakers (e.g., TV, computer or mobile phone screens) to active noise cancellation systems.

Finally, a large area sample (10 ft long and 6-inch-wide) has been produced to demonstrate the scalability of the manufacturing process via a novel custom-built 44 ft long roll-to-roll production line which was also designed by
Artificial touch and pressure sensing have become a critical technology. New generation neural implants with multifunctional, high resolutions minimally invasive brain-machine interfacing techniques made it possible to control external devices by assigning them to corresponding cortical networks in the brain. Researchers have shown that it is also feasible to interface a touch-sensitive pressure sensor with somatosensory cortex to transfer the touch feeling to the human brain. Such superior multi-disciplined studies converging both medical and engineering skills are the next milestones of technology shortly. State of the art technological requirements drives engineers to create robotic arms, skin-like functioning electronics and versatile sensors necessary to cure the disabilities and deformations in animals and human. Although researchers have shown a great success for mimicking the motion systems, they have yet to show the same performance to explore sensor tools entirely. Here, we developed piezoelectric fiber-based, large area, transparent, modular, and flexible devices for small pressure sensing and cardiac activity recording. Nano-structured piezoelectric fibers were produced using a two-step thermal size reduction (TSR) technique. In TSR, we start with designing a macroscopic preform which works as a template for the resulting fibers. Our initial preform contains a poly(vinylidene fluoride trifluoroethylene) (PVDF-TrFE) slab made from powders using a hot press at ~20 Barr pressure and above 90°C. This preform was embedded in polysulfone (PSU) protective cladding and drawn in fiber tower. Resulting fibers were between 10 µm to 1 mm. We stacked and stretched the first step fiber in a second PSU preform in order to obtain < 400 nm structure. TSR method simultaneously orients PVDF-TrFE molecules along the fiber length and creates dipoles perpendicular to the molecular chains. Piezoelectric characterizations have shown that the d33 constant of these fibers is exceptional (> 300 pm/V). This performance metrics have proved to be enhancing the performance of large area piezoelectric devices. We demonstrated a proof principle energy harvesting device, larger area electronic skin, an arterial pressure measurement system and an anthropometric artificial hand mimicking the human neural pressure measurement mechanism. We expect this work will find a broader range of application including smart and nano-textile, structural health monitoring, implantable high precision sensors.

Ferroelectric polymers from the PVDF-family have proven to be multifunctional and self-sustaining materials with a broad deployment in printed and flexible electronics. They can be used in large and flexible form factors for detecting mechanical excitations such as pressure variations, force touch and impact, for sensing human-body radiation and proximity, as vibration sensors for structure-borne sound detection and acoustics, as stretchable vital parameter sensors for movement, heart and respiratory rate monitoring, as well as piezoelectric energy harvesting elements, just to name a few [1]. Our multimodal ferroelectric polymer sensors are entirely fabricated by screen printing which is one of the most common techniques used in printed electronics, since it is highly tolerant to the type and form factor of substrates, the rheology of ink materials, provides sufficient alignment accuracy for multilayer printing and can be done in a sheet-to-sheet or roll-to-roll schemes. By optimizing the design, the printing and annealing process as well as the poling conditions and the source material, functional sensors with a yield of more than 98% with less than ± 5% deviation in the performance (e.g. remanent polarization) were demonstrated. It is also interesting to note that extended aging tests under definite climate and shock conditions revealed more than 98% preservation of the remnant polarization for high molecular weight PVDF-TrFE polymers. The sensors come in two versions; (i) either they have a sandwich-type structure of three layers that are printed onto a flexible or stretchable substrate (e. g. plastic films, paper and textiles) and response accurately, fast and reproducibly to pressure and temperature changes over large dynamic ranges or (ii) a two layer structure that is predominantly sensitive to lateral strain and vibrations and provides accurate direction sensitivity.
First a short overview of applications of printed PVDF-TrFE sensors will be given covering flexible 3D user interfaces [2,3], large-area force, impact and proximity sensors, ultrathin object-integrated microphones as well as medical patches.

One focus will be the realization of a concept for direction-sensitive and flexible strain sensors based on the ferroelectric copolymer P(VDF:TrFE) with a single layer of interdigitated embedded electrodes. The process employed for producing the embedded electrodes is based on a combination of (self-aligned) photolithography and electroforming or, alternatively, on capillary force driven filling of microfluidic channels hot embossed into P(VDF:TrFE) with conductive ink.

Finally, a novel printable nanocomposite material, which allows reducing the cross-sensitivity between the pyro- and piezoelectric sensing modes, will be presented. This material is composed of inorganic ferroelectric nanoparticles blended in a ferroelectric polymer matrix. By exploiting the fact that the piezoelectric coefficient in inorganic ceramics has an opposite sign to that one of the ferroelectric polymer either the piezo- or the pyroelectric activity can be suppressed by independently defining the poling direction of particles and matrix in a clever poling procedure [4].

EL02.09.03
Designing High-Capacitance Polymers Using Side Chain Sequence Control Anneliese Schmidt, Tara Meyer and Geoffrey Hutchison; University of Pittsburgh, United States

High dielectric and low energy loss polymers are of great interest for electrical components and energy storage devices, as they enable high power density and energy density while maintaining dielectric strength. While much of the work in this area has focused on ever increasingly complex donor and acceptor units in the backbone of polymers, this work incorporates the conjugated species, with highly polarizable end groups, as the polymers’ side chains. Synthesis of a flexible polymer with precisely sequenced phenylene vinylene pendant groups provides improved control over the side chains’ alignment, and the local dipole moment, while poling. Strategic control of the side chains’ sequence produces a material with tunable dielectric behavior and capacitance.

EL02.09.04
Role of Vertically Aligned and Randomly Placed Zinc Oxide (ZnO) Nanorods in PVDF Matrix—Used for Energy Harvesting Abhishek Anand; Indian Institute of Technology New Delhi, India

The nanocomposite of ZnO nanorods and ZnO vertically aligned nanorods with polyvinylidene fluoride (PVDF) are prepared via a solution casting method to make flexible and cost-effective piezoelectric nanogenerator. The structural and surface morphological studies of nanocomposite films have been carried out by X-ray diffraction (XRD) and Scanning electron microscopy (SEM) respectively. The crystalline polar β-phase of nanocomposite films has been evaluated by Fourier transform infrared spectroscopy (FTIR). The results showed enhancement in this phase from 53% in PVDF to 80.6% in PVDF-ZnO vertically aligned nanorods (VANRs) nanocomposite films, respectively. The electric polarization studies showed the maximum value of remnant polarization P_r is 0.2188 μC/cm² for PVDF-ZnO VANRs nanocomposite film, measured by Polarization-electric field (P-E) hysteresis loop. The value of output voltage for PVDF-ZnO VANRs is found to be 46.64 V which is more than seven times in comparison to PVDF-ZnO nanorods (NRs) based nanocomposite film generated by repeated human finger imparting on these nanocomposite films. The value of power density obtained for PVDF-ZnO VANRs is 45.87 μW/cm² at the load resistance of 15 MΩ, which can be used to drive energy to small-scale electronic appliances.

EL02.09.05
Systematic Optimization of Electrospinning Flow Rate for Preparing Highly β-crystalline Poly(vinylidene fluoride) Nanofibers Subramaniyan Ramasundaram, Ashiqu Rahaman, Abdelrahman Hussein and Byungki Kim; Korea University of Technology and Education, Korea (the Republic of)

Simultaneous application of uniaxial stretching and electrical poling made the electrospinning process as a suitable method for preparing poly(vinylidene fluoride) nanofibers (PVDF NFs) containing β-crystalline phase. To facilitate the rapid and large scale preparations, flow rate (FLr) of electrospinning must be optimized. In this regard, the efforts made in the literature were lacking in terms of systematic evaluation of crystalline composition, mechanical properties, and the assessing the role of residual solvents during annealing. In the present investigation, an attempt has been made to systematically evaluate the FLr on these properties. A 15% PVDF solution was used for this study. A 70:30 (v/v%) mixture of N, N’-dimethylformamide and acetone mixture was used as the solvent. First, at the FLr of 5 ml/h and the nozzle voltage of +20 kV, the voltage applied to collecting roller (CR) was optimized to control the loss of fibers due to web drifting. Application of -20 kV to CR was fully controlled the web drifting and favored the collection of nearly all fibers ejected from the nozzle. Primarily, NFs were prepared at the FLr of 2.5, 5.0, 7.5 and 10 ml/h. Field-emission scanning electron microscopic studies confirmed that the NFs prepared at 2.5 ml and above had the average diameter of 466 and 225 nm, respectively. The composition of crystalline phases were evaluated using the Fourier-transform infrared (FTIR) spectroscopy. The integral area under the characteristics peaks of α (975 cm⁻¹), β (1275 cm⁻¹) and γ (1275 cm⁻¹) were taken for consideration. The as prepared NFs, showed ~75% of β-phase, the rest 25% was shared by α- and γ-phases. Upon annealing at 150 °C, the NFs prepared at 2 ml/h found to be the best and contained 90% β-, 2.5% α- and 7.5% γ-phases. Differential scanning calorimetry, and X-ray diffraction studies were proved the composition of crystalline phases identified in FTIR studies. As observed in thermogravimetric studies, in as prepared NFs, the peak degradation temperature and residue content were higher for NFs prepared at 2.5 ml/h (466 °C and 32.5%) and the annealed NFs did not show any drastic change. Further, NFs will be prepared up to the maximum achievable flow rate (40 ml/h), the mechanical and piezoelectric characteristics of representative samples will be evaluated.

**Improved Energy Harvesting Characteristics by Structure Optimization of Flexible Modules Based on Lead-Free Piezoceramic Nanofibers** Sang Hyun Ji and Ji Sun Yun; Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

We optimized the module structure based on the lead-free piezoceramic nanofibers to improve flexible energy harvesting characteristics. Flexible lead-free piezoceramic nanofibers were prepared by the electrospinning process, and then flexible energy harvester modules based on piezoelectricity were fabricated through WIP process. The shapes, intervals and widths of electrodes in the flexible piezoelectric single modules were controlled, and the energy harvesting characteristics of the modules were investigated according to the oscillation frequency and the bending motion. Furthermore, the displacement and vibrational mode shapes of the flexible modules were analyzed using a laser scanning vibrometer. The flexible piezoelectric dual modules were fabricated according to x- and z-axis array arrangements of the single modules with the optimized electrode structures, and were connected to serial and parallel methods. The energy harvesting properties of the optimized dual modules were measured at various running speeds, after directly attached to the shoes. These results confirmed that the flexible piezoelectric modules can be applied as a sub-power source for wearable devices.

**Wearable Power Generation Biodevices on Body Surface** Taiki Takamatsu, Yin Sijie and Takeo Miyake; Waseda University, Japan

Wearable skin electronics is a next generation product that monitor biological signals from the human to the electronic devices. Numerical technological advances have been reported for thermal, strain and chemical sensors on the skin and for neuron-stimulated soft electronics on the brain. Even we could have a lots of wearable devices on the human skin, the final question is “the power supplies from where? on the skin”. To overcome this issue, we have developed two types of wireless power generation devices: one is enzymatic power generation from biofuels, especially glucose in sweat or blood, and the other is wireless power transfer system between an eyeglass/contact lens. To generate a power on the skin, we used two types of enzymes as biocatalysts and then developed enzyme/CNT hybrid electrodes: bioanode for glucose oxidation and biocathode for oxygen reduction. In contrast, the wireless power transfer system is based on two types of inductance(L)-capacitance(C) resonant circuits at the resonant frequency of 13.56 MHz. In the both cases, we demonstrated a LED lighting on the skin or on the eye surface.

**Kinetic Monte Carlo Simulations of Supramolecular Organic Ferroelectric Materials** Tim Cornelissen¹, Indre Urbanaviciute¹, Michal Biler², Mathieu Linares²,¹ and Martijn Kemerink¹; ¹Linköping University, Sweden; ²KTH Royal Institute of Technology, Sweden

Organic ferroelectrics can find application in a broad range of fields. They might, for instance, solve the ‘missing memory’ problem in printed electronics. However, a full understanding of their switching kinetics on all length and time scales is still lacking. A variety of computational models have previously been used to tackle this problem and to study different aspects of both inorganic and organic ferroelectrics. Unfortunately, these are usually restricted to idealized morphologies or short time scales.

In contrast, we have developed an electrostatic kinetic Monte Carlo model that can reproduce the static and kinetic ferroelectric properties for realistic 3D morphologies on experimental time scales. We apply this model to the prototype small molecular ferroelectric trialkylbenzene-1,3,5-tricarboxamide (BTA).

We simulate hysteresis loops, depolarization curves, and switching transients, and find good agreement with experiments. The simulations provide molecular-scale insight in the thermally activated nucleation-limited switching behavior that was also observed in experiments.

Specifically, we investigate the effect of structural disorder on the ferroelectric properties. When the disorder in the system is increased, the retention time decreases dramatically, while the coercive field remains mostly unchanged. This is due to different nucleation mechanisms: field-driven switching nucleation happens at the contacts, while for spontaneous depolarization nucleation occurs at disorder-induced defects. The switching transients become highly dispersive in the presence of disorder. We find that especially the presence of chiral defects has a retarding effect on the switching kinetics, suggesting chiral ferroelectrics might provide sub-µs switching times.

Our results thus provide a detailed insight in (the limiting factors in) polarization switching processes on
experimental length and time scales. Furthermore, we have shown that reducing the disorder can lead to an organic ferroelectric with moderate coercive field, long retention, and fast switching.

**Rational Design of Organic Supramolecular Ferroelectrics**  
Indre Urbanaviciute$^1$, Nicolas M. Casellas$^2$, Subham Bhattacharjee$^3$, Michal Biler$^4$, Tim Cornelissen$^1$, Mathieu Linares$^{1,5}$, Rint Sijbesma$^6$, Miguel García-Iglesias$^2$ and Martijn Kemerink$^1$; $^1$Linköping University, Sweden; $^2$Universidad Autonoma de Madrid (UAM), Spain; $^3$Eindhoven University of Technology, Netherlands; $^4$KTH Royal Institute of Technology, Sweden

With an increasing demand for cheap, efficient, lightweight and bendable electronics, a matching memory technology is required. Ferroelectricity-based memory devices assure non-volatility and low energy consumption, while organic materials, potentially used for this purpose, guarantee easy processability, low cost and advantageous physical properties including flexibility. A recently discovered class of organic self-assembling supramolecular ferroelectrics has emerged as a promising candidate for memory applications [1], [2], yet it lacked interest from a device perspective due to typically high operation temperature, modest remnant polarization and/or poor polarization retention. Here, we show that rational design and optimization of the molecular structure leads to advanced supramolecular materials that not only demonstrate excellent ferroelectric properties but also semiconductivity, opening new application possibilities arising from the hybridization of both phenomena [3].

The synthesized molecules are based on a C3 symmetry core-shell template, comprising three equally important structural units: a planar n-stacking core, to which three strong dipolar amide groups (O=C-NH) are attached, that are followed by flexible solubilizing alkyl (-CH$_2$-)$_n$ chains. While the conjugated cores and the hydrogen-bonding amide moieties are responsible for the axial self-assembly and stabilization of the columnar structure, the mesogenic sidechains separate the columns and provide sufficient molecular mobility to flip the columnar macrodipole, i.e. facilitate ferroelectric switching. Consequently, a charge transport channel is formed at the centre of the column, which is surrounded by directional and switchable polarization field.

To obtain structure-property relations we tested molecules with varied tail substitutions as well as different molecular cores, both experimentally and in computer simulations [4], [5]. We find that, and rationalize why, all key properties of the ferroelectric – remnant polarization, coercive field, operational temperature range, polarization switching time and data retention – depend strongly on these molecular modifications. As a result, ferroelectric and ferro-semiconductive materials with high remnant polarization (~60 mC/m$^2$), low electrical fatigue, temperature stability surpassing P(VDF-TrFE) and polarization retention exceeding the 10-year requirement for commercial memory devices even at high temperatures, are unearthed. The conclusions of this structural optimization study provide guidelines for further advancement in molecular engineering of self-assembling multifunctional materials.

**EL02.09.11**

**Porosity as a Tool to Increase the Power Output of Polymeric Nanogenerators**  
Mohammad Mahdi Abolhasani and Kamal Asadi; Max-Planck Institute for Polymer Research, Germany

Polymeric piezoelectric nanogenerators (PNGs) have emerged as a suitable candidate to harvest waste mechanical energy to power up portable electronic devices. Smart textiles, with piezoelectric functionalities integrated into the fabrics, have been envisioned. In this regards, numerous piezoelectric (nano-) generators based on PVDF or P(VDF-TrFE) nanofibers have been reported. However, the piezoelectric polymer (nano-)generators have typically shown low output energy densities; A the
common issue hindering their application. Introduction of porosity into the piezoelectric polymer has been proposed to increase the voltage output of PNGs. However, designing a process that allows the introduction of pores in polymer fibers with a typical diameter of the order 100 nm, would be a breakthrough in the field of PNGs. In this contribution, we discuss an elegant approach to tailor porosity in electrospun P(VDF-TrFE) nanofibers. The approach is based on the thermodynamics of polymer solutions, and solvent/non-solvent interactions with the polymer. We calculated the ternary phase diagram of P(VDF-TrFE)/non-solvent (water)/solvent, and experimentally verified it. Based on the phase diagram, a conscious amount of water is intentionally added into the P(VDF-TrFE) solution to induce porosity in the fiber. PNGs based on the porous electrospun P(VDF-TrFE) nanofibers show systematic increases of the output voltage with porosity. The output power increased from 0.1 mW/cm³ for PNGs with zero porosity to 7 mW/cm³ for PNGs with 50% porosity. Dielectric spectroscopy of the nanofibers attributes the enhanced output to the reduced dielectric permittivity of the fibers and that the voltage generation in the porous fibers is of the same origin as in neat piezoelectric P(VDF-TrFE) films and is due to the relaxation of segments within the restricted amorphous phase.

EL02.09.12
Analog Synaptic Transistors Based on Ferroelectric Hafnium Oxide Min-Kyu Kim, Youngjun Park, Dongshin Kim and Jang-Sik Lee; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Neuromorphic computing has attracted much attention due to its power-efficient data processing. To realize efficient neuromorphic hardware systems, the development of reliable and robust synaptic devices is essential. However, the limited performance of the synaptic devices remains as a challenge for realization of neuromorphic hardware systems. Ferroelectric materials have a great potential to meet the requirements for synaptic devices. Here, we report analog memory characteristics in the ferroelectric thin-film transistor (FeTFT) based on oxide semiconductor and ferroelectric hafnium oxide layer [1]. The conductance of the oxide semiconductor channel is modulated by controlling the polarization of the ferroelectric hafnium oxide layer. Conductance modulation characteristics of FeTFT are used to demonstrate potentiation and depression characteristics. The desired synaptic device characteristics, such as linear weight update, small variation, and multiple states are achieved in FeTFTs. In addition, the possibility of FeTFT as a synaptic device in neural network is evaluated by artificial neural network simulation. In simulations, the neuromorphic system based on FeTFTs achieves 91% recognition accuracy for handwritten digits. This work can offer a possibility for FeTFT as a synaptic device to be used in neuromorphic hardware systems. In this presentation, analog memory characteristics of FeTFT for neuromorphic applications will be presented in detail.

In Situ Characterization of Active Polymers Using Terahertz Time Domain Spectroscopy Nha Uyen Huynh; San Diego State University, United States

The class of active polymers is gaining an increasing attention since it combines the appealing mechanical properties of polymers of strength and toughness to weight ratio with additional functionalities such electrical, magnetic, or luminescence. For example, a subset of electroactive polymers exhibit electromechanical coupling, where an application of electric field results in a mechanical deformation and vice versa. The latter coupling situates this class of materials for sensing and actuation applications. Despite the appealing attributes and potential application, characterization protocols are limited to the macroscale when it comes to the concurrent interrelationship between mechanical and electrical energies. Terahertz Time Domain Spectroscopy (THz-TDS), on the other hands, is capable of elucidating the simultaneous intrinsic electromechanical coupling since the energy below the activation energies of polymers that are also transparent to terahertz waves. In other words, the propagation of terahertz waves becomes intimate with the polymer continue, hence the reported frequency spectrum inherit the intermolecular vibrations resulting from either applying electrical field or mechanical stresses. In this presentation, the electromechanical response of standalone, ultrathin Poly (vinylidene fluoride-co-trifluoroethylene) film fabricated using spin coating technique. The frequency spectra of propagating terahertz waves are compared before, during, and after the application of varying electric field and mechanical stresses.

EL02.09.14
Tuning the Energy Storage Performance of Core-Shell Crumpled GO@BaTiO3 Nanoparticles Filled PVDF Nanocomposites by Interface Engineering Yan-Ge Yu1,1, Wen-Zhu Shao1,1, Cheng-Yan Xu1,1,2, Jing Zhong1,
Yang Li,1,1 and Liang Zhen,1,2; 1Harbin Institute of Technology, China; 2School of Materials Science and Engineering, Harbin Institute of Technology (Shenzhen), China

Ferroelectric polymer poly(vinylidene fluoride) (PVDF) and PVDF based polymer nanocomposites have received booming interest for film capacitor applications due to their relatively high permittivity at approximate. However, the addition of highly polarized fillers with a high proportion into PVDF leads to poor film processability and high energy loss, which significantly destroy the structural integrity of the film and limits the practical application of film capacitors. Herein, we prepared a unique core-shell structured GO@BaTiO3 nanoparticle by a simple and continuous process, and then obtained the nanoparticle filled PVDF films (GO@BTO/PVDF), which exhibited excellent energy storage performance. BaTiO3 nanoparticles were successfully wrapped in crumpled graphene oxide (GO), and the core-shell structured GO@BTO nanoparticles were well dispersed in PVDF film, which was demonstrated by transition electron microscopy (TEM) and scanning electron microscopy (SEM). Compared with PVDF films, the GO@BTO/PVDF films with a ultralow filler content of 0.8 wt% show a high discharged energy density at 225 MV/m, which is 40% higher than PVDF films, as well as a 15% enhancement of discharged efficiency at 225 MV/m. These superior performance is resulted from the interfacial engineering based on GO. GO is capable to reduce the huge difference between polymer and ceramic particles, making the film have less defective and present higher discharged efficiency. Moreover, the ultralow content of fillers can greatly improve the film processability, maintaining the structural integrity and performance stability of the films during stretching. This work provides an efficient strategy to enhance the energy conversion efficiency.

EL02.09.15
Hybrid Tribo-Piezo-Electric Nanogenerator with Unprecedented Performance Based on Ferroelectric Composite Contacting Layers Linards Lapēnskis, Kaspars Malnieks, Artis Linarts and Andris Šutka; Riga Technical University, Latvia

Triboelectric nanogenerators (TENG) are appealing mechanical energy harvesting devices that could power small portable devices and detectors. They can also act as self-powered sensors for mechanical displacement, chemical, acoustic sensing, and biomedical monitoring. The working principles of TENG devices are based on friction-related electrification – triboelectrification. Some of the recent works report that TENG output can be improved by using polarized ferroelectric films as the contacting layers. In the present work, porous polyvinylidene fluoride (PVDF) and BaTiO3 nanocomposite films (BaTiO3 content in a range from 0 to 35 vol%) have been prepared using spin-coating and consecutive immersion-precipitation. A clear correlation between the piezoelectric response of inversely polarized ferroelectric PVDF/BaTiO3 nanocomposite films and the performance of the TENG device based on these films is demonstrated. Nanocomposite films with the optimal composition (25 vol% BaTiO3) show a 48 pC N−1 piezoelectric coefficient, considerably higher than usually reported for such composites, and in TENG mode a record-high 2.7 kV open-circuit voltage is achieved. This observation is explained by magnified electrostatic induction that is driven by the piezoelectric charges and ferroelectric properties of these films. However, our results also indicate that piezoelectric charges cannot be solely responsible for great TENG performance; thus, a “double capacitor model” has been introduced. The mechanism involves interaction between two charged ferroelectric layers during contact–separation and contacted inversely polarized layers can be considered as capacitors connected in series. Air gap formation during separation rapidly decreases the total capacitance while the potential difference increases. The induced charge redistribution in the external circuit is registered as a current. Predictions of our model also hold true when experimentally obtained charge density (6.55 nC cm−2) values are compared with ones obtained from model calculations (6.60 nC cm−2). Furthermore, findings uncover the potential for vast improvement in the field of nanogenerators for mechanical energy harvesting as a significantly better piezoelectric performance of flexible nanogenerators has been reported elsewhere. As triboelectric research continues to thrive and expand, we anticipate that our work will help the TENG community to further improve the performance of ferroelectric-based TENG devices.

EL02.09.16
The Role of Intermolecular Forces in Contact Electrification on Polymer Surfaces Kaspars Malnieks, Andris
The contact electrification of polymer interfaces opens the possibility to harvest energy from triboelectric (nano)generators (TEG). The electron transfer between contacted-separated surfaces has been considered as the main electrification mechanism for polymers in TEG. The electron transfer mechanism requires to contact chemically different materials, as well as to increase specific contact area, which has been accomplished via nano-structuring. Here we show that contact electrification can be controlled by intramolecular forces in polymer bulk and adhesive forces at contact interface. Results also confirm covalent bond breaking as a mechanism for contact electrification of polymer insulators. By taking in account findings mentioned above, we produced a TEG device using soft thermoplastic styrene-ethylene-co-butylene-styrene (SEBS) block copolymer, which had shown the highest surface charging. We modified the surface of SEBS to make it more adhesive by treating the surface with hydrogen peroxide solution. As a result, we observed increase in separation stress by 38% from 2.97 N/cm² to 4.11 N/cm². The increased adhesion of peroxide treated SEBS surfaces can be attributed to formation of quasi-free ends of macromolecular chains. As expected, for modified SEBS surface charge increased 3.14 times from 0.92 nC/cm² to 2.89 nC/cm².

**Post-Annealing Process Dependent Electric Properties of (Hf, Zr)O₂ Thin Films Made by RF Sputtering Deposition Method**

Seung Eon Moon¹,², Yeriaron Kim¹,³, Jiyoung Woo¹, Jeong Hun Kim¹, Jong-Pil Im¹, Solyee Im¹ and Sung Min Yoon³; ¹ETRI, Korea (the Republic of); ²UST, Korea (the Republic of); ³Kyung Hee University, Korea (the Republic of)

To study the applications for ferroelectric non-volatile memory and ferroelectric memristor, etc, post-annealing process dependent electric the properties of (Hf, Zr)O₂ thin films by RF sputtering deposition method were investigated. The bottom electrode was TiN thin film to produce stress effect on the formation of orthorhombic phase and top electrode was Pt thin film by DC sputtering deposition. Post-annealing process, for example, post-annealing temperature, annealing gas, annealing time, etc, was varied along with the same other deposition conditions, for example, sputtering power, target to substrate distance. The structural and electric properties of the above thin films were investigated. As a result, it is confirmed that the electric properties of the (Hf, Zr)O₂ thin films depend on the post-annealing process which affects structural properties of the thin films, such as, structural phase, ratio of the constituents, etc.

**Modeling of Trialkylbenzene-1,3,5-Tricarboxamide (BTA) Molecules for Ferro- and Piezoelectric Applications**

Michal Biler¹, Patrick Norman¹ and Mathieu Linares²; ¹Royal Institute of Technology, KTH, Sweden; ²Linköping University, Sweden

Trialkylbenzene-1,3,5-tricarboxamide (BTA) is an archetypical amide-based liquid crystalline ferroelectric. It is a C₃ symmetry discotic molecule with a benzene core, to which three amide groups, having a dipole moment of around 3 Debye each, are attached. These amides form intermolecular N–H–O hydrogen bonds that induce molecular self-assembly into columns with a triple-helix H-bonded network. Microdipoles within this system add up to a net axial macrodipole in a cooperative manner. The π-π stacking of the benzene cores and packing of the tails further stabilize the molecular arrangement, which allows for unhampered dipole-flipping. When flexible mesogenic peripheral tails are attached, BTA enters a well-ordered liquid-crystalline columnar hexagonal phase, which facilitates rotation of the macrodipole and thus ferroelectric behavior. The length and the nature (linear or branched) of the tails can play a crucial role in the data retention as well as in the growth of the coercive field. Molecular simulations combining Density Functional Theory (DFT) and Molecular Dynamics (MD) are a precious tool to understand and rationalize the behavior of BTA liquid crystalline ferroelectric at the molecular level. We
were able to decipher the detailed nature of the switching of the amide groups under an electric field and how those changes between the different possible conformations influence the helicity of the stack. [1] Moreover, the influence of the side chains were investigated. We showed that morphological factors like improved packing quality and reduced disorder, rather than electrostatic interactions or intra/inter-columnar steric hindrance, underlay the superior properties of the branched-tailed BTAs in comparison with linear-tailed BTAs. [2] Finally, we were able to demonstrate a pronounced negative piezoelectric effect in the family of BTA molecules, which can be tuned by mesogenic tail substitution and structural disorder. [3]

Polar Mixed Molecular Crystals by Stereospecific Doping—Design Principle and Contributions to the Macroscopic Polarization Elena Meirzadeh1,2, David Ehre1, Igor Lubomirsky1 and Meir Lahav1; 1Weizmann Institute of Science, Israel; 2Columbia University, United States

Doping of molecular crystals is a promising avenue to design of functional materials. Stereospecific occlusion of guest molecules in host crystals reduces their symmetry by creation of polar domains, engendering macroscopic polarization and thereby inducing pyroelectricity and piezoelectricity. We have investigated the possibilities of stereospecific doping of non-polar molecular crystals comprising of molecules with a large dipole moment, in particular, crystals of amino acids: (i) asparagine monohydrate(ASN) doped with aspartic acid (ASP) and (ii) glycine (GLY) doped with L-alanine (ALA), L-threonine (THR), L-serine (SER), L-allo-threonine (ATH), L-phenylalanine (PAL), L-glutamic acid (GLU), and L-tyrosine (TYR).

We show that the macroscopic polarity in such crystals has two contributions: a) the polarity arising from the difference between the dipole moment of the guest molecule with respect to the dipole moment of the host molecule; and b) the polarity induced by distortion of the local environment pushing the host molecules out of perfect mutual compensation, leading for the case of zwitterionic amino acids (dipole moment of ≈14 D), to particularly large polarization.

For the case of ASN-ASP, the concentration dependence of the pyroelectric coefficient shows three distinctively different regions. Below 8 mol%, the pyroelectric coefficient, $a$, increases linearly with ASP concentration, $C$, indicating that the dopant molecules do not interact and their polarity is additive. This allows to introduce a pyroelectric coefficient per molecule $a_n=\frac{d(a)/d(C)}{(r×q)}=0.005$ pm/K, where $r$ is molecular density (cm$^{-3}$) and is the elemental charge. Between 8 and 12 mol% ASP, there is a sharp increase in the pyroelectric coefficient reaching at its peak 0.18 nC/(cm$^2$×K) and $a_n=0.016$ pm/K, indicating strong interactions between the polar domains. Above 12 mol% ASP, the pyroelectric coefficient decreases indicating anti-polar domain arrangement. The XRD data on macroscopic symmetry support the data on the pyroelectric coefficient. For the case of doped GLY, although dopant solubility is limited to <1 mol%, the pyroelectric coefficient reaches $a=0.02$ nC/(cm$^2$×K), leading to $a_n=0.001-0.005$ pm/K. Two substantially different types of temperature dependence of the pyroelectric coefficient were observed. For ALA, THR, ATH and PAL-doping, the pyroelectric coefficient remains negative with respect to the crystal growth direction in the range 0-100 °C. For SER, GLU and TYR-doping the pyroelectric coefficient changes from positive at 0 °C to negative at 100 °C. So far, this is the only example, not associated with a phase transition, when a pyroelectric coefficient crosses a zero point. We attribute this behavior to the different temperature dependence of the guest and host polarization.

Our experiments demonstrate that stereospecific doping of centrosymmetric crystals comprising polar molecules is a viable route to design functional polar materials.

Computational Approaches for Studying Organic Ferro-, Antiferro- and Piezoelectric Materials Shoji Ishibashi1, Sachio Horuchi1, Reiji Kumai2 and Kiyojuki Terakura1; 1National Institute of Advanced Industrial Science and Technology (AIST), Japan; 2High Energy Accelerator Research Organization (KEK), Japan
We present examples of computational approaches for studying organic ferro-, antiferro- and piezoelectric materials. The first example is a study about the origin of exotic ferroelectricity in tetrathiafulvalene-p-chloranil (TTF-CA). As reported by Kobayashi et al. [1], its polarization (6.3 \( \mu \)C/cm\(^2\)) is more than 20 times larger than that expected by the point charge model (PCM), and their directions are opposite. TTF-CA is in strong contrast to typical inorganic perovskite ferroelectrics. Recently, we proposed a procedure to analyze the polarization mechanism within the framework of maximally-localized Wannier orbitals and applied it to TTF-CA as well as to perovskite transition metal oxides (BaTiO\(_3\) and PbTiO\(_3\)) [2,3]. For TTF-CA, only 2 bands below the band gap are responsible for the emergence of polarization, while, for BaTiO\(_3\) and PbTiO\(_3\), even relatively-deep states show significant contributions. The polarization has been decomposed into three contributions: (1) the PCM, (2) the local polarization (LP) and (3) the electron flow (EF) from cell to cell. It has been revealed that the EF term amounts to more than 100\% for TTF-CA, 68\% for BaTiO\(_3\), and 56\% for PbTiO\(_3\) of the total polarization. As for the LP term, it is nearly zero for TTF-CA or BaTiO\(_3\) while 12\% for PbTiO\(_3\). The valence top is derived from the anion (oxygen) states for BaTiO\(_3\) and PbTiO\(_3\) while it is from the cation (TTF) states for TTF-CA. Consequently, the EF term has the same sign as the PCM term in BaTiO\(_3\) and PbTiO\(_3\), whereas the EF term has the opposite sign to the PCM term in TTF-CA. For TTF-CA, as mentioned above, the predominant contribution to the polarization is from the EF term. This is the reason for the opposite polarization direction to that expected by the PCM in TTF-CA. Thus, the distinct polarization mechanism for TTF-CA has been figured out.

The second example is a simulation of the antiferroelectric-to-ferroelectric transition in squaric acid (SQA). Recently, in SQA, we observed experimentally, the transition from an antiferroelectric phase to a ferroelectric phase in the presence of a strong electric field [4]. Furthermore, we proposed two possible ferroelectric phases (FE-α and FE-β) with their molecular arrangements and space groups. The experimentally observed ferroelectric phase is thought to be the FE-α phase. On the other hand, the FE-β phase could not be practically achieved because of the dielectric breakdown of crystals. We simulate the antiferroelectric-to-ferroelectric transition [5] by computationally applying a static electric field [6]. Depending on the direction of the electric field, two different metastable ferroelectric (and piezoelectric) phases have been found. One of them corresponds to the experimentally confirmed FE-α phase, whereas the other corresponds to the FE-β phase, which has not yet been experimentally confirmed. The structural details of these phases have been determined as a function of the electric field. The spontaneous polarization values of the phases are 14.5 and 20.5 \( \mu \)C/cm\(^2\), respectively, and are relatively high among those of the existing organic ferroelectrics. Significant converse piezoelectric effects are observed for both the phases (~10 pm/V).

Some other examples (e.g. ferroelectrics based on proton tautomerism such as croconic acid and benzimidazoles [7]) will also be presented.

Photolithographic Patterning of Fluorinated Electroactive Polymers and Applications to Electronic Devices
Georges Hadziioannou; University of Bordeaux, France
Fluorinated electroactive polymers (FEPs) are materials of increasingly high interest due to their ferroelectric and relaxor-ferroelectric properties and find application in electronic devices such as sensors, actuators, organic field-effect transistors (OFETs) and electrocaloric devices. Before devices that use those materials find wider commercial applications, patterning issues need to be solved. Limited compatibility of those polymers with photolithography, which is the method of choice for large throughput electronics production, prevents their wider commercial realization. In this work we present a method to make those fluoropolymers cross-linkable upon UV irradiation by grafting photo-initiator groups directly on the fluoropolymer’s backbone. Such photo cross-linkable materials can be used as negative photoresists in conventional photolithographic patterning process for the fabrication of electronics. Main challenges of this approach, include the poor chemical reactivity of fluoropolymers as well as the negative effect that modification can have on the crystallinity and thus on the electroactive properties of the polymer.

Polar Crystallization of Boron Nitride Nanotube-Polyvinylidene Fluoride Nanocomposites Dongwon Lee1,2,3, Sang-Hyon Chu2,3, Fuh-Gwo Yuan1, Catharine Fay2 and Cheol Park2, 1North Carolina State University, United States; 2National Institute of Aerospace, United States; 3NASA Langley Research Center, United States

A boron nitride nanotube (BNNT), an electrically-insulating counterpart of a carbon nanotube (CNT), is a great nanofiller candidate for ferroelectric polymeric nanocomposites due to BNNT’s exceptional properties in piezoelectricity, thermal stability, mechanical strength, and radiation shielding capability. Fast and high-yield polar crystallization of polyvinylidene fluoride (PVDF) was accomplished by incorporating BNNTs as a nucleating agent. As-fabricated BNNT-PVDF nanocomposites were characterized by Fourier-transform infrared spectroscopy (FTIR), wide-angle X-ray diffraction (XRD), and differential scanning calorimetry (DSC) to identify and quantify chain conformations. Besides, piezoelectric coefficients, \( d_{33} \), of BNNT-PVDF nanocomposites were measured and compared with that of a mechanically drawn \( \beta \) phase polar PVDF. The polar transformation due to BNNT incorporation has a great advantage over conventional \( \beta \) or \( \gamma \) phase transformation methods that require (1) mechanical drawing often resulting in defects or (2) high-temperature annealing for an extended time. In addition to the fast polar crystallization, BNNTs had a role of reinforcement of the polymer matrix. The improved Young’s modulus and electromechanical coupling coefficient of BNNT-PVDF nanocomposites indicated potential applications in energy harvesting under harsh environments such as large deformation, wide temperature cycles, and high radiation.

11:00 AM EL02.11.03
A Low-k Interfacial Layer Induced by Interface Trap Charge for P(VDF0.75-TrFE0.25) in Metal-Organic Ferroelectric-Semiconductor Device Yu-Chia Chen, Po-Han Chen and Chih-Ting Lin; National Taiwan University, Taiwan

The characteristics of high dielectric constant in poly(vinylidene fluoride-trifluoroethylene) (P(VDF-TrFE)) copolymer has attracted research attentions. However, previous literatures have shown that the dielectric constant would be decreased with film thickness reduced in metal-organic ferroelectric-metal device [1]. Furthermore, the metal-organic ferroelectric-semiconductor (MFS) device also has this phenomenon [2,3]. This phenomenon is caused by the capacitance of low-k interfacial layer (between P(VDF-TrFE)-metal or silicon) in series with dielectric capacitance. The molecular chains are constrained by the restrictive force from the substrate surface. It results in the low-k interfacial layer between the ferroelectric and semiconductor. The characteristics of semiconductors are more complex than metals. Therefore, it is necessary to explore whether there have the other causes that may cause the interfacial layer between P(VDF-TrFE) and silicon heterojunction.

In this work, we investigate the interface trap charges induced P(VDF-TrFE) dielectric characteristics which is study by a MFS device structure. To explore this effect, different interface trap density at P(VDF-TrFE)-silicon interface is generated. The generated interface trap density can be measured by a conductance technique at room temperature. The interface trap density of the two sample is approximately \( 4.1 \times 10^{11} \) – \( 2.2 \times 10^{12} \) and \( 1.3 \times 10^{12} \) – \( 2.6 \times 10^{12} \) eV\(^{-1}\)cm\(^{-2}\), respectively. The experiment results show that the lower interface trap density of MFS capacitor has lower...
interfacial layer effect. It is mean that the interface dipoles switching is influenced by the interface trap charge, which will lead to more significant interfacial layer effects. On top of that, we propose a mechanism to explain how the interface trap charge influences the interface dipoles switching.

Crossover from Synaptic to Neuronal Functionality through Control of Polarization Dynamics in Organic Ferroelectric Tunnel Junctions Sayani Majumdar1,2, Hongwei Tan2 and Sebastiaan van Dijken2; 1VTT Technical Research Centre of Finland, Finland; 2Aalto University, Finland

Parallel information processing, energy efficiency and unsupervised learning make the human brain a model computing system for unstructured data handling. Oxide memristors, from filamentary to metal-insulator transition devices have been shown to emulate synaptic and neuronal functionalities in artificial neuromorphic circuits. However, challenges like non-linear conductance update, cycle-to-cycle and device-to-device variability and leakage current related issues in a dense crossbar structure are still not resolved. For neurons, often a circuit with multiple active or passive components are required which can complicate circuit designs in a large-scale neural network. Earlier, we found out that solution-processable ferroelectric tunnel junctions (FTJs) with P(VDF-TrFE) copolymer barriers on semiconducting bottom electrode can show analog memristive behavior with a broad range of accessible conductance states and low energy dissipation of 100 fJ for the onset of depression and 1 pJ for the onset of potentiation by resetting small tunneling currents on nanosecond timescales. Key synaptic functions like programmable synaptic weight, long- and short-term potentiation and depression, paired-pulse facilitation and depression, and Hebbian and anti-Hebbian learning through spike shape and timing dependent plasticity can be demonstrated.1 In our current work, we demonstrate that by manipulating the carrier concentration of the semiconducting bottom electrode in our FTJs, it is possible to control the dynamics of ferroelectric domain rotations and their subsequent relaxation in a way so that from synaptic devices they can act similar to neuronal devices.2 These results offer a promising outlook for the FTJ memristors on semiconducting bottom electrodes as both synapse and neuron devices in artificial neural networks by controlling carrier doping concentrations only.

Tailoring Piezo- and Magnetoelectric Polymers Shape and Response for Specific Applications Senentxu Lanceros-Mendez1,2,3; 1BCMaterials, Spain; 2Ikerbasque, Spain; 3Universidade do Minho, Portugal

Electroactive polymer and polymer composites offer large application potential in areas such as sensors and actuators, energy generation and storage, filtration membranes and biomedical applications, among others. Many of
the applications rely both in the ability to properly tailor polymer properties, including microstructure, crystallinity and phase, and/or in the suitable choice of micro and nanofillers.

In this talk the main properties and characteristics of piezoelectric and magnetoelectric polymer will be presented. In particular, the main aspects for properly process materials with tailored shape and response as well the reasons and strategies for the development of specific magnetoelectric composites will be shown. Finally, some of the most interesting applications will be discussed, in which specific shape and/or materials response are particularly relevant. Finally, the main challenges and future directions in this research field will be outlined.

Magneto-Mechano-Electric Characterization of Polarized 0-3 Terfenol-D/PVDF-TrFE Composites Scott Newacheck1,2 and George Youssef1; 1San Diego State University, United States; 2University of California, San Diego, United States

Conductive metallic particulate inclusions in an electroactive polymer matrix composite have been widely studied for enhanced sensitivity applicable to sensors, energy harvesters, electromechanical actuators, and high charge storage capacitors. Moreover, if the metallic particulates exhibit magnetostrictive properties, the domain of applications expands due to the direct and converse magnetoelectric coupling between electric displacement and magnetization by strain-mediation. One such composite has been analytically postulated to have a giant magnetoelectric coupling, namely Terfenol-D magnetostrictive particles embedded into PVDF-TrFE electroactive matrix, but has been proven difficult to experimentally polarize due to electrical breakdown and percolation. This presentation will discuss one method to synthesize Terfenol-D/PVDF-TrFE composites which are capable to become polarized by direct contact electrodes. The experimental protocol and results to elucidate the magnetic, electric, and mechanical properties of the composite is also discussed. First, it was observed that the ferroelectric polarization was improved with a small weight fraction of Terfenol-D particles, but the polarization was hindered as the weight fraction of the particles increased. Second, the permittivity of the composite rapidly increased with the addition of more Terfenol-D particles, which was attributed to the reduction in polarization of the PVDF-TrFE matrix and discussed through a modified Maxwell-Wagner model developed herein. Third, a notable phase delay was observed in the piezoelectric strain in response to a high frequency electric field, such a delay was directly proportionally to the addition of Terfenol-D particles. Fourth, the addition of the stiff Terfenol-D particles were found to enhance the storage modulus of the composite near glass transition but had negligible effect at the crystallization temperature. A modified thermomechanical model was used to fit the experimental data, which provided insights into the interrelationship between thermal transition and mechanical performance. Finally, microscale characterization using scanning electron microscopy (SEM) and magnetic force microscopy (MFM) were conducted on the polarized composite. SEM micrographs provided evidence to the complete enclosure of the magnetostrictive particles into the electroactive matrix, a perquisite for enhanced strain-mediated magnetoelectric coupling. MFM scans of the composite indicate that the Terfenol-D magnetic particles retained magnetic properties from synthesis process and are indeed dispersed within the matrix.

2:15 PM EL02.12.03
Voltage Controlled Molecular Spin State Switching in a Fe (II) Spin Crossover Molecular Complex Guanhua Hao1, Aaron Mosey2, Xuan Yuan Jiang1, Andrew Yost1, Keshab Sapkota3, George Wang3, Xin Zhang1, Jian Zhang1, Alpha T. N'Diaye4, Ruihua Cheng2, Xiaoshan Xu1 and Peter Dowben1; 1University of Nebraska–Lincoln, United States; 2Indiana University Purdue University-Indianapolis, United States; 3Sandia National Laboratories, United States; 4Lawrence Berkeley National Laboratory, United States

The spin crossover (SCO) phenomenon, in 3d transition metal compounds, has potential applicability in molecular spintronic devices for “flexible” memory. Voltage-controlled isothermal changes in the electronic structure of the spin crossover molecular system have now been achieved for the Fe (II) spin crossover complex \[ \text{[Fe[H$_2$B(pz)$_2$]$_2$(bipy)]}, \text{ where pz = tris(pyrazol-1-yl)-borohydride and bipy = 2,2'-bipyridine.} \] This isothermal voltage-controlled switching is evident in thin film bilayer structures where the molecular spin crossover film is adjacent to a molecular ferroelectric thin film (the tested examples being polyvinylidene fluoride
hexafluoropropylene or croconic acid (C₅H₂O₅)) [1]. These organic ferroelectric substrates appear to lock the spin crossover \([\text{Fe\{H₂B(pz)₂\}_2(bipy)\}}\) molecular complex largely in the low or high spin state depending on the direction of ferroelectric polarization [1,2]. This is clear evidence that a molecular multiferroic is possible. In both a planar two terminal diode structure and for a transistor structure, the voltage controlled isothermal reversible spin crossover switching of \([\text{Fe\{H₂B(pz)₂\}_2(bipy)\}}\) is accompanied by a conductance change, where higher conductance occurs at a high spin state while lower conductance is observed for a low spin state, and is seen to be nonvolatile, i.e. retained in the absence of an applied electric field. Nonvolatility arises from the interface between the SCO with nonconducting ferroelectrics which have a non-trivial coercive voltage and can be engineered to test and monitor the spin state of the film. The transistor structure fabricated with an interface between the SCO film and the ferroelectric polymer polyvinylidene fluoride hexafluoropropylene [1] is very different from other molecular spin transistors, a number of which have been fabricated, but are only functional at very low temperatures (i.e. below 10 K). The devices described in this talk are functional at room temperature and above. Like other spin crossover molecular complexes, voltage control of the \([\text{Fe\{H₂B(pz)₂\}_2(bipy)\}}\) spin state is possible, but the voltage control of the spin state becomes volatile when the net electric field from the adjacent ferroelectric is absent. With the very small gap between electrodes (around 160 nm), the ferroelectric fails to lock the changing conductance state of \([\text{Fe\{H₂B(pz)₂\}_2(bipy)\}}\) at zero applied voltage. Yet the conductance change is seen to be about 4 orders of magnitude. This suggests a large on/off ratio is possible. Because these molecular thin films are easily fabricated, and compatible with flexible substrates, there is the potential here for "inkjet printable" low cost molecular solid state memory from this next generation of molecular spintronic devices.

Materials with a negative piezoelectric effect demonstrate atypical, inverse strain-field and polarization-stress characteristics. While mechanisms driving the conventional — positive — piezoelectricity are transparent and manifest in a plethora of organic and inorganic materials, the negative piezoelectricity requires special conditions and is only found in few unique systems, which P(VDF:TrFE) is the most renowned example of [1].

Here, we investigate the piezoelectric activity in a family of small-molecular organic ferroelectrics – the liquid-crystalline BTAs (benzene-1,3,5-tricarboxamides) [2]. Curiously, both the large- and small-signal piezoelectric responses, measured interferometrically on solution-processed thin-film capacitors of BTAs, reveal a pronounced negative piezoelectric effect with \(d_{33}\) reaching values as high as \(-20\) pm/V for short substituted homologues [3]. The measured ‘inverted’ piezoelectric butterfly hysteresis loops are of close-to-ideal form with a well-expressed negative linear slope.

The dipolar disc-like BTA molecules self-assemble into hydrogen-bonded axial aggregates resulting in columnar macrodipoles that pack tightly in a hexagonal lattice. Considering a single ideal molecular stack, a positive piezoelectric response is expected due to the applied field stretching the macrodipole, as confirmed by DFT and MD simulations. However, in real device conditions, the columnar-hexagonal ordering is interrupted by zones of higher disorder. The negative \(d_{33}\) in such structures can therefore be explained by the so-called dimensional effect, which considers the ferroelectric layer as a set of rigid dipoles that are distributed in a deformable matrix. In BTAs this leads to a counterintuitive positive correlation between the large-signal piezoelectric constants and the structural disorder in the bulk, while the small-signal response remains unaffected. Comparison of the piezoelectric response under large- and small-signal conditions for different disorder further reveals that irreversible extrinsic polarization switching processes dominate the large-signal strain.

While the negative sign of the piezoelectric constants is determined by the dimensional effect, the linear strain-field trends in the short-tailed BTAs are caused by polarization-coupled electrostriction (or piezostriction). In longer-substituted BTAs quadratic stain-field relations can be observed due to the negative Maxwell strain starting to dominate because of their lower ferroelectric polarization and higher mechanical compliance. Strong modulation of the elastic constant upon polarization switching further leads to a unique amplification of the large-signal electromechanical response.

Due to their self-healing properties, flexibility and a large figure of merit for energy harvesting, BTAs may become relevant for a wide variety of applications like conformal and/or flexible sensors, energy harvesters and actuators for which rigid crystalline ferroelectrics are unsuited and can be outperformed.

performance of model polymer systems, which have been identified through rational co-design strategy based on advanced computational screening procedures. The proposed framework can augment screening procedures for identifying new polymer materials that are significantly better than the current state of the art.

Design and Synthesis of Self-Assembled Organic Ferroelectrics Miguel García-Iglesias1,2, Nicolás M. Casellas1,2, E. W. (Bert) Meijer1, Martijn Kemerink4 and Tomas Torres1,2; 1Universidad Autónoma de Madrid, Spain; 2IMDEA Nanoscience, Spain; 3Institute of Complex Molecular Systems, Netherlands; 4Department of Physics, Chemistry and Biology (IFM), Sweden

Recent progresses in self-assembly and supramolecular chemistry have paved the way achieving control over the structure and function of organic and polymeric materials in an elegant and effective way. This bottom-up strategy, ubiquitous in biology, leads to dynamic and ordered nanostructures which function is directly related to the non-covalent interactions used to ensemble them. Therefore, a careful design of the building blocks and the resulting supramolecular interactions allows for the preparation of a great variety of macro- and nanoscopically ordered materials which combine different properties.1

Organic non-volatile memory devices based on ferroelectricity represent a promising approach towards the development of a low-cost, efficient and mechanically robust bendable memory technology.2 However, an important drawback of these materials is the utilization of insulating ferroelectrics, necessitating a destructive information read-out. In this context, the combination of ferroelectric and semiconducting properties in a functional material emerges as a valuable solution to this problem, resulting in a ferroelectric diode that retains the information when the power is turned off, and can be written, erased and non-destructively read. This bifunctionality was first achieved by blending distinct semiconducting and ferroelectric molecules in the bulk.3 Nonetheless, the possibility to combine these properties in a single molecular component is highly desirable since the interplay between the ferroelectric and the semiconducting nature would take place at the molecular level, diminishing phase segregation phenomena between dissimilar moieties.

Within this context, we present the synthesis of nanometer-sized self-assembled non-centrosymmetric architectures exhibiting intrinsic permanent polarization and, among others, ferroelectric properties or/and semiconducting properties.

These materials consist of disc-like organic molecules4 that (i) are semiconducting, (ii) possess dipolar side groups and (iii) can be organized into columnar morphologies that have sufficient long-range order to support both ferroelectric coupling between the dipolar groups and quasi-1D charge transport. In these materials the ferroelectric polarization is shown to couple strongly to the materials’ bulk conductivity, giving rise to switchable and rectifying current-voltage characteristics. The observed phenomenon is highly relevant for the fabrication of low-cost non-volatile rewritable memory devices.5 Moreover, making use of the previous design we envision the preparation of the next-generation of macro- and nanostructured organic photovoltaic devices (OPVs) using self-assembled donor-acceptor conjugates that demonstrate both a permanent dipole moment and light-harvesting properties. The use of non-centrosymmetric columnar aggregates in OPVs devices should promote fast photoinduced charge separation, as well as good electron transport and extraction features due to the extraordinary control over the internal structure and the presence of an intense permanent macroscopic dipole within the active layer.

Potential of SrTiO3-Based 2DEG for Spin-Charge Interconversion
Agnès Barthelemy; Unité Mixte de Physique CNRS/Thales, France

While classical spintronics has traditionally relied on ferromagnetic metals as spin generators and detectors, a new approach called spin-orbitronics exploits the interplay between charge and spin currents enabled by the spin-orbit coupling in non-magnetic systems. We studied the potential of the bidimensional electron gases (2DEG) that forms at the interface between LaAlO3 and SrTiO3 [1] or by deposition of Al on SrTiO3 by sputtering [2]. We exploited the sizeable Rashba spin-orbit coupling of the gas to obtain a very large spin-current to charge-current conversion through the inverse Edelstein effect [2, 3]. The efficiency of the conversion, characterized by the Inverse Edelstein effect length, \( l_{\text{IEE}} \), is larger than the one measured for the topological insulator a-Sn or at Bi/Ag interfaces [4]. Moreover, this conversion efficiency can be highly modulated by a gate voltage. We used angle-resolved photoemission spectroscopy and Boltzmann calculations to map this peculiar gate dependence and linked it to the band structure. We will show that the conversion process is amplified by enhanced Rashba-like splitting due to orbital mixing, and in the vicinity of avoided band crossings with topologically non-trivial order [3]. This suggest that oxide interfaces have a strong potential for spin-based information readout in novel memory such as the magneto-electric spin-orbit transistor proposed by Intel[5].

Chiral Domain Topology, Moire Patterns and Magnetism in Intercalated Transition Metal Dichalcogenides
Sang Wook Cheong and Kai Du; Rutgers University, United States
Transition metal dichalcogenides (TMDs) have been extensively investigated as 2D materials last decade. A large amount of transition metals (M) can be intercalated into the van der Waals gaps of a wide range of TMD materials, but a limited recent studies in intercalated TMDs have been reported. The limited examples include Fe$_{x}$TaS$_2$ crystals with $x=1/4$ and $1/3$, which exhibit intriguing configurations of antiphase and/or chiral domains related to the ordering of intercalated M ions with $2a \times 2a$ and $\sqrt{3}a \times \sqrt{3}a$ superstructures, respectively. In addition, Cr$_{1/3}$NbS$_2$ undergoes helical spin order below 133 K, and shows an interesting soliton-lattice behavior when in-plane magnetic fields are applied in the helical spin state. We have explored a series of chiral M$_{1/3}$Ta(Nb)S(Se)$_2$ to investigate the correlation among crystallographic symmetries, magnetic domain topologies and their physical properties. These results as well as Moire patterns with self-twisted TMDs induced by intercalation will be discussed.

Multiferroics—Hidden Functionalities beyond Magnetoelectric Coupling Manfred Fiebig; ETH Zurich, Switzerland

Requirements to "good multiferroics" are tough. They are supposed to have a spontaneous magnetization and polarization, preferably parallel to each other, with a strong magnetoelectric coupling between them. Inevitably, this leads to a multiferroic state that is described by a very complex set of order parameters – complex enough to provide the symmetry degrees of freedom to fulfil so many requirements at once [1]. With the focus on electric-field-controlled magnetic order, it may go unnoticed that these degrees of freedom will permit many functionalities other than bulk magnetoelectric coupling. In my talk, I will describe the quest for such functionalities in our group. This includes inversion of a ferroelectric or a ferromagnetic multi-domain state in a homogeneous electric or magnetic field: In each domain, the direction of the order parameter is reversed but the domain pattern as such is left untouched [2]. In addition, a ferroelectric domain pattern on a uniformly magnetized background is transduced into a ferromagnetic domain pattern on a uniformly polarized background. Finally, a multiferroic bulk state is "condensed" into a multiferroic domain wall in a non-multiferroic environment.

New Concepts for the Direct Conversion of Heat to Electricity Using Multiferroics Richard D. James; University of Minnesota, United States

We describe recent progress on materials and devices for the direct conversion of heat to electricity applicable to the small temperature difference regime, 10-200 C. This regime includes abundant natural and waste heat sources, but there is currently no reasonable method to harvest the energy. We are pursuing an idea based on the use of first order phase transformations with either an abrupt change of magnetization or polarization at the transformation. In the ferromagnetic case the electricity is harvested by induction; in the ferroelectric case, by capacitance. It is a “direct” method in the sense that there is no separate electrical generator. We survey the theory of this method, the design of the materials and devices, and the analysis of various cycles. We compare theoretical predictions and the behavior of a prototype under cyclic heating/cooling. These devices provide interesting possible ways to recover the vast amounts of energy stored on earth at small temperature difference. They move heat produced by natural and man-made sources from higher to lower temperature and therefore contribute negatively to global warming. This lecture draws on work with Kanwal Bhatti, Ashley Bucsek, Xian Sherry Chen, Bharat Jalan, Bill Nunn, Yintao Song and Vijay Srivastava.

11:00 AM *EL03.01.05
Electric Field-Controlled Magnetism in (Bi,R)FeO$_3$ Solid Solutions Xiang Ming Chen$^1$, Jing Chen$^1$, Xin Xin Shi$^1$, Bin Xu$^2$, Ting Ting Gao$^1$ and Laurent Bellaiche$^3$; $^1$Zhejiang University, China; $^2$Soochow University, China; $^3$University of Arkansas, United States

BiFeO$_3$ has attracted the increasing scientific attention as the most important room temperature single phase multiferroic material. However, the weak magnetoelectric coupling in BiFeO$_3$ seriously obstructs its applications.
The cycloidal spin structure is actually a hint of the existence of the magnetoelectric coupling. In the present work, the magnetoelectric coupling has been realized by destroying the cycloidal state and switching it to the weak ferromagnetic state through symmetry modulation. Electric field-controlled magnetism is achieved in Bi$_{1-x}$R$_x$FeO$_3$ solid solutions by tuning the symmetry from polar $R3c$ to polar $Pna2_1$, where two morphotropic phase boundaries (MPB) are detected together with the greatly enhanced ferroelectric polarization and magnetism. The electric field-controlled magnetism is realized by an electric field induced structural transition from $Pna2_1$ back to $R3c$ which results in the magnetic transition from weak ferromagnetic state to cycloidal state, and this transition is shown to be reversible with additional thermal treatment.

11:30 AM  EL03.01.06
Coexistence of Multiferroicity and Metallic Conductivity in One-Dimensional Single-Component Radical
Yong Hu and Shengqiang Ren; University at Buffalo, United States

Multiferroics and metallic conductivity seem mutually exclusive and cannot be obtained in one material.[1] Dielectric property requires the localized charge and the electrical conducting behavior is based on the free charge carriers. The confined electronic structure in one-dimensional (1D) materials might break this long-standing contradiction. Electrons confined to a 1D chain exhibit various instabilities followed by symmetry breaking, such as superconductor,[2] topological insulator[3] and multiferroics[4]. Here we report the discovery of laser shock induced insulator-metal transition in K-TCNQ radical,[5] where the effect of antiferromagnetic spin ordering causes dipole ordering. The manipulation of spin exchange interaction with external laser shock wave, electric field and magnetic field is accompanied by insulator to metal transition, gigantic magnetoelectric and magnetocapacitance effects, respectively. Therefore, 1D systems with strongly coupled multiple degrees of freedom of electrons-spin, charge, and orbital-provide a new area to search for conducting magnetoelectric media. Our study opens the way for electron engineering, symmetry breaking and establish of self-organized electronic order from modular building blocks, permits the rational design of functional electronic materials that exhibit technologically useful behaviour.

Spintronics with Magnetoelectric Antiferromagnetic Thin Films
Tobias Kosub and Denys Makarov; Helmholtz-Zentrum Dresden-Rossendorf e.V., Germany

Thin film magnetoelectric antiferromagnets (AF) have potential to revolutionize spintronics due to their inherently magnetic-field stable magnetic order and high-frequency operation. To explore their application potential, it is necessary to understand modifications of the magnetic properties and magnetoelectric responses of AF thin films with respect to their bulk counterparts.

Our approach is based on the electron transport characterization of magnetic responses of thin film antiferromagnets [1-4]. This task is difficult as minute uncompensated surface magnetization of antiferromagnets needs to be detected, which imposes strict requirements to the sensitivity of the method. We will outline our developments of zero-offset anomalous Hall magnetometry [3] applied to study the physics of insulating magnetoelectric Cr2O3 antiferromagnets. To build a reliable description of the material properties, the analysis of the transport data is backed up by structural characterization and real space imaging of AF domain patterns using NV microscopy [1,2]. Considering grainy morphology of thin films, we address questions regarding the change of the intergranular exchange [2], criticality behavior and switching of the order parameter [3].

The fundamental understanding of the magnetic microstructure of magnetoelectric α-Cr2O3 thin films and the possibility to read-out its antiferromagnetic order parameter all-electrically enabled the entirely new recording concept where a magnetoelectric memory cell can be addressed without using a ferromagnet, the purely antiferromagnetic magnetoelectric random access memory (AF-MERAM) [1]. In addition to the outline of the
memory concept, we discuss on the physics of the readout signal in α-Cr2O3 interfaced with Pt [4].

SESSION EL03.02: Magnetoelectrics I

Recent Progress in Spintronics for Energy Efficient Systems Kang L. Wang, Armin Razavi and Hao Wu; University of California, Los Angeles, United States

Spintronic devices take advantage of the nonvolatility of magnetism and electrical control high energy efficiency, and thus offer promise to deliver next-generation systems in memory and computation as well as RF devices and systems. Spintronic devices offer the advantages of non-volatility, low switching energy (< fJ), high speed/frequency (<10 ns), and an almost unlimited endurance (>10^16). The development of this technology is especially crucial in the advent of big data and artificial intelligence, which demand fast access to large amounts of data at high processing speeds. In particular, recent advances on memory (magnetic random-access memory, MRAM) and logic devices have also drawn interest in memory-centric computing paradigms. In this talk, we will first provide an overview of the progress of magnetic materials for high spin orbit coupling (SOC) and spin orbit torque (SOT) applications. We will discuss SOC and magnetoelectric effects as two routes for energy efficient MRAMs. In SOT systems, a high spin-SOC material is used to create a transverse spin current to manipulate or switch the magnetic moment of an adjacent magnet through a torque in a magnetic tunneling junction device (MTJ). We will discuss recent advances in SOTs, including the applications of topological insulators surface states for increasing the switching energy efficiency. A major challenge for SOT switching is that it requires an additional inversion symmetry breaking to become deterministic, which is usually provided by applying an in-plane external magnetic field. We discuss the recent progress for realizing field-free deterministic SOT switching through symmetry breaking using various techniques, including antiferromagnetic materials and structural symmetry breaking.

Second, we will highlight progress in synthetic layered materials to achieve magnetoelectric effects for memory and logic devices using the voltage-controlled magnetic anisotropy (VCMA) effect, very much like multiferroic materials. In this case, a voltage is applied across the magnetic tunnel junction to reduce the anisotropy energy barrier to allow for the voltage controlled switching of the free layer in an MTJ but with a thicker MgO barrier layer, instead of of passing current through the MTJ. VCMA devices are two-terminal and have a much higher density compared to SOT structures which require three terminals for read/write. The reduction of energy barrier per unit voltage is characterized by the VCMA coefficient; to improve the effectiveness of voltage control and scaling to high densities, it is necessary to improve the VCMA coefficient > 1,000 fJ/Vm (first 1,000 challenge). We discuss the recent progress in this area, with a focus on interface and seed/spacer/insertion engineering. For this and related MTJ devices, the readout uses a tunneling magnetoresistance ratio (TMR). The state of the art TMR is of 200~300%. For improved read operation a large signal-to-noise ratio for readout in large arrays, TMR > 1,000%, is desirable and warrant as the second 1,000 challenge. We show strategies for enhancing TMR based on using materials with high spin polarization, such as Heusler alloys. Another challenge for VCMA devices is their high write-error-rate, which can be mitigated by using circuits-based approaches or new device concepts (such as skyrmion-mediated switching). The similar concepts may be applied to energy efficient RF systems. Lastly, for THz applications, ferrimagnetic and antiferromagnetic materials for enhancing the operation speed/frequency will also be briefly discussed.

2:00 PM *EL03.02.02
Thin Film Magnetoelectric Composite Sensors—Sensitivity and Bandwidth at Low Frequency
Dirk Meyners: Kiel University, Germany

Composite materials consisting of magnetostrictive and piezoelectric constituents are known for efficient strain mediated magnetoelectric (ME) coupling. Magnetic field sensors made out of such composites yield high sensitivity and low detection limits in the pT field range. Thin film ME sensors reach sensor performance similar to that of their bulk material counterparts provided that the frequency of magnetic field coincides with a mechanical resonance frequency of the sensor structure. In general this condition is not fulfilled. The measurement of e.g. biomagnetic signals requires extremely low detection limits at frequencies of few Hertz and a minimum bandwidth in the order of 20 Hz.

This presentation considers three different ME sensor concepts to enhance sensitivity to low frequency signals, i.e. magnetic frequency conversion (MFC), surface acoustic wave (SAW) sensors, and piezoelectrically driven sensors based on converse ME effect and inductive read-out by a surrounding pick-up coil. The focus is on designing the magnetostrictive phase, which must be tuned to the sensor concepts differing in underlying effects, utilized substrate, sensor size and thickness, as well as operating magnetic or piezoelectric excitation. In MFC the ME sensor structure is exposed to strong modulating magnetic fields changing the magnetization of the magnetostrictive film periodically with a frequency of about 1 kHz. In contrast to that, the converse ME effect sensors are piezoelectrically driven at comparably high frequencies (515 kHz). The SAW sensors are operated by means of interdigital transducer electrodes at 146 MHz leading to mechanical wave propagation at the device surface and thus through the magnetoelastic phase. Utilizing the ΔE effect, phase change between input and output signal serves as a measure of the applied field. With regard to the various concepts, the interplay between magnetic configuration, associated magnetic noise, and resultant ME sensor performance is investigated.

All sensors are fabricated by bulk micromachining. The sensors for MFC and converse ME effect are of Si cantilever type with 2 µm thick AlN serving as piezoelectric phase. The cantilevers are 350 µm thick and have lateral dimensions of 2.2 mm x 25.2 mm. Enabled through the thin film approach and magnetron sputter deposition, single FeCoSiB and complex multilayers comprising up to 80 individual layers form the magnetostrictive phase. The multilayers consist of repetitions of the stacking order unit Ta 5 / Cu 3 / MnIr 8 / FeCoSiB x [thickness in nm] with varying thickness x of the FeCoSiB layer. The total thickness of the FeCoSiB layers adds up to 1 µm, 2 µm, and 4 µm.

The SAW sensors are based on single crystal Quartz substrates with a 4.5 µm thick silicon oxide layer functioning as guiding layer for horizontal shear waves. Single FeCoSiB layers with a thickness ranging from 25 nm to 750 nm are deposited on the guiding layer and in between the transducers. SAW sensor sensitivity and insertion losses are investigated in dependence on the FeCoSiB layer thickness.

At current status, similar detection limits ranging between 60 pT/Hz1/2 and 150 pT/Hz1/2 are observed at 10 Hz frequency for all three kinds of sensor concepts. However, converse ME effect sensors and SAW sensors benefit from wider bandwidth of about 1 kHz and 1 MHz, respectively.

The presented work was conducted within the framework of the Collaborative Research Center CRC 1261, funded by the German Research Foundation (DFG).

Synthesis of Coaxial Nanofibers of Hexagonal Ferrites and Ferroelectrics and Studies on Strain Mediated Magneto-Electric Interactions
Ying Liu1,2, Peng Zhou2, Wei Zhang1, Tianjin Zhang2 and Gopalan Srinivasan1; 1Oakland University, United States; 2Hubei University, China

We report on the synthesis of coaxial nanowires of ferrimagnetic hexagonal ferrites and ferroelectric lead zirconate titanate (PZT) or barium titanate (BTO), assembly of nanostructures into superstructures with the aid of magnetic and/or electric fields, and studies on the nature of coupling between the magnetic and electric subsystems [1]. Such multiferroic nano-composites are expected to show strong strain mediated magneto-electric (ME) coupling due to very high surface area-to-volume ratio [2]. The efforts were on fibers of Y- or W-type hexagonal ferrite and PZT or BTO and their assemblies. Core-shell fibers with (Ni, Zn) Y-type or (Co, Zn) W-type hexaferrites and ferroelectrics were prepared by electrospinning. The choice of Zn-substituted ferrites with planar or uniaxial anisotropy was aimed at control of magnetic order parameters for ME studies at low frequencies and at resonance modes of electric and
magnetic subsystems and over a wide frequency range, from 1Hz to 110 GHz. The fiber synthesis was carried out by dispensing sol gels of ferrites and ferroelectrics through a coaxial syringe with a dual syringe pump. It was possible to control the core and shell diameters by controlling the gel viscosity, strength of the electric field and core and shell diameters of the needle. Electron-, scanning probe-, and scanning microwave microscopy of fibers annealed at 700-900 C showed fibers of shell diameter 200-800 nm and core diameter of 50-200 nm with well defined core-shell interface. Fibers were characterized in terms of magnetic, ferroelectric, and electromagnetic parameters. The magnetization for the fibers were in general agreement with values for bulk ferrites, but the polarization was one to orders of magnitude smaller than expected values. Investigations on ME effects were performed on 2D and 3D fibers assembled in a magnetic field and on discs of the fibers annealed at high temperatures. Low-frequency ME voltage coefficients (MEVC) for the films and discs were in the range 0.3 to 3 mV/cm Oe with the highest values measured for fibers of (Ni, Zn) Y and PZT. Magnetic field assembled films showed a higher MEVC than un assembled films. Polarization P vs electric field E measurements under an applied static magnetic field H on discs indicated a fractional change in the remnant polarization as high as 7% for H = 7 kOe. Magneto-dielectric measurements on films at 12-26 GHz showed 2-3 % fractional change in the dielectric permittivity for H = 7 kOe. The nanofibers studied in this work show strong ME coupling and are of interest for application in sensor and energy harvesting technologies.

The research was supported by a grant from the NSF (DMR-1808892)

4:00 PM EL03.02.05
Smart Magnetolectric Antennas for Magnetic Sensing and Energy Harvesting Mohsen Zaeimbashi1, Mehdi Nasrollahpour1, Xianfeng Liang1, Huaihao Chen1, Anthony Romano1, Ziyue Xu1, Ankit Mittal1, Nikita Mirchandani1, Gaurav Jha1, Isabel Martos-Repath1, Adam Khalifa2, Marvin Onabajo1, Aatmesh Shrivastava1, Sydney Cash2 and Nian Sun1; 1Northeastern University, United States; 2Massachusetts General Hospital, Harvard Medical School, United States

Recent progress in the field of magnetolectric (ME) materials have led to ultra-compact ME antennas with size of 2-3 order of magnitude smaller than that of conventional state-of-the-art compact antennas [1]. These miniaturized antennas could be suitable for Medical Implant Communications Service (MICS), in particular for wireless brain monitoring. A wireless implantable device should be able to perform multiple tasks in order to effectively monitor an individual’s condition. For instance, a wireless implantable device should harvest their required energy in order to power their circuitry systems. In addition, the implant needs to record the body’s information such as magnetic or electric fields in order to successfully track the changes the body. Finally, the implant should transmit the recorded data to the external antenna or device.

In this work we’re presenting an ultra-compact and smart magnetolectric antenna that can single-handedly perform all three above-mentioned tasks: energy harvesting, magnetic field sensing, and data communication. This complimentary combination makes ME antennas suitable for brain implantation where magnetic field recording is required to monitor the brain functionality. Fig. 1 shows the optical microscope image of fabricated ME antenna with AlN/FeGaB thin-film structure. AlN acts as a piezo-material and FeGaB as a magnetostrictive material. Proposed antenna has three parallel ME element, each with the size of 50×250 µm². Fig. 2a shows the architecture of energy harvesting setup. Fig. 2b shows the ME antenna concept and its functionality in receiving (energy harvesting) mode. Fig. 2c shows the S11 of ME antenna showing the resonant frequency of 2.25GHz. Fig. 2d shows the harvesting voltage from ME antenna, showing an induced voltage of 2.13mV when ME antenna is in presence of a 4.5nT RF magnetic field. Fig. 3a shows the ME antenna’s phase response in magnetic sensing mode. Here, ME antenna is in presence of a 1kHz magnetic field with 6.6µT strength. Fig. 3b is the zoomed-in version of Fig. 3a and shows the 1kHz phase peak which corresponds to the 6.6µT magnetic field under measurement. The limit of detection of this antenna is 917pT.

Charge-Lattice and Spin-Lattice Interactions in Multiferroics and Magnetoelectrics Yimei Zhu; Brookhaven National Laboratory, United States

Topological structures and defects including ferroelectric and ferromagnetic vortices emerging near spontaneous symmetry-breaking transitions are ubiquitously observed in wide branches of science. They are invariant under continuous deformations, or perturbations, and protected by topology, thus are promising candidates as information carriers for future memory and logic devices. However, their controlled manipulation including creation and annihilation remains an important challenge towards practical applications. In this presentation I will give a few examples. 1) Structural transformation of sixfold ferroelectric vortex domains into crystallographically forbidden two-, four-, and eightfold vortices via a second topological defect in hexagonal manganites. Combining high-resolution electron microscopy and Landau-theory-based numerical simulations, we investigate the remarkable atomic arrangement and the intertwined relationship between polarization and topological defects. 2) Controlled evolution of helical and skyrmion phases in multiferroic oxides as function of doping, temperature, and magnetic field from direct imaging using in-situ Lorentz phase microscopy. We reveal that skyrmion channeling effectively suppresses the second skyrmion phase formation at low temperature, envisaging designing of skyrmion flow circuits based on multiferroic thin films for spintronics. If time allows, other material systems will also be presented.

Collaborations with S. Cheng, J. Li, and MG. Han at BNL and Jan Seidel at UNSW are acknowledged. Work at BNL was supported by DOE/BES-MSD under Contract DESC0012704.

Emission and Active Manipulation of Spin Waves in Multiferroic Heterostructures Huajun Qin, Sampo J. Hämäläinen and Sebastiaan van Dijken; Aalto University, Finland

Multiferroic heterostructures comprising strain-coupled ferromagnetic and ferroelectric layers can be exploited as programmable hybrids in magnonics. Attractive properties of multiferroic heterostructures include the imprinting of magnetic domain patterns with a regular modulation of magnetic anisotropy, the creation of abrupt anisotropy boundaries, strong pinning of straight magnetic domain walls, and electric field control of magnetic anisotropy, magnetic switching, and magnetic domain wall motion [1-3]. Here we show that these attributes provide an attractive platform for the emission of short-wavelength spin waves [4], the confinement of spin-wave modes in structurally uniform films [5], and the manipulation of spin-wave transmission [6]. In our studies, the multiferroic heterostructures consist of a ferroelectric BaTiO$_3$ substrate and a strain-coupled ferromagnetic film with a thickness of 20 – 50 nm. At room temperature, this material system comprises fully correlated stripe domains in the ferroelectric and ferromagnetic subsystems. Utilizing strong pinning of ferromagnetic domain walls onto ferroelectric boundaries, we demonstrate active manipulation of spin wave transmission from ~0% to ~100 % by non-volatile reprogramming of the domain-wall spin structure in a magnetic field [6]. We also present results on electric field control of spin wave transmission using local domain switching via lateral wall motion in perpendicular electric fields. Many of the magnonic concept realized in multiferroic heterostructures are extendable to other material systems with regular modulations of magnetic anisotropy.

EL03.03.01
Electronic and Magnetic Transitions in LaNiO$_{3-\delta}$ Nickelate Perovskites with Ordered Oxygen Vacancies
Yongjin Shin and James Rondinelli; Northwestern University, United States

Rare-earth nickelates perovskites (RNiO$_3$, with R=rare earth) are of high academic interest as they show sensitive variability in their properties with subtle structural changes. Unlike other RNiO$_3$ compounds, LaNiO$_3$ is the only compound showing no metal-insulator transitions with temperature as the relatively large size of La suppresses the distortive mode stabilizing insulating phase. Instead, LaNiO$_{3-\delta}$ exhibits interesting electronic/magnetic transitions with varying oxygen contents $\delta$. Specifically, the metal-semiconductor-insulator transition occurs concurrently with paramagnetic (PM)-ferromagnetic (FM)-antiferromagnetic (AFM) transition in bulk materials [1]. The origin of these transitions can be associated with ordered oxygen-vacancies in LaNiO$_{3-\delta}$, which transforms NiO$_6$ octahedra to NiO$_4$ square planer units along (110)$_p$ direction. As the square planar units are with different coordination environment and crystal-field splitting of d-orbital states, the assembly of two units results in unique electronic/magnetic structures.

In this work, we investigate the role of ordered-oxygen vacancies in LaNiO$_{3-\delta}$ by using first-principles calculations on LaNiO$_{3-\delta}$ phases with $\delta=0$, 0.25, and 0.5. The LaNiO$_{2.75}$ is composed of octahedral slabs separated by square planer plane, while LaNiO$_{2.5}$ is with a columnar arrangement of square planes and octahedra. We show that the magnetic properties of LaNiO$_{3-\delta}$ are mainly determined by octahedral units with limited connectivities, as Ni$^{2+}$ on square planar unit is with low-spin configuration and magnetically inactive. We also explain the structural distortions induced by insertion of square planar units, and conclude by connecting our findings to experimental bulk properties.

EL03.03.02
Enhanced Magnetoelectric Properties and Structural Phase Transition in BiFeO$_3$:YbEr Thin Films
Ricardo Martinez Valdes$^1$, Claudia Zuluaga$^1$, Blanca Y. Rosas$^1$, Javier Wu$^1$, Ram S. Katiyar$^1$, Shawn Zografos$^1$, Hannu Huhtinen$^2$, Wojciech Jadwisienczak$^3$ and Ratnakar Palai$^1$; $^1$University of Puerto Rico, United States; $^2$University of Turku, Finland; $^3$Ohio University, United States

Multiferroics materials are scientifically and technologically promising because of their potential applications in multi-state memory for data storage, magnetic recording, spintronics, quantum electromagnets, and sensors. BiFeO$_3$ (BFO) is one the rare single-phase room temperature multiferroics and shows ferroelectricity up to 820$^\circ$C and antiferromagnetism below 370$^\circ$C. However, high leakage current, weak magnetoelectric coupling, presence of cycloidal spin spiral, and critical structural stability of BFO are the bottlenecks for practical applications. Rare earths show many Interesting optoelectronic and magnetoptic properties. In order to enhance the magnetoelectric properties, we investigated Yb and Er co-doped BFO [Bi$_{1-2x}$(Yb$_x$Er$_{2-x}$)FeO$_3$] ($x = 0.05, 0.10, 0.15, 0.2$, and 0.25) bulk and thin film samples. We found that samples with $x =$0.1 and 0.15. Samples with 20 and 30% rare earth show significant improvement in magnetoelectric properties with very high polarization ($\sim 100 \mu$C/cm$^2$). The enhanced magnetic properties can be explained by the localization of 4f electrons and high effective magnetic moments of rare earth. A structural phase transition has been observed above 20% doping of rare earth. The effect of co-doping of rare earth on enhanced magnetoelectric properties and phase transition will be discussed in detail.

EL03.03.03
A Study on the Multiferroic Properties of Bi- and Tri-Layer Hydrogenated Graphene
Samuel Escobar, Rajesh Katiyar, Ernesto Espada, Vladimir I. Makarov, Brad Weiner, Gerardo Morell and Solimar Collazo; University of Puerto Rico at Rio Piedras, United States

Hydrogenated graphene has been of great interest for the scientific community due to properties like ferromagnetism and piezoelectricity that are not usually present in graphene; requiring subsequent functionalization after synthesis to obtain them. Hereby, we present a novel method for synthesizing hydrogenated graphene via a single-step process. Hydrogenated graphene was characterized primarily by Raman spectroscopy, X-ray Photoelectron Spectroscopy
(XPS), X-ray Diffraction spectroscopy (XRD) and Physical Properties measurement system (PPMS). Our Raman spectra confirms the presence of the 2930 cm⁻¹ peak associated with hydrogen functionalization, while the PPMS reveals the strongest ferromagnetism at room-temperature of a carbon-based material with a Curie temperature higher than 350 K. Preliminary research also suggests the presence of ferroelectricity within our material. These results are strong evidence of hydrogenated graphene’s capabilities for its implementation to spintronics & memory applications.

**EL03.03.04**
**Rashba Spin Splitting and Perpendicular Magnetic Anisotropy of Gd-Adsorbed Zigzag Graphene Nanoribbon Modulated by Edge States under External Electric Fields**
Zhengzhen Qin¹, Guangzhao Qin², Bin Shao¹ and Xu Zuo³; ¹Zhengzhou University, China; ²University of South Carolina, United States; ³Bremen University, Germany; ⁴Nankai University, China

The one-dimensional (1D) Rashba effect has become much important due to its key role in basic science to realize exotic electronic phenomena, such as Majorana bound states. Similar to the 2D or 3D systems, the modulation of Rashba effect in 1D matrix is the kernel of spintronics for manipulating electron spin. Herein, by investigating the effects of transverse and vertical external electric field (EEF) on the Rashba spin splitting and magnetic anisotropy energy (MAE) in a new type of highly flexible 1D system (Gd-adsorbed zigzag graphene nanoribbons) from first principles, we found that the Rashba spin splitting in such 1D system can be effectively regulated by the transverse EEF. Moreover, perpendicular magnetic anisotropy holds with either transverse or vertical EEF applied, despite obvious modulation of the MAE contributions in k-space as well as the Rashba spin splitting. Based on the analysis of the orbital-decomposed band structures and in-plane spin density under EEF, it is revealed that the MAE contributions along k-line as well as the Rashba spin splitting can be modulated by E_z due to the regulated coupling of Gd-5dₓ²-ᵧ² and dₓᵧ orbitals near E_f, which is driven by the edge states. The modulation of Gd-5dₓ²-ᵧ², dₓᵧ by C-pₓ orbitals of edge states is the key to manipulating the magnetic anisotropy, which even plays a decisive role on modifying the Rashba spin splitting in such 1D nanoribbon system. The MAE and 1D Rashba spin splitting are expected to be controlled through modifying the edge states in such systems via EEF or other means. Our study introduces a new strategy to manipulate Rashba spin splitting by edge states and provides new insight into the magnetic anisotropy in 1D Rashba system, which would revitalize further research in ZGNR-based systems within the spintronics and exotic electronic phenomena.

**Understanding the Origin of Magnetism in Anatase TiO₂ Using Free-Standing Membranes**
Sonu Devi and Thirumalai Venkatesan; NUSNNI-Nanocore, Singapore

Anatase titanium dioxide (TiO₂) is an important dilute magnetic semiconductor (DMS) as it exhibits room temperature ferromagnetism. However, even after a decade of research, the origin of ferromagnetism in this material system has not reached consensus. In this study, the magnetic properties of two systems, Ta-doped anatase-TiO₂ and undoped-anatase-TiO₂ had been studied in detail. To avoid the effects from a substrate and the interface we have fabricated free-standing membranes using water-soluble Sr₃Al₂O₆ sacrificial layer. A strong correlation between the observed ferromagnetism and Ta-doping has been observed. The magnetic centers and the exchange mechanism in the undoped-anatase TiO₂ have identified. This study proves the intrinsic nature of these dilute magnetic semiconductors.

**Dynamics of Phase Transition and Spin-Phonon Coupling in Ho₂Ti₂₋ₓO₇₋ δ**
Karuna K. Mishra¹, Ricardo Martinez Valdes¹, SM Koohpayeh² and Ratnakar Palai¹; ¹University of Puerto Rico, United States; ²Institute for Quantum Matter, Johns Hopkins University, United States

A₂B₂O₇ pyrochlores are of great scientific interest because of their interesting magnetic orderings (spin-liquid, spin-ice state, Neel-order) and crystal structure. Rare earth pyrochlores shows Ising-like spins, frustrated ferroelectricity, and multiferroic behavior. Pyrochlores also have the ability to immobilize actinides, thus could be used for the disposal of nuclear waste. We report on dielectric, electrical conductivity, magnetic behavior of pyrochlore Ho₂Ti₂₋ₓO₇₋ δ (x = 0.0 and ± 0.08) down to 5 K. For the better understanding of dynamics of phase transition and spin-phonon coupling, we employed micro-Raman spectroscopic studies of phonon spectra from 82 K- 700 K. Magnetic excitation induced phonon renormalization is evident in the low temperature magnetic phase. The presentation will
discuss the results in details.

**EL03.03.07**  
**Room Temperature Lead Palladium Titanate Nanoscale Multiferroic Thin Films**  
Karuna K. Mishra, Mohan K. Bhattarai and Ram S. Katiyar; University of Puerto Rico, United States

The discovery of single-phase magnetoelectric materials and their analysis of coupling mechanisms between spin and polarization is important from the point of view of next generation logic and memory devices. Herein, we report fabrication, dielectric, ferroelectric and magnetic measurement of a Pd-doped room-temperature magnetoelectric multiferroic PbPd₀.₃Ti₀.₇O₃ (PbPdT) thin film. Highly oriented PbPdT thin films were deposited on (LaAlO₃)₀.₃(Sr₂AlTaO₆)₀.₇ substrates by following laser ablation processes in oxygen atmosphere using pulsed laser deposition technique. Diffraction studies revealed that the film had tetragonal phase with (001) orientation. The surface morphology studies using atomic force and scanning electron microscopic techniques suggest a smooth and homogeneous distribution of grains on the film surface with roughness ~2 nm. The dielectric measurements as a function of temperature were carried out in Pt/PbPdT/LSMO metal-dielectric-metal capacitors that showed diffused behavior over a large range of temperatures at several frequencies, and exhibited a higher dielectric constant ~3200 at room temperature. The measured polarization hysteresis loops at room temperature were attributed to its ferroelectric behavior. A well-saturated magnetization \( M_H \) loop with remanent magnetization of 3.5 emu/cm² was observed at room temperature. The origin of magnetization is argued on the mixed oxidation states of Pd²⁺/Pd⁴⁺ in the PbTiO₃ matrix and complemented by x-rays photoelectron spectroscopic experimental results. These results suggest that our thin films are multiferroic (ferroelectric-ferromagnetic) at room temperature. The details will be presented in the meeting.

**EL03.03.08**  
**Electrical and Magnetic Properties of Thin Single Crystal Cr₂O₃ Films**  
Nguyen M. Vu¹, Xiangpeng Luo¹, Steve Novakov¹, Wencan Jin¹, Johanna Nordlander², Peter B. Meisenheimer¹, Morgan Trassin², Liuyan Zhao¹ and John Heron¹; ¹University of Michigan, United States; ²ETH Zürich, Switzerland

Magnetoelectric materials have been of great interest due to their potential for low-power spintronic devices via the electric field switching of magnetization. Antiferromagnet Cr₂O₃ is one of a very few room temperature magnetoelectrics and possesses unique properties such as uncompensated surface spins and perpendicular magnetic anisotropy. [1] Since the first demonstration of the electric field control of exchange bias in bulk single crystal Cr₂O₃ heterostructures [2], intense effort has focused the demonstration of magnetoelectric switching using Cr₂O₃ thin films at room temperature. [3,4] The existence of twin domains in thin films grown on metallic electrodes, however, leads to high leakage current and dielectric breakdown fields that can only be circumvented by growing rather thick films (250-500 nm). [4,5] By using an isostructural epitaxial oxide electrode, V₂O₃, recent studies have shown the reduction and even possible elimination of twin domains in Cr₂O₃ films. [3] Dielectric and magnetoelectric switching studies of 200 nm thick films show bulk like performance, however, for next generation logic and memory the films must be scaled down. [6]

Here we present an investigation of the electrical endurance and magnetic properties of very thin (30-60 nm) single crystal Cr₂O₃ films grown by pulsed laser deposition onto V₂O₃ buffered (0001) oriented Al₂O₃ substrates. Our results show that 60 nm single crystal thin film has bulk-like resistivity (10¹² cm) and significantly improved breakdown voltage (150-300 MV/m). Using magnetometry, we investigate exchange bias of thin film Cr₂O₃/ferromagnet heterostructure. The blocking temperature is found to be at 285 K which is higher compared to twinned films with similar or greater thickness in literature. [7] Further, Second Harmonic Generation confirms bulk magnetoelectric order of our single crystal thin film at room temperature. These results indicate the importance of crystallinity to realize bulk like properties in very thin films at room temperature.

Flexible Bismuth Ferrite Heteroepitaxy

Yu-Hong Lai\textsuperscript{1} and Ying-Hao Chu\textsuperscript{1,2}; \textsuperscript{1}National Chiao Tung University, Taiwan; \textsuperscript{2}Academia Sinica, Taiwan

In recent years, the multifunctional electric systems have a strong tendency toward flexibility because of the flourishing development of wearable and portable devices. As the candidate for non-volatile memory of next generation, Bismuth ferrite (BiFeO\textsubscript{3}), one of multiferroics, draws our attention due to its large ferroelectric polarization and antiferromagnetism with high transition temperature. This work presents a direct way to combine BiFeO\textsubscript{3} with muscovite in order to make it meet the requirement of the wearable device. In this study, we successfully fabricate high-quality BiFeO\textsubscript{3} thin film on muscovite through van der Waals heteroepitaxy via pulsed laser deposition. In analyses of X-ray diffraction, BiFeO\textsubscript{3} thin film has great crystallinity with the out-of-plane (111), which exactly is the direction of the strongest polarization. Through the PFM and the CV measurements, the results exhibit excellent ferroelectricity. Furthermore, the ferroelectricity does not show observable difference under bending test, which means its great stability against external stress. In the oncoming future, this innovative BiFeO\textsubscript{3}/muscovite system will be the most powerful elements in the application of electric technology.

Multiferroic Behavior in Na\textsubscript{0.5}Bi\textsubscript{0.5-x}Eu\textsubscript{x}TiO\textsubscript{3}

Ricardo Martinez Valdes\textsuperscript{1}, S. K. Behara\textsuperscript{2}, P. Kuruva\textsuperscript{2}, T. Thomas\textsuperscript{2}, Rattanakar Palai\textsuperscript{1} and Wojciech M. Jadwisienczak\textsuperscript{3}; \textsuperscript{1}University of Puerto Rico at Rio Piedras, United States; \textsuperscript{2}IIT Madras, India; \textsuperscript{3}Ohio University, United States

The complex perovskite Na\textsubscript{0.5}Bi\textsubscript{0.5-x}TiO\textsubscript{3} (NBT) is a promising lead-free piezoelectric with interesting ferroelectric (T\textsubscript{c} = 670 K) property and phase transition. The unusual A-site positional disorder and relaxor ferroelectric behavior in NBT makes it an important material for practical applications. Rare earth doped perovskites show interesting magneto-optic and opto-electronic properties. In order to develop a room temperature magneto-electric multiferroic material, we explored Eu-doped NBT Na\textsubscript{0.5}Bi\textsubscript{0.5}TiO\textsubscript{3} (NBT:Eu) with different concentrations. In this paper we report on optical, dielectric, ferroelectric, magnetodielectric, and magnetic properties NBT:Eu prepared by solid-state reaction. The as-synthesized NBT:Eu materials have Eu concentration between 1 to 20 at.% using A-site substitution in the general ABO\textsubscript{3} perovskite oxide are single phase, polycrystalline materials as determined by powder X-ray diffraction study\textsuperscript{[1]}. The luminescence intensity monitored at 617 nm increases linearly with the Eu concentration increase up to 20 at.% without indication of typically observed concentration quenching effect. The photoluminescence (PL) and cathodoluminescence (CL) spectra are dominated by sharp characteristic emission lines corresponding to Eu\textsuperscript{3+} intra-4f\textsuperscript{6} shell transitions centered at 593 nm (5D\textsubscript{0}→\textit{7}F\textsubscript{1}), 617 nm (5D\textsubscript{0}→\textit{7}F\textsubscript{2}) and 700 nm (5D\textsubscript{0}→\textit{7}F\textsubscript{4}), respectively. The PL excitation spectroscopy reveal that optically active Eu\textsuperscript{3+} ion centers can be effectively excited with photons between 325 nm to 550 nm via energy migration or direct resonant excitation processes. The electron paramagnetic resonance shows that characteristic electron spin resonance signal of Eu\textsuperscript{3+} ions are not observed in these material. The crystal field calculations and temperature dependent PL and CL studies have shown that the luminescence of Eu\textsuperscript{3+} ions occupying centro-symmetric and non-centro-symmetric sites; however corresponding luminescence temperature thermal quenching mechanisms are different for photon- and electron-excited spectra. Recently studied dielectric permittivity, dielectric loss, impedance, and phase angle of NBT:Eu as function of frequency\textsuperscript{[2]} were correlated with corresponding magnetic properties of the NBT:Eu subjected to up to 1 Tesla. It was found that material shows a novel room temperature ferromagnetic like behavior, which is unusual, but can be explained by the local structural disordering or phase coexistence. Finally, we will discuss the defects in NBT:Eu and their effect on observed optical, electric and magnetic properties of this novel multiferroic material.

Heterointegration of Complex-Oxide Epitaxial Films

Hyunseong Kum\textsuperscript{1}, Hyungwoo Lee\textsuperscript{2}, Sungkyu Kim\textsuperscript{1}, Shane Lindemann\textsuperscript{2}, Chang-Beom Eom\textsuperscript{2} and Jeehwan Kim\textsuperscript{1}; \textsuperscript{1}Massachusetts Institute of Technology, United States; \textsuperscript{2}Korea Advanced Institute of Science and Technology

To date, physical coupling of complex-oxide materials has been predominantly demonstrated through epitaxial means, which limits the breath of possible combinations of materials and restricted by lattice mismatch conditions between the epitaxial layer and substrate. Therefore, there is an increasing trend across all functional single-crystalline materials to lift-off the epitaxial layer from the substrate and transfer the membrane onto foreign substrates. This not only opens up immense amount of freedom to integrate various functional materials on one platform, it also potentially allows reuse of expensive and exotic substrates, expediting commercialization. To this end, we have developed a method to generate freestanding complex-oxide membranes by growing on top of graphene as well as precise cleaving at an epitaxial interface. This allows us to transfer and stack arbitrary complex-oxide membranes which was not possible by epitaxial means, allowing us to study new oxide interfaces and coupling phenomena.

We exfoliated several single-crystalline complex oxide films (e.g. SrTiO3, CoFe2O4, Y3Fe5O12 etc.) by growing them on top of graphene coated substrates. The graphene layer acts as a slippery exfoliation layer which allows crystal growth but also epitaxial lift-off. Additionally, we have found that it is possible to exfoliate single crystalline PMN-PT from STO surface with atomic precision. PMN-PT has one of the highest piezoelectric coefficients, and also shows exotic properties such as high pyroelectricity which has only started to be investigated. Not only were we able to exfoliate the films, we were able to reuse the substrate several times to continuously produce freestanding oxide membranes using a single substrate.

Using these films, we were able to fabricate a freestanding multiferroic bilayer laminate (CFO/PMN-PT), where CFO is a magnetostrictive material and PMN-PT is a piezoelectric material. We compared the magnetoelastic coupling of our freestanding device to a device not exfoliated from the substrate. An order of magnitude larger signal could be measured for the freestanding device compared to the device still clamped to the substrate, which demonstrate the applicability of our method.

Phase transitions in transition metal oxides, such as metal-Insulator transition, ferromagnetic, ferroelectric materials, are useful phenomena to realize novel electrical/magnetic switching and sensing devices. Among them, the strongly correlated electron system of VO2 exhibits an ultrafast metal-insulator transition (MIT) under external stimuli. If the MIT in VO2 can be controlled by a voltage, a field effect transistor (FET) could be demonstrated with ultrafast and ultralow power consumption switching properties. Here, to enhance the resistance modulation in VO2 FETs, we employ, as a gate insulator, a layered material of hexagonal boron nitride (hBN) which is atomically flat and has much fewer electron trap sites than the other gate oxides have. The VO2 thin film with a thickness of 10 nm was grown on TiO2 by the pulsed laser deposition method and, then, was etched down to 5 micrometer in width. The thickness of hBN was 30nm as top gate geometry. This VO2 thin channel undergoes a metal-insulator transition at around 325 K in the heating process. The transfer curve and gate leakage current of the VO2 FET was measured at 310 K (the drain bias V d is 1.0 V). The drain current increased clearly when applying the positive gate voltage (electron doping), while the current decreased under the application of the negative gate voltage (hole doping). We find no hysteresis and memory behavior in the VO2 FET under gating, indicating no chemical reactions and trapping at the interface. This gate-response speed was observed to be faster than the measurement limit of 400 ms. Namely, a slow response caused by the carrier trap at the interface was not observed. We also investigated the stability of the hBN gate insulator under gating. We can find that the drain current rarely changes during the application of the gate voltage for 3000sec. These observations show that hBN is a chemically and electrically stable material for the gate insulator application. The resistance of VO2 was modulated by up-to 1.2% at a gate voltage of 20 V, which is 4 times larger than in previously reported VO2 FETs with oxide gate insulators such as SiOx. This is likely because with hBN the interface carrier scattering is strongly suppressed. Our results indicate the advantage of use of h-BN as 2D material in order to demonstrate voltage control of transition metal oxides via electrostatic modulation.
Rashba spin texture is the property of inversion asymmetric systems to maintain a momentum-dependent spin splitting in the reciprocal space. This property has been predicted to support an electric-field control of spin degree of freedom promising for spintronic and magnetoelectric applications. Till now, its tunability is not so satisfactory. Here, we predicted that substantial modulation of Rashba splitting strength can be realized in the ferroelectric (FE) perovskite trilayers by reversing the FE polarization. Using first-principles calculations, we demonstrate that PbTiO$_3$/Bi$_M$O$_3$/PbTiO$_3$ ($M$=Al, Ga, In, Sc) heterostructures along [001] direction are promising candidates accessible experimentally. The middle layer supports large Rashba splitting at the CBM and the change of Rashba spin-orbit strength by FE polarization exceeds 80%. The splitting bands are locked at the band edge by carefully choosing the middle layer and are adjustable due to oxygen network. The designed structure improves the feasibility of utilizing Rashba effect in spintronic devices.

**EL03.03.16**

**The Magneto-Impedance and Magneto-Capacitance Effect in Different Magnetoelectric Composite Resonators**

Lei Chen$^{1,2}$ and Nian Sun$^2$; $^1$Chongqing University of Arts and Sciences, China; $^2$Northeastern University, United States

The magnetoelectric (ME) composite has recently attracted considerable attention both for ME effect and for its potential applications[1-2]. S.X. Dong et al. reported that the ME composite can detect a small DC magnetic field less than 10$^{-7}$ Tesla[2]. Especially, the ME effect based on magnetic sensor can be used to measure both DC and AC magnetic fields. In this report, we study the extracting equivalent circuit model and electrical impedance and capacitance dependence on dc magnetic field of magnetoelectric composite resonators. Our research exhibits that the equivalent circuit parameters are strong function of external DC magnetic field. The properties of magnetostRICTive materials dependence on external dc magnetic field lead to magneto-impedance and magneto-capacitance effects. Furthermore, the magneto-impedance and magneto-capacitance effects for FeGa/PZT, Terfenol-d/PZT, FeSiB/PZT and FeNiCoSiB/PZT composite resonators are presented. The experimental results show that the magneto-impedance and magneto-capacitance effects for the magnetoelectric composite resonator strongly depends on DC magnetic field ($H_{dc}$). 240% and 170% of the magneto-impedance can be achieved at anti-resonance frequency ($f_a$) of the FeGa/PZT and FeNiCoSiB/PZT resonator, respectively. The variation of magneto-capacitance for FeNiCoSiB/PZT composite resonator exceeds ~112% at anti-resonance frequency. This find represents another principle for design dc magnetic field sensors, MI devices, or tunable electronic devices.

**EL03.03.17**

**Electrostatically Tunable Mutual Inductance with Magnetoelectric Core for Wireless Power Transfer**

Changxing Sun$^1$, Wenrong Yang$^1$ and Nian Sun$^2$; $^1$Hebei University of Technology, China; $^2$Northeastern University, United States

Multiferroic composite materials with strong magnetoelectric (ME) coupling have led to many novel devices, such as information storage, sensors, energy harvester and tunable magnetic inductors. The capability of tuning magnetic properties by electric field makes such multiferroic composites have great potential for tunable magnetic devices application. Magnetic coupled resonance wireless power transmission whose energy is delivered from the transmitter (Tx) coil to the receiver (Rx) coil by mutual coupling has received considerable attention because of its use in applications in recent years. The mutual inductance is distance dependent when the coils have been designed, therefore the transfer efficiency of the magnetic resonance coupled wireless power transfer system decreases rapidly once the transfer distance is extended to the undercoupled region or the distance is shortened to the overcoupled region. High permeability materials, such as ferrite cores, are utilized to enhance the mutual inductance in the undercoupled region to achieve high transfer efficiency. In contrary, different coils configurations are presented with lower mutual inductance in overcoupled region to suppress frequency splitting to increase the efficiency. Mutual inductance...
should be enhanced by using magnetic core in undercoupled region and be reduced by using complicated loop structure in overcoupled region to achieve high transfer efficiency in. However, the mutual inductance value is usually determined in a previously built prototype, the transfer efficiency is decreased when the transfer distance is changed. The mutual inductance determined by coils configuration limits the transfer efficiency in the overcoupled region and undercoupled region for magnetic resonance coupled wireless power transfer system.

The tunable mutual inductance by electric field using multiferroic composite core has a potential application for efficient magnetic resonance wireless power transfer. Electrostatically tunable mutual inductance with multiferroic composite core consisting of two layers of Nanocrystalline ribbons and one slab have been demonstrated to tune the mutual inductance.

The multiferroic composite coil core consists of two layers of Nanocrystalline ribbons Metglas 1K107 (30μm thick each) and one PZT (0.5 mm thick) piezoelectric slab that was poled along its thickness direction were bonded together with ethyl cyanoacrylate glue. A control voltage ranging from 0 to 600 V, which results in an electric field from 0 to 12 kV/cm in the PZT slab, was applied across the thickness direction of the PZT slab.

The magnetic hysteresis loops of ME core is tested by VSM (Vibration Sample Magnetometer), the magnetic hysteresis loops is changed when the control voltage is applied on the PZT slab. Since the magnetic anisotropy is different under different electric field, the relative permeability of the matglas ribbons $\mu_{\text{eff}} = 4\pi M_s / H_{\text{eff}} + 1$ can be changed, where $H_{\text{eff}}$ is the total effective anisotropy fields in the magnetic ribbons, thus a tunable mutual inductance is expected.

Electrostatic tunable mutual inductance based on multiferroic composite core has been made and tested. According to the experiments results, the mutual inductance tunability, which is mediated by electric field controlled magnetic anisotropy and permeability, achieved a high value of 63.2% with minimum negligible power consumptions, which can be assumed to be a passive devices. The change of the magnetic anisotropy can also been observed in magnetic hysteresis loops. The mutual inductance tunability achieved in such coils based magnetoelectric core has a great potential for efficiency optimization of wireless power transfer in a large region of distance.

**EL03.03.18**

*Structural, Magnetic and Transport Properties of Nd$_2$CoFeO$_6$ and Pr$_2$CoFeO$_6$ Double Perovskites*  
Leonardo Oliveira and Jose A. Souza; Federal University of ABC, Brazil

Double perovskite (DP) compounds with general formula $A_2BB'O_6$ (where $A$ = alkaline-earth or rare-earth ions and $B$ = transition metal elements), belong to a family of materials that have attracted much attention due to their numerous fundamental physical properties. In these materials, the $d$ electrons at $BB'$ sites give rise to strongly correlated electronic and magnetic properties, such as metal-insulating transition, half-metallicity, large magnetoresistance, multiferroicity, long/short-range and frustrated magnetic ordering and many others. In this research, we obtained new DP compounds by traditional solid-state reaction method at 1300 K in air. Rietveld refinement of Nd$_2$CoFeO$_6$ and Pr$_2$CoFeO$_6$ indicates that both compounds crystallize in the orthorhombic $Pnma$ space group with similar lattice parameters, and with the $BO_6$ octahedral half occupied by Co and Fe ions at $4b$ Wyckoff site. Electrical transport measurements have shown a huge decreasing in the electrical resistivity from 10$^7$ Ω.mm to 1 Ω.mm as a function of temperature. DC magnetization of both compounds indicates a critical temperature around 220 K. Above this critical temperature and up to 380 K, the magnetic susceptibility does not follow the conventional Curie-Weiss law in the paramagnetic state. At higher temperature interval, from 380 K up to 700 K, we found a lower second slope in $\chi' \times T$ suggesting an unexpected increase in effective magnetic moment which are not predicted by taking into account the possible scenarios where one considers different valences and spin states for Nd/Pr, Fe and Co ions. Interesting, another peak in $dM/dT$ curve is observed at low temperature. In this context, we will discuss these results correlating the complex magnetic, electrical transport, and structural properties of these disordered double perovskite compounds.

**EL03.03.19**

*A Potential Multiferroic Material—Co Doped Hf0.5Zr0.5O2*  
Zimeng Zhang, Xiaoxi Huang, Vishal Thakare, Vishal Ravi, Yen-Lin Huang and Ramamoorthy Ramesh; University of California, Berkeley, United States

There is currently quite a bit of interest in multiferroics and magnetoelectrics for low power electronics. While there have been many new multiferroics added to the well-studied BiFeO$_3$ system, most of them have transition temperatures below room temperature. Thus, discovering new multiferroic and magnetoelectrics is desirable. Doped magnetic ferroelectrics (DMFE) are attracting attention in this regard since many of them have to potential to multiferroic/magnetoelectric property at room temperature. One such model system is BaTiO$_3$ doped with magnetic

Final Program 1/13/2020  165
impurities. Our strategy is to take well known ferroelectrics, such as Hf0.5Zr0.5O2 (HZO) and introduce magnetic impurities, such as cobalt into the lattice. Prior work on Co-doping of TiO2 has revealed interesting magnetic effects and that forms the backdrop for our work. HZO is a simple fluorite showing robust ferroelectricity at the nanoscale and good compatibility with silicon and hence is a favored candidate for the next generation memory and logic devices. HZO has many phases, among which orthorhombic and rhombohedral phases possess ferroelectricity. Using epitaxy as the underlying driver, we have been able to demonstrate high quality HZO thin films in the 1-20nm thickness range. Doping with 5% Co does show the existence of a magnetic moment. We are presently studying the effects of Co concentration on the magnetic and ferroelectric stability. We demonstrated the existence of ferroelectricity by PFM and P-E loop measurements and tested the magnetic hysteresis loops. We will present results of this investigation on the role of HZO crystallinity and Co-doping on the magnetoelectric properties.

**EL03.03.20**

*Magnetodielectric Properties of Co/PZT/Co Spin Capacitor*  
Fernando Aponte, Roberto Masso-Ferret, Ricardo Martinez Valdes and Ratnakar Palai; University of Puerto Rico at Rio Piedras, United States

Spin capacitors have the potential to store both the electronic charge and magnetic spin that can produce conventional electric current and spin polarized current. The time evolution of spin polarized electrons injected into the piezoelectric material can be used for accurate sensing of magnetoelectric fields. To further study the application of multiferroic spin capacitors for future use in memory applications, Ferromagnetic/Ferroelectric/Ferromagnetic tri-layer artificial multiferroelectric structures in spin capacitor configuration were fabricated. Previous experiments were done by sputtering Iron (Fe) and Nickel (Ni) electrodes on lead zirconate titanate (PZT). In this paper, we report dielectric, magnetic, and magnetoelectric coupling in the tri-layer composite with Cobalt (Co) as the magnetic electrode sputtered onto PZT polycrystalline of different thickness. Various dielectric measurements were carried out, including: capacitance, impedance, loss coefficient, dielectric permittivity, and phase angle measurements done by a wide range of frequencies (100 Hz – 5 MHz) and magnetic fields (0 Tesla – 2.0 Tesla) at room temperature, and their interaction with the presence of the applied magnetic field (magnetocapacitance and magnetoimpedance) were analyzed. We also compared the magnetodielectric measurements of the Co/PZT/Co spin capacitor with Co/PZT/Ag and Ag/PZT/Ag tri-layers structures with their respective their behaviors. The magnetodielectric studies of different PZT layer thickness will be discussed in details.

**EL03.03.21**

*Charge Transfer and Hybridization Induced In-Plane Magnetic Uniaxial Anisotropy on the Co/NiO(110) Interface*  
Liang Yuhan and Yuanhua Lin; Tsinghua University, China

Emergent phenomenon is observed on the heterostructure interface, consisting of complex coupling of spin, orbital, lattice and charge. As a room-temperature stabilized G-type antiferromagnetic materials, the NiO is a favourable physic stage for investigating the interfacial magnetic coupling. Co/NiO interface has been investigated continually for its magnetic coupling and domain structure in (100) and (111) orientation, but few researchers focus on the in-plane orbital structure and related magnetic anisotropy in (110)-oriented Co/NiO interface. We find in-plane magnetic uniaxial anisotropy of polycrystalline Co films grown on the (110)-NiO, contrast to its isotropic crystallography nature. Depending on the X-ray linear dichroism spectrum(XLD) and X-ray circular dichroism spectrum(XMCD) shows, we found this uniaxial anisotropy emergent from the charge transfer of Co to Ni in the [-110] direction, and the hybridization of d-orbitals of Ni and Co. This work promotes the comprehension of the complex coupling of spin, orbital and charge, and provides possibilities for the NiO-based spintronics.

*Magnetic and Dielectric Properties of Potential Multiferroic GdCrO3*  
Jianhang Shi, Yanliu Dang, Steven L. Suib and Menka Jain; University of Connecticut, United States

Multiferroics materials have attracted a lot of attention due to their potential technological applications. GdCrO3 that belongs to the family of rare-earth chromites (RCrO3) has recently been reported to be a single phase magnetoelectric multiferroic. However, the origin or existence of ferroelectricity in GdCrO3 remains ambiguous. We have, therefore, examined the properties of bulk and thin film samples to explore their multiferroic properties. Magnetic measurements have revealed that it shows an antiferromagnetic transition with weak ferromagnetism below the Néel temperature $T_N$ of 169 K as well as spin reorientation, and giant magnetocaloric effect (MCE) at lower temperatures. In this work, structure, particle size, substitution effect, magnetic, and dielectric properties of this
family of material will be presented.

**Investigation of Interface Structure in Multiferroic h-ScFeO₃ Film**

Yosuke Hamasaki¹, Shintaro Yasui², Takahisa Shiraiishi³, Akihiro Akama⁴, Takanori Kiguchi³, Tomoyasu Taniyama⁴ and Mitsuru Itoh²; ¹National Defense Academy, Japan; ²Tokyo Institute of Technology, Japan; ³Tohoku University, Japan; ⁴Nagoya University, Japan

Polar iron oxides, which exhibit both ferroelectricity and (anti)ferromagnetism, are multiferroic materials, which promises potential application for new type memory devices. Hexagonal ReFeO₃ (Re = Rare earth element) with YMnO₃(YMO)-type structure exhibits ferroelectricity and weak-ferromagnetism. First principle calculation revealed that h-ReFeO₃ exhibits improper ferroelectricity (geometric ferroelectricity). Due to the strong magnetic interactions between Fe³⁺ cations, the higher magnetic order temperature in h-ReFeO₃ compared with hexagonal manganites is expected. A magnetic phase transition temperature of h-ReFeO₃ increases with decreasing ionic radius of Re cation. h-ReFeO₃ which consists of small ionic Re cation is a candidate for a high temperature multiferroic material.

Metastable h-ReFeO₃ were obtained by containerless melt crystallization process and crystallization from amorphous phase. Masui et. al. prepared Sc substituted LuFeO₃ by containerless process, and h-Lu₁₋ₓScₓFeO₃ was obtained in the range of x = 0 - 0.8. h-ReFeO₃ (Re = Tb, Lu, Y ) were stabilized on substrates such as YSZ(111) and Pt(111)/Al₂O₃(0001) in film form by pulsed laser deposition (PLD) and sputter techniques. Previously, we stabilized h-ScFeO₃ film on an Al₂O₃(0001) substrate using PLD technique. However, preparation of h-ScFeO₃ have not been reported yet. In this study, we attempted to prepare h-ScFeO₃ film on electrodes and investigated their physical properties and interface structure.

h-ScFeO₃ was deposited on various electrodes such as ITO, ZnO, SrRuO₃, and (La,Sr)MnO₃ by PLD technique. Single phase h-ScFeO₃ was obtained on La₀.₈Sr₀.₂MnO₃//SrTiO₃(111). Crystal structure of film was characterized by X-ray diffraction (XRD) and scanning transmission electron microscope (STEM). XRD measurements and HAADF-STEM observation revealed that h-ScFeO₃ with YMO-type structure was epitaxially grown with the relationships of ScFeO₃(0001)//La₀.₈Sr₀.₂MnO₃(111)//SrTiO₃(111).

The YMO-type ScFeO₃ film showed a ferroelectric P-E hysteresis loop with Pr ~ 4.9 μC/cm² and weak ferromagnetism with Tₘ = 195 K. The Tₘ value is the highest in hexagonal ReFeO₃ and ReMnO₃. Interface studies revealed that the monolayer consisted of two paired Sc cations connected to the YMO-type and perovskite structures. One of two paired Sc cations was displaced upward because of Coulomb repulsion from the Mn cations of La₀.₈Sr₀.₂MnO₃. We deposited ScFeO₃ film on various perovskite films or substrates. Single phase h-ScFeO₃ film was obtained on perovskite films or substrates with low valence B site cations. This results indicated that the valence of B cations in perovskite played an important role in the formation of the interface monolayer.

**Magnetic and Magnetocaloric Properties of Pd Doped in FeRh Alloy with Large Refrigerant Capacity**

Yafen Shang¹,², Yutao Cao¹, Ravi L. Hadimani³, Yurij Mozharivskyj² and Hao Fu¹; ¹University of Electronic Science and Technology of China, China; ²McMaster University, Canada; ³Virginia Commonwealth University, United States

The B2-ordered intermetallic magnetic compound FeRh exhibits a thermodynamically first-order phase transition in vicinity of room temperature that makes it a highly intriguing subject for both fundamental and applied study. The structure, magnetic, and magnetocaloric properties of Pd doped in FeRh alloy have been investigated. Experiments revealed that there are same structures type FeRh (CsCl-type) with different lattice parameters and Fe₁₅.₇Rh (bcc-W type) phases coexist in FeRh₀.₉₅Pd₀.₀₅ sample. The wide phase transition temperature range is about 250 K, which is from 150 K to 400 K for this alloy. The maximum magnetic entropy change (-ΔSₘ) is 16.6 J/kg K for 0 - 30 kOe field changes and refrigerant capacity (RC) of 1347 J/kg was obtained due to the contribution of large transition temperature range. The excellent magnetocaloric performance indicates the applicability of FeRh₀.₉₅Pd₀.₀₅ as an appropriate candidate for magnetic refrigerant.

**EL03.03.26**

**Magnetic Properties of Co₃₋ₓNiₓO₄ (0 ≤ x ≤ 1.28) Particles Synthesized from Co₁₋ₓNiₓ(OH)₂: Precursors**

Kensuke Hayashi, Keisuke Yamada and Mutsuhiro Shima; Gifu University, Japan
Magnetic properties of cobalt nickel spinel oxides $\text{Co}_{3-x}\text{Ni}_x\text{O}_4$ (CNO) have been extensively studied over decades [1,2]. In the Co-Ni-O system, CNO is known to be metastable under atmospheric conditions as the rock-salt phase ($\text{Co}_1\text{Ni}_3\text{O}_4$) is stable when $T > 1173$ K while NiO and $\text{Co}_3\text{O}_4$ phase are stable when $T \leq 1173$ K [3]. Due to CNO’s metastability, it is believed to be difficult to chemically synthesize CNO for $X > 1$ through conventional process such as thermal decomposition and co-precipitation [2,4]. CNO thin films grown by physical vapor deposition for $X > 1$ [5,6], reportedly yield relatively low Curie temperatures ($T_C = -100$-200 K for $X = 1$) in contrast to higher $T_C$ for powder CNO ($T_C = -400$ K) [1]. Recently, it was reported that CNO samples for $X > 1$ can be synthesized by thermal decomposition of organic metal frameworks (MOF) for super capacitor electrodes applications [7]. In this case, CNO for $X > 1$ can be synthesized from Co-Ni MOFs where Co and Ni ions are uniformly mixed at an atomic scale. In this study, we report successful synthesis of CNO particles for $X = 0$-1.28 from $\text{Co}_{1.7}\text{Ni}_3\text{OH}_2$ precursors in which Co and Ni ions are uniformly mixed at an atomic scale, and the magnetic properties of the CNO at room temperature.

[Experimental] The $\text{Co}_{1.7}\text{Ni}_3\text{(OH)}_2$ precursors were prepared from a hydrochloric aqueous solution containing $\text{Co}^{2+}$ and $\text{Ni}^{2+}$ by a uniform precipitation process. The were the annealed at 573-873 K for 3 hours in the air to transform into CNO particles. Their magnetic properties were investigated by vibrating sample magnetometry (VSM), electromagnetic resonance (EMR) spectrometry, and superconducting quantum interference device (SQUID) magnetometry at temperature from 5 K to room temperature (RT). [Results and Discussion] X-ray diffraction spectrometry (XRD) of the samples have shown that CNO particles are successfully synthesized for $X \leq 1.28$ without producing any other phases. The lattice parameter of CNO increases linearly with increasing $X$, yielding with Vegard’s law. The mean particle size of CNO estimated from XRD data using Scherrer’s equation is 8–33 nm. Magnetic measurements by VSM show that CNO particles for $X \geq 0.74$ possess remanent magnetization and coercivity at RT, it reveals that the CNO particles are ferrimagnetic at RT. Microwave absorption peaks are observed in the ENR spectra of CNO particles for $X \geq 0.74$. The EMR spectra of the CNO samples exhibit absorption peaks best fitted only by the Gaussian function. The peaks can generally be fitted by the Gaussian when it contains a ferromagnetic (ferrimagnetic) component and/or the Lorentzian when it has a paramagnetic one in the sample. Hence, it is suggested that the ferromagnetic CNO samples possess a fairly high crystallinity with few defects breaking magnetic interaction in the crystal. SQUID measurements of the samples shows that their saturation magnetization increases with increasing $X$ for $X < 0.74$ and decreases for $X \geq 0.74$. [References]

and Ho Co-Doping Jogender Singh, Ashish Agarwal and Sujata Sanghi; Guru Jambheshwar University of Science and Technology, India

Multiferroics having composition Bi_{0.80-x}Ba_{0.20}Ho_xFeO_3 (BBFO, BBHFO-5, BBHFO-10, BBHFO-15 and BBHFO-20 for x = 0, 0.05, 0.10, 0.15 and 0.20 respectively) were synthesized by method of solid state reaction. The crystal structure has been studied using X-ray diffraction technique. The X-ray patterns show enormous transform in crystal structure at concentration x=0.20. The Rietveld refinement of XRD patterns indicates that at concentration x=0 sample have rhombohedral structure with R3c space group while for the concentration x= 0.05, 0.10, 0.15 and 0.20, the mixed phase including rhombohedral R3c and triclinic P1 space groups were obtained with best fitting. This phase transformation in crystal structure is observed due to mismatching of ionic radii of doped ions and parent ions. Magnetic properties of all samples were carried out by using vibrating sample magnetometry. M-H hysteresis loops shows that with doping of Ba and Ho antiferromagnetic BiFeO_3 (BFO) transforms into ferromagnetic. The dielectric properties were carried out by impedance spectroscopy which shows that dielectric properties are enhanced with co-doping in comparison of the pristine BFO due to structure deformation and decrease in oxygen vacancies with higher concentration of Ho.

EL03.03.29
Probing the Ferromagnetic Resonance of the Si/Ge_{2}Sb_{2}Te_{5}/FeCoB Heterostructures Induced by Phase Change Yuyi Wei, Xinjun Wang, Jiawei Wang and Nian Sun; Northeastern University, United States

Over the past few decades, phase change materials (PCM) has received a lot of attention for its application such as novel non-volatile memory,[1-4] switches[5,6] and sensors.[7] Typically, PCMs exist in an amorphous and one or more crystalline phases, in which significant optical and electrical contrast can be observed. The change in state can be rapidly and repeatedly switched by inducing optical pulses or electrical (Joule) heating.[8,9] In 2011, F. Xiong et al. proposed a low power switching using GST with programming current of 1 to 8 µA and programming voltage of below 1V, indicating an energy loss of femtojoules scale.[5] This design not only brought a promising prospect to ultra-low power electronics and memory development but also proposed inspiration in voltage control of ferromagnetic resonance (FMR).

Here, a systematic study of the coupling effect in Si/Ge_{2}Sb_{2}Te_{5}/FeCoB heterostructures is presented. We investigated the FMR change in FeCoB film induced by crystalline phase change in GST film. A large shifting in FMR field of 15 mT in FeCoB film can be observed when GST is highly crystallized after annealing at 300 °C. And the uniaxial magnetic anisotropy field is also strengthened when Ge_{2}Sb_{2}Te_{5} is highly crystallized in hexagonal phase via interfacial coupling effect. With all these results, a novel structure using PCMs for voltage control of FMR is proved to be applicable. This structure can be predicted to have very low operation voltage as well as ultra-low energy consumption, showing an extraordinary advantage in the development novel fast response, energy efficient tunable microwave devices and non-volatile magnetic memory.

EL03.03.30
Two-Dimensional Transport in LaTiO_3 Thin Films Embedded in SrTiO_3 Jiyeon N. Lee and Mikk Lippmaa; University of Tokyo, Japan

Oxide materials with unexpected transport and magnetic properties at interfaces have generated great interest in multifunctional heterostructure design. One of the best-known systems is the interface between LaAlO_3 and SrTiO_3[1], exhibiting a two-dimensional electron gas in a strongly asymmetric quantum well due to possible switching or spintronic device application[2]. There is growing experimental evidence that the carrier accumulation in a quantum well at the interface leads to magnetic order that may be tunable or switchable if sufficient carrier density control can be achieved. However, except for limited tunability by electrostatic back-gating, it has proven to be difficult to control the carrier density in the electron gas.

In this work, we have chosen to use a similar electronic system consisting of a thin LaTiO_3 film, with a thickness of a few unit cells, embedded in SrTiO_3. While metallic conductivity at the LaAlO_3/SrTiO_3 interface appears abruptly when the LaAlO_3 film thickness exceeds 4 unit cells, the total carrier number in the LaTiO_3/SrTiO_3 system is continuously tunable over a wide range by changing the number of La atoms in the LaTiO_3 layer. Since the presence of a single LaO layer in the perovskite lattice is sufficient to induce metallic conductivity, a polar discontinuity does not arise, but carriers are still confined in a quasi-2D quantum well and form a high-mobility layer, similar to the LaAlO_3/SrTiO_3 interface. When the heterostructure is grown on a single crystal SrTiO_3 substrate and capped with a SrTiO_3 film that is grown at low temperature, the difference in the dielectric permittivities of the substrate and the
cap layer leads to an asymmetric quantum well, similar to the LaAlO$_3$/SrTiO$_3$ heterostructures. By using this specially designed heterostructure, we discuss how to determine the depth distribution of carriers while changing the LaTiO$_3$ or SrTiO$_3$ cap layer thickness and look at the effect of the carrier distribution on the magnetotransport characteristics. Our experiments show that a large negative in-plane magnetoresistance effect occurs at low temperature when the magnetic field is applied parallel to the current, in a qualitatively similar fashion to LaAlO$_3$/SrTiO$_3$ interfaces[3]. We also discuss the effects of back-gating on the magnetotransport characteristics and interpret the results in terms of carrier depth distribution changes in the heterostructure under electrostatic bias. We attempt to distinguish whether the observed negative in-plane magnetoresistance is related to carriers confined at the interface or those that distribute over a larger depth in the substrate-side tail of the quantum well and how such carrier redistribution affects the carrier density in the quantum well.

Rare Earth Ortho-Chromate HoCrO$_3$—A Structure-Property Investigation into Its Multiferroic Nature
Santhosh Nagappan Nair and Anusree V K; Indian Institute of Technology Madras, India

Multiferroics are materials possessing different ‘ferroic’ orders such as ferro-magnetism, ferro-electricity, ferro-elasticity etc. Many rare earth ortho-chromates and ferrites were reported to exhibit multiferroic properties and magneto-electric coupling[1]. It was reported that in many of the rare earth chromates, the onset of polar ordering appears at temperatures slightly higher than their antiferromagnetic ordering[2]. Here we investigate the temperature evolution of structural and dielectric properties of Holmium based ortho-chromate, HoCrO$_3$. Polycrystalline HoCrO$_3$ was prepared by conventional solid-state synthesis route. Reitveld refinement of the synchrotron x-ray diffractogram at room temperature confirms the perovskite orthorhombic structure crystallizing in the Pbnm space group. Temperature evolution of synchrotron x-ray diffraction points to the presence of variation in unit cell volume around 242 K and 100 K. Magnetic measurement confirms the antiferromagnetic transition at 140 K. The compound exhibits a dielectric constant of 19.46 at 1.784 kHz at room temperature. Also, temperature variation of the real part of the dielectric constant reveals a typical relaxor-like behaviour with low temperature and high temperature plateaus along with two anomalies at 240 K and 140 K. Analysis of peaks in the loss tangent curves confirms thermally activated dielectric relaxation. The dielectric anomaly at 140 K indicates a possibility for magneto-electric coupling in the material. However, the peak at 242 K corroborates the volume change observed in synchrotron analysis, which is associated with a possible structural transition (Pbnm to Pna2$_1$), usually observed in similar rare earth based ortho-chromates having ferroelectric ordering. Two feeble features around 100 K and 242 K were observed in the temperature dependence of specific heat curve and these corresponds to the structural transitions observed in the unit cell volume derivative curve with respect to temperature. In the present work synchrotron x-ray diffraction technique was used for the first time to confirm the structural transition in HoCrO$_3$.

Investigation of Geometry Parameters Influencing the Performance of Cantilever Magnetoelectric Sensors
Jingxiang Su$^1$, Florian Niekiel$^1$, Simon Fichtner$^1$, Christine Kirchhof$^2$, Dirk Meyners$^2$, Eckhard Quandt$^2$, Bernhard Wagner$^1$ and Fabian Lofink$^1$; $^1$Fraunhofer Institute for Silicon Technology, Germany; $^2$Kiel University, Germany

Magnetoelectric (ME) sensors currently have attracted great interest due to their capability to detect magnetic fields in the picotesla regime at room temperature, showing a high potential in the biomagnetic field detection. Based on the magnetoelectric effect of ME sensors, the applied magnetic field induces a change in the strain of magnetotriective layer which will be transferred to the piezoelectric material via the mechanical coupling. An electrical voltage across the piezoelectric layer is thus generated and can be measured directly. However, for the application of non-invasive medical imaging like magnetoencephalography or -cardiography (MEG, MCG), a magnetic field sensor with a limit of detection (LOD) in the range of picotesla is required. To reach this goal, the LOD of ME sensors still needs to be further improved.
There are many approaches to improve LOD of ME sensors, either by increasing the sensitivity, or by decreasing the intrinsic noise level. A simple solution for improving the sensitivity is to optimize the geometry parameters of the ME sensor through a parameter study. Recent studies have investigated the influence of the geometry parameters of the individual layers and the substrate layer on the sensitivity of cantilever ME sensors using finite element model [1][2]. Here, an experimental model is built up for determining the basic parameters of the cantilever ME sensor.

In this study, we present cantilever ME sensors based on magnetoelectric composites with various geometry parameters. The cantilever contains poly-silicon layer, piezoelectric material (AlN) and magnetoelectric material (FeCoSiB) in sequence. The performance of the presented sensors is studied based on the sensitivity, voltage noise density, quality factor and LOD. Three different parameters including the cantilever length, the substrate thickness and the thickness ratio between the magnetostrictive and piezoelectric layers are analyzed to understand their effect on sensors’ performance. Since the devices were fabricated in 8 inch silicon technology, the availability of a relevant number of devices allows a statistical analysis. The results are used to identify the optimal geometry parameters for cantilever ME sensors and can be applied to develop next generation devices.

Funding by the DFG via the Collaborative Research Center SFB 1261 is gratefully acknowledged.

EL03.03.33
Lead Free Multiferroic Nano-Heterostructured Films for Energy Storage Applications Mohan K. Bhattarai, Sita Dugu and Ram S. Katiyar; University of Puerto Rico, Rio Piedras, United States

Lead free environment friendly multiferroic perovskites thin films are of research interest due to its reduction in dimensionality leading to high energy storage and magneto electric behavior and hence are suitable for several electronic device applications. Herein, we report the tetragonal multiferroic heterostructure thin films fabricated by pulse laser deposition technique consisting alternate of Ba(Zr0.30Ti0.70)0.99 Fe0.01 O3 (BZTF) and Ba(Zr0.30Ti0.70) O3 (BZT) layers grown upon LSMO coated on MgO (100) substrate. X-ray diffractometry data analysis suggests phase purity of thin films oriented along (100) direction. Micrograph structural analysis using atomic force microscopy revealed a homogeneous distribution of grains with roughness ~ 3- 5 nm. Dielectric measurements on Au/BZT/BZTF/LSMO and Au/BZTF/BZT/LSMO metal insulator metal capacitors using a impedance analyzer as a function of temperature (100-650 K) and frequency (10^2-10^6 Hz) suggest their relaxor behavior. The slim P-E loop also corroborate relaxor behavior. The temperature dependent magnetic measurements using a physical property measurement system suggest the existence of magnetic nano clustures dispersed in a paramagnetic matrix and attributed to its super para magnetic behavior. A large energy storage density is estimated from our P-E loop data. These results suggest the present heterostructured thin films could be promising multiferroic materials for high energy density applications.

EL03.03.34
High Energy Density and Efficiency Achieved in Lanthanide-Substituted Bismuth Titanate Dielectric Films Shun Lan, Hao Pan and Yuanhua Lin; Tsinghua University, China

Dielectric capacitors with high electrostatic energy density, long-term stability, and environmental friendliness are strongly demanded in modern electrical devices. Here we fabricated Bi_{4-x}La_{x}Ti_{3}O_{12} (x = 0.75, 1.0 and 1.2) thin films by pulse laser deposition. It is revealed that the substitution of Bi by La leads to a continuous transition from ferroelectric to relaxor-ferroelectric and then to paraelectric with concurrently improved energy density and efficiency. Based on the transition, high energy densities of ~60 J cm\(^{-3}\), together with high efficiency(>80 %) as well as excellent cycling(~10^6 cycles) and thermal stability(-100~130'C), can be achieved in the Bi_{4-x}La_{x}Ti_{3}O_{12} films. These excellent performances should be ascribed to the paraelectric characteristics and suppressed leakage current of the film. The results prove the great potential of the Bi_{4-x}La_{x}Ti_{3}O_{12} films for electrostatic energy storage. More importantly, our findings show the advantage of paraelectrics as high performance energy storage dielectric materials.

EL03.03.35
Ferroelectric-Paraelectric Phase Transition in SnTiO\(_3\), a Lead-Free Putative Ferroelectric Rajesh K. Katiyar,
Karuna K. Mishra, Gerardo Morell, Brad Weiner and Ram S. Katiyar; University of Puerto Rico, San Juan, United States

The environmentally benign nature of Sn$^{2+}$ would make SnTiO$_3$ (SnTO) derived compounds an attractive alternative to lead-free dielectric material. Several theoretical studies suggested that the spontaneous polarization of SnTO is larger than that of classical ferroelectric PbTiO$_3$. Pure phase of SnTO is one of the challenging jobs due to often mixed oxidation states of Sn$^{2+}$ and Sn$^{4+}$ in perovskite titanates. The material was synthesized using a chemically route followed by a solid-state reaction method and were annealed it in a mixture ratio of 1:1 methane-hydrogen environment. The phonon spectra of tetragonal ferroelectric SnTO compound were measured as a function of temperatures in the range 82-1250 K using a micro-Raman spectrometer equipped with a CCD detector. Seven phonons are identified in the frequency range 100-1000 cm$^{-1}$ at the room temperature and are assigned as per the C$_{4v}$ point group symmetry. The reduced temperature dependent spectra were analyzed using the damped harmonic oscillator model to obtain the thermal evolution of the mode frequencies and their intensities. Upon increasing temperature, the optical phonon modes were found to be soften and their intensities decreases, as normally expected, due to involved multi-phonon scattering processes. At 823 K, the A$_1$(TO) phonon located at 441 cm$^{-1}$, exhibits anomaly and begins to harden upon further increase in temperature; in addition, the E(LO) mode at 827 cm$^{-1}$ disappear around 823 K, suggesting a tetragonal ferroelectric to a high symmetry paraelectric cubic phase transition. The nature of transition is found to be first order displacive type. The appearance of symmetry forbidden broad Raman bands in the high temperature cubic phase is attributed to contribution from phonon density of states. These studies on phonon behaviors on this putative green ferroelectric could provide insight about its structure-property relations and its thermodynamics properties as well. The detail results will be presented at the meeting.

EL03.03.36
Temperature-Induced Phase Transitions and Charge Transport in Ferroelectric [K NbO$_3$]$_{1-x}$[ (BaNi$_{1/2}$Nb$_{1/2}$O$_{3-δ}$)$_x$], Electroceramics Blanca Y. Rosas, Alvaro Instan, Karuna K. Mishra and Ram S. Katiyar; University of Puerto Rico, United States

Potassium niobate (KNbO$_3$) is a lead-free piezoelectric material, respectful of the environment and technologically very important. This is because it has excellent electromechanical properties and diverse applications in electronic and photonic devices. The electro-physical properties, such as the crystalline phase transition, the optical band gap, the dielectric constant, the Curie temperature, the electrical conductivity and the ferroelectric behavior of KNbO$_3$ can be tuned by suitable dopant, such as isovalent Ba in its A-site, and heterovalent Ni on B-site results in a single phase ceramic material with stoichiometric formula [KNbO$_3$]$_{1-x}$ [(Ba$_{1/2}$Ni$_{1/2}$)O$_{3-δ}$], for x = 0.1 and δ = 0.25 (KBNNO). The structural, optical, dielectric, charge transport phenomena and ferroelectric properties of this solid solution were systematically investigated. The ceramic material was prepared by the solid-state reaction method and calcined at 1198 K, using starting precursors as K$_2$CO$_3$ (99.5%), BaCO$_3$ (99.95%), Ni$_2$O$_3$ (99.9%) and Nb$_2$O$_5$ (99.9%). The orthorhombic ferroelectric phase formation of the synthesized samples is confirmed by using X-ray diffractometry and Raman spectroscopic analysis. Surface morphology study using scanning electron microscopy revealed well-sintered nature of the sample with grains are interconnected and densified. Temperature-dependent in-situ x-rays diffraction studies (300-873 K) revealed the phase transitions from room temperature orthorhombic to tetragonal to a cubic phase at elevated temperatures. The temperature dependent Raman spectra studies in the T-range 82-1000 K suggest that several bending and stretching phonon mode frequencies and their intensities exhibit anomalous changes across the phase transitions temperatures. These transition temperatures were corroborated with the DSC measurements. A direct optical band gap of 3.16 eV is estimated from the analysis of the diffuse reflectance spectra using Kubelka-Munk analysis. The dielectric properties of KBNNO were studied as a function of temperature between 80-500 K in a frequency range from 100 Hz to 1 MHz in a metal-ferroelectric-metal capacitor nanostructure. The dielectric constant and the loss tangent at 100 kHz were 280 and 0.01, respectively. The frequency dependence of the AC conductivity showed typical characteristics of the universal dynamic response. Our studies reveal the structure-property relation, fundamental physics and materials science of KBNNO electroceramics, and establishing its potential for ferroelectric device applications.

Breaking Symmetries to Create a Robust Room-Temperature Ferrimagnetic Ferroelectric in LuFeO₃/CoFe₂O₄ Superlattices
R. Steinhardt¹, M. E. Holtz¹, P. Barrozo²,³,⁴, A. Coleman¹, I. Glushchenko¹, C. J. Fennie¹, D. A. Muller¹,⁵, Ramamoorthy Ramesh³,⁴ and Darrell G. Schlom¹; ¹Cornell University, United States; ²Federal University of Sergipe, São Cristóvão, Brazil; ³University of California, Berkeley, United States; ⁴Lawrence Berkeley National Laboratory, United States; ⁵Kavli Institute at Cornell for Nanoscale Science, United States

Materials that exhibit simultaneous order in their electric and magnetic ground states hold tremendous promise for use in next-generation, low-power memory and logic devices in which electric fields control magnetism. Such materials are, however, rare as a consequence of the competing requirements for ferroelectricity and magnetism, and until recently BiFeO₃ was the only material with this functionality at room temperature. Interface materials are a way to overcome these competing requirements, as was recently demonstrated for (LuFeO₃)₅/(LuFe₂O₄)₁ superlattices [J.A. Mundy et al. Nature 537 (2016) 523–527]. The rumpling imposed by the geometric ferroelectric hexagonal LuFeO₃ imposes a local distortion on the neighboring LuFe₂O₄—a distortion that removes the mirror symmetry that the LuFe₂O₄ layers would otherwise have. This breaking of symmetry enables the LuFe₂O₄ to become simultaneously ferrimagnetic and ferroelectric. This rumpling is distinct from strain engineering because no macroscopic strain is involved. In this presentation we extend this atomically engineered design methodology to LuFeO₃/CoFe₂O₄ superlattices producing a robust ground state that is simultaneously ferroelectric and ferrimagnetic at temperatures well above room temperature.

Electric Field Control of Magnetism at Room Temperature
Ramamoorthy Ramesh; University of California, Berkeley, United States

There is currently a lot of R&D activity worldwide on two broad, systems level topics, both within the field of Microelectronics. One of them has to do with the emergence of the “Internet of Things”, which is the interconnectivity of microelectronics based sensing, communicating and information processing systems. The second has to do with the re-emergence of Artificial Intelligence/ Machine Learning, which is currently experiencing a worldwide explosion. Thus, the worldwide market for microelectronics is likely to go up significantly. A key side consequence of this is the total energy consumed in such applications, which could skyrocket towards 20-25% of primary energy and thus of concern. Indeed, in the field of AI, a “Computing Wall” driven by a “Memory Wall” has emerged as a key bottleneck in systems level applications, such as in “Connected Autonomous Vehicles” or driver-less cars. At the same time, the key driver for the field of Microelectronics, namely Moore’s Law, is reaching the end of size scaling and power scaling. As a consequence, there is a large amount of research activity focused on the new Moore’s Law that is instead focused on Energy Scaling. Thus, looking for a new generation of ultra-low power memories and switches is an area of significant current research. Complex perovskite oxides exhibit a rich spectrum of functional responses, including magnetism, ferroelectricity, highly correlated electron behavior, superconductivity, etc. The basic materials physics of such materials provide the ideal playground for interdisciplinary scientific exploration with an eye towards such applications. Over the past decade the oxide community has been exploring the science of such materials as crystals and in thin film form by creating epitaxial heterostructures and nanostructures. Among the large number of materials systems, there exists a small set of materials which exhibit multiple order parameters; these are known as multiferroics, particularly, the coexistence of ferroelectricity and some form of ordered magnetism (typically antiferromagnetism). The scientific community has been able to demonstrate electric field control of both antiferromagnetism and ferromagnetism at room temperature. Current work in our collaboration is focused on ultralow energy (1 attoJoule/operation) electric field manipulation of magnetism as the backbone for the next generation of ultralow power electronics. We are exploring many pathways to get to this goal. In this talk, I will describe our progress to date on this exciting possibility. The talk will conclude with a summary of where the future research is going.

Magnetic Monopoles Hidden in Magnetoelastic Materials
Nicola Spaldin; ETH Zurich, Switzerland
In linear magnetoelectric materials, an electric (magnetic) field induces a magnetization (electric polarization) with a magnitude that is linearly proportional to the applied field strength. Here we use the prototypical magnetoelectric material, Cr$_2$O$_3$, to show that magnetoelectric materials with a diagonal magnetoelectric response host a hidden hedgehog-like magnetic order known as the magnetoelectric monopolization. We describe several consequences of this hidden order: First, we show that the magnetoelectric monopolization leads to a surface magnetization, independently of the choice of surface cut, that in turn should influence the exchange bias coupling in a heterostructure. Second, we show that a charge on the surface of such a magnetoelectric induces a divergent magnetic field above the surface, and describe an experimental search for this monopolar field using muon spin resonance spectroscopy [1]. Finally, we discuss the implications of an isotropic diagonal magnetoelectric response, and propose candidate materials for such behavior.

Structure and Properties of Freestanding Two-Dimensional Oxide Perovskites
Dianxiang Ji, Songhua Cai, Haoying Sun, Yi Zhang, Wenpei Gao, Huaxun Huyan, Lu Han, Zhengbin Gu, Tula Paudel, Evgeny Y. Tsybalk, Peng Wang, Yuefeng Nie and Xiaoqing Pan, Nanjing University, China; University of California, United States; University of Nebraska–Lincoln, United States

Two-dimensional (2D) materials such as graphene and transition metal dichalcogenides reveal the electronic phases that emerge when a bulk crystal is reduced to a monolayer. Transition-metal oxide perovskites host a variety of correlated electronic phases, so similar behavior in monolayer materials based on transition metal oxide perovskites would open the door to a rich spectrum of exotic 2D correlated phases that have not yet been explored. Here we report the fabrication of freestanding perovskite films with high crystalline quality almost down to a single unit cell. Using a method based on water-soluble Sr$_3$Al$_2$O$_6$ as the sacrificial buffer layer, recently developed at Stanford University, we synthesize freestanding SrTiO$_3$ and BiFeO$_3$ ultrathin films by reactive molecular beam epitaxy and transfer them to diverse substrates, in particular crystalline silicon wafers and holey carbon films. We find that freestanding BiFeO$_3$ films exhibit unexpected and giant tetragonality and polarization when approaching the 2D limit. Our results demonstrate the absence of a critical thickness for stabilizing the crystalline order in the freestanding ultrathin oxide films. Furthermore, the systematic characterization of the cross-sectional samples by atomic resolution electron microscopy reveals that the crystal symmetry and physical properties such as local electrical polarization are strongly dependent on the local strain and boundary conditions of the film. The ability to synthesize and transfer crystalline freestanding perovskite films without any thickness limitation onto any desired substrate creates opportunities for research into 2D correlated phases and interfacial phenomena that have not previously been technically possible.

Creating the Next Device for Moore’s Law with Room Temperature Quantum Materials
Sasi Manipatruni, Kepler Computing, United States

The nanoscale transistor is perhaps the most numerous man made object, exceeding $10^{18}$ transistors used in ubiquitous computing and communications devices. However, as we reach the hyper scaled dimensions for electronic transistors (smallest transistors reaching sub 10 nanometer dimension) [i], a search for identifying the next scalable transistor is ongoing. For use in ubiquitous computing, such a “transistor” not only needs able to operate at room temperature but also possess features commensurate with beneficial miniaturization (Moore’s law). We have studied >25 device topologies for new transistor technologies and have considered the use of nearly all the breakthroughs in materials science from the last 3 decades [ii]. We have come to the understanding that new materials and phenomenon enabled by quantum materials form the path to the next “transistor” that is suitable for consumer electronics and cloud computing.

The Technology Need: We describe the imminent need for a revolutionary new transistor for classical Boolean
computing based on a) The thermal power limit of the computers reaching the historic trigger point of 10 W/cm² (Figure 1), this has earlier led the conversion of computing from Bipolar to CMOS in 1980s. Another such trigger is imminent b) The exponential growth in energy demands due to proliferation of compute devices c) The continued need for classic computations that are described by a large variety of computational algorithms (e.g. Geometric, combinatorial problems, graphical processing, computational fluid dynamics, prediction of complex physical/biological phenomenon).

**A Quantum Materials pathway for new computing[iii]:** We will describe a fundamentally new scaling path for computing where we bridge the breakthroughs in quantum materials for creating the next general purpose, room temperature computing technology. The term Quantum Materials is used to describe a broad class of materials that exhibit strong interactions amongst the charge, spin, orbital and lattice degrees of freedom. Over the past 2-3 decades, since the advent of high temperature superconductivity in cuprates, there have been several classes of quantum materials that include i) the CMR manganites where new states of matter and exquisite tunability of such states with external stimuli are driven by the strong electron-electron correlations and the consequent mesoscale phase coexistence, and ii) topological insulators that are driven by strong spin-orbit coupling leading to unusual band topology and Dirac-like fermion behavior, as key examples.

**Magneto-electrics and Topological Conversion Pathway for Computing[iv]:** I will describe the concept device (named Magneto-electric Spin Orbit Logic) to drive high functionality materials in magneto-electrics and topological materials. In particular, the path to computing at 10-bit (~30X more energy efficient than advanced CMOS) with 10-20X relaxation of the interconnect requirements will be described.

11:30 AM EL03.04.07
**Stabilization of a New Antiferroelectric Phase of BiFeO₃ through Electrostatic Engineering in Oxide Heterostructures** Bastien F. Grosso, Quintin N. Meier and Nicola Spaldin; ETH Zürich, Switzerland

BiFeO₃ (BFO) is one of the most studied multiferroic materials because of the coexistence of magnetic and polar orders at room temperature. Here we show that previously unidentified structural phases of BFO, with functional properties different from those of the rhombohedral ferroelectric bulk structure, can be stabilized by exploiting the electrostatic boundary conditions in thin film heterostructures. This provides a complementary approach to the earlier successes in stabilizing some of the many low-energy phases that have been identified computationally, by using coherent heteroepitaxial strain [1,2]. Using density functional theory, we identify a new antipolar phase of BFO and find that the energy barrier to convert it into a ferroelectric phase is small enough for it to be a candidate antiferroelectric. According to our strain calculations and a simple electrostatic model, this antipolar phase can be stabilized with insulating non-polar electrodes for a certain thickness range of the BFO layer on a substrate imposing a small amount of compressive strain; the rhombohedral phase can be recovered by increasing the thickness. These predictions are consistent with a new antipolar phase recently observed experimentally in Laₓ,BiₓFeO₃/BiFeO₃ superlattices, which reveal a double hysteresis loop, characteristic of an antiferroelectric material [3]. Finally, we identify other new low-energy phases for BFO and propose possible ways to stabilize them experimentally.

Understanding Magnetoelectric Switching in Lanthanum-Doped BiFeO₃ Thin Films

Yen-Lin Huang¹, Rajesh V. Chopdekar², Chirs Addiego³, Xiaoqing Pan³, Heng-Jui Liu⁴, Ying-Hao Chu⁵ and Ramamoorthy Ramesh¹;
¹University of California, Berkeley, United States; ²Lawrence Berkeley National Laboratory, United States; ³University of California, Irvine, United States; ⁴National Chung Hsing University, Taiwan; ⁵National Chiao Tung University, Taiwan

The key to integrating the concepts of spintronics into conventional nanoelectronics lies with the ability to control the magnetic order in nanoscale devices. With the continuous shrinkage of integrated circuits, the energy efficiency required to control these tiny magnets as power dissipation becomes a determining factor below 7 nm node. Over the past decades, the oxide community has been exploring the materials that can provide opportunities to control magnetism. Among the large investigated materials, multiferroics might be one of the most promising material family. Multiferroics are defined as the materials which possess at least two order of parameters, particularly, the coexistence of ferroelectricity (P) and magnetism (M), and exhibit coupling from one to another. In this talk, I will discuss the magnetoelectric switching mechanism in lanthanum-doped BiFeO₃ thin films. BiFeO₃ is by far the best-studied multiferroic, which shows strong ferroelectricity (~100 \( \mu \)C/cm²) and G-type antiferromagnetism, above room temperature. It also shows weak ferromagnetism (Mₓ) induced by the canted spin configuration described by the Dzyaloshinskii–Moriya interaction (DMI). Moreover, these ferroic orderings, \( P \) and \( Mₓ \), are strongly coupled, thus one can switch the magnetism by an electric field. However, the strong spontaneous polarization in BiFeO₃ needs a large voltage to switch. Here, we introduce the chemical doping to modify the order parameters in BiFeO₃ and achieve an ultralow-voltage (< 500 mV) and non-volatile manipulation of ferromagnetism at room temperature. Moreover, while the lanthanum-doping increased, we observed a very different magnetoelectric switching pathway and magnetic anisotropy compare to pure BFO. This discovery leads to the enhancement of perpendicular magnetic anisotropy (PMA) on multiferroics thin film, which will be very attractive to the practical applications. Finally, I will conclude this talk with a summary of current challenges and future direction of multiferroics, especially BFO, toward the low-power electronics.

Multiferroic Self-Assembled Oxide Nanocomposites Incorporating BiFeO₃, YFeO₃ and SrFe₁₋ₓCoxO₃
Caroline A. Ross and Shuai Ning; Massachusetts Institute of Technology, United States

Self-assembled two phase epitaxial oxide nanocomposites, in which a magnetic phase and a ferroelectric phase are coupled via strain transfer at their interfaces, can exhibit multiferroic and magnetoelectric responses. Such nanocomposites hold promise for making new types of electrically-switchable magnetic devices. The most commonly studied nanocomposite consists of a perovskite matrix (e.g. BiFeO₃ (BFO)) surrounding vertical pillars of a ferrimagnetic spinel (e.g. CoFe₂O₄ (CFO)). An electric field applied to the BFO changes its strain state and hence the strain state and magnetic anisotropy of the CFO, promoting changes in magnetization and even reversal. We will first describe BFO/CFO nanocomposites including strategies for templating the pillar positions and the behavior of (110)-oriented nanocomposites with fin-shaped CFO exhibiting in-plane anisotropy, and compare the structure and properties of nanocomposites grown by sputtering vs. pulsed laser deposition. We then describe nanocomposites containing YFeO₃ (YFO) as the ferroelectric phase. Bulk YFO is not ferroelectric, but thin films of YFO grown on certain substrates exhibit a polarization that can exceed 100 \( \mu \)C/cm². Based on first principles calculations the polarization is attributed to epitaxial mismatch strain which promotes off-centering of the cations. YFO/CFO nanocomposites grown on SrTiO₃ (001) substrates show a magnetoelectric coupling in which the ferroelectric hysteresis is sensitive to an in-plane magnetic field. We also demonstrate the control of the magnetic properties of nanocomposites containing SrFe₁₋ₓCoxO₃ (SFCO) using ionic liquid gating. Single phase films of
SFCO are non-magnetic as grown and form either a perovskite or brownmillerite phase depending on deposition conditions and Fe:Co ratio. However, negative gating inserts oxygen and leads to a magnetization of up to 100 emu cm\(^{-3}\) and a structural change from brownmillerite to perovskite with an associated substantial volume change. This magnetic switching is reversible over multiple cycles and is also observed in nanocomposites of SrFeCoO\(_3\) codeposited with a spinel phase including Co\(_3\)O\(_4\) and CFO. The inclusion of new materials, SFCO or YFO, in nanocomposites therefore expands the palette of possible structures, properties and control strategies, enhancing the functionality of these magnetoelectric heterostructures.

2:00 PM *EL03.05.02
A Route to Low Noise Magnetoelectric Sensors—Controlling Magnetic Domain and Domain Wall Effects in Magnetoelectric Sensor Devices Jeffrey McCord; Kiel University, Germany

The role of magnetic domain formation and reorientation processes reveals fascinating physics and is of great relevance for technological applications. Especially the class of magnetic sensors that depend on magnetic thin film technology, rely on magnetic domain control for proper operation. Recent advances in thin film magnetoelectric (ME) composites offer a promising route for sensing ultra-low magnetic signals. Yet, one obstacle of achieving very low limit of detection is caused by magnetic domain activity, which is a well-known noise source in various magnetic field sensing applications. Irreversible and hysteretic magnetization changes from domain nucleation and other hysteretic domain effects impact the sensor’s performance. Moreover, the characteristics of magnetic domains reflect stress induced spatial alterations in the magnetic anisotropy distribution. Overall, due to the formation of magnetic domains in the piezomagnetic phase, the magnetization reversal in magnetic layers is complex. The role and relevance of magnetic domains and domain walls for the ME response will be discussed in detail. Domain effects in different types of ME devices, including magnetically and electrically modulated thin film devices as well as surface acoustic wave (SAW) devices will be discussed. Domain activity in operating devices is studied from low frequencies, in the hundred kHz range, and at 150 MHz. Domain investigations at the operational frequencies of modulated and SAW sensors are performed by time-resolved magneto-optical Kerr effect microscopy.

A direct connection between specific magnetic domain activities and the exhibited noise characteristics is obtained. Even minimal domain activity is restricting magnetic sensor performance. Magnetic noise density and not sensitivity is the main figure-of-merit for optimizing sensor performance. Controlling magnetic domain behavior is a key to improved sensor performance.

Support through the DFG through the Collaborative Research Centre SFB 1261 is highly acknowledged.

The field of nanoscale strain mediated multiferroics has grown considerably during the last decade due to the promise offered for efficiently controlling magnetism in the small scale. Strain mediated multiferroics consist of piezoelectrics mechanically coupled to magnetoelastic materials. An applied voltage to the piezoelectric induces a strain in the magnetoelastic material reorienting the magnetic spin moments. This approach is contrasted with electrical current approaches to control magnetic moment such as to reorient small magnetic bits with spin transfer torque STT. For informational purposes the energy required to reorient a 100 nm magnetic memory bit using STT is on the order of 100 fJ with the promise that strain mediated multiferroic is less than 0.1 fJ, i.e. > 4 orders of magnitude improvement. While strain mediated multiferroic approaches promise substantial efficiency improvements, many research efforts focus on magnetic materials that are on moderately or weakly magnetoelastic due to fabrication related issues. In this presentation a review of progress on fabricating and testing Terfenol-D (Tb0.3Dy0.7 Fe1.92) small scale structures, i.e. one of the highest room temperature magnetoelastic materials, is described to help advance the multiferroic field. This work includes discussions of fabrication, magnetic spin assessment, thermal effects, corrosion properties, and application demonstrated work.

Polycrystalline Terfenol-D thin films (<100 nm) are produced using a DC magnetron sputtering process on Sapphire, Si and PMN-PT substrates. The crystallized Terfenol-D films are micropatterned with photolithographic methods using Ar etching. The continuous and micropatterned (<20 microns) structures are characterized with XRD, SQUID, MOKE, MFM, PEEM, and XMCD to evaluate magnetoelastic properties. For micro-patterned structures as large as 20 microns in diameter, magnetic single domain structures are observed (MFM and PEEM) which is unusually large for this soft magnetic material. The large single domain behavior is attributed to the residual stresses produced during fabrication to further stabilize the magnetic spin states along preferred magnetic easy axis. Furthermore, an absence of oxidation is observed in these small-scale structures. While there is a capping layer on the Terfenol-D films, one would expect stress corrosion cracking to arise along the micropatterned side walls but this is absent. We attribute the corrosion absence to both the capping layer as well as the residual stresses preventing stress propagation and arresting oxidation. XMCD results on elemental spin states in the Terfenol-D reveal that the magnetic moments predominantly arise from the Tb and Dy spin/orbital contributions with Fe magnetic spin pointing in the opposite direction, i.e. ferrimagnetic material. However, the main contribution for the Dy element arises from orbital moment rather than spin which is slightly unusual. Furthermore, the Dy elements spin orbital moment changes prominently as a function of temperature. We believe that the spin orbit moment coupling arising from Dy significantly contributes to the changes observed in the magnetocrystalline anisotropy as a function of temperature. Finally, demonstrations of a multiferroic PMN-PT/Terfenol-D (20 micron size microstructure) to capture and release magnetic particles attached to cells are presented for showing efficient control of magnetism in the small scale.

Materials for STT-MRAM Applications Guohan Hu and Virat Mehta; IBM T.J. Watson Research Ctr, United States

Spin Transfer Torque Magnetic Random Access Memory (STT-MRAM) is a type of emerging memory which holds the promise of high speed, high endurance, non-volatility, and good scalability. Since the theoretical prediction of the STT switching mechanism in 1996, significant progress has been made in the field, largely through materials innovations. In this talk, I will review the key materials discoveries that enabled the advancement of STT-MRAM technology. This includes the theoretical prediction and experimental realization of large tunneling magnetoresistance (TMR) with MgO tunnel barrier and the discovery of CoFeB based materials with interfacial perpendicular magnetic anisotropy (IPMA). This talk will also discuss our recent results at IBM on methods to lower the switching current of Spin-Transfer-Torque MRAM and achieve low write-error-rate by using optimized magnetic materials.

Efficient Energy Harvesting from Low Ambient Stray Magnetic Field Using Magnetoelectric Coupled Magneto-Mechano-Electric Generator Min Gyu Kang1, Hyeon Lee2, RamMohan SriRamdas1 and Shashank Priya1; 1Pennsylvania State University, United States; 2Virginia Tech, United States
Electrically modulated magnetoelectric AlN/FeCoSiB film composites for DC magnetic field sensing.

Smart infrastructure functionalized with Internet of Things (IoT) technology is driving need of the wireless sensor network system and its sustainable power source. Magneto-mechano-electric (MME) energy conversion is the most promising technology to supply a sustainable power into the IoT sensor devices as it efficiently converts low frequency stray magnetic field (50/60 Hz), which exists everywhere in modern infrastructure, into the electricity. However, currently reported MME generators produce relatively low power under low magnetic field ($\leq$300 $\mu$T), which commonly exist in infrastructure. In this work, we demonstrate magnetoelectric (ME) coupled MME generator to produce high output power from low amplitude magnetic field. Comprehensive energy conversion mechanisms of ME coupled MME generator, including structural factors and contribution of ME coupling on power output, are investigated in order to achieve high energy conversion efficiency in low amplitude magnetic field. Building upon the mechanism study, an optimum MME generator, producing milliwatt power below 300 $\mu$T magnetic field, is realized utilizing outstanding magnetoelectric composite cantilever. Exploiting the harvested power near a home appliance, sustainable powering integrated sensors and wireless communication system is demonstrated. The fundamental study performed in this work provides a direction to achieve the efficient magnetic field energy harvesting and this will enable practical implantation of the IoT devices into the smart infrastructure.

4:15 PM EL03.05.06
Electrically Modulated Magnetoelectric Thin-Film Sensors for Sensing Small Magnetic Fields
Patrick Hayes1, Sebastian Toxværd1, Phillip Durdaut1, Matic Jovičević Klug1, Dmitri A. Burdin2, Viktor Schell1, Yuri K. Fetisov2, Reinhard Knöchel1, Jeffrey McCord1 and Eckhard Quandt1; 1Kiel University, Germany; 2MIREA - Russian Technological University (MIREA), Russian Federation

Magnetoelectric (ME) thin film composites consisting of a sputtered piezoelectric (PE) and a magnetostrictive (MS) layer may be employed for measurements of magnetic fields passively, i.e. an AC magnetic field generates an ME voltage by mechanical coupling of the MS deformation to the PE phase, thus exploiting the direct ME effect. In order to achieve high field sensitivities a magnetic bias field, necessary to operate at the maximum piezomagnetic coefficient of the MS phase is used, using mechanical resonances further enhances this direct ME effect size. Despite being able to detect very small field amplitudes passively, by exploiting mechanical resonances, implies a limitation to available signal bandwidth, because of rather high Q factors. The requirement for a magnetic bias field along with the inability to detect DC magnetic fields makes practical implementation troublesome.

In the presented work the PE phase of such thin film ME composites is actively excited, thus exploiting the converse ME effect [1], remedying shortcomings of the direct ME effect. The experimental work makes use of surface micromachined thin film cantilever composites of mesoscopic scale (25mm x 2.5mm x 0.35 mm) of which a high frequency mechanical resonance at about 500 kHz, showing a mechanical quality factor of about Q~1000 is analyzed. This mechanical oscillation, being rigidly coupled to the magnetostrictive material, leads to a voltage induced in a pickup coil surrounding the sensor composite, giving rise to magnetoelastic interactions. Major signal components of bio magnetism lie in the range from DC to 500 Hz and amplitudes are of vanishingly small amplitude $\sim 50$ pT, this regime is targeted by this research. This entirely passive readout, combined with low spatial and power requirements makes the presented ME sensor system suitable for integration into arrays as anticipated for biomagnetic imaging. The converse ME voltage response with respect to small external fields shows sensitivities up to 40 kV/T, offering linearity up to a field magnitude of several $\mu$T, no external magnetic driving field is required. The sensor sensitivity scales nearly linearly with drive amplitude supplied to the PE phase, unfortunately the measured noise floor in the frequency regime of interest shows an abrupt increase as soon as an excitation threshold of about 200 mV is reached. Massive magnetization activity in the MS phase is presumably the dominant source of noise. High speed vibrometry measurements give insight concerning the high frequency mechanical oscillation mode, magneto optical imaging reveals magnetoelastic modulations of the MS phase.

Furthermore, we demonstrate the performance of electrically modulated thin film ME composites, using magnetron sputtered AlN and amorphous FeCoSiB films. This approach enables composite magnetoelectrics to detect low DC ($\sim 250$ pT/sqrt(Hz)) as well as AC ($\sim 75$ pT/sqrt(Hz) @ 10 Hz) magnetic fields without the need of an external magnetic AC or DC bias field. Finally, lower system noise is achieved using specially tailored antiparallel exchange biased MS layers thus inhibiting domain wall activity and even further improve the detection limit. Funding via DFG, SFB1261 “Magnetoelectric Sensors: From Composite Materials to Biomagnetic Diagnostics” is gratefully acknowledged.

References
Magnetostriiction makes it possible to drive a magnet into resonance using purely a voltage signal. In a piezoelectric-ferromagnetic bi-layer, an alternating voltage applied to the piezoelectric transforms into a pseudo alternating magnetic field for the magnet. Combined with an internal static field that comes from the magnetic anisotropy, this alternating magnetic field can put the magnet into resonance. We shall describe our recent experimental work that demonstrates this effect in a LiNbO3/Ni heterostructure. It was observed that a highly efficient transduction (>99.9%) is possible in this process. A magnet put into resonance in this way also shows potential for sensing very small magnetic fields (~pT/sqrt(Hz)). In addition, they can be used for locally driving two level quantum systems without needing an optical excitation. We shall discuss our recent progress regarding these applications.

EL03.06.01
Some Interesting Properties Associated to an Unusual High Iron Valence in the FeSr2YCu2O7.85 Superconducting Cuprate
Miguel Angel Alario-Franco, Sara Lopez-Paz, Xabier Martinez de Irujo-Labalde, Jorge Sanchez-Marcos, Clemens Ritter and Emilio Moran; Universidad Complutense, Spain

Iron containing perovskites have been intensively studied as potential functional materials with applications ranging from Solid Oxide Fuel Cell (SOFC) cathodes[1] and magnetoelectric multiferroics[2] to half-metallic magneto resistive[3] materials. On the other hand, high temperature superconducting cuprates are another example of correlated materials that are placed in the frontier between localized and itinerant electronic behaviour[4], with superconductivity emerging from a Mott insulating type material upon doping.

The title material combines two functionalities: magnetism and superconductivity, associated to the presence of separated Fe-O2 and Cu-O2 layers orderly stacked along the c-axis.

The formal presence of FeV cations resulted from ozone oxidation, leads to a long-range magnetic ordering, coexisting with the superconducting interactions (TN= 110 K > Tc= 70 K). The somewhat unexpected A-type AFM structure, with a μ(Fe) approximately 2 μB magnetic saturation moment, associated to the hypervalent iron sublattice, suggests an unusual low spin state for the iron cations; on the other hand, the low dimensionality of the magnetic structure results in a soft switching towards ferromagnetism under small external magnetic fields.

It is also interesting to mention the relatively high superconducting Tc in a highly overdoped cuprate [5]. The role of the crystal structure and the high charge concentration in the stabilization of this unusual electronic configuration for the iron cations is discussed.

Perovskite rare earth nickelates (RNiO₃), where R is a rare earth cation are well-known for the sharp metal-to-insulator transition (MIT) observed when decreasing temperature, at \(T = T_{MI}\) (R different than La) (1-3). Many studies have focused on manipulating the MIT for instance through strain (4), growth direction (5) and superlattice heterostructure (6). In this work, we use experimental and theoretical methods to design and study superlattices of two distinct rare earth nickelate oxides SmNiO₃ (SNO) and NdNiO₃ (NNO) that in bulk form show a MIT at two very different temperatures (400K and 200K, respectively). We find that these new complex oxide superlattices display different behavior than that of either bulk material, showing either a single MIT at an intermediate temperature, or two transition temperatures that converge asymptotically towards the strained bulk values of each material. This system allows the origin of the coupling at such interfaces to be studied. We show that the length scale of the MIT transition in the superlattices is set not by the length scale of the propagation of structural motifs across the two materials, which ab-initio calculations and TEM analysis suggest is minimal, but rather by the balance between the energy cost of having metallic-insulating domain walls (the cost of bending the order parameter across the metallic-insulating interface) and the energy gain of the bulk phases.

EL03.06.03 Length Scales and Heterostructuring in the Metal-Insulator Transition of RNiO₃ Alexandru Bogdan Georgescu¹, Claribel Dominguez², Oleg E. Peil³, Jennifer Fowlie², Ankit S Disa⁴, Jean-Marc Triscone², Antoine Georges⁴,⁵ and Andrew Millis¹,⁶;
¹Flatiron Institute, United States; ²University of Geneva, Switzerland; ³Materials Center Leoben, Austria; ⁴Max Planck Institute for Solid State Research, Germany; ⁵College de France, France; ⁶Columbia University, United States

The metal-insulator transition (MIT) of transition metal oxides is often associated with a simultaneous lattice and electronic symmetry breaking; however the relative roles of the electronic and lattice degrees of freedom is still an unresolved question. Further, the length-scale of the metal-insulator transition and what sets it is not well understood. Through the study of heterostructures of rare-earth nickelates (RNiO₃), we get insight into these questions. First, using a combination of first-principles, many-body computational methods and experiment [1,2,3,4], we study the effect of heterostructuring NdNiO₃ with the band insulator NdAlO₃. We find two competing effects: the effective lattice cost to disproportionate the NiO₆ octahedra increases due to resistance from the interfacial Al-O bonds. Separately, electronic confinement favors an insulating state by lowering the electronic kinetic energy. These effects combined lead to a higher MIT temperature than the bulk, accompanied by a lower signature of bulk disproportionation on the X-Ray spectra. To understand the length scales involved in the MIT we study superlattices of two nickelate materials that have the same type of transition but two different transition temperatures (NdNiO₃~150K and SmNiO₃~400K). We find that for thin enough layers of each material, a single transition at an intermediate temperature exists, while at higher layer thickness two MITs appear at temperatures that asymptotically tend to the bulk MIT temperatures with increasing layer thickness. We find that this behavior is set not by the gradual propagation of structural motifs, but by the competition between the domain wall energy cost at the interface between the metallic and insulating materials and the bulk free energy cost of the materials not being in their favored state. Our work thus opens new paths in the systematic study of complex oxide materials.

EL03.06.04
Ferroelectric Polarization-Switching Dynamics and Fatigue Behavior in Si-Doped HfO₂
Myeongseop Song and Seung Chul Chae; Seoul National University, Korea (the Republic of)

HfO₂-based ferroelectrics exhibits two regimes of “wake-up” and “fatigue” in which remnant polarization increases and decreases during electric field cycling, respectively. These two phenomena are considered as the effect of defect generation and diffusion including redistribution of oxygen vacancies. The structural transition in the wake-up stage has been focused in ferroelectric HfO₂ thin film. However, in order to operate a reliable device, it is necessary to understand the ferroelectric characteristics and dielectric properties in wake-up and fatigue processes.

Grimley et al. proposed that the variation of bulk defect concentration which constrains domain wall motion by defect pinning is the origin of fatigue behavior. However, Lou et al. suggested that the structure decomposition caused by charge carrier injection was the main reason for fatigue endurance. The mechanism of fatigue behavior of HfO₂ thin films is still unclear. So, understanding of the ferroelectric characteristics with respect to the fatigue behavior is required for practical device operation.

We report on the ferroelectric switching dynamics of fatigued 4.2% Si-doped HfO₂ thin film. Prior to the fatigue behavior, Si-doped HfO₂ thin films exhibited the wake-up behavior where the remnant polarization value increased with the repeat of external bias cycling. After the wake-up behavior, Si-doped HfO₂ film exhibited the degradation of the remnant polarization value alongside the sweep of external bias, i.e., fatigue behavior. The investigation of ferroelectric switching dynamics revealed the retardation and recovery of the characteristic switching time for ferroelectric nucleation coincident with the wake-up behavior and fatigue behavior, respectively. We analyzed the interface trap density with the capacitance-voltage characteristics and attributed the fatigue behavior to the increase of oxygen vacancies with fatigue behavior.

EL03.06.05
Unconventional Stability of Sub-Loop Behavior in Ferroelectric HfO₂
Kyoungjun Lee and Seung Chul Chae; Seoul National University, Korea (the Republic of)

Ferroelectricity with partial polarization switching is considered as one of a feasible candidate for an analog device in the form of the ferroelectric tunnel junction and ferroelectric transistor. However, deterministic control of ferroelectric polarization states with conventional ferroelectric materials have been met with accessibility problems due to the complex nature of ferroelectric switching mechanism and/or defect mediated uncertainty. Ferroelectric HfO₂ thin film has been investigated intensively as an alternative to perovskite materials in ferroelectric random access memory due to the advantages for nonvolatile memory applications, such as good scalability, compatibility with conventional complementary metal-oxide-semiconductor (CMOS) process technology.

Here, we report unprecedented stability of the sub-loop switching behavior in ferroelectric HfO₂. We suggest that the stable accessibility with robust stability of multiple polarization states in ferroelectric HfO₂ can be attributed to the large activation field for ferroelectric switching with small critical volume for the ferroelectric nucleation of HfO₂. The switching dynamics indicated a large activation field for ferroelectric switching. The temperature dependence of hysteresis and piezoresponse force microscopy measurements indicated a small critical volume for ferroelectric nucleation. The theoretical calculation demonstrated the stable switching energy landscape for single dipole flip in ferroelectric HfO₂. Monte-Carlo simulation demonstrated that the small critical volume for nucleation induces stable accessibility of multiple polarization states in ferroelectric HfO₂.

EL03.06.06
Electromechanical Performance of Core-Shell Structured Relaxor Ceramics and the Impact of Interfacial Stress
Julia Glaum¹2, Yooun Heo², Matias Acosta³, Jan Seidel² and Manuel Hinterstein²4; ¹Norwegian University of Science and Technology, Norway; ²UNSW Sydney, Australia; ³Technische Universität Darmstadt, Germany; ⁴Karlsruhe Institute for Technology, Germany

The unique properties displayed by canonical relaxor systems, such as the electric field induced transformation from a pseudo-cubic relaxor state to a polar ferroelectric state[1], the associated huge strain [2] and the phase transition mediated polarization reversal mechanism [3], make these materials highly interesting objects for fundamental studies as well as versatile components for industrial applications.

Especially, the achievement of high strains has drawn significant attention, the origin of which is based on the reversibility of the phase transformation between the ferroelectric and the relaxor state [4]. Many relaxor-
ferroelectric systems exhibiting high actuating performance are located in the morphotropic phase region. They often exhibit multiple crystallographic phases arranged as core and shell within single grains and their ability to adapt the phase ratio depending on the external stimuli [5], is another important factor contributing to their exceptional electromechanical performance.

Here, we report on the development of interfacial stresses between different crystallographic phases in a multiphase \((\text{Bi}_{1/2}\text{Na}_{1/2})\text{TiO}_3-\text{BaTiO}_3\) relaxor ceramic as induced by thermal treatment. Upon electric field application, this system exhibits an “intrinsic core-shell structure” of a polar minority phase embedded into a polar majority phase. While the majority phase stays stable with increasing temperature up to the transition into the relaxor state, a gradual de-texturization of the minority phase is observed over the whole temperature range. The surface domain structure was found to decay already at significantly lower temperatures than expected from bulk observations. Development of interfacial stresses due to thermal expansion mismatch between majority and minority phases as well as differences in local stress state between surface and bulk are discussed as driving factors of the phase transition dynamics.

Tailoring of interfacial stresses through adaption of phase fractions opens up a pathway to optimize the strain performance of actuator materials and can become a useful tool for the stabilization of usually metastable crystallographic phases as well as for property tuning e.g. in piezotronics.

**Large Pyroelectric Energy Conversion Density in Lead-Free Relaxor-Ferroelectric Heterostructure**

Amrit Sharma, Makhes K. Behera, Sangram K. Pradhan, Bo Xiao and Messaoud Bahoura; Norfolk State University, United States

The need for efficient energy utilization is driving research into ways to harvest waste-heat which is ubiquitous, abundant and free. Thermal harvesting is a promising method for capturing freely available heat and converting it to a more usable form, such as electrical energy. Thermal harvesting for low power electronic devices using ferroelectric materials is one of the emerging areas of research because these ferroelectric materials possess spontaneous polarization and exhibit excellent piezoelectric as well as pyroelectric coefficients. These materials are unique as they only sense time-dependent temperature change to generate electric power. We have grown lead-free \(\text{BaZr}_{0.2}\text{TiO}_3\) (BZT)/ \(\text{Ba}_0.7\text{Ca}_0.3\text{TiO}_3\) (BCT) multilayer heterostructures and studied their structural, dielectric, ferroelectric, and pyroelectric properties. The BZT/BCT multilayer epitaxial heterostructures were grown on \(\text{SrRuO}_3\) (SRO) buffered \(\text{SrTiO}_3\) (STO) single crystal substrate by optimized pulsed laser deposition technique. The large angle x-ray scans showed only diffraction peaks from the substrate and pseudocubic reflections \((100)\) from the multilayer heterostructure, confirming that these films are phase pure, highly crystalline, and epitaxial in nature. The atomic force microscopy (AFM) studies indicate that the surface roughness is low and that film growth is of high quality. The ferroelectric phase transitions have been probed above room temperature with a relaxor behavior. The polarization versus electric field \((P-E)\) measurement shows that the multilayer heterostructure exhibits slim and well-saturated hysteresis loop with high saturation and low remnant polarization of 100 and 20 \(\mu\text{C/cm}^2\), respectively at 1.7 MV/cm. Solid-state, thin-film devices, that convert low-grade heat into electrical energy, are demonstrated from temperature dependent \(P-E\) loops using pyroelectric Ericsson cycles with energy conversion density of 1.61 J/cm\(^3\). Our findings suggest that the BZT/BCT multilayer ferroelectric thin film may be competitive with other thermoelectric materials for low-grade thermal harvesting.

**Ferroelectricity in BiNbO\(_5\)Cl Single Crystal Nanosheet**

Zhizhong Chen and Jian Shi; Rensselaer Polytechnic Institute, United States

While ferroelectric-field-controlled Rashba-Dresselhaus effect has long been proposed as a method to manipulate...
the valley and spin degrees of freedom in ferroelectrics with strong spin-orbit coupling, the experimental realization of such device concepts remains limited. Although ferroelectric two-dimensional (2D) materials with strong spin-orbit coupling have been widely investigated, most chalcogenide layered 2D or quasi 2D materials considered suffer from low band gap, low Curie temperature or high electrical leakage, rendering the electrical control difficult at room temperature, while the insulating nature of most ferroelectric (quasi-) 2D oxides with heavy elements limits their optical activity. In this work, we report the first experimental observation of ferroelectricity in a quasi-2D 10–100 nm thick nanosheet Sillen-Aurivillius semiconducting split-ion oxyhalide perovskite at room temperature. Optoelectronic, transport and temperature-dependent time-resolved photoluminescence studies show that Bi$_4$NbO$_8$Cl single crystal exhibits a direct band gap of 2.4 eV, decent optical quantum efficiency and carrier dynamics, making it promising candidate for photon-valley coupling. Electrical transport shows up to 100× I-V rectification in Bi$_4$NbO$_8$Cl single crystal nanosheet-based planar devices with symmetric graphite as electrodes. By electrical poling, the diode polarity becomes switchable, rendering repeatable rectified current. Such diode effect in Bi$_4$NbO$_8$Cl is attributed to the asymmetric Schottky barriers at Bi$_4$NbO$_8$Cl–graphite interfaces that could be adjusted by switchable ferroelectric dipoles. In the oxyhalide Bi$_4$NbO$_8$Cl, the combination of appropriate band gap from ion splitting, considerable visible light optical quantum efficiency, strong polarization and the possible strong spin-orbit coupling from Bi provides a novel design platform for realizing emergent spin-orbitronics.

Local Ferroelectric Properties of Free-Standing Single-Crystal Complex Oxides
Saidur R. Bakaul$^1$, Amanda K. Petford-Long$^1$, Claudy Serrao$^2$, Mathew R. Cherukara$^1$, Sayeef Salahuddin$^3$, Ramamoorthy Ramesh$^4$, Dillon Fong$^1$, Tao Zhou$^1$ and Martin Holt$^1$; 1Argonne National Laboratory, United States; 2Intel Corporation, United States; 3University of California, Berkeley, United States; 4University of California Berkeley, United States

The last few decades have seen significant scientific discoveries in single crystal complex oxide materials including colossal magnetic resistance, superconductivity, voltage control of magnetism and many different ferroic orders, many of which could lead to completely new applications. However, integration of such oxides using direct synthesis on microelectronics-platforms such as Si, amorphous SiO$_2$, GaN, and unconventional flexible substrates has faced significant challenge due to various growth-related issues and the interface chemistry at high temperature. Therefore, the functionality and performance that are otherwise available for epitaxial, single-crystal, perovskite materials have remained unachievable in microelectronic devices for a long time. The recent invention of complex oxide layer transfer techniques (LTT) has opened a promising route to the monolithic integration of these materials with arbitrary substrates$^{[1][2][3]}$– thus offering a possible replacement to the rarely-successful direct growth techniques.$^{[4]}$

In LTT, complex oxides epitaxially grown on the lattice-matched substrate are made free-standing and then interfaced with arbitrary material on-demand. Although proof-of-concept devices such as field effect transistor and memory devices have already been demonstrated using such transferred complex oxide ferroelectric (FE) materials.$^{[1][2][3]}$ little is known about their ferroic properties, particularly at the mesoscopic length scale. In this work, we have studied free-standing, single-crystal PbZr$_{0.2}$Ti$_{0.8}$O$_3$ using piezoforce (PFM) and electrostatic force microscopy (EFM) and synchrotron X-ray nanodiffraction techniques. We find that the epitaxial strain imposed on the ferroelectric layers by the substrate during growth by pulsed laser deposition technique is alleviated when the layers are made free-standing. The reduction of elastic strain slightly widens the domain walls, reduces the spontaneous polarization and increases the piezoelectric response. We have studied ferroelectric properties of both the top layers and interfacial layers (which were in contact with the substrate) and found a negligible difference between them. This hints that the intrinsic dead-layer issues may not be the limiting factors for utilizing transferred epitaxial layers in electrostatically controlled devices.

Novel Epitaxial Strain Effects on the Hybrid Improper Ferroelectrics from First-Principles Xuezeng Lu and James Rondinelli; Northwestern University, United States

Epitaxial strain is a powerful tool to generate ferroelectricity owing to polarization-strain coupling. Local lattice degrees-of-freedom such as rotations of metal-oxygen octahedral also couple to strain, and can be used to tune a material’s oxygen rotational-related properties such as metal-insulator transitions and magnetic reconstruction by strain. Here, we first use electronic structure calculations to investigate the strain effects on (001) thin films of the hybrid-improper ferroelectric (HIF) A3B2O7 compounds. Surprisingly, other than the bulk polar Cm21 phase, we find a new nonpolar phase becomes the ground state under both experimentally accessible biaxial compressive and tensile strains, which is beyond the people’s believe about the rule of the polarization-strain coupling. Furthermore, the generality of the polar-to-nonpolar (N-NP) transition in HIFs (not only in A3B2O7 compounds) leads us to find a novel route to tune the physical properties that are classified as mechanical, optical and magnetic responses, which we also propose could be electric-field tunable, near the P-NP phase transition boundary. Our results may offer a route to search for new functionalities in hybrid-improper ferroelectrics.

EL03.06.11
Pure Piezoelectricity Generation by a Flexible Nanogenerator Based on Lead Zirconate Titanate Nanofibers Horim Lee, Hyeon Kim and Yongsok Seo; Seoul National University, Korea (the Republic of)

Lead Zirconate Titanate (PbZr0.52Ti0.48O3, PZT) alloy has been extensively studied to be used for piezoelectric nanogenerators to harvest energy from mechanical motions. In this study, PZT nanofiber-based nanogenerators were fabricated to test its true piezoelectric performance without triboelectric effect. Aligned PZT nanofibers were fabricated by sol-gel electrospinning process. The thickness, area, and orientation of the PZT textile made by electrospinning the PZT solution onto multi-pair metal wires or metal mesh were controlled to form a composite textile. After the calcination, the PZT textile mixed with polydimethylsiloxane (PDMS) was placed between two flexible ITO-PEN substrates. The performance parameters of the nanogenerators were investigated under the bending motion, which excludes the triboelectric effect. The assembled nanogenerator of an area of 8 cm² and a thickness of 80 mm could generate an electrical output voltage of 1.1 V and a current of 1.4 mA under the bending strain. The piezoelectric voltage depended on the thickness of the PZT textile, while the piezoelectric current depended on both the thickness and the area of the PZT textile. The electrical performance of the device was significantly affected by the orientation of the PZT fiber and the bending direction. The output voltage and the output current were strain-dependent, while the total integrated charge was independent of the strain rate. The properties of the flexible nanogenerator could be quantified to verify the pure piezoelectric performance of the device.

EL03.06.12
Polymorphic Phase Transition in BaTiO3 by Ni Doping Nguyen Xuan Duong1, Jong-Seong Bae2, Jongchul Jeon3, So Yeon Lim4, Soo Han Oh5, Aman Ullah6, Muhammad Sheeraz7, Jin San Choi8, Jae-Hyeon Ko9, Sang Mo Yang10, Kyou-Hyun Kim11, Ill Won Kim12, Chang Won Ahn13 and Tae Heon Kim14; 1University of Ulsan, Korea (the Republic of); 2Korea Basic Science Institute (KBSI), Korea (the Republic of); 3Korea Institute of Industrial Technology, Korea (the Republic of); 4Sookmyung Women’s University, Korea (the Republic of); 5Hallym University, Korea (the Republic of)

Hexagonal barium titanate (h-BaTiO3, P63/mmc), which is structurally non-perovskite and energetically stable above 1460 °C, can be an excellent platform for designing an exotic phase which does not exist in nature and for achieving new room-temperature multiferroics with high performance. Owing to the high synthetic temperature, a phase transition to the h-BaTiO3 and the related physical properties have not been studied in detail. In this work, we experimentally demonstrate a structural phase transition from perovskite BaTiO3 with tetragonal symmetry to non-perovskite hexagonal polymorph in Ni-doped BaTiO3 ceramics. Using various experimental techniques, we monitored the evolution of the structural, ferroelectric/dielectric, and electronic properties in our Ni-doped BaTiO3. We found that the reduction of Ti oxidation state by Ni doping plays a key role in the observed structural transition to h-BaTiO3. More details of our experimental results will be presented in conjunction with a discussion about the underlying mechanism of this polymorphic phase transition in BaTiO3.

EL03.06.13
Three-Dimensional Atomic Scale Electron Density Reconstruction of Octahedral Tilt Epitaxy in Functional
Perovskites Yanfu Lu, Yakun Yuan, Venkatraman Gopalan and Susan B. Sinnott; The Pennsylvania State University, United States

Octahedral tilts are the most ubiquitous distortions in perovskite-related structures that can dramatically influence ferroelectric, magnetic, and electronic properties; yet the paradigm of tilt epitaxy in thin films is barely explored. Non-destructively characterizing such epitaxy in three-dimensions for low symmetry complex tilt systems composed of light anions is a formidable challenge. Here we demonstrate that the interfacial tilt epitaxy can transform ultrathin calcium titanate, a non-polar earth-abundant mineral, into high-temperature polar oxides that last above 900 K. The comprehensive picture of octahedral tilts and polar distortions is revealed by reconstructing the three-dimensional electron density maps across film-substrate interfaces with atomic resolution using coherent Bragg rod analysis. The results are in excellent agreement with density functional theory. The study could serve as a broader template for non-destructive, three-dimensional atomic resolution probing of complex low symmetry functional interfaces.

EL03.06.14
Advanced Techniques in Ultralow Voltage Piezoelectric Characterization of Ferroelectric Thin Films with Piezoresponse Force Microscopy Aviram Bhalla-Levine1, Ryan Wu1, Sujit Das1, Roger Proksch2 and Ramamoorthy Ramesh1; 1University of California, Berkeley, United States; 2Asylum Research, United States

There is currently significant interest in ultralow power microelectronics for memory and logic functions. Recent reports have identified multiferroic systems as possible candidates for such applications, with the ultimate goal of reducing the switching voltage to below one hundred millivolts (translating to approximately one attojoule per unit operation). Thus, measuring the ferroelectric and piezoelectric responses of ultrathin ferroelectric layers at such low voltage scales is essential. Piezoelectric measurements are, in principle, easier to execute and analyze since the primary response arises solely from the ferroelectric state (unlike polarization based measurements that are susceptible to leakage and nonlinear dielectric effects). To understand switching at voltages on the order of one hundred millivolts, we are carrying out a careful study of the piezoelectric switching of five, ten, fifteen, and twenty nanometer thick lead zirconate titanate films as a model system. We specifically focused on characterizing the piezoresponse of such nanoscale thin films using very low alternating current voltages (down to ten millivolt excitations). Our research indicates that statistically credible piezoelectric switching information can be obtained at these voltages. We will report the results of these scaling studies using piezoresponse force microscopy (PFM) as well as pulsed polarization measurements.

New Lead-Free Materials on the Base of Sodium-Potassium Niobate and Sodium-Bismuth Titanate Perovskites Ekaterina Politova; Karpov Institute of Physical Chemistry, Russian Federation

New Lead-Free Materials on the Base of Sodium-Potassium Niobate and Sodium-Bismuth Titanate Perovskites E.D. Politova1, G.M. Kaleva1, A.V. Mosunov1, N.V. Sadovskaya1, S. Yu. Stefanovich1,2 D.A. Kiselev3, A.M. Kislyuk3, T.S. Ilina3,
1L.Ya.Karpov Institute of Physical Chemistry, Vorontsovo pole str. 10, Moscow 105064 Russia,
2Lomonosov Moscow State University, Leninskie gory 1, Moscow 119992 Russia,
3National University of Science and Technology “MISiS”, Leninskii pr. 4, Moscow 119991 Russia,
E-mail: politova@nifhi.ru

Lead-free materials are being intensively studied in order to replace widely used Pb-based ones. We study influence of cation substitutions and preparation conditions on structure parameters, microstructure, dielectric, relaxor ferroelectric, and piezoelectric properties of solid solutions in the systems based on (Na0.5Bi0.5)TiO3 (NBT) and (K0.5Na0.5)NbO3 (KNN) perovskites.

Ceramic samples in systems (Na0.5Bi0.5)TiO3 - BaTiO3 (NBT-BT) and (K0.5Na0.5)NbO3 – BaTiO3 (KNN-BT) with compositions close to Morphotropic Phase Boundaries (MPB) were prepared by the two-step solid-state reaction method at temperatures of 900 – 1500 K. To modify properties of the samples, in A- and B-sites of perovskite lattice Li+, La3+, Mn3+, Ni3+, Fe3+, Nb5+, Sb5+ and W6+ cations were added. To improve density of ceramics
overstoichiometric KCl and LiF additives were used. The samples were characterized using the X-ray Diffraction, Scanning Electron Microscopy, Second Harmonic Generation (SHG), Dielectric Spectroscopy (DS), and Atomic Force Microscopy in Piezoresponsive Force mode (PFM) methods. The unit cell volume changes were observed in modified KNN- and NBT-based ceramics depending on ionic radii of substituting cations. Ferroelectric phase transitions at ~ 400-500 and 600 – 700 K were confirmed using the DS and SHG methods. Phase transitions near ~ 400 K in NBT-based compositions revealed typical relaxor behavior due to the presence of polar nanoregions in a nonpolar matrix. At high temperatures > 700 K effects of dielectric relaxation were observed in ceramics studied caused by formation of oxygen vacancies in compositions with aliovalent substitutions. At the room temperature, non monotonous changes of the dielectric parameters and increase in the spontaneous polarization value was proved for modified ceramics. Using the PFM method ferroelectric polarization switching at nanoscale was observed, and in some KNN-based ceramics high values of effective $d_{33}$ piezoelectric coefficient up to 300 pm/V were observed. The results obtained confirmed prospects of new lead-free materials development on the base of modified KNN- and NBT-based compositions.

Acknowledgment. The work was supported by the Russian Foundation for Basic Research (Project 18-03-00372).

EL03.06.16
Giant Polarization in Super-Tetragonal Ferroelectric Thin Films through a New Concept of Interphase Strain
Linxing Zhang; University of Science and Technology Beijing, China

Generally, the chemical or physical properties strongly depend on the change of lattice. The control of lattice strain, therefore, much affects the chemical or physical properties of functional materials, which has been widely used in superconductivity, giant magnetoresistance, multiferroics, catalysis and etc. Ferroelectrics are an important functional material, which has been widely used in the field of ferroelectric memories, tunable microwave devices, large-capacity capacitors, piezoelectric sensor devices, etc. The intriguing properties of ferroelectric materials utilize the basic functional primitive parameter of polarization. This team has realized this method, interphase strain, by creating a single-lattice-parameter epitaxial composite film on SrTiO$_3$ substrate from two tetragonal materials but with different lattice parameters, PbTiO$_3$ ferroelectrics and PbO non-ferroelectrics. The results show that the method improves the lattice distortion of PbTiO$_3$ to $c/a = 1.238$, compared to 1.065 in bulk. The remanent polarization is as high as 236.3 μC/cm$^2$, which is near twice the highest value of the known ferroelectrics. This composite ferroelectric thin film is very stable, and the super-tetragonal ferroelectric phase is stable up to 725 °C, compared to the bulk transition temperature of 490 °C.

The proposed “interphase strain” is a new concept for strain engineering to regulate lattice strain of ferroelectrics, and successfully achieved giant polarization in the super tetragonal PbTiO$_3$/PbO based ferroelectric thin films. The idea of "interphase strain" is as follows: if two kinds of materials with similar crystal structures, but different lattice parameters, are growing into a single-lattice-parameter epitaxial film, the material of the small lattice is inevitably subjected to the tensile stress from the large lattice material, thereby introducing a large lattice strain. The regulation of lattice strain can cause significant changes in the physical and chemical properties of the material. This new approach of interphase strain for strain engineering can be utilized to enhance the physical and chemical properties of other functional materials, such as superconductivity, giant magnetoresistance, multiferroic, and catalysis.

EL03.06.17
In-Plane Ferroelectricity in Epitaxial Dion-Jacobson CsBiNb$_3$O$_7$ Jie Jiang$^{1,2}$, Lifu Zhang$^1$ and Jian Shi$^1$; 1Rensselaer Polytechnic Institute, United States; 2Kunming University of Science and Technology, China

Conventional ferroelectric perovskite materials carry a debatable critical thickness below which the depolarization field is large enough to destabilize ferroelectricity. 2D ferroelectric materials are discovered to hold robust in-plane polarization down to a single unit cell, contending the continuous miniaturization of ferroelectric devices. However, due to the nonuniformity of the electrostatic field from quasi-2D metal electrodes, the in-plane intrinsic dipoles would experience a mismatched screening (screening frustration) making the in-plane polarization switching
dynamics complex. Until now there is rare direct experimental proof of the in-plane polarization switching in a 2D crystal. In this talk, for the first time, we will present the in-plane polarization switching in a Dion-Jacobson quasi-2D layered oxide. The coupling between the in-plane ferroelectricity and other physical properties, e.g. the switchable photo diode effect and the photon-induced domain switching, in layered materials may enable versatile applications down to the atomic scale.

**Nontrivial Topological Polarization Field Self-Ordered in Nanoporous Ferroelectrics—A Phase-Field Modeling**

Takahiro Shimada¹, Le Van Lich¹,², Takayuki Kitamura¹ and Hiroyuki Hirakata¹; ¹Kyoto University, Japan; ²Hanoi University of Science and Technology, Viet Nam

Topological objects or field textures, such as skyrmions, merons, and vortices, are intriguing features found in ordered systems with spontaneously broken symmetry. A plenty of topological field textures have been discovered, especially in magnetic and ordered soft matter systems, due to the existence of chiral interactions, and this has provided a fruitful platform for unearthing additional groundbreaking functionalities. However, despite one of the most important classes of ordered systems, ferroelectrics scarcely form topological polarization structures due to lack of such chiral interactions. Here, we show that a rich assortment of nontrivial topological polarization textures, including hedgehogs, antivortices, multidirectional vortices, and vortex arrays, can be spontaneously formed in three-dimensional nanoporous ferroelectric structures using the phase-field modelling based on the Ginzburg–Landau theory. We demonstrate that confining ferroelectrics to trivial geometries that are incompatible with the orientation symmetry may impose extrinsic frustration to the polarization field through the enhancement of depolarization fields at free porous surfaces. This frustration yields symmetry breaking, resulting in the formation of nontrivial topological polarization field textures. We also characterize the topological feature of polarization structures according to the topological theory of defects and homotopy theory. The results indicate that the nanoporous structures possess topological objects composed of two or more elementary topological polarization structures. This study therefore offers an intriguing playground for exploring novel physical phenomena in ferroelectric systems as well as a novel nanoelectronics characterization platform for future topology-based nanotechnologies.

**EL03.06.19**

**Frustrated Dipole Order Induces Noncollinear Proper Ferrielectricity in Two-Dimensions**

Ling-Fang Lin¹,²,³, Yang Zhang¹,²,³ and Shuai Dong¹; ¹Southeast University, China; ²The University of Tennessee, Knoxville, United States; ³Oak Ridge National Laboratory, United States

Within Landau theory, magnetism and polarity are homotopic, displaying a one-to-one correspondence between most physical characteristics. However, despite widely reported noncollinear magnetism, spontaneous noncollinear electric dipole order as ground state is rare. Here a dioxydihalides $MO_2X_2$ family (layered structure, where $M=Mo$ and $W$; $X=Cl$ and Br) is predicted to display noncollinear ferrielectricity, induced by competing ferroelectric and antiferroelectric soft modes. This intrinsic noncollinearity of dipoles generates unique physical properties, such as $Z_2 \times Z_2$ topological domains, atomic-scale dipole vortices, and negative piezoelectricity.

**Defect Complex and Hopping Mechanism in (Li, Al) Co-Doped ZnO Ceramics**

Dong Huang and Francis Chi Chung Ling; The University of Hong Kong, Hong Kong

Systematic studies on sintering temperature and Li:Al stoichiometry of Li and Al co-doped ZnO ceramic shows that the Zn$_{0.99}$(Li$_{0.1}$, Al$_{0.2}$)$_{0.03}$O sample exhibits a colossal dielectric constant (CDC) phenomenon with low dielectric loss ($\epsilon'' = 0.159$ at the frequency of 1 kHz) at the room-temperature. The CDC and low dielectric loss have good frequency stability. SEM and CL measurements show the grain boundary of the as-grown LAZ sample is accumulated with high density of V$_{O}$, and the spatial non-uniformity of V$_{O}$ concentration is removed after the O$_2$ annealing. With the impedance analysis, it is shown that the $R_{GB}$ (resistance of grain boundaries) is only $\sim$16 times larger than $R_g$ (resistance of grain), and the $CPE_{GB}$ is even smaller than $CPE_g$, implying that internal barrier layer capacitance (IBLC) effect is not likely the dominant source for the observed CDC of the LAZ samples. Dielectric spectrum analysis shows that the CDC is associated with two relaxation processes P1 and P2. Annealing the sample at 900 °C in oxygen leads to the drop of to 2250 but maintaining a low dielectric loss of $\sim 0.10$, while P1 vanishes and P2 persists. Comparing the synchrotron based hyperfine Al 2p X-ray photoelectron (XPS) spectra of the purely
Al-doped ZnO sample and the Li+Al co-doped ZnO sample shows that the electronic environment around the Al_{Zn} in these two samples are different, indicating that defect complex consisting of Al_{Zn} and Li_{Zn} is probably present in the Li+Al co-doped sample. Furthermore, after the Raman comparisons among the co-doped, singly Li- or Al-doped ZnO, it is shown the defect complex has altered the Zn-O bond’s local environment, which lead to the shift of A_1 stretching mode. This defect complex is possibly the electron pinning defect dipole responsible for the CDC associated with the P2 relaxation process. With the correlated barrier hopping model fitting, it is found that two energy level E_c~0.34 eV and E_c~0.87 eV are existed in as grown and O_2 annealed LAZ sample, causing the P1 and P2 relaxation, respectively. With two potential well model, we theoretically calculate the dielectric constant and loss against frequency for P1 and P2 relaxation, which are around ~7173 and ~2817.

Structure-Property Correlation in the Multiferroic (Bi_{1-x}Ba_{x})(Fe_{1-x}Ti_{x})O_3 System Arun Kumar and Dhananjai Pandey; Indian Institute of Technology (BHU), India

Magnetoelectric multiferroics offer the possibility of controlling the electric (magnetic) polarization by applying a magnetic (electric) field and have attracted significant interest in view of the interesting physics of coupling between magnetic and ferroelectric order parameters and potential technological applications in several multifunctional devices. BiFeO_3 is unique amongst various magnetoelectric multiferroics, as its ferroelectric and magnetic transition temperatures (T_C~1103 K, T_N~643 K) are well above the room temperature. In recent years, the (Bi_{1-x}Ba_{x})(Fe_{1-x}Ti_{x})O_3 (BF-xBT) system have received considerable attention due to large ferroelectric polarization, large remnant magnetization, linear magnetoelectric coupling and highest depolarization temperature for piezoelectric applications and considered to be alternative to toxic lead (Pb) containing piezoelectric ceramics like Pb(Zr,Ti)O_3 and (1-x)Pb(Mg_{1/3}Nb_{2/3})O_3-xPbTiO_3. In the present investigation, we have carried out a comprehensive study on 0.3 wt% Mn-doped BF-xBT samples in the composition range 0≤ x ≤1.0. Our synchrotron x-ray diffraction results reveal two structural phase boundaries, one from rhombohedral (R3c space group) to cubic (Pm-3m space group) at x<~0.33 and other from cubic (Pm-3m space group) to tetragonal (P4mm space group) at x<~0.80. The composition dependence of the polarization and dielectric constant at room temperature exhibits a peak around x=0.33. This confirms the existence of morphotropic phase boundary at this composition due to a rhombohedral (R3c) to cubic (Pm-3m) phase transition across the morphotropic phase boundary. We also present a magnetic phase diagram of BF-xBT.

Phase-Field Simulation and High-Throughput Calculation of Resistive Switching Behavior in Random Access Memory Kena Zhang1, Jianjun Wang2 and Ye Cao1; 1The University of Texas at Arlington, United States; 2The Pennsylvania State University, United States

Metal-oxide based Resistive Random-Access-Memory (RRAM) which exhibits multiple resistive/memory states by the formation/dissolution of a conductive filament (CF), has potential to be the next generation memory technology. The performance of RRAM relies on the fast switching speed, large current on/off ratio, and minimized device variability, which are critically dependent on the ion (such as oxygen vacancies) migration driven by the concentration gradient, electrical bias, heat generation and dissipation. In this work we report that the mechanical stress induced by the growth and retraction of the conductive filament is equally important to the resistive switching dynamics. The stress inhibits the ion diffusion and segregation along the electric field direction and reduces the current on/off ratio and the switching time. To further understand the role of this mechanical stress in the resistive switching process, we developed a comprehensive phase-field model taking into account the electrical, thermal, and mechanical energy, and studied their relative effects on the RRAM resistive switching dynamics. We choose hafnium oxide as an example, and compare the simulation results with existing experimental results to validate the model. Based on this, high-throughput phase-field simulations for different oxides of different properties are performed to help selecting the potential candidates as the oxide switching layer materials with optimized switching speed, current on/off ratio and device uniformity. Our work thus provides fundamental insights into the resistive switching mechanism, and establishes a theoretical framework of materials selection and design for metal-oxide based RRAMs.

Symmetry Mismatch at Heterointerfaces and Photovoltaic Effect in BiFeO3/LaFeO3 Ferroic Superlattices Mimoun El Marsssi, Jamal Belhadi, Said Yousfi, Benjamin Carcan and Houssny Bouyanfif; University of Picardy,
France

Bismuth ferrite (BiFeO₃ or BFO) is the most studied multiferroic due to its robust ferroelectric state coexisting at room temperature with an antiferromagnetic order. Such coexistence and the possible cross coupling between both ferroic orders pave the way to so-called MagnetoElectric RAM combining advantages of the ferroelectric and the antiferromagnetic state. Similarly to the relaxor-ferroelectric systems a morphotropic phase boundary has been observed in La doped BFO (Bi,La)FeO₃ solid solution with peculiar nanoscale mixture. Emergence of such MPB is believed to arise from the competition between antiferrodistortive and ferroelectric instabilities. Our approach to investigate the structural interaction between BFO and LFO is based on superlattices that are ideal platforms for exploring antagonistic interactions at the origin of many exotic systems. For instance Cuprates combined with Manganites in superlattices were investigated to better understand the competition between magnetic and superconducting orders. Similarly to this strategy we grew series of SLs made of BiFeO₃ and LaFeO₃. Structural characterizations and Raman spectroscopy indicate an anti-polar structure in the BFO layers that is strongly dependent on the BFO thickness and temperature [1,2]. This antiferroelectric like structure very similar to the PbZrO₃ system cannot be explained by the nature of the induced strain but by the symmetry mismatch at the interfaces of the SLs. Compatibility of the octahedral tilt system seems to be the main driving force for this induced anti-polar state. Thickness-temperature phase diagram is constructed. We have highlighted a switchable PV effect in these artificial structures at room temperature. By changing the thickness of the BFO layer we have evidenced a change of PV characteristics from a positive Voc and a negative Jsc to an inverse effect. These results, compared to our results obtained on BFO single films [3], indicate different origin of the mechanisms of photo-carries separation in PV devices. Our results are promising and indicate the possibility to employing the vertical geometry of measurements for tuning the PV effect in multiferroic SLs.

EL03.06.25
Effect of Quadravalent Heavy Transition Metal Cations on Microwave Properties of Co₂Z Ferrites Piotr Kulik, Gavin Winter, Katherine Murphy, Jason Adams, Ogheneyunume Fitchorova and Vincent Harris; Northeastern University, United States

The demand for miniaturized and high performing broadband communication systems in the GHz frequency range is steadily growing due to severely crowded and rapidly changing modern commercial and military spectral environments. Hexaferrite composites have proven to be one of the few key enablers in providing miniaturized form factors due to their high permeability and permittivity as well as their capability to reach high resonance frequencies up to 100 GHz. In this work, a series of Z-type barium hexaferrites were prepared in which dopants of heavy transition metals, i.e., Mo⁴⁺ and Hf⁴⁺, were employed to modify structure and microwave properties. Through systematic measurements it was revealed that each dopant affected the hexaferrites’ properties differently by both shifting the resonant frequency and altering magnetic properties without strongly varying the hexaferrite crystallographic structure. Additionally, ε’ = μ’ was realized without any additives such as Bi₂O₃, which had been previously been used for tuning permeability and permittivity. Polycrystalline Co₂Z ferrites, having a nominal composition of Ba₃Co₂₋ₓHfₓFe₂₄₋₂ₓO₄₁ and Ba₃Co₂₋ₓMoₓFe₂₄₋₂ₓO₄₁, where x=0 to 0.05, were prepared by a solid-state process. BaCo₃, HfO₂, MoO₂, Co₃O₄, and Fe₂O₃ of high purity were mixed and calcined in oxygen for 5-8 hours at 800-1050 °C, which then were ball milled for 18-24 hours to reduce the grain size to under 1 µm. After ball-milling, ISOBAM was added as a binder and mixed for several minutes. Samples were then pressed to form toroids with an inner diameter of 3 mm and an outer diameter of 7 mm. The toroids were pressed by a cold isostatic press in order to maximize compaction before sintering in oxygen for 4-6 hours at 1000-1250 °C. Finally, samples were measured using the Agilent E864A PNA and a 7 mm precision airline, showing permeability and frequency changes. Results show that a nine-time reduction in size can be achieved while maintaining an impedance of 360 Ω close to that of free space over a broadband.

Insights into Magneto-Electric Coupling Using X-Ray Photoemission Electron Spectro-Microscopy Rajesh V. Chopdekar; Lawrence Berkeley National Laboratory, United States

Ferromagnetic-ferroelectric (FM-FE) heterostructures have been studied as a route to obtain strong room-
temperature magneto-electric interactions not commonly found in single-phase materials. In such composites it is critical to understand the role of charge- and strain- mediated interactions at interfaces of the constituent phases, and spatially resolved probes such as x-ray photoemission electron microscopy (XPEEM) at the Advanced Light Source PEEM-3 beamline can observe such interface interactions at the scale of a single FE or FM domain. Polarization-dependent soft x-ray spectro-microscopy as a function of temperature and applied electric and magnetic fields can offer unique insights into coupling at heterointerfaces with sub-100 nm resolution by exploiting the x-ray linear dichroism (XLD) and magnetic circular dichroism (XMCD) effects. I will present a detailed analysis of the magneto-electric coupling in model multiferroic systems (e.g. FM layers grown on FE single crystals, or single phase multiferroic epitaxial thin films) using XLD- and XMCD-PEEM imaging. While the 3D vector orientation of ferromagnetic domains can be mapped with XMCD imaging at different azimuthal orientations, anisotropic strain interactions between FE and FM phases can be mapped by XLD imaging in an analogous fashion. The anisotropic nature of the strain imprinted by the FE induces a local variation of the magnetic anisotropy of the FM phase due to large magnetoelastic anisotropy, and by varying applied electric fields or changes in temperature we can observe both the FM domain structure and imprinted strain state evolve due to such perturbations. Furthermore, we can compare spatially averaged electric-field dependent magnetometry to spatially resolved XMCD images in applied magnetic fields, and directly correlate a giant anisotropy rotation and change of anisotropy symmetry to the local tuning of magnetic anisotropy at the scale of single FE and FM domains. Similarly, PEEM-based mapping of multiple ferroic orders can offer insight into optical switching mechanisms of single-phase multiferroic materials. Thus, XLD- and XMCD-PEEM imaging offer a facile method to visualize magneto-electric coupling at the sub-micron scale by probing FE, FM, or antiferromagnetic domain evolution as a function of stimuli such as in situ applied electric or magnetic fields.

MoS₂ Negative Capacitance Field-Effect Transistor Based on PLD Grown Hf₀.₅Zr₀.₅O₂

Hae Won Cho, Seongin Hong, Junwoo Park, Sunkook Kim and Jeonghyeon Oh; Sungkyunkwan University, Korea (the Republic of)

Recently, the power consumption density has increased compared to the transistor which has increased exponentially per unit chip, making it difficult to store and process a large amount of data. Therefore, the development of low-power semiconductor technology is inevitable. In order to solve this issue on power consumption, research on a negative capacitance field-effect transistor (NCFET) is being actively conducted. In case of metal oxide semiconductor field-effect transistor (MOSFET), which is a conventional CMOS device, the subthreshold slope (S.S) value cannot fall below 60 mV/decade. NCFET, the next generation low-power device to replace MOSFET that encounters this limitation, can dramatically reduce power consumption density. Ferroelectric is negative capacitor in the gate structure of the NCFET, allowing channel surface potential to be amplified more than the gate voltage, enabling drive at less than 60 mV/dec S.S at room temperature. In this study, the ferroelectric Hf₀.₅Zr₀.₅O₂ (HZO) material in the gate structure was grown through pulsed laser deposition (PLD) process, and MoS₂ was used as a channel material to develop low power, high mobility 2D-NCFET. Conventionally, the ferroelectric HZO grown by atomic layer deposition (ALD), has been widely studied in electronic device development. In addition, research has been carried out focusing on HZO epitaxial growth at various substrates by PLD process. For the first time, we have introduced a new process to operate MoS₂; NCFET based on HZO, grown on Si substrate by PLD. The process conditions such as oxygen partial pressure were controlled during the experiment, and the Al₂O₃ (k~9) as bottom dielectric layer scaling resulted in a five-fold improvement in the subthreshold slope (S.S), operating the device at low power, from approximately 500 mV/dec to 100 mV/dec. To develop low power devices obtaining less than 60 mV/dec, the PLD process will further be optimized for the enhancement of ferroelectricity to obtain larger NC effect.

Anomalous Remnant Magnetization in Gadolinia Nanospindles at Room Temperature?

Parvez Akhtar, Sandeep Kumar and Madhusudan Singh; Indian Institute of Technology Delhi, India

Gadolinium oxide (Gd₂O₃) is expected to exhibit strong interactions with external magnetic fields due to the high
magnetic moment of Gd (7.94 μB). Applications range from a positive contrast agent in magnetic resonance imaging (MRI) to use as a cooling agent in magnetocaloric effect (MCE) based refrigerators. In this work, we report on the preparation of Gd₂O₃ nanospindles by a hydrothermal method, followed by measurement of its mass magnetization. Powdered Gd₂O₃ source (CAS: 12064-62-9, 99.9% trace metals basis, Sigma-Aldrich) was subjected to aqueous colloidal hydrothermal synthesis and subsequently annealed at 500°C to produce cubic phase (JCPDS: 882165) Gd₂O₃, inferred from powder X-ray diffraction (PXRD, Advance Bruker D8, Ni-filtered Cu Kα radiation (λ = 1.5418 Å)). The morphology of nano-spindles (length ~100 ± 10 nm) was studied by field-emission scanning electron microscopy (FESEM-FEI QUANTA 3D FEG). Raman spectra confirmed the cubic phase of Gd₂O₃ with a highly intense and characteristic peak at 361 cm⁻¹. A small quantity of the product (1.23 mg) was wrapped in Teflon tape and exposed to magnetic fields in the range [-2,2] kOe in an Alternating Gradient Magnetometer (Micromag 2900 PMC) at room temperature. Measurements of magnetic moment (emu), converted into mass magnetization (emu/g), exhibit a quasi-saturated hysteresis behavior at limits of magnetic field excitation. The saturation magnetization (Mₘ), retentivity (Mᵣ) and coercivity (Hᵥ) are found to be 540.809 ± 4.381 m emu/g, 23.348 ± 0.186 m emu/g, and 21.218 ± 1.024 Oe, respectively over multiple measurements. The absence of saturation at the applied field in the magnetic hysteresis (M-H) curve suggests a mix of paramagnetic (PM) and ferromagnetic (FM) phases at room temperature. We are performing further materials analysis and investigating this magnetization result at different temperatures to validate it, and to understand the precise mechanism, in light of known defect-induced magnetization in various materials, albeit at lower temperatures. Potential applications include possible low-cost solution-processable magnetic devices and sensors.

EL03.06.29
Enhanced Gilbert Damping in Sputter Deposited Topological Insulator/Ferromagnet Heterostructures
Nirjhar Bhattacharjee¹, Ivan Lisenkov², Alexandria Will-Cole¹, Jiawei Wang¹ and Nian Sun¹ ²; ¹Northeastern University, United States; ²Winchester Technologies, LLC, United States

Topological insulators (TI) have been known to possess topologically protected surface conducting states [1] and Rashba 2D electron gas (2DEG) due to band bending at interfaces [8]. A TI placed in contact with a ferromagnetic (FM) metal generates spin-orbit torques (SOT) on the magnetization in FM [2,3]. A signature of SOT in TI/FM bilayers is an increase in Gilbert damping in FM. SOT in TI/FM (ferromagnet) films have been reported previously with TI films epitaxially grown with molecular beam epitaxy [2, 3]. Here we report enhanced Gilbert damping in sputter deposited TI/FM, BiₓTe₁₋ₓ/CoFeB (BT/CFB) films (x = ~0.4). Samples of 20nm BT film were grown on a Si/SiO₂ substrate at 250C and at 30C followed by 20nm CFB deposition at 30C (room temperature) using RF and DC magnetron sputtering respectively. X-ray diffraction (XRD) measurements reveal a crystalline 250C BT film compared to an amorphous 30C BT film. Room temperature broadband ferromagnetic resonance (FMR) measurements were conducted for 250C and 30C heterostructures and a control sample where the TI was substituted with 3nm Al. A full width at half maximum (FWHM) resonance linewidth was extracted as a function of frequency to calculate Gilbert damping. The control and 30C samples show almost identical linewidth, but the 250C sample linewidth is much broader. The Gilbert damping coefficient, α, for 250C sample is α = 0.3, compared to α = 0.03 for 30C and α = 0.02 for control. The calculated spin-mixing conductance for 250C sample is g = 4e²/2 m-2 which is in an order of magnitude higher than reported value for CFB/Pt films [4]. Moreover, the presence the crystalline TI film adjacent to FM induces static effects on the magnetization. M-H loop measurements reveal emergence of out of plane magnetic anisotropy (OPMA) for the 250C sample at lower thicknesses (<5nm) of CFB films. This change in the magnetic anisotropy and spin pumping in the BT/CFB heterostructure is attributed to presence Rashba 2DEG because of strong spin-orbit coupling [5-8] at the interface, which is enhanced for the crystalline phase of BT. Further, spin-torque FMR studies on our samples is being carried out to characterize the effects on magnetization dynamics due to sputtered TI/FM interfaces.

Substrate-Modulated Ferromagnetism of Two-Dimensional Fe$_3$GeTe$_2$  Luyao Song, Luman Zhang, Xinyu Huang, Lei Ye and Junbo Han; Huazhong University of Science and Technology, China

Ferromagnetism in two-dimensional (2D) Van der Waals materials promises to revolutionize and develop spintronic devices and has received increased attention due to the electrical stability and sensitive tunability of an external field. To achieve high performance in spintronic devices, the effect of device substrates on the ferromagnetism of 2D materials also plays a critical role in practical device design and fabrication but has not yet been examined. Here, we systematically demonstrated the substrate-modulated ferromagnetism of 2D Fe$_3$GeTe$_2$ based on different substrates. The out-of-plane ferromagnetism of Fe$_3$GeTe$_2$ thin films prepared on Al, SiO$_2$ and Au substrates was probed using Magnetooptical Kerr effect techniques. Based on the experimental data, Fe$_3$GeTe$_2$ thin films with the same thickness were modulated to show different $T_C$ on different substrates, with the highest $T_C$ on Au substrate, especially in a thin layer. The underlying reason was explained by the first-principle calculation and mean field approximation, revealing that the charge redistribution and lattice distortion play an important role on magnetic properties changes. Our work provides a practical way to modulate the magnetic properties of ferromagnetic materials permanently without applying any additional treatment processes, and a feasible theoretical method to study the fundamental physical properties of ferromagnetic materials.

Electrically Reversible Spin Texture in Ferroelectric Oxides  Evgeny Y. Tsymbal; University of Nebraska-Lincoln, United States

Spin-orbit coupling is known to be responsible for non-trivial spin configurations and a number of emergent physical phenomena. Ferroelectric materials are especially interesting in this regard due to broken space inversion symmetry, which enforces the emergence of the bulk Rashba and Dresselhaus spin-orbit coupling, and reversible spontaneous polarization, which allows for a non-volatile electrical control of the spin degrees of freedom. This talk addresses two classes of ferroelectric oxide materials exhibiting dissimilar spin textures due to different space-group symmetries. First, we consider a technologically relevant oxide material, HfO$_2$, which is known to be ferroelectric in a non-centrosymmetric orthorhombic phase. We show that HfO$_2$ exhibits Dresselhaus-type spin texture driven by spin-orbit coupling, and argue that this material can be used as a tunnel barrier to produce tunnelling anomalous and spin Hall effects that are reversible by ferroelectric polarization. Another example involves a class of materials capable to maintain a persistent spin texture. This property has been predicted to support an extraordinarily long spin lifetime of carriers promising for spintronics applications. We show that the persistent spin texture can be enforced by non-symmorphic space-group symmetry of the crystal, which makes it a robust intrinsic property of the bulk material. Using symmetry analyses and theoretical modelling based on density-functional theory, we demonstrate this property for a handful of oxide materials, which can be synthesized in laboratory. Among them BiInO$_3$, a wide band gap ferroelectric semiconductor, is the most promising candidate which sustains persistent spin texture around the conduction band minimum. The reversible spontaneous polarization of BiInO$_3$, allows for an electrical control of the spin polarization, which can be selectively induced by circular polarized optical pumping.

Tunable Magnetotransport Properties of Epitaxial Nanocomposite Films Aiping Chen¹, Haiyan Wang², Judith L. MacManus-Driscoll¹ and Quanxi Jia⁴; ¹Los Alamos National Laboratory, United States; ²Purdue University, United States; ³University of Cambridge, United Kingdom; ⁴University at Buffalo, The State University of New York, United States

Over the past two decades, new discoveries and major advances have been made to enhance controlled synthesis of epitaxial ferromagnetic oxide films and to gain fundamental understanding of their physical properties. Tunable magnetotransport properties, in particular, have been achieved through interfacing ferromagnetic materials with binary oxides at the nanoscale by forming nanocomposite films, where both the ferromagnetic and binary oxides are of nanoscale dimensions. In this talk, we will overview our strategies in synthesis and characterization of epitaxial magnetic nanocomposite films. Using controlled synthesis, advanced probing, and theoretical modeling, we are able to understand the effect of interface strain on the magnetotransport properties of ferromagnetic materials such as Laₐ₀.₇Sr₀.₃MnO₃ films.

Magnetoelectric Coupling by Giant Piezoelectric Tensor Design Chang-Beom Eom; University of Wisconsin--Madison, United States

Strain-coupled magnetoelectric (ME) phenomena in piezoelectric / ferromagnetic thin-film bilayers are a promising paradigm for sensors and information storage devices, where strain manipulates the magnetization of the ferromagnetic film. In-plane magnetization rotation with an electric field across the film thickness has been challenging due to the virtual elimination of in-plane piezoelectric strain by substrate clamping, and in two-terminal devices, the requirement of anisotropic in-plane strain. We have overcome both of these limitations with lithographically patterned devices with a piezoelectric membrane on a soft substrate platform, in which in-plane strain is freely generated, and a patterned edge constraint that transforms the nominally isotropic piezoelectric strain into the required uniaxial strain. We fabricated 500 nm thick, (001) oriented [Pb(Mg₁/₃Nb₂/₃)O₃]₀.₇-[PbTiO₃]₀.₃ (PMN-PT) unclamped piezoelectric membranes with ferromagnetic Ni overlayers. Guided by analytical and numerical continuum elastic calculations, we designed and fabricated two-terminal devices exhibiting Ni magnetization rotation in response to an electric field across the PMN-PT. Similar membrane heterostructures could be used to apply designed strain patterns to many other materials systems to control properties such as superconductivity, band topology, conductivity, and optical response.

This work has been done in collaboration with J. Irwin, S. Lindemann, W. Maeng, J. J. Wang, V. Vaithyanathan, J.M. Hu, L.Q. Chen, D.G. Schlom, C.B. Eom, M.S. Rzchowski.

Towards Low-Voltage Multiferroic/Magnetoelectric Operation Lane W. Martin¹,²; ¹University of California, Berkeley, United States; ²Lawrence Berkeley National Laboratory, United States

Applications in advanced, beyond Moore’s law computing are driving researchers and industry alike to explore a broader set of materials than ever before. While industry has maintained, in some form, their ability to continually meet the demands of Moore’s law by increasing the number of transistors on chip, largely in part from efforts in scaling and size reduction of the transistors themselves and the associated circuit area, the same cannot be said for energy scaling. In the last fifteen years, scaling has deviated from Dennard’s trend which states that the power density of circuits stays roughly the same as transistors get smaller, assuming, concurrent voltage reductions are made. Herein lies the challenge – while we have reduced transistor and circuit size, voltages of operation have not been scaled at the same rate. As a result, power and energy dissipation now stands as one of the most pressing challenges for advanced nanoelectronics. This has motivated renewed attention to a wide variety of routes to reduce the voltage of operation of next-generation logic. Such approaches have thrust materials – including multiferroics and magnetoelectrics – back into the mix as candidates for beyond CMOS computing.

Despite considerable research on multiferroic and magnetoelectric materials in the last decade and advances in our
ability to synthesize, control, characterize, and fabricate these materials, the requirements of beyond Moore’s law computing are already pushing these materials to their limits. In this talk, we will explore recent efforts to reduce the operating voltages of multiferroic and magnetoelectric devices including exploring both new and old materials in ever decreasing sizes. In particular, we will explore efforts to push the size limits of these materials whereby reducing the thickness of films provides a direct pathway to reduced operation voltages. Special attention will be given to challenges in achieving ultra-thin-film operation in multiferroics such as BiFeO$_3$ and Bi$_{1-x}$La$_x$FeO$_3$ as well as in magnetoelectric composite structures based on piezoelectric/ferroelectric materials such as BaTiO$_3$ and (1-x)PbMg$_{1/3}$Nb$_{2/3}$O$_3$-(x)PbTiO$_3$ (PMN-PT). For example, while considerable work has been done in PMN-PT as bulk ceramics, single crystals, and thick films, essentially no work on ultra-thin films has been considered. We will explore the evolution of relaxor order and actuation potential as we reduce relaxor film thicknesses to the range of 5-100 nm. Studies suggest surprising enhancement of relaxor character with reducing thickness and the presence of a complex, thickness evolution to structure and properties. We will explore other approaches including orientation dependence and chemical routes to reduce polarization or manipulate structure in such a fashion that it reduces the costs of switching polarization. For example, in PbZr$_{0.2}$Ti$_{0.8}$O$_3$ thin films, it has been shown that merely changing film orientation from (001)- to (111)-oriented structures can dramatically change coercive field scaling (thus avoiding classical Janovec-Kay-Dunn scaling trends) as a result of changes in materials symmetry which produce low-energy switching pathways. Finally, we will explore the effects of these approaches on the realization of low-voltage magnetoelectric coupling in heterostructures such as BiFeO$_3$-based spin valves and composite ferromagnet/piezoelectric stacks. To end, we will discuss where these ideas could lead us next and what metrics can be met using these materials and methods.

Voltage Controlled Néel Vector Switching in High-$T_N$ Magnetoelectric Thin Films Christian Binek, Ather Mahmood, Will Echtenkamp, Junlei Wang, Takashi Komesu and Peter Dowben; University of Nebraska-Lincoln, United States

Voltage-controlled magnetization switching at interfaces or boundaries enables dissipationless control of remnant magnetic states. It paves the way towards ultra-low power and non-volatile spintronics. We exploit substitutional Boron doping of the magnetoelectric antiferromagnet Cr$_2$O$_3$ to fabricate voltage switchable all antiferromagnetic memory devices which operate between room temperature and 400K, i.e., significantly above the antiferromagnetic ordering temperature $T_N = 307$ K of pure Cr$_2$O$_3$. $T_N$-enhanced and anisotropy reduced magnetoelectric films are grown via pulsed laser deposition in the presence of borane background gases. Boundary magnetization associated with two degenerate orientations of the Néel vector serves as state variable which can be isothermally written and read out. Writing is achieved through voltage-controlled switching of the Néel vector. Read out takes place by sensing an anomalous Hall-like signal originating from an electric current driven through a lithographically patterned Pt Hall bar deposited on top of the B-doped Cr$_2$O$_3$ film. In device architectures based on voltage-controlled exchange bias where remnant magnetization of a ferromagnetic film serves as state variable, B-doping does not translate into improved performance. Although B-doping can increase the blocking temperature, exchange coupling is not accompanied by effective pinning and thus voltage-control of the ferromagnet. The detrimental effect of B-doping on perpendicular exchange bias is attributed to reduced magnetic anisotropy and canting of the interface magnetization relative to the surface normal. It takes place despite perseverance of antiferromagnetic order and magnetoelectric functionality above 307 K as evidenced by magnetometry and photoemission spectroscopy. In contrast to pure chromia, where order parameter switching is controlled by the competition between magnetoelectric and anisotropy energy, the switching mechanism in B-doped chromia seems to be additionally affected by a sizable electric field dependence of the magnetic anisotropy. Our results demonstrate that $T_N$-enhancement and anisotropy reduction through B-doping of Cr$_2$O$_3$ is successfully utilized in voltage-controlled spintronic devices with reduced complexity. Our Hall bar structures based on B-doped chromia show voltage-controlled switching up to 100 K above room temperature paving the way to CMOS compatible ultra-low power magnetoelectric MRAM and logic devices.

SHG-Active Boundaries between Nonpolar Magnetic Domains in MnWO$_4$ Shingo Toyoda$^1$, Manfred Fiebig$^{1,2}$, Takahisa Arima$^{1,3}$, Yoshinori Tokura$^{1,3}$ and Naoki Ogawa$^{1,4}$; $^1$RIKEN CEMS, Japan; $^2$ETH Zürich, Switzerland;
Domain walls often show a novel functionality very different from that of bulk states. Despite their importance, the domain wall physics are not well understood compared to the bulk cases because of the lack of experimental techniques to investigate the confined walls. In the present study, we conducted a SHG imaging measurement which allows us to probe the domain walls in MnWO4. We found multiferroic domain walls in a non-multiferroic environment.

MnWO4 crystalizes in a centrosymmetric space-group $P2_1/c$, and shows successive magnetic phase transitions below the Néel temperature $T_N = 13.5$ K. In the AF2 phase, the magnetic order breaks the space-inversion symmetry and ferroelectric polarization appears along the $b$-axis [1], while the other phases have non-polar magnetic structures. Correspondingly, SHG is allowed only in the AF2 phase, while it is forbidden in the AF1 and AF3 phases. However, it was found that non-zero SHG signal exists even in the SHG-forbidden AF1 phase [2]. We revealed that the SHG signal in the AF1 phase comes from wall-like structures. Polarization anisotropy and spectroscopy measurements of the SHG signal suggest that the wall in the AF1 phase should have a magnetic structure similar to that of the multiferroic AF2 phase. The results indicate the existence of domain walls breaking space-inversion symmetry, although the bulk phase is centrosymmetric. We propose the emergence of multiferroic domain walls in a non-multiferroic environment.

11:45 AM EL03.07.07
A Dynamical Magnetic Field Accompanying the Motion of Ferroelectric Domain Walls Dominik M. Juraschek1,2, Quintin N. Meier1, Morgan Trassin2, Susan E. Trolier-McKinstry3, Christian Degen2 and Nicola Spaldin2; 1Harvard University, United States; 2ETH Zürich, Switzerland; 3The Pennsylvania State University, United States

The domain walls that separate different orientations of electric polarization in ferroelectric materials have long been of interest because their motion governs the process of ferroelectric switching in an electric field [1]. Recently, a range of unexpected behaviors have been discovered at domain walls that do not occur in the bulk of the domains, such as ferrielectricity, magnetoelectricity, and electrical conductivity or even superconductivity, suggesting additional interest in domain walls as functional entities in their own right [2].

At the same time, the magnetization caused by the usual motion of electric charges has been revisited over the last years in the context of time-varying ferroelectric polarizations. This newly described dynamical multiferroicity, associates a magnetization $\mathbf{M}$ of the form $\mathbf{M} \sim \mathbf{P} \times \partial_t \mathbf{P}$ with a ferroelectric polarization $\mathbf{P}$. A range of existing coupled electric-magnetic phenomena fall within the dynamical multiferroicity framework, and new behaviors, including a phonon Zeeman effect, exotic quantum criticality and phonon orbital magnetism have been proposed [3-5].

Here we establish the link between these two concepts -- dynamical multiferroicity and ferroelectric domain wall functionality -- by showing theoretically that the motion of ferroelectric domain walls can be accompanied by a dynamical magnetic field. We extend the formalism of dynamical multiferroicity to the case of domain wall motion and present numerical results for the prototypical ferroelectric barium titanate (BaTiO3), based on a combination of density functional theory calculations and phenomenological modeling. We propose two experimental setups that possibly allow the detection of the dynamical magnetic field using nitrogen-vacancy center magnetometry, and we show that the magnitude of the effect lies well above the present detection limit.

1:30 PM *EL03.08.01
**Delta-E Effect Magnetic Field Sensors** Benjamin Spetzler, Sebastian Zabel, Phillip Durdaut, Anne Kittmann, Cai Müller, Julius Schmalz, Gerhard Schmidt, Martina Gerken, Jeffrey McCord, Reinhard Knöchel, Michael Höft, Eckhard Quandt and Franz Faupel; Kiel University, Germany

Magnetic field sensors based on the delta-E effect utilize the resonance shift of a high frequency mechanical resonator in a magnetic field, due to the change in Young’s modulus of a magnetostrictive material. Delta-E effect sensors are not affected by 1/f amplifier noise and allow broadband magnetic field measurements at low frequencies down to DC with very high dynamic range. Moreover, they are robust against microphony effects and mechanical noise. Fully integrable magnetic field sensors were achieved via replacement of magnetic by electric excitation.

Since our first publication of this sensor concept in 2011 [B. Gojdka et al., Appl. Phys. Lett. 99, 223502 (2011); Nature 480, 155 (2011)], much progress has been made in understanding the complex interplay of magnetic, mechanical and electrical properties. This holds for different designs of cantilever sensors, but also for surface acoustic wave devices. Here we present a comprehensive magneto-electromechanical model that considers the interaction of magnetic, mechanical and electrical properties and show current experimental results. We discuss the delta-E effect in general and its application in diverse types of electrically excited sensors, including the most common types such as bending or bulk resonators, but also shear resonators and surface acoustic wave sensors. The model provides detailed understanding of the general limits of the sensitivity, which arise from using the delta-E effect as the sensing principle. Realistic detection limits are predicted in combination with a noise equivalent model. The simulations are validated with experimental data using different sensor designs and magnetic layers. We also discuss simultaneous operation of delta-E sensors in the delta-E mode and the direct magnetoelectric mode, e.g. for localization of the sensor.

2:00 PM *EL03.08.02
**Magnetoelectric MEMS Doubly-Clamped Resonators for Vector Magnetic Field Sensing** Margo Staruch, Steve Bennett, Jeff Baldwin, Konrad Bussmann and Peter Finkel; U.S. Naval Research Laboratory, United States

Magnetoelectric (ME) resonators are of significant interest for next generation magnetic field sensors, as the direct coupling of magnetostrictive and piezoelectric phases enables high magnetic field sensitivity with exceptionally low operational power requirements. In this work, we present silicon based ME thin film resonators with clamped-clamped boundary conditions, that are fully suspended to achieve a string mode resonance. The heterostructure is comprised of a magnetoelastic FeCo or FeCoV layer, which is coupled through strain to an AlN piezoelectric layer with high $\varepsilon_{31,fpiezoelectric}$ coefficients. A negative or positive shift in the resonant frequency was observed for fields applied parallel and perpendicular to the length of the beam, respectively, consistent with the magnetostriction measurements and the expected magnetoelastic strain developing in the beams due clamped-clamped boundary conditions. A linear behavior in the field dependent resonant frequency when the field is perpendicular to the length is most likely due to a well-defined hard axis in this direction resulting from high shape and stress-induced anisotropy energies. Together, these results suggest that through modification of the magnetic anisotropy, the frequency shift and angular dependence can be tuned, producing highly directional structures for magnetic field sensors. Finally, the sensor performance is evaluated and benchmarked against conventional magnetic field sensors.

**Phase-Field Modeling of Multiferroic Heterostructures** Jia Mian Hu$^{1,2}$, Jianjun Wang$^1$, Tian-Nan Yang$^1$ and Long-Qing Chen$^1$; $^1$The Pennsylvania State University, United States; $^2$University of Wisconsin–Madison, United States

Phase-field method has been applied to modeling both direct and converse magnetoelectric effects in multiferroic heterostructures including the coupled evolution of magnetic and ferroelectric domain under electric fields. This
presentation will discuss our recent applications of the phase-field method to understanding the strain-mediated voltage control of magnetic skyrmions in nanoscale multiferroic heterostructures. It is shown that a nanoscale skyrmion in a magnetic disk can be repeatedly created and deleted by strain imparted from the underlying piezoelectric layer. We analyzed the strain-mediated skyrmion switching dynamics based on both phase-field simulations and analytical theories. We will discuss the possibility of performing high-throughput phase-field simulations of magnetic switching of multiferroic heterostructures. In particular, using a combination finite-element calculations and phase-field simulations, we studied the 3D geometrical effects of Ni islands on the strain relaxation and magnetic domain structures and switching in Ni/PMN-PT nanoscale heterostructures under an external electric field. Finally, we will also discuss potential applications of a dynamical phase-field model to understanding the ultrafast dynamics of ferroic domains in multiferroics.

4:00 PM *EL03.08.04
Strain-Mediated Magnetoelectric Effect in Self-Assembled Epitaxial Nanocomposites  
Xiao Tang, Min Gao, Jiefang Li and Dwight Viehland; Virginia Tech, United States

Spinel magnetostrictive cobalt ferrite (CoFe$_2$O$_4$, CFO) can vertically integrate nanopillars embedded in a matrix of perovskite piezoelectric bismuth ferrite (BiFeO$_3$, BFO), self-assembling the ‘1-3’-type nanocomposites [1, 2]. These two phases exhibit a considerable magnetoelectric (ME) effect due to the coupling via strain at the interfaces [3]. The ME effect of CFO with either rhombohedral or tetragonal BFO has been studied [4, 5]. To further increase the ME coefficient, such ‘1-3’-type nanocomposites were epitaxially deposited on piezoelectric single crystal substrates (i.e. Pb(Mg$_{1/3}$Nb$_{2/3}$)$_2$O$_3$-x%PbTiO$_3$, PMN-xPT). An applied electric field (E) of 3 kV/cm was able to induce a giant magnetization change (~93% for ΔM/M$_r$), equivalent to a converse ME coefficient of 1.3×10$^{-7}$ s/m [6]. Moreover, multiple distinguishable magnetization states were obtained, which were stable on removal of the E [6]. This multi-state ME nanocomposite thus has potential for neuromorphic-like computing and multilevel-cell memory devices.

From an energy-saving perspective, CuFe$_2$O$_4$ (CuFO) that shows low loss and high mechanical quality factor was used to replace the typical CFO in our ME nanocomposites [7]. The CuFO-BFO/PMN-PT nanocomposites exhibited notably slimmer M-H loops than CFO-BFO/PMN-PT ones, and a significantly larger ME coupling effect than pure CuFO/PMN-PT heterostructures [7, 8]. The findings demonstrate a trade-off between ME effects and energy losses that can be modified by material choices and nanocomposite topography.

Our investigations on CFO-BFO and CuFO-BFO shed light on the feasibility to approach non-volatility in nanocomposites, even though the individual phases/substrate had only volatile properties [8]. It simplifies materials selection for multi-state systems, averting difficulties with compositional non-uniformity and property repeatability in particular with regards to PMN-xPT crystal substrates.

Tsymbal$^6$, Siyoung Choi$^5$, Mark Rzchowski$^1$, Yong Baek Kim$^3$, Daniel C. Ralph$^2$ and Chang-Beom Eom$^1$; $^1$University of Wisconsin Madison, United States; $^2$Cornell University, United States; $^3$University of Toronto, Canada; $^4$Argonne National Laboratory, United States; $^5$POSTECH, Korea (the Republic of); $^6$University of Nebraska, United States; $^7$Northeastern University, United States

Spin-orbit coupling (SOC), the interaction between the electron spin and the orbital angular momentum, can unlock rich phenomena at interfaces, in particular interconverting spin and charge currents. Conventional heavy metals have
been extensively explored due to their strong SOC of conduction electrons. However, spin-orbit effects in classes of materials such as epitaxial 5d-electron transition metal complex oxides, which also host strong SOC, remain largely unreported. In addition to strong SOC, these complex oxides can also provide the additional tuning knob of epitaxy to control the electronic structure and the engineering of spin-to-charge conversion by crystalline symmetry. Here, we demonstrate room-temperature generation of spin-orbit torque on a ferromagnet with extremely high efficiency via the spin-Hall effect in epitaxial metastable perovskite SrIrO$_3$. We first predict a large intrinsic spin-Hall conductivity in orthorhombic bulk SrIrO$_3$ arising from the Berry curvature in the electronic band structure. By manipulating the intricate interplay between SOC and crystalline symmetry, we control the spin-Hall torque ratio by engineering the tilt of the corner-sharing oxygen octahedra in perovskite SrIrO$_3$ through epitaxial strain. This allows the presence of an anisotropic spin-Hall effect due to a characteristic structural anisotropy in SrIrO$_3$ with orthorhombic symmetry. Our experimental findings demonstrate the heteroepitaxial symmetry design approach to engineer spin-orbit effects. We therefore anticipate that these epitaxial 5d transition-metal oxide thin films can be an ideal building block for low-power spintronics.

SESSION EL03.09: Multiferroics IV
Session Chair: Jinxing Zhang

Hynes, Level 1, Room 101

8:30 AM *EL03.09.01
Theoretical Design of Low Dimensional Polar Materials Shuai Dong; Southeast University, China

Achieving novel physical properties, such as superconductivity, ferromagnetism, and ferroelectricity, in two-dimensional (2D) materials should enable numerous functionalities in nanoscale devices. In recent years, interests in high-performance 2D ferroelectric materials have also grown rapidly across multiple scientific and engineering disciplines. Here, two new 2D polar materials are predicted based on physical analysis and by using density functional theory calculations. The first one is a 2D type-II multiferroic magnetoelectric material (MXene Hf$_2$VC$_2$F$_2$) and and the second one is a noncollinear ferrielectricity materials (dioxydihalides $M$O$_2$X$_2$ family, where $M$= Mo and W; $X$= Cl and Br).

For multiferroic MXene Hf$_2$VC$_2$F$_2$ monolayer, its ferroelectricity originates directly from its magnetism [1]. The noncollinear 120° Y-type spin order generates a polarization perpendicular to the spin helical plane. Remarkably, the multiferroic transition is estimated to occur above room temperature.

For dioxydihalides $M$O$_2$X$_2$ monolayer, it is predicted to display noncollinear ferrielectricity, induced by competing ferroelectric and antiferroelectric soft modes [2]. More importantly, this intrinsic noncollinearity of dipoles generates unique physical properties, such as $Z_2 \times Z_2$ topological domains, atomic-scale dipole vortices/anti-vortices, and negative piezoelectricity.

Our studies will open the door to a new branch of 2D materials in the pursuit of intrinsically strong magnetoelectricity and noncollinear ferrielectricity.

Strong Magnetoelectric Coupling by Tailoring Interfacial Chemistry and Physics in Correlated Oxides Jinxing Zhang; Beijing Normal University, China

Magnetoelectric effects, magnetic-field-mediated polarization and/or electric-field-controllable magnetism, have attracted enormous attentions owing to the growing demands of new-generation information technologies. However, large direct and/or converse magnetoelectric coupling in thin-film materials is challenging (Nat. Mater. 18, 203
(2019)), which inhibits the practical application in future high-density and high-throughput electronic/spintronic devices. Here, via artificially design of correlated oxides at atomic scale, large magnetoelectric response by controlling the interfacial chemistry and physics has been achieved, accompanying the strong interplay of spin, charge, orbital and lattice degrees of freedom. This atomic tailoring of the quantum order parameters in oxide interfaces provides an alternative pathway towards realizing strong and controllable magnetoelectric effects with thin-film integrations.

Arseneau$^4$, Sarah Duniger$^4$, Bassam Hitti$^4$, Stefan Holenstein$^5$, Michael Fechner$^6$, Hubertus Luetkens$^7$, W Andrew MacFarlane$^1$, Ryan M. McFadden$^1$, Quintin N. Meier$^3$, Gerald D. Morris$^4$, Zaher Salman$^7$, Nicola Spaldin$^3$ and Robert F. Kiefl$^{1,2}$; $^1$University of British Columbia, Canada; $^2$Stewart Blusson Quantum Matter Institute, Canada; $^3$ETH Zürich, Switzerland; $^4$TRIUMF, Canada; $^5$Universität Zürich, Switzerland; $^6$Max Planck Institute for the Structure and Dynamics of Matter, Germany; $^7$Paul Scherrer Institut, Switzerland

The bulk properties of the prototypical linear magneto-electric (ME) antiferromagnet Cr$_2$O$_3$ have been extensively studied. Here, we report on a muon spin rotation (μSR) study using spin polarized muons to probe the local ME effect. This was motivated by the recent prediction that a point charge inside a linear ME creates a monopolar magnetic field distribution [1]. μSR is a unique and novel way to test such predictions since the muon may act both as a test charge and a sensitive probe of the induced local magnetic field.

Prerequisite for a search for such local or muon induced magnetoelectricity is a thorough understanding of the local electronic structure and magnetic interaction of the muon within the host material. We find that the muon, a light interstitial probe, occupies several distinct stopping sites in Cr$_2$O$_3$, and displays a rich dynamic behavior that we interpret in the context of local muon hopping, thermally activated site transitions and the formation of a charge-neutral muon-polaron complex.

Furthermore, when Cr$_2$O$_3$ is prepared in a single magnetic domain, a shift in the local magnetic field is observed in response to an applied electric field, with the sign of the shift depending both on the field direction and domain state. The origin of this apparent magneto-electric effect is discussed.

Concept of Artificial Magnetoelectric Materials via Geometrically Controlling Curvilinear Helimagnets
Oleksii Volkov$^1$, Ulrich Rößler$^2$, Jürgen Fassbender$^1$ and Denys Makarov$^1$; $^1$Helmholtz-Zentrum Dresden-Rossendorf e.V., Germany; $^2$Leibniz Institute for Solid State and Materials Research Dresden, Germany

Magnetoelectric materials are of the great interest due to their unique coupling of the magnetic and electrical order parameters. In these materials magnetic states can be manipulated via electric field and vice versa, offering exciting prospectsives for energy efficient memory, logic and sensor devices. However, a sizeable magnetoelectric coupling for technologically relevant applications is obtained for a limited set of single-phase bulk materials. Typically, this restriction can be removed by using two-phase materials, containing strain-coupled magnetoelectric heterostructures based on piezoelectric-magnetostrictive bilayers. Although the concept is promising, there is a clear limitation regarding the fact that strain-induced changes result in the modification of all intrinsic magnetic parameters, in particular anisotropic couplings. Ideally, it would be advantageous that electric field control of magnetic state is achieved without change of global intrinsic magnetic parameters.

We propose a novel type of artificial magnetoelectric material [1], which allows an electric field-induced deterministic switching between magnetic states without influencing intrinsic magnetic parameters. The proposal refers to geometrically curved helimagnets [2,3] embedded in a piezoelectric matrix or sandwiched between two piezoelectric layers. In contrast to typical strain-coupled magnetoelectric heterostructures, we exploit the geometric coupling between the piezoelectric matrix and curvilinear helimagnets. Namely, a small geometrical deformation causes a drastic modification of magnetic state of the helimagnet through a magnetic phase transition between a homogeneous magnetic state and a periodical one. Resulting transformations of the average magnetization from non-zero to zero value can be uniquely assigned to logical “1” and “0”. This paves the way towards the realization of novel magnetoelectric devices with geometrically tunable and deterministically switchable magnetic states.
We provide not only the general concept but also show analytical validation for a prototypical example of torsional nanospring helimagnets. Furthermore, we put forth a discussion on the feasibility of the experimental realization of the concept including the choice of materials and fabrication approaches.

Contact-Free Measurement of Light-Induced Currents at Domain Walls in Multiferroic BiFeO₃
Burak Guzelturk¹, Antonio Mei², Lei Zhang³, Liang Z. Tan⁴, Anisha Gurcharn Singh¹, Darrell G. Schlom³, Lane W. Martin¹ and Aaron Lindenberg¹; ¹Stanford University, United States; ²Cornell University, United States; ³University of California, Berkeley, United States; ⁴Lawrence Berkeley National Laboratory, United States

Multiferroic BiFeO₃ (BFO) films with periodic stripe domains produce anomalously large open circuit voltages under visible light illumination with exciting promise in solar energy applications. However, the microscopic origin of this photovoltaic effect has not been understood yet. Here, we make contact-free measurements of light-induced currents in stripe domain BFO films with 71° domain walls using terahertz emission spectroscopy. With this approach, we avoid undesired modifications to the ferroelectric polarization due to the physical electrodes, hence allowing us to disentangle different photovoltaic responses intrinsic to the BFO films. Analyzing the radiated terahertz fields, we find that the current flows perpendicular to the domain walls. This observation strongly indicates the predominant role of the domain walls in the separation of photogenerated charges and enables quantitative estimates of the currents and built-in fields associated with the domain walls. Furthermore, samples with increasing domain wall density show enhanced terahertz emission providing additional evidence for domain wall-mediated charge separation. On the other hand, we find that bulk photovoltaic effects only play a minor role in the photovoltaic response of the stripe domain BFO films with a contribution smaller than 5%. This work enables new fundamental understanding of photoferroelectric responses and defines novel opportunities for ferroelectric-based optoelectronics and efficient bias-free terahertz emitters.

10:45 AM EL03.09.06
Magnetoelectric Switching Dynamics in BiFeO₃
Eric K. Parsonnet¹, Yen-Lin Huang¹, Bhagwati Prasad¹, Chia-Ching Lin², Tanay Gosavi², Dmitri Nikonov², Ian Young², Vishal Ravi¹, Jonathan Reichanadter¹, Akshay Pattabi¹, Lei Zhang¹, Jeffrey Bokor¹, Lane W. Martin¹ and Ramamoorthy Ramesh¹,¹; ¹University of California, Berkeley, United States; ²Intel Corporation, United States

With room temperature coupling between magnetic and electric degrees of freedom, BiFeO₃ (BFO) has attracted much attention as a leading candidate for magnetoelectric applications. These include a variety of spintronic applications such as a magnetoelectric spin orbit (MESO) logic device where there exist stringent requirements on switching speed. Although there does not exist a wealth of true time-dynamics studies of ferroelectrics, a previous study on Pb(Nb₀.₀⁴Zr₀.₂₈Ti₀.₆₈)₀₃ found ultrafast ferroelectric switching at ~220ps. Time-resolved BFO measurements have, to date, not been reported. There has been extensive work studying the equilibrium or quasi-static magnetoelectric coupling in BFO, but dynamics and fundamental limitations on switching have yet to be explored. Via pulsed ferroelectric (PUND) I-V measurements we provide novel data probing the limits of magnetoelectric switching speeds and study the effect of film thickness on dynamics. We probe the effects of chemical composition on magnetoelectric switching by studying two model systems, namely BFO and La-doped BFO. The data reveal low-nanosecond switching, much faster than previously reported in (La)BFO. Importantly, by exploring lateral scaling of device size, we demonstrate a pathway to the switching speeds required for spintronic applications. By employing giant magneto-resistance (GMR) and longitudinal magneto-optical Kerr effect (MOKE) studies, we are working towards direct observation of voltage control of magnetization on such timescales.

High-Throughput Phase-Field Simulations of Anisotropy and Voltage-Controlled Magnetization in Multiferroic Heterostructures
Jianjun Wang, Tian-Nan Yang, Jacob Zorn and Long-Qing Chen; The Pennsylvania State University, United States
Understanding magnetic domain structures and their responses to electric fields in multiferroic heterostructures is critical to the design of electric-field-driven spintronic devices. In this presentation, I will show high-throughput finite-element and phase-field simulations of piezoelectric strain anisotropy and its relaxation, magnetic domain structures and their responses to applied voltages as function of the in-plane dimensions and thickness of the magnetic Ni nanoslands grown on a Pb(Mg₁/₃Nb₂/₃)O₃-PbTiO₃ (PMN-PT) membrane. The piezoelectric strain anisotropy is found to increase with the in-plane aspect ratio, but it can be significantly relaxed, as large as >80%, in nanoslands of thickness larger than >15 nm. Magnetic domain diagrams are established to identify the domain structures for Ni nanoslands of different lengths of in-plane major and minor axis, as well as thickness. When a voltage is applied to the multiferroic heterostructure, the single-domain magnetic domain can be switched by the piezoelectric strain, whereas the vortex domain is not switched. However, for a multiferroic heterostructure with a thick nanosland wherein most of the piezoelectric strain is relaxed, the single-domain magnetic domain shows a weak response to the voltage and cannot be switched by the voltage.

I will also show how to use a phase-field approach to identifying the magnetic anisotropy, which is similar to experimental rotating magneto-optical Kerr effect method and anisotropic magnetoresistance measurement. By performing high-throughput phase-field simulations to obtain thousands of $M-H$ loops, hundreds of remanent magnetization and coercive field versus external magnetic-field direction polar diagrams can be established, which are used to further construct directional angle and coercive field of the easy axis versus strain anisotropies diagrams. Thermodynamic energy analysis are performed to understand the simulation results, which revealed that the strain anisotropy impacts the directional angle and the coercive field of the easy axis by modifying the valley and peak positions, as well as the barrier of the free energy profile. This presentation will contribute to a computational understanding of strain anisotropy and voltage-controlled magnetic properties in strain-mediated multiferroic heterostructures.

**Template Free Fabrication and Characterization of Vertically Aligned BiFeO₃ Nanorods**

Swati Dhua and Somnath C. Roy; Indian Institute of Technology Madras, India

BiFeO₃ (Bismuth Ferrite or BFO) is a complex oxide that has been widely investigated for multiferroic properties as well as solar energy harvesting. In the recent times, various different nanostructures such as nanoparticles, thin films, nanowires and nanorods have been reported. In the case of 1D nanostructures such as nanorods and wires, vertical alignment from the underlying substrate holds special importance because of resulting ordered morphology and higher surface to volume ratio. Theoretically it is shown that the intrinsic stress generated due to the quantum confinement may result in shifting the ferroelectric and ferromagnetic transition temperature and also can induce giant magnetoelastic effect. Literature review suggests that, although different morphologies of 1D structures of BFO have been fabricated, highly aligned and vertically oriented nanorods have not been fabricated in template free conditions. Such structures hold special importance, particularly in solar energy and piezoelectric nanogenerator applications.

This work presents first successful fabrication of vertically aligned BiFeO₃ nanorods on FTO coated glass substrate using chemical bath technique followed by the deposition of Bismuth layer by DC sputtering. The significance lies in achieving such structures in template free condition that allows tailoring of the diameter and length and also the formation of heterostructures during the growth process. The crystallinity, microstructure, morphology and chemical composition have been confirmed by XRD, TEM, SEM and XPS. The multiferroic properties have been investigated by Piezoelectric Force Microscopy (PFM), P-E loop measurements and Vibrating sample magnetometry. The maximum obtained value of $d_{33}$ is 54 pm/V whereas a weak remnant magnetization of around 3 emu/cm³ is observed even at low temperature of 5 K. Finally, the optical and photocatalytic characteristics have been investigated by optical absorption and photo-electrochemical water splitting experiments. At 1 Sun illumination, a photocurrent density of around 55 μA/cm² (0.8 V vs Ag/AgCl) is observed which is found to be stable with time. The developments open up new avenues for BiFeO₃ where 1D nanostructures are desired.

**11:30 AM EL03.09.09**
**Control of Highly Anisotropic Ferroelastic Domains in LaCoO₃ Films and Ferromagnetism Using Strain**
Coupling of ferroelastic and ferromagnetic order parameters in materials offers a means to achieve novel multiferroic applications. We report the observation of one-dimensional ferroelastic domains in LaCoO$_3$ thin films that are intimately linked to magnetization. Unidirectional structural modulation is achieved by selective choice of substrate or growth plane, which produces broken in-plane rotational symmetry. Structural modification either through film growth or application of pressure is shown to affect the magnetism. Modification perturbs the crystal field energy, which leads to unexpected in-plane anisotropy of the orbital configuration and the magnetization.

Work funded by the U.S. Department of Energy, Basic Energy Sciences

SESSION EL03.10: Magnetoelectrics IV
Session Chair: Sarah Tolbert
Thursday Afternoon, December 5, 2019
Hynes, Level 1, Room 101

1:30 PM *EL03.10.01
Solution Processed Nanostructured Multiferroic Materials  Sarah Tolbert; University of California-Los Angeles, United States

In this talk, we examine multiple ways to control magnetism in solution processed nanostructured materials using an applied electrical bias. We begin with traditional multiferroic coupling, where electricity and magnetism are coupled through strain, and consider two systems. The first is a nanoporous magnetic or ferroelectric network produced using polymer templating of sol-gel oxides. The pores are then conformally filled with the opposite phase (either ferroelectric or magnetic) using atomic layer deposition to produce a three dimensional nanoscale composite. For these materials, we find the largest multiferroic response in materials with partly filled pores, emphasizing the role of residual porosity in controlling the elastic behavior and thus the multiferroic coupling of these composite materials. We next consider strain mediated switching in monolayer nanocrystal arrays. Here we show that nanocrystals can be controllably and reversibly switched from a superparamagnetic state, which has no time-averaged magnetic moment, to a ferromagnetic state using an applied bias. Finally, we explore a new type of multiferroic material, termed granular multiferroics, where exchange coupling between closely spaced magnetic nanocrystals can be modified by tuning the dielectric environment around the nanocrystals using either temperature or an applied electric field. In this work on nickel nanocrystals coupled to a soft ferroelectric, both temperature and field dependent changes in magnetism are observed in the vicinity of the ferroelectric Currie temperature, indicating that magnetism in nanocrystal arrays can indeed be tuned using dielectric changes.

2:00 PM *EL03.10.02
Voltage Control of Interfacial Magnetism in Multiferroic Based Spintronic Devices  Shishun Zhao, Qu Yang, Mengmeng Guan, Zhongqiang Hu, Ziyao Zhou and Ming Liu; Xi'an Jiaotong University, China

One of the central challenges in realizing magnetoelectric (ME) devices lies in finding a deterministic way to modulate magnetism in integrated circuits with a circuit-operation voltage. Ionic liquid (IL) gating on magnetic thin films with abundant electronic, chemical and magnetic interactions at the interface has become an emerging technology for controlling magnetism in a fast, compact and energy-efficient way. Compared with conventional strain effect dominated piezo/ferroelectric layer multiferroics, IL gating method has advantages like small gating voltage ($V_g<5$ V), easy-to-integration and compatibility with varied substrates such as Si, flexible substrates etc. In additional, unlike the oxide structures require a high temperature to overcome the oxidation energy barrier, the IL gating control process can be operated at room temperature, suitable for applications in room temperature environment. Here, we will summarize our recent progresses of IL gating control of magnetism in varied magnetic
heterostructures, as well as in different manners.[1-5] As IL gating process, proven to be a truly powerful and compatible gating method, enables giant ME tunability in different heterostructures and provides a tremendous potential in next generation of voltage-tunable spintronics/electronics.

Investigation of Diverse Magnetic Materials via Acoustically Driven Ferromagnetic Resonance Michael Page1, Piyush J. Shah2, Derek A. Bas1, Vladimir L. Safonov1, Maksym Popov3, Alexei Matyushov4, Anne Kittmann2, Viktor Schell5, Eckhard Quandt5, Ivan Lisenkov6, Gopalan Srinivasan7, Nian Sun4 and Michael E. McConney1; 1Air Force Research Laboratory, United States; 2Apex Microdevices, United States; 3Taras Shevchenko National University of Kyiv, Ukraine; 4Northeastern University, United States; 5Kiel University, Germany; 6Winchester Technologies, United States; 7Oakland University, United States

Recently, magnetoelastic coupling has been exploited to detect ferromagnetic resonance (FMR) using surface acoustic waves (SAWs)1, a technique known as ADFMR. GHz-frequency SAWs are produced and detected electrically using pairs of interdigital transducers (IDTs). A magnetic material is placed in the path of the SAWs, which can then interact with magnetic moments via magnetoelastic coupling. Absorption of the SAWs occurs at FMR, modulating the measured output. Landau-Lifshitz-Gilbert theory describes the interaction in terms of the external magnetic field with a characteristic four-lobe pattern, from which the magnetic anisotropy field, FMR resonance field, and magnetoelastic coupling coefficient can be inferred.

We study the effects of a variety of magnetic materials including Ni, FeCo, FeGaB, and FeCoSiB, to examine the dependence of ADFMR patterns on material parameters and geometries. We use a range of SAW frequencies from ~300 to 2000 MHz to explore spectral effects of the IDT design on transduction efficiency, and the frequency dependence of the resonance field. We also calculate the FMR linewidth and quality factor-figures of merit useful for determining the efficacy of future ADFMR devices.

2:45 PM EL03.10.04
Love Wave Magnetic Field Sensors Viktor Schell, Phillip Durdaut, Cai Müller, Anne Kittmann, Jeffrey McCord, Michael Höft and Eckhard Quandt; Kiel University, Germany

For the measurement of bio-magnetic signals there are high demands on the performance of the respectively utilized sensors. The requirements for these specific applications are a limit of detection (LOD) of significantly below 100 pT/Hz^{1/2}, a frequency bandwidth of 1 Hz to at least 20 Hz, better 100 Hz or above and a reduced size for achieving high spatial resolution or for the case of limited installation space. Further the device should be operable at room temperature and without magnetic shielding.

Promising candidates for fulfilling all these requirements are surface acoustic wave (SAW) magnetic field sensors, especially those using shear horizontal SAWs1. These so-called Love waves result from a piezoelectric substrate generating shear horizontal waves caged with a guiding layer with lower acoustic impedance confining the acoustic wave at the surface. As the sensitive element in these devices amorphous magnetostrictive thin films such as the alloy (Fe_{90}Co_{10})_{78}Si_{12}B_{10} seem to be particularly promising due to their high magnetostriction with simultaneously having a low magnetic anisotropy. Operating in a delay line configuration the magnetoelastically-induced change of shear modulus of the sensitive layer (ΔE/ΔG-effect) yields in a corresponding phase shift of the acoustic wave. While the application of amorphous magnetostrictive thin films in magnetoelectric cantilever composites was already studied extensively, the sensitivity and noise behavior in SAW sensors is not quite understood yet. However the quartz based Love wave devices with a working frequency of approximately 150 MHz show already very high sensitivities of up to 2000 °/mT and an equivalent LOD of 70 pT/Hz^{1/2} at 10 Hz and 30 pT/Hz^{1/2} at 100 Hz.

This work was funded by the German Research Foundation (DFG) through the Collaborative Research Centre CRC 1261 “Magnetoelectric Sensors – From Composite Materials to Biomagnetic Diagnostics”.

3:30 PM EL03.10.05
**picoTesla Magnetoelectric Sensors with Low-Curvature Nano-Plate Resonators** Alexei Matyushov¹, James Zhou², Zhenyun Qian¹, Mohsen Zaeimbashi¹, Menghui Li¹, Cheng Tu¹, Huaihao Chen¹, Yingxue Guo², Matteo Rinaldi¹ and Nian Sun¹; ¹Northeastern University, United States; ²The University of Chicago, United States

Prior studies have shown the effectiveness of piezoelectric/magnetostrictive MEMS magnetometers featuring a nano plate resonator and using the ΔE effect for highly sensitive detection of DC magnetic fields. By monitoring changes in resonance frequency from applied magnetic fields, a sensitivity of a few Hz/nT has been achieved in unshielded lab environments. With dimensions of ≤ 200 μm across, and < 1 μm thick, these devices offer the advantages of small scale, including portability and low power consumption, as well as high spatial resolution in sensor arrays. However, a thorough understanding of magnetic properties and other performance aspects in these magnetometers has not been developed. In this study we report on the strong effects of resonator plate curvature on sensor performance. It was found that the total resonance frequency shift dropped off exponentially with increasing curvature by as much as two orders of magnitude. By fabricating a ΔE effect magnetometer with low curvature in the nano plate resonator, we achieved maximum magnetic field sensitivity of 4.98 Hz/nT. This is as much as two orders of magnitude higher frequency sensitivity than in other recently reported magnetometers, that also utilize the delta E effect, but which are composed of a cantilever structure and generally operate at lower frequencies.

3:45 PM EL03.10.06
**Cantilever Beam Magnetometer for Electric Field Induced Magnetization Measurements** Harinath Aireddy¹,²; ¹Alliance University, India; ²IIT Kharagpur, India

Optical double cantilever beam magnetometer was designed, fabricated and demonstrated its ability to measure magnetostriction (in-plane and out-of-plane), magnetization and magnetocrystalline anisotropy of ferromagnetic thin films as a function of the magnetic field. Notably, for the first time, here we demonstrate the well-established and simple cantilever beam technique for electric field modification of magnetization of ferromagnetic/ferroelectric heterostructures by considering the induced strains in ferromagnetic thin films through the converse piezoelectric effect in piezoelectric films. Moreover, this set-up also allows measuring the electromechanical properties such as transversal piezoelectric strain $(d_{31})$ and stress $(e_{31})$ coefficients of piezoelectric thin films. This magnetometer is simple in construction, inexpensive to manufacture, easy to operate along with noise subtraction provision and having sensitivity nearly 8 nm in the determination of cantilever beam deflection.

4:00 PM EL03.10.07
**Magnetoelectric Composite Sensor Based on Magnetostrictive Multilayers for Magnetic Frequency Conversion** Lars Thormählen, Matic Jovičević Klug, Sebastian Toxværd, Michael Höft, Eckhard Quandt, Jeffrey McCord and Dirk Meyners; Faculty of Engineering CAU Kiel, Germany

Magnetoelectric composites have been studied intensively in the recent past because of their preeminent magnetoelectric coupling, opening the path to highly sensitive magnetic field sensors operating at room temperature [1]. Moreover, this sensor approach yields the advantage to optimize the constituting phases independently. In the context of magnetic field sensing, the role of the magnetostrictive component is to respond to an external magnetic field by generating mechanical stress onto the piezoelectric phase. At least as important, irregular magnetization changes resulting from hysteretic effects have to be avoided in order to prevent significant noise contribution to the sensor output [2]. The multilayer approach increases the parameter space, which can be used to jointly attune the
magnetoelastic response towards high sensitivity and improved control of magnetization reversal [3].

The presented work focuses on thin film magnetostrictive phase composites, composed of (Fe90Co10)78Si12B10 multilayers. These layers are based on the stacking order unit Ta 5 / Cu 3 / MnIr 8 / FeCoSiB x [thickness in nm] with varying the FeCoSiB layer thickness x. The total thickness of the FeCoSiB layers is adjusted to 1 µm, 2 µm and 4 µm. The piezoelectric component is a 2 µm thick AlN layer. The constituents are grown on a Si substrate, one each side, by RF and pulsed DC sputter deposition respectively. Using UV lithography combined with dry and wet etching, magnetoelastic cantilever structures are fabricated with typical lateral dimensions of 2.3 mm x 25 mm.

Applying a multistep thermal treatment, parallel and antiparallel alignment of magnetizations in adjacent ferromagnetic layers is achieved in order to formulate a stable domain configuration in the magnetic layers [4].

The presentation reports on recent advances achieved by utilizing magnetostrictors that are exchange biased layer by layer. Applying magnetic frequency conversion yields minimum detectable magnetic fields as low as 50 pT/ Hz1/2 at 10 Hz [5], demonstrating the significantly improved performance of such macroscopic magnetoelastic field sensors.

Funding of the project work by the German Research Foundation through the CRC 1261 Magnetoelectric Sensors: From Composite Materials to Biomagnetic Diagnostics is gratefully acknowledged.

4:15 PM EL03.10.08
TiNiCu Thin-Film Shape Memory Alloy Substrates for Tunable Resonant Frequency Magnetoelectric Sensors Sabrina M. Curtis1,2, Duygu Dengiz1, Hanna Lewitz1, Lars Thommählen1, Justin Jetter1, Dirk Meyners1 and Eckhard Quandt1; 1Kiel University, Germany; 2University of Maryland, United States

Magnetic field sensors based on magnetoelectric composites can offer powerful diagnosis of biomagnetic signals originating in the brain and torso. Thin-film magnetoelectric (ME) composites comprised of FeCoSiB as the magnetostrictive layer and AlN as the piezoelectric layer have demonstrated sensors with a high sensitivity and low limit of detection at biomagnetic relevant frequencies. A magnetoelectric sensor will have its highest sensitivity when operated at its mechanical resonant frequency. Some medical operations, such as deep brain stimulation, would require a ME sensor with a tunable resonant frequency to locate the stimulated area of the brain during operation. This is a major limitation as most state-of-the-art ME sensors are mechanically designed to operate at one single resonant frequency. In this work, we show introducing a functionalized shape memory alloy (SMA) layer to the ME composite can offer a tunable ME sensor through a reversible gradual change in the Young’s modulus (E) of SMA material.

Here, AlN / FeCoSiB thin-film magnetoelectric composites are fabricated and characterized on functional TiNiCu SMA substrates. Through an induced temperature pulse, it is possible to gradually change the Young’s modulus of the SMA, thereby changing the mechanical resonant frequency of the magnetoelectric sensor [1]. Our analytical calculations show that the resonant frequency can be altered by 6% for a magnetoelectric sensor (2 µm AlN / 2 µm FeCoSiB / 25 µm TiNiCu / 100 µm Si) through a temperature induced reversible solid-to-solid phase transformation of the SMA from martensite (E = 41 GPa) to austenite (E = 83 GPa). For a 2.5 mm x 20 mm cantilever the resonant frequency can be gradually increased from 318 Hz to 340 Hz purely through this transformation. The difference in frequency between martensite and austenite phases becomes enhanced by increasing TiNiCu film thickness, or by eliminating the Si substrate.

Currently, MEMS compatible fabrication routes are being explored to build a full magnetoelectric sensor onto a TiNiCu substrate for experimentally verification. Characterization results on the effect of heat treatment and TiNiCu surface roughness on the growth and material performance of the piezoelectric layer (AlN) through piezoforce microscopy (PFM), X-ray diffraction (XRD), double beam laser interferometry (DBLI) and transmission electron
microscopy (TEM) will be presented.

Funding from the DFG is greatly acknowledged for this work

400MHz MEMS Antenna Based on Magnetoelastic Coupling Effect Huaihao Chen1, Xianfeng Liang1, Neville Sun1, Hwaider Lin2, Yuan Gao2 and Nian Sun1;2; 1Northeastern University, United States; 2Winchester Technology, LLC, United States

400MHz frequency band is the most commonly used band for Medical Implant Communications Service (MICS). However, most of recent antenna researches for this application are based on electromagnetic wave resonance, which lead to a comparable size to the wavelength [1, 2]. To solve this problem, a new antenna design based on the magnetoelastic coupling is introduced by our group [3], which is a thin-film bulk acoustic resonance (FBAR) antenna for 2.5GHz applications, based on the AlN resonator and magnetoelastic coupling. Since acoustic wave has smaller wavelength than electromagnetic wave, the antenna size can be easily scaled down by more than 100 times. However, for most AlN resonator designs, impedance matching is a problem because of the high electric impedance. Hence, a parallel antenna array structure is applied to reduce the impedance and increase the antenna gain [4]. In this work, nano-plate resonance (NPR) antenna arrays for 400MHz application are designed, fabricated and tested. This antenna is based on the magnetoelastic coupling between AlN thin film and FeGaB/SiO2 multilayer. The antenna array structure is shown in Fig. 1 (a) with 8um width and array numbers of 1, 4, 8 and 16. This strip structure resonates at in-plane mode, and this resonance is limited in width direction by the strip. The measured S-parameters are shown in Fig. 1 (b), with operating frequency of 371MHz, and 10dB-bandwidth of 3.875MHz. A radiation peak of S21 is observed clearly at the resonant frequency, and a peak antenna gain of -54.82dBi is achieved. This radiation peak is from the vibration and domain rotation of magnetic film. The measured S11 and calculated Z11 are shown in Fig. 2. For fewer array numbers, the impedance is higher, and the related return loss is also higher, so the radiation peak is cover by the baseline. For this reason, array structure with more than 16 strips is necessary for impedance matching and high antenna gain.

Electric Field Control of Magnetism in Double Perovskites Coupled with Bismuth Ferrite Vishal Ravi1, Bhagwati Prasad1, Yen-Lin Huang1, Jose Flores2, Fengyuan Yang2 and Ramamoorthy Ramesh1; 1University of California, Berkeley, United States; 2The Ohio State University, United States

Multiferroic materials offer exciting pathways to manipulate both magnetic and electronic properties simultaneously, which, in the case of bismuth ferrite, stem from the intrinsic linking of ferroelectric and antiferromagnetic degrees of freedom. By leveraging this fundamental coupling, we can modify and indeed switch the ferromagnetism of materials such as Co0.9Fe0.1 that sit adjacent to ferroelectric bismuth ferrite thin films, using only electric fields [1]. Using an oxide ferromagnet instead, such as La0.5Sr0.5MnO3, could potentially confer on these devices an improved fatigue life, as oxidation may be less critical [2].

This electric field control of magnetism through magnetic coupling opens up a vast array of applications, particularly in logic, data, and spintronics, where we may manipulate magnetic memories such as magnetic tunnel
junctions with the application of an electric field, instead of through more energy-intensive spin-transfer torque currents [3].

Double perovskites, such as Sr₂FeMoO₆ (SFMO) and Sr₂CrReO₆ (SCRO), are promising candidates for ferromagnets that may provide such coupling with bismuth ferrite. As half-metallic oxides with Curie points higher than room temperature, both materials exhibit spin-polarised currents and potential perpendicular magnetic anisotropy, which are desirable for magnetic tunnel junctions and other magnetoresistance-based devices [4][5]. Additionally, as these films are oxides rather than pure metals, they could provide an interface that is more robust against oxidation, leading to longer fatigue life.

We show the enhancement of these double perovskites’ coercive fields atop bismuth ferrite when compared to their isolated phases, which could uncover clues as to the strength of any magnetic coupling at the interface. We also explore magnetoelastic coupling by studying the effects of electric fields on the magnetisation of these double perovskites on bismuth ferrite, through giant magnetoresistance and anisotropic magnetoresistance measurements, in addition to correlated magnetic force microscopy and piezoresponse force microscopy images. These materials could lead to the next generation of low-power data storage and logic device technology.

mechanisms, a necessary step in ultimately optimizing system performance and efficiency. However, these can be strongly influenced by often experimentally inaccessible sub-surface effects, including thickness dependencies, microstructural or compositional heterogeneities, interfaces, and depending on the device design even simple geometric influences. Therefore, we recently introduced Tomographic-AFM for direct volumetric materials property mapping. 3-D resolved domain configurations and thickness dependent switching are specifically reported for monolithic La doped BiFeO$_3$, and a BiFeO$_3$/CoFeO$_3$ vertically aligned nanocomposite. In each case, ferroelectric domain nucleation and growth are further investigated as a function of thickness. Pure BiFeO$_3$ clearly obeys Kay-Dunn thickness scaling and a multistep switching process, and such multistep 180° switching is also observed for the La doped and nanocomposite films despite the substantially different local microstructure and even composition. Reconfigurations of domain walls upon electric field annealing furthermore lend insight into domain and domain wall stabilities.

**9:00 AM *EL03.11.02*

**Functionally Active Domain Walls in Ferroics and Multiferroics** *Marty Gregg*; Queen's Univ Belfast, United Kingdom

It is now well established that ferroelectric and multiferroic domain walls often have unique functional properties that are completely different from the domains that they surround: they can be semiconducting, metallic and even superconducting when the rest of the material is insulating; they can display magnetic order, which is absent elsewhere, and can possess aligned electrical dipoles when the matrix surrounding them is non-polar. In effect, ferroelectric and multiferroic domain walls represent a new class of nanoscale functional material. Crucially, they can be controllably shunted from point to point, created, or made to disappear; hence, a completely new paradigm of transient nanoscale devices may be possible, based on a “now-you-see-it, now-you-don’t” dynamic deployment of domain walls.

This talk will explore progress towards the realisation of these kinds of dreams and in particular show how injection, movement and removal of domain walls have enabled active control of nanoscale thermal conduction (in LaAlO$_3$ and LiNbO$_3$), the appearance of local negative capacitance (in Cu-Cl boracites), the existence of 1D mobile p-n junctions (in ErMnO$_3$ and Cu-Cl boracites) and the design of a new form of domain-wall memristor (in LiNbO$_3$).

**Design and Fabrication of ZnO-Based SMR Magnetoelectric Antennas for High-Gain Applications** *Xianfeng Liang*¹, Huaihao Chen¹, Neville Sun¹, Yuan Gao², Hwaider Lin² and Nian Sun¹; ¹Northeastern University, United States; ²Winchester Technologies, LLC, United States

Magnetoelectric (ME) antennas based on the suspended ME circular disk consisting of FeGaB/AlN thin-film have been demonstrated recently [1]. However, the FBAR devices are very fragile and delicate due to the releasing structure, although the complicated packaging process [2] is able to solve this problem. From the device point of view, the solid mounted resonator (SMR) with Bragg reflector has attracted much attention as a promising technology for the film bulk acoustic wave resonator (FBAR) devices [3]. Typically, the SMR devices are formed of a piezoelectric film, such as ZnO that is sandwiched between top and bottom metal electrodes, on top of a Bragg reflector. A resonance is created when a radio frequency (RF) signal is applied across the FBAR device. There are a variety of products such as filters [4], duplexer [4], and voltage controlled oscillators (VCOs) [5] based on SMR designs have been developed in past years.

In this work, we designed, fabricated and tested ZnO-based SMR ME antennas that operate at GHz with high gain performance. As shown in Fig. 1, the Bragg reflector consisting of three pairs of SiO$_2$/W layers was sputter deposited in one run with RF reactive magnetron sputtering for SiO$_2$ and DC sputtering for W. The piezoelectric ZnO layer was sputter deposited by RF reactive sputtering with Zn target and high-purity Oxygen gas. The XRD curves and rocking curves for ZnO films under different temperature were measured and exhibited in Fig. 2. In order to grow high quality ZnO films, it is vital to have sufficient ion bombardment during deposition. Therefore, high temperature of 450 degrees Celsius is preferred here with rocking curve FWHM of 2.25 degrees. After optimizing the performance of Bragg reflector and piezoelectric ZnO films, we fabricated and tested the SMR ME antennas. A gain enhancement of 12 dB was achieved in this novel design for robust ME antennas. Therefore, it is very promising in practical applications.
One of the key challenges to state-of-the-art antennas lies in their size miniaturization. Conventional antennas rely on an EM wave resonance and require a size of more than one tenth of the EM wavelength $\lambda_0$. In this work, a new miniature magnetoelectric (ME) antenna is presented utilizing the multilayer Bragg reflector structure of a solidly mounted resonator (SMR) to enhance small scale antenna gain up to -16 dBi. The antenna radiates using a magnetoelectric heterostructure consisting of AlN and FeGaB with resonator diameters of 500 um and 1000 um. Different ME resonator shapes and sizes are designed, fabricated and compared along with varying anchor widths and lengths to provide better impedance matching. The acoustic resonance in the heterostructure films operates with an out-of-plane mode of vibration so that the thickness of each layer was optimized to produce a resonant frequency at 1.5 and 2.45 GHz to allow for seamless on-chip integration with WiFi, Bluetooth and GPS devices. The SMR structure replaces the freestanding membrane structure \cite{1} with a Bragg acoustic reflector for concentrated energy confinement. The Bragg reflector was fabricated with a quarter wavelength mode configuration to create maximum particle displacement in the AlN and FeGaB layers. Three periods of alternating low and high acoustic impedance films, using silicon dioxide and tungsten respectively, were deposited on top of a silicon substrate to provide greater acoustic resonance within the ME heterostructure. Antenna gain measurements were performed in an anechoic chamber using a GSG probe and a reference horn antenna linked to a vector network analyzer. The robust features of the SMR has more advantages compared to its FBAR freestanding membrane counterpart allowing for low cost monolithic integration, high operating frequency, better thermal dissipation and structural stability that will be vital for small-scale antennas and other wireless applications.

---

Composite multiferroics, composed of a magnetostrictive ferromagnet and a piezoelectric ferroelectric, have widely been targeted for beyond-CMOS logic due to their large coupling coefficients and high operating temperature\textsuperscript{1-3}. Magnetoelectric multiferroic systems potentially offer the lowest energy dissipation per bit operation in a scalable platform, yet significant materials challenges still exist in the field. For composite multiferroics, this requires finding
pathways to enhance piezomagnetic effects and coupling between layers, an effort that has seen relatively little work\(^4\). Here, we present a means to boost the magnetostriction of Fe\(_{1-x}\)Ga\(_x\) alloys and magnetoelectric coupling in a Fe\(_{1-x}\)Ga\(_x\)-(PMN-PT) composite multiferroic heterostructure through epitaxy.

In bulk, the magnetostriction coefficient of Fe\(_{1-x}\)Ga\(_x\) alloys versus Ga composition peaks near ~18% Ga occurring due to a phase change from the disordered A2 phase to an ordered BCC phase (D0\(_3\)), which reduces the magnetostriction coefficient\(^5\). A distinct advantage of thin film deposition is the potential to access metastable phases through epitaxy, allowing us to promote the chemically disordered BCC (A2) phase in our film at high (22%) Ga concentrations. We demonstrate that thin film epitaxy stabilizes a chemically disordered BCC Fe\(_{0.78}\)Ga\(_{0.22}\) alloy where the magnetostriction is enhanced by 200-300% relative to the bulk.

Transport-based magnetoelectric characterization shows 90 electrical switch of magnetic anisotropy and one of the largest converse magnetoelectric coefficients ever achieved at room temperature in a composite multiferroic\(^6\) and energy dissipation per operation scaling to 5.9 J cm\(^{-2}\), making our devices competitive with other state-of-the-art beyond CMOS technologies\(^6\). This hyperactive performance is achieved through epitaxial stabilization of a disordered, metastable phase of earth-abundant and rare-earth-free magnetostrictor, Fe\(_{0.78}\)Ga\(_{0.22}\). By epitaxially engineering our ferromagnetic layer to prevent the formation of deleterious intermetallic nanoregions, we provide a pathway to engineering new performance levels in rare-earth free magnetoelastic and magnetoelectric heterostructures.

**Room Temperature Lead Zirconium Palladium Titanate Multiferroic Nanoscale Films**

Karuna K. Mishra, Alvaro Instan, Mohan K. Bhattarai and Ram S. Katiyar; University of Puerto Rico, United States

Growth of single-phase magnetoelectric materials and their analysis of coupling mechanisms between ferroic order parameters (spin and polarization) is important from the point of view of next generation logic and memory devices. Herein, we report fabrication, dielectric, ferroelectric and magnetic measurement of a Pd-doped room-temperature magnetoelectric multiferroic Pb(Zr\(_{0.20}\)Ti\(_{0.80}\))\(_{0.70}\)Pd\(_{0.30}\)O\(_{3-\delta}\) (PZTPd) thin film. Highly oriented PZTPd thin films were deposited on (LaAlO\(_3\))\(_0.3\)((Sr\(_2\)AlTaO\(_6\))\(_0.7\)) substrates by following laser ablation processes in oxygen atmosphere using pulsed laser deposition technique. X-rays diffraction studies revealed that the film had tetragonal phase with c-axis orientation. The surface morphology studies using atomic force and scanning electron microscopic techniques suggest a smooth and homogeneous distribution of grains on the surface of the film with roughness \(\sim 1.8\) nm. Temperature dependent dielectric measurements were carried out in Pt/ PZTPd /LSMO metal-ferroelectric-metal capacitors that showed diffused behavior over a large range of temperatures at several frequencies, and exhibited a higher dielectric constant \(\sim 3000\) at 100 Hz at room temperature. The polarization hysteresis loops were obtained at room temperature, attributed to its ferroelectric behavior. Piezo force microscopy suggests a random polarization orientation in a grown film, whereas polarizations could be switched easily with a positive and negative electric bias. A well-saturated magnetization \(M-H\) loop with remanent magnetization of 1.6 emu/cm\(^3\) was observed at room temperature. The reason for magnetization in PZTPd thin film is found to be due to mixed oxidation states of Pd\(^{2+}\)/Pd\(^{4+}\) in the Pb(Zr\(_{0.20}\)Ti\(_{0.80}\))O\(_3\) matrix as complemented by x-rays photoelectron spectroscopic results. These findings suggest that our thin films are multiferroic (ferroelectric-ferromagnetic) at room temperature. The details will be presented in the meeting.

**Hydrogen-Driven Switching of Magnetic Anisotropy—Insights from First-Principles**

Konstantin Klyukin\(^1\), Geoffrey S. Beach\(^1\) and Bilge Yildiz\(^2\); \(^1\)Massachusetts Institute of Technology, United States; \(^2\)Department of Nuclear Science and Engineering, United States

Resistive and magnetic switching phenomena have recently attracted large interest for ultra-scaled non-volatile
memory and logic devices. The incorporation of hydrogen can significantly influence magnetic and electronic properties of functional materials allowing effective tuning magnetic anisotropy, magnetic moment and electroresistance. Despite extensive experimental investigations, very little is known about the phenomena on a molecular level and systematic investigations are needed to provide fundamental insights on the physical origin of phenomena. In this work, we consider a series of heterostructures (Co/Pd, MgO/Fe, etc) exhibiting perpendicular magnetic anisotropy (PMA) and employ density functional theory calculations (DFT) to determine the critical concentration of hydrogen needed for magnetic anisotropy switching. We show that anisotropy switching effect is mainly attributed to the electronic structure changes at the interface, while lattice expansion caused by hydrogen insertion plays a minor role. These results clarify the underlying mechanisms of magnetic anisotropy switching and help optimizing material combinations for hydrogen-based magneto-ionic devices.

11:15 AM EL03.11.08
First-Principles Prediction of Muon Stopping Sites in Magnetoelectric Cr$_2$O$_3$

Martin H. Dehn$^{1,2}$, Stefan Holenstein$^{3}$, J. Kane Shenton$^{4}$, Quintin N. Meier$^{4}$, Donald J. Arseneau$^{2}$, Sarah Dunsiger$^{3}$, Bassam Hitti$^{5}$, Hubertus Luetkens$^{3}$, W Andrew MacFarlane$^{2,1}$, Ryan M. McFadden$^{1}$, Gerald D. Morris$^{2}$, Zaher Salman$^{6}$, Nicola Spaldin$^{4}$, Michael Fechner$^{6,4}$ and Robert F. Kiefl$^{1,2}$; $^{1}$University of British Columbia, Canada; $^{2}$TRIUMF, Canada; $^{3}$Paul Scherrer Institut, Switzerland; $^{4}$ETH Zurich, Switzerland; $^{5}$Max Planck Institute for the Structure and Dynamics of Matter, Germany

Recent conceptual advances in our understanding of magnetoelectrics have led to renewed interest in materials such as Cr$_2$O$_3$. Muon spin rotation (µSR) is a promising technique for investigating recently predicted local magnetoelectric phenomena, acting as a probe of the local magnetic field at the muon stopping site(s). The ab initio prediction of muon stopping sites in materials is crucial to correctly interpreting µSR experiments. However, the quantum nature of the muon, together with its short lifetime (~2.2 µs), allow the muon to exhibit a rich range of dynamical phenomena that are challenging to capture using standard first-principles methods. Furthermore, the impact of the positively charged muon on the surrounding lattice can lead to significant changes to the muon behaviour and experienced local field.

Here we report on a µSR study of Cr$_2$O$_3$, focussing on the theoretical prediction of muon stopping sites and dynamics. We find that quantum corrections beyond the harmonic approximation are required to obtain accurate energy barriers between muon stopping sites. We also find strong evidence for a charge-neutral muon-polaron complex in Cr$_2$O$_3$, stabilised by a Jahn-Teller distortion. The latter finding has important implications for the charge state and behaviour of hydrogen defects in Cr$_2$O$_3$ and related materials.

**SYMPOSIUM EL04**

TUTORIAL: Introduction to Chalcogenide Discovery and Design
December 1 - December 1, 2019

* Invited Paper

TUTORIAL
Introduction to Chalcogenide Discovery and Design

Sunday Morning, December 1, 2019
Hynes, Level 2, Room 201
This tutorial will offer a brief introduction to theory and computations as well as to synthesis and characterization, in particular when applied to sulfides, selenides, tellurides, and multi-anionic systems. Oxide materials will also be included as it relates to chalcogenides more broadly. The focus of the symposium will be on understanding the distinctive nature of this group of materials in the context of materials discovery and design.

8:30 AM
**Density Functional Theory and Electronic Structure Calculations** Elif Ertekin, University of Illinois at Urbana-Champaign

We will discuss the application of first-principles density functional theory to the predicting bulk and defect properties of chalcogenides. This discussion will include a brief introduction to density functional theory, a practical discussion of how to carry out simulations, and an in-depth look at which properties can be reliably predicted, which properties require more scrutiny, and why. Our discussion will emphasize and distinguish between ground state and excited state, and equilibrium and non-equilibrium (i.e. response functions) properties of materials. Drawing from the fields of photovoltaics and thermoelectrics, several examples pertaining to chalcogenides will be described, including bulk properties and the prediction of phase stability, and simulations of point defects (formation energies, charge transition levels) and related properties such as dopability and carrier concentrations. This discussion is aimed at providing a basic understanding of the level of accuracy that is achievable or to be expected from density functional theory, as well as to serve as a guide to non-specialists what to look for when assessing results from electronic structure calculations.

9:15 AM
**Bulk Crystal Growth and Phase Diagrams for Metal Chalcogenides** Albert Davydov, National Institute of Standards and Technology

The tutorial focuses on single crystal growth of metal chalcogenide electronic materials, including layered van-der-Waals compounds, such as TMDC semiconductors and semimetals, Bi2(Se,Te)3 based topological materials, InSe and GeSe semiconductors, etc. The experimental methods will cover: a) vapor growth techniques including sublimation/crystallization and chemical vapor transport (CVT); and b) melt solidification that includes crystallization from near-stoichiometric compositions as well as from ‘self-flux’ or ‘foreign-element-flux’ solutions. Use of phase diagrams will be exemplified to guide choices for the crystal growth approaches: for example, why Bi2Se3, InSe, and GeSe can be grown both by CVT and Bridgman (i.e., direct melt solidification) methods, while TMDCs such as MoSe2 and WS2 can only be grown by CVT and not from the melt? The importance of often ignored ‘pressure variable’ when describing phase diagrams for metal-chalcogen systems will also be highlighted.

10:00 AM BREAK

10:30 AM
**High-Throughput Computations** Prashun Gorai, Colorado School of Mines and National Renewable Energy Laboratory

This talk will cover the recent developments in high-throughput (HT) computations that have led to a new paradigm in materials discovery and design. First, typical workflows for HT computations will be introduced followed by a discussion of software for HT workflows. Next, several examples of successful chalcogenide materials discovery, enabled by HT computations, will be discussed while also highlighting the challenges and downfalls of HT computations. Finally, materials databases that have resulted from these large-scale computational efforts will be briefly discussed. In closing, we will review the role of data informatics (e.g. data mining, machine learning) in the context of HT computations.

11:00 AM
**Thin Film Characterization** Akshay Singh, Massachusetts Institute of Technology
Now that we have prepared the bulk crystals and thin films of TMDs, how do we characterize the purity of the synthesized materials? Also, how do we qualify these materials for photonics and opto-electronic applications? In this part of the tutorial, we will discuss optical constants measurements using spectroscopic ellipsometry and fourier transform infrared spectroscopy (FTIR). We will discuss how performing cross-sectional transmission electron microscopy (TEM, to measure native oxides), atomic force microscopy (AFM, to measure roughness), and X-ray photoelectron spectroscopy (XPS, to measure composition profiles) techniques are important to uncover actual optical constants from thin films and bulk crystals. These techniques are also shown to help differentiate chalcogenides from undesirable oxide phases, and improve synthesis procedures.

11:30 AM
Tailor-Made Chalcogenide Colloids: Tuning Size, Composition and Structure of Nanomaterials Maksym Yarema, ETH Zürich

Colloidal chalcogenide nanocrystals are convenient building blocks of various solution-processed devices, such as displays, photovoltaics, thermoelectrics, and phase-change memory. Likewise, chalcogenide colloids are handy materials for the fundamental and use-inspired research, featuring size-dependent optical and electronic properties in addition to composition dependences and structure diversity. In this talk, we will summarize the state-of-the-art for the colloidal chalcogenide nanocrystals, outline challenges and future directions in the field. In particular, we will focus on multicomponent nanocrystals, for which composition-dependent effects are superimposed on size dependences. We will also discuss opportunities for chalcogenide colloids with metastable and amorphous structures.
lower temperatures due to facile diffusion and chemical reactions with and within the flux itself. The liquid fluxes are bona-fide solvents similar to conventional organic or aqueous solvents. These reactions can produce a wide range of materials, often metastable, from oxides to intermetallics, but typically the formation mechanisms are poorly understood. In this talk I will describe how we design, approach, perform, observe, understand, and engineer the formation of compounds from inorganic melts. I will focus on how novel chalcogenides can form using the fluxes but also design concepts such as the “dimensional reduction” and “panoramic synthesis”. For example, in systems such as K-Cu-S and K-Sn-S compounds that span metallic and insulating behavior can be isolated. Common structural motifs within these materials systems belie structural precursors in the melt that may be controlled by tuning reaction conditions and composition. Using complementary techniques of in-situ x-ray diffraction we can create time-dependent maps of reaction space and probe the mobile species present in melts. An important link in our chemistry is the concept of a ‘functional group,’ a fragment of a few atoms that behave predictably when combined with other functional groups or reagents. When well-defined building blocks are present and stable in the reaction, prospects for increased structural diversity and product control increase substantially. In such tunable and dynamic fluxes, synthesis can be directed towards new materials with an astonishing variety of properties ranging from nonlinear optics to energy conversion.

9:15 AM EL04.01.02
Cation Order and Band Gap Tuning across the Visible Spectrum Robert Makin III1, Krystal York1, Steven M. Durbin1, Nancy Senabulya2, Christina Jones2, Zihao Deng2, Logan Williams2, James Mathis2, Emmanouil Kioupakis2, Roy Clarke2 and Roger Reeves3; 1Western Michigan University, United States; 2University of Michigan, United States; 3University of Canterbury, New Zealand

Interest in alternative semiconductors to traditional indium- and gallium-containing compounds has prompted a large number of potential materials to be investigated recently, especially where earth-abundant, sustainably-sourced elements are available constituents. In the case of ternary heterovalent compounds such as those comprised of cations from columns II (e.g. Zn, Mg) and IV (e.g. Ge, Sn) along with an anion from column V (e.g. N, P), an interesting opportunity for band gap tuning arises from the ability to introduce a selective degree of ordering among the cation atoms [1,2]. Although somewhat analogous to what has been previously demonstrated in the case of the compound GaInP2, we see the opposite trend in these heterovalent materials: the band gap energy decreases with decreasing cation ordering. Using MgSnN2 and ZnSnN2 as a case study, we demonstrate an unprecedented degree of band gap tuning (a range of ~0.9 eV for ZnSnN2 and ~1.6 eV for MgSnN2) in each material as the order parameter is varied from its minimum value of zero to a maximum value of unity. Consequently, the two materials can be used to tune over the entire visible spectrum, from approximately 1.12 eV to 3.43 eV – without alloying. Instead, the order parameter is tuned by adjustment of process parameters describing the plasma-assisted molecular beam epitaxy growth technique, with better than 1% reproducibility. The order parameter is extracted from any of the following techniques: in-situ reflection high-energy electron diffraction (RHEED), x-ray diffraction, or Raman spectroscopy. We find that the value obtained from each technique agrees to within two decimal places. We demonstrate that the band gap variation with cation ordering can be understood in terms of an Ising model, which provides a numerical foundation for understanding variable ordering in terms of two endpoint states (fully ordered, and fully randomized). The major factor influencing the semiconductor band gap is in fact the motif distribution which correlates to the order parameter. The trend is replicated by hybrid density functional theory calculations implemented using the Vienna Ab initio Simulation Package (VASP); disordered structures were modeled using 2x2x2 special quasi-random supercells (SQS). We further demonstrate the viability of this approach by applying the model to published data for ZnGeN2, ZnSnP2, CuGaS2 and CuInS2, showing a reliable method for predicting the expected band gap energy as a continuous and quantitative function of cation ordering, and explaining the wide variation reported in the literature [3].

9:30 AM BREAK

10:00 AM *EL04.01.03
Coupling of Structure and Magnetism in Some $AB_4Q_8$ Lacunar Spinel Compounds
Emily Schueller, Julia Zuo, Stephen Wilson and Ram Seshadri; University of California, Santa Barbara, United States

The lacunar spinels $AB_4Q_8$ are compounds whose properties are dominated by tetrahedral clusters of $B$ atoms and are exemplified by compounds such as GaV$_4$Se$_8$. This compound is known to undergo a polar distortion to a ground state structure in the $R3m$ space group, and orders ferromagnetically with a relatively small magnetic moment. We develop an understanding into the relationship between crystal structure and magnetic order in this material, and the influence of electron correlations in establishing the observed ground state using first-principles density functional theory (DFT) electronic structure calculations. Because electrons are delocalized within V$_4$ clusters but are localized between them, the usual approaches to simulate electron correlations — such as the use of the Hubbard $U$ in DFT + $U$ schemes — do not adequately recreate the experimental ground state. Additionally, we find that magnetism and crystal structure are strongly coupled in this material, and only certain arrangements of magnetic moment within a V$_4$ cluster can stabilize the observed structural distortion. Once distorted, these compounds are capable of exhibiting skyrmionic ground states, and these are described in GaV$_4$Se$_8$ and some related compounds.

10:30 AM EL04.01.04
Designer Metal-Insulator Transition Compounds from Bayesian Optimization
Yiqun Wang, Akshay Iyer, Wei Chen and James Rondinelli; Northwestern University, United States

The chalcogenide lacunar spinel structures with composition AM$_4Q_8$ can host novel electronic responses, including metal-insulator transitions (MITs) for resistive random-access memory platforms and skyrmionic spin textures for novel spin-based logic. Indeed, many of the known compounds within the family are narrow-gap semiconductors that undergo structural, electrical, and magnetic phase transitions with external stimuli, e.g. pressure, electric pulse. Based on the current understanding of how local structure affects these functional responses, one may ask the naïve question of how to rationally select the chemistries for quaternary spinels to achieve improved performance and to what extent Vegard’s principle holds in ordered compositional variants. Here we utilize Bayesian optimization with Gaussian processes (BOGP) to identify quaternary lacunar spinels superior to their ternary counterparts. Our model successfully discovers most of the compounds on the Pareto front by exploring only less than 20% of the entire design space, leading to accelerated materials discovery via BOGP approach. We then perform density functional theory simulations to both validate the MITs in the predicated compounds and assess synthesizability, but also to expand our materials physics understanding. Our model presents an effective way for accelerated materials design and discovery in chemical composition space without using extra features (e.g. bond length, electronegativity). This method may be readily applied to other challenges in materials sciences and chemistry, especially where existing data is limited, and new data acquisition is costly.

10:45 AM EL04.01.05
Computational Prediction and Experimental Discovery of Semiconducting High-Entropy Chalcogenide Alloys
Zihao Deng, Alan Olvera, Joseph Casamento, Juan Lopez, Logan Williams, Ruiming Lu, Guangsha Shi, Pierre F. P. Poudeu and Emmanouil Kioupakis; University of Michigan, United States

High-entropy materials are formed by mixing typically five or more principal components into a single crystal structure, and show improved thermodynamic stability due to the large configurational disorder. This simple design principle has led to the discovery of a series of novel crystalline materials stabilized by the configurational entropy, from high-entropy metallic alloys, to entropy-stabilized oxides, carbides, and borides. While significant progress has been made to synthesize entropy-stabilized metals and ceramics for structural applications, little attention has been paid to the discovery of new semiconducting materials using the design principle of entropy stabilization.

Here, we present a new class of entropy-stabilized semiconducting alloys based on the IV-VI binary chalcogenides, namely Ge$_x$Sn$_{1-x}$Pb$_{1-z-y}$Sb$_z$Se$_{1-t}$Te$_{1-t}$ high-entropy chalcogenides (HECs). By utilizing high-throughput first-principles calculations, we investigate the thermodynamic stability of HECs over their entire composition space, and show that more than 50% of the investigated compositions are stable with respect to phase segregation to the competing binary ingredients at the experimental synthesis temperature. We further studied the enthalpic effect of the individual elements via machine learning with Gaussian Kernel-Ridge Regression on the high-throughput data. We show that
Sn and Se lower the enthalpy of mixing, while S is detrimental to the phase stability of HECs. We validate our theory prediction by synthesizing the equimolar GeSnPbSSeTe HEC using solid-state synthesis techniques. We find that the HEC crystalizes in a single-phase rocksalt structure upon fast quenching in liquid nitrogen, and shows a reversible phase transition in both DSC and temperature-dependent XRD, driven by the configurational entropy. In terms of their functional properties, equimolar HEC shows promising ambipolar dopability with Bi donors and Na acceptors, which opens up a wide range of possibilities for semiconducting electronic and energy applications. Our work demonstrates the potential of entropy stabilization in the discovery of novel multicomponent semiconductor alloys.

Designing Chalcogenide Interfaces as a Pathway to Topological Devices  Stephen D. Albright1,1, Ke Zou2, Frederick J. Walker1,1 and Charles H. Ahn1,1,1; 1Yale University, United States; 2University of British Columbia, Canada

Engineering interfaces of topological materials with other classes of functional materials, such as oxides, ferromagnets, or superconductors, serves as the basis for designing novel electronic devices based on topological materials. Topological crystalline insulators (TCIs), such as SnTe, are a particularly promising class of materials, possessing the same properties as conventional topological insulators and controllable by electric fields when integrated with oxide field effect devices. This work presents growth and characterization of SnTe films thin enough for incorporation with other functional materials. X-ray diffraction and atomic force microscopy confirm we achieve single-domain and continuous SnTe film growth on SrTiO3 substrates by integrating molecular beam epitaxy with net SnTe sublimation at raised substrate temperatures. By analyzing the hole carrier density, extracted from Hall measurements over a range of film thicknesses, we observe two-dimensional carriers confined to the SnTe/SrTiO3 interface. Magnetoconductance measurements confirm the observation of two-dimensional transport and furthermore reveal that conduction is consistent with topological states. The growth of ultrathin TCI films on an oxide substrate presented here provides a foundation for designing additional TCI interfaces and engineering novel topological devices.

Synthesis of Compounds with Targeted Structures—Probing the Energy Landscape with Designed Precursors  David Johnson1 and Sven Rudin2; 1Univ of Oregon, United States; 2Los Alamos National Laboratory, United States

Unraveling structure-property relationships is often limited by the inability to test proposed relationship by synthesizing either isomaterials compounds or homologous series of compounds. Major limitations to discovering these "missing" compounds with targeted structures include the lack of synthetic routes to compounds that are metastable and the challenge of predicting the energy landscape around local free energy minima to assess potential metastability. Traditional solid-state reactions are typically diffusion limited, producing thermodynamic products as a result of high reaction temperatures and long reaction times. Fluid phase approaches are nucleation limited with high diffusion rates enabling much of the energy landscape to be explored, but limited means to control what crystallizes. We will discuss a third approach, based on controlling the composition of an amorphous intermediate on the nanoscale. Nucleation is typically the rate-limiting step, but slow diffusion rates limit the extent that the energy landscape is explored. Hence the nanoarchitecture of the precursor is preserved, enabling many new compounds to be synthesized that are intergrowths of two targeted constituents. The periodic structure of the precursor enables a variety of analytical approaches to be used to determine the reaction pathway, total and local compositions, and the structure of interlayer stabilized structures. In parallel, we have developed a theoretical approach to probe the energy landscape around proposed target compounds. We create islands of different known structures of a particular stoichiometry between slabs of the other constituent structure and allow the system to relax. One of three limiting situations typically occurs. The interlayer atoms may react with the known structure, rearrange into a disordered "island of disaster" or they can maintain the initial structure with surface and edge distortions. These last cases, where the structures are preserved, become potential synthetic targets. This approach lets islands with structures or compositions not known as bulk compounds to be tested for stability. Several examples will be presented showing that predicted structures could be synthetically prepared.

Control of Structural Polymorphism in MnTe  Yanbing Han1,2, Sebastian Siol1, Aaron Holder2, Bethany
Matthews⁴, Matthew Young¹, Janet Tate⁴, Stephan Lany¹, Qun Zhang² and Andriy Zakutayev¹; ¹National Renewable Energy Laboratory, United States; ²Fudan University, China; ³University of Colorado Boulder, United States; ⁴Oregon State University, United States

Chalcogenide semiconductors constitute an important class of electronic materials with a broad range of crystal structures and a plethora of useful properties. Independent control of chalcogenide composition and structure holds a promise to design these properties for practical applications. Recently, we demonstrated synthesis of low-density polymorphs of chalcogenide semiconductors by heterostructural alloying in the MnTe₁₋ₓSeₓ materials system [1]. The resulting “negative pressure” MnTe₀.₅Se₀.₅ alloy has noncentrosymmetric wurtzite structure and piezoelectric response that is not present in either of the MnSe or MnTe parent compounds.

This presentation will focus on two additional methods to synthesize metastable wurtzite structure of manganese telluride (MnTe), as a prototypical chalcogenide material with known polymorphism. The first approach is alloying MnTe with a small amount (10-20 %) of ZnTe, which drives the structural phase transition similar to that in yttria-stabilized zirconia (YSZ) [2,3]. The second approach is templated growth on MnTe on 5 nm thin ZnTe seed layers deposited on amorphous glass substrates.[3] Both methods lead to metastable wurtzite polymorph of MnTe with very different properties compared to the ground state nickeline structure, including 1 eV wider band gap and 1000–10 000 times lower electrical conductivity.

Overall, these results demonstrate new methods to synthesize metastable polymorphs of chalcogenide semiconductors, broadening the range of materials design methods for this class of compounds.

[4] Y. Han et al. under review
For the last 30 years, researchers in Southampton have been developing a novel family of chalcogenide glasses, driven initially by infrared optical applications. These materials, which include gallium and lanthanum sulphides and selenides, offer improved thermal and mechanical properties over commercially available chalcogenides. Today, the application space has shifted considerably and these same materials are increasingly being explored for electronic applications.

In this talk, we describe our work in this field, giving an overview of a glass fabrication and characterization before focusing on three specific devices under development; photonic crystals, flexible thermoelectric generators and electrochemical cells leading to new research in chalcogenide based solid-state batteries.

Three-dimensional complete photonic bandgap materials or photonic crystals block light propagation in all directions. The rod-connected diamond structure exhibits the largest photonic bandgap known to date and supports a complete bandgap for the lowest refractive index contrast ratio down to $\sim 1.9$. We have confirmed this threshold by measuring a complete photonic bandgap in the infrared region in Sn–S–O ($n \sim 1.9$) and Ge–Sb–S–O ($n \sim 2$) inverse rod-connected diamond structures. The structures were fabricated using a low-temperature chemical vapor deposition process via a single-inversion technique.

Flexible thermoelectric generators (TEGs) can provide uninterrupted, green energy from body-heat, overcoming bulky battery configurations that limit the wearable-technologies market today. High-throughput production of flexible TEGs is currently dominated by printing techniques, limiting material choices and performance. Here we report on the properties of roll to roll sputtered Bi2Te3 films are reported and we demonstrate the ability to tune the power factor by lowering run times, lending itself to a high-speed low-cost process. To further illustrate our route to high speed printing, we fabricate a thermoelectric device using Virtual Cathode Deposition, a novel high deposition rate PVD tool, for the first time. This Bi2Te3/Bi0.5Sb1.5Te3 TEG exhibits $S = 250 \ \mu V/K$ per pair and $P = 0.2 \ \text{nW}$ per pair for a $20 \ ^\circ C$ temperature difference.

Finally we have recently fabricated electrochemical metallization cells using a GaLaSO solid electrolyte focussing on endurance testing. Using ITO and silver electrodes, up to 4000 cycles were measured, (limited by the measurement equipment) with some deterioration in the on/off ratio seen after 1000 cycles and we are currently optimizing performance through doping with Se.

**Dimensional Control of Light-Matter Interaction in Perovskite Chalcogenides**  
Jayakanth Ravichandran;  
University of Southern California, United States

Perovskite Chalcogenides are a new class of semiconductors, which have large chemical and structural tunability that translates to tunable band gap in the visible to infrared part of the electromagnetic spectrum. Besides this band gap tunability, they offer a unique opportunity to realize large density of states semiconductors with high carrier mobility. In this talk, I will discuss some of the experimental advances made both in my research group and in the research community on the theory, synthesis of these materials and understanding their optoelectronic properties.

Perovskite structure is composed of an octahedrally coordinated transition metal or main group element with anions such as oxygen, chalcogen or halogens. The octahedra is typically connected in the corners and the voids are filled by alkali, alkaline or rare earth elements. The valence and the size of the cations and anions can lead to different connectivity of these octahedra, which offers a knob to control both the chemical composition and the dimensionality of these materials. Moreover, the large number of elements in the periodic table can be accommodated in these extended perovskite and related structures, which allows us finer knobs to control the physical and chemical properties, in our case, we tailor light-matter interaction precisely over a broad energy range spanning the visible to infrared spectrum. We leverage this effect in early transition metal based perovskite chalcogenides and related phases to achieve properties such as highly anisotropic absorption and refraction ($\text{BaTiS}_3$, $\text{Sr}_{1+x}\text{TiS}_3$), unconventional band gap evolution ($\text{BaZrS}_3$ and $\text{Ba}_{n-1}\text{Zr}_n\text{S}_{3n+1}$ for $n \geq 1$). Finally, I will provide a general outlook for future studies on these exciting new class of materials.

In-Memory Computing—Accelerating AI Applications Evangelos S. Eleftheriou; IBM Research GmbH, Switzerland

In today’s computing systems based on the conventional von Neumann architecture, there are distinct memory and processing units. Performing computations results in a significant amount of data being moved back and forth between the physically separated memory and processing units. This costs time and energy and constitutes an inherent performance bottleneck. It is becoming increasingly clear that for AI application areas, we need to transition to computing architectures in which memory and logic coexist in some form. Brain-inspired neuromorphic computing and the fascinating new area of in-memory computing or computational memory are two key non-von Neumann approaches being researched. A critical requirement in these novel computing paradigms is a very-high-density, low-power, variable-state, programmable and non-volatile nanoscale memory device. There are many examples of such nanoscale memory devices in which the information is stored either as charge or as resistance. However, one particular example are phase-change-memory (PCM) devices, which are very well suited to address this need, owing to their multi-level storage capability and potential scalability.

In in-memory computing, the physics of the nanoscale memory devices, as well as the organization of such devices in cross-bar arrays, are exploited to perform certain computational tasks within the memory unit. For instance, crossbar arrays of PCM or other memristive devices can be used to store a matrix and perform analog matrix-vector multiplications at constant O(1) time complexity without intermediate movements of data. I will present how computational memories accelerate AI applications and will show small- and large-scale experimental demonstrations that perform high-level computational primitives, such as ultra-low-power inference engines, optimization solvers including compressed sensing and sparse coding, linear solvers and temporal correlation detection [1-3]. Moreover, the efficacy of this approach to efficiently address not only inferencing but also training of deep neural networks is discussed.

However, enhancing the performance of the devices is crucial for increasing the range of targeted applications and building the next-generation of computational memory-based systems. For example, PCM devices exhibit a limited dynamic range and the conductance response is highly nonlinear and stochastic. Moreover, additional technology-specific device behavior such as the conductance response asymmetry and temporal evolution of conductance values pose significant challenges for PCM. One approach to address some of these challenges is advances in synaptic-cell architectures. We will show how by using multiple PCM devices as a single synaptic unit we can improve the conductance change granularity, as well as the effects of nonlinearity, asymmetry, stochasticity and drift of PCM cells[4]. A second approach is the so-called projected PCM concept that aims to decouple the device read out from the electrical properties of the amorphous phase, thus significantly reducing the drift, noise and temperature-sensitivity [5-6]. We will also elucidate implementation and functionality of this class of devices.

The results show that this co-existence of computation and storage at the nanometer scale could be the enabler for new, ultra-dense, low-power, and massively parallel computing systems. Thus, by augmenting conventional computing systems, in-memory computing could help achieve orders of magnitude improvement in performance and efficiency.

4:00 PM EL04.03.02
Switching Effects in Ge-Te/Sb-Te Superlattices in the Presence of External Magnetic Fields Kirill V.
Interfacial phase-change memory (iPCM) based on chalcogenide superlattices have lower switching energy requirements than conventional phase-change memory [1]. The reason for this is believed to be associated with the minimization of thermal losses in the superlattice during the switching process [1-4]. Recently, it was reported that iPCM devices based upon Ge-Te/Sb-Te superlattices exhibit differences from GeSbTe-alloy phase-change memory devices, such as resistance dynamics at elevated temperatures [5]. Furthermore, bipolar switching [6] and the dependence of the switching properties of iPCM devices on the presence of an external magnetic field was found [7]. The latter suggests that the presence of an external magnetic field can affect the structure of Ge-Te/Sb-Te superlattices. In the current work, we used pre-magnetized TbFeCo bottom contacts in iPCM devices in order to explore the effects of magnetic fields applied to Ge-Te/Sb-Te superlattice films during their growth with regards to the switching properties of the fabricated iPCM devices.

The iPCM devices fabrication process have been reported in ref. [8, 9]. The bottom contact was formed by a 50 nm TbFeCo layer grown at room temperature. The contact was magnetized by applying an external magnetic field (1.5 T) after deposition at room temperature. Lower temperatures were used (150°C) for the superlattice growth in order to prevent demagnetization of the TbFeCo contacts. Thus, the Ge-Te/Sb-Te superlattices were grown in the presence of the external magnetic field induced by the bottom contact and this condition was maintained during device characterization: R-V, R-I, and I-V curves were obtained.

Under normal conditions, Ge-Te/Sb-Te superlattice structures used as an active (programmable) medium in iPCM devices do not contain elements sensitive to magnetic fields. However, according to recent reports [7], an iPCM device in the presence of an external magnetic field during the switching process at elevated temperatures, could lead to the localization of spin-polarized electrons, which would in turn result in a significant change in the resistance of the device. Therefore, a superlattice film grown in the presence of a magnetic field could exhibit enhanced magnetoresistance effects, especially when the switching process is performed at elevated temperature. In this work, it is shown that iPCM devices grown in the presence of a magnetic field have switching characteristics different from conventional iPCM devices. For example, bipolar switching was achieved in DC mode, similar to previously reported results [6]. But in the short pulse switching regime, it was found that the RESET process shows a lower switching voltage than it is required for the SET process, which is opposite to the typical iPCM switching behavior.

In conclusion, we achieved enhancement of magnetoresistance effects in Ge-Te/Sb-Te superlattices by use of a novel iPCM device structure with pre-magnetized bottom contacts.

4:15 PM EL04.03.03
Low Temperature Characterization of Resistance Drift in Amorphous Ge:Sb:Te3 Raihan Sayeed Khan, Helena Silva and Ali Gokirmak; University of Connecticut, United States

Phase change memory (PCM) is an emerging high speed, high density, scalable non-volatile memory that can be switched electrically between amorphous (high resistivity) and crystalline (low resistivity) phases of chalcogenides materials such as Ge:Sb:Te3 (GST) [1]. The resistance of GST drifts spontaneously after amorphization following a power law [2]. This behavior limits the utilization of intermediate states for multi-bit storage due to potential overlap of different resistance levels. Multiple processes may be contributing to resistance drift, including structural relaxation, crystallization and charge trapping. It is possible to get a better understanding of the relative contributions of these various phenomena by performing measurements at cryogenic temperatures.

In this work, we have electrically characterized resistance drift of melt-quenched amorphous Ge:Sb:Te3 (GST) line cells [3] in the 125K – 300 K temperature window with and without optical illumination using high resolution I-V
sweeps. Each device is amorphized using a 500 ns pulse and drift is monitored at the same temperature up to 10^4 seconds. We have found the drift coefficients to be approximately 0.1 in dark, with slightly decreasing trend with decreasing temperature. The experiments under light show a significant decrease in cell resistance and a distinctly different drift behavior from dark. Periodic switching of light shows upward resistance drift in dark and recovery under light with long time constants (> 10^2 s at 150K). The presence of resistance drift at cryogenic temperatures with similar drift coefficients as room temperature, as well as different behaviors with and without light, suggest that charge trapping is the dominant mechanism that contributes to resistance drift in amorphous GST.

Solution Processed Copper Sulfide Based Resistive Switching Devices Prashant Kumar1, Murali Gedda1, Kalaivanan Loganathan1, Dipti Naphade1, Abhinav Sharma1, Hendrik Faber1, Emre Yengel1, Leonidas Tsetseris2, and Thomas Anthopoulos1,1 King Abdullah University of Science and Technology (KAUST), Saudi Arabia; 2National Technical University of Athens, Zografou Campus, Greece

Because of its fast operation speed, resistive random-access memory (RRAM) is widely anticipated to dominate future’s non-volatile memory (NVM) device technologies. However, the often high operating voltage window, the complex and hence expensive fabrication process are some of the major technological and economic obstacles for its commercialization. Here, we describe the development of solution processable copper sulfide materials and their application in high performance two-terminal NVM devices. We show that carefully controlled composition of copper sulfides (i.e. Cu2S, Cu2-xS and CuS) yields fast responsive memory device with remarkably low operating voltage window and highly reprogrammable operating characteristics. In particular, we demonstrate NVM devices with highly reprogrammable memory window of <300 mV, write/erase channel current ratio of >10^3, excellent data retention and superior memory endurance in excess of 1500 write/erase cycles. Finally, we demonstrate successful resistive switching in planar two-terminal sub-20 nm scale NVM devices. Using complementary suite of characterization techniques in combination with density functional theory calculations, we are able to elucidate the nanoscopic origin of the resistive switching mechanism.

SESSION EL04.04: Spotlight Talk: Phase-Change Materials
Session Chairs: Paul Fons and Prashun Gorai
Monday Afternoon, December 2, 2019
Hynes, Level 1, Room 104

4:45 PM EL04.04.01
Spotlight Talk—Growth of GeTe and Sb2Te3 Interlayer Structures for Interfacial Phase Change Devices via Molecular Beam Epitaxy Adrian Podpirka, David Shrekenhamer, Christine Zgrabik, Jonathan Pierce, Jarod C. Gagnon and Andrew Strikwerda; Johns Hopkins University Applied Physics Laboratory, United States

Phase change memories (PCMs) are based on the bad glass forming ability and metastability of the thermodynamic and kinetic transition in chalcogenide materials. This relies on the electrical and optical properties changing substantially when the atomic structure of the materials is altered. This transition, between a significant electrical resistance in the amorphous phase and a highly conductive state in the crystalline phase, has lent itself to numerous applications that include optical storage (i.e. blue ray and CDs) to electronic devices (i.e. Intel x-point technology). A novel subset of these materials uses the superlattice structure in order to greatly reduce the switching current and
total energy required, thereby overcoming the joule heating constraint common to conventional PCMs. These are known as interfacial phase change materials (iPCM). Though currently unsettled as to the origins of the mechanism, they have shown promise for use in microwave devices based on interlayer switching by reducing the thermal loads required. In this presentation, we investigate the growth of interfacial GeTe-Sb2Te3 structures via Molecular Beam Epitaxy (MBE) with differing orientations and various substrates (GaAs, Si, Al2O3) and report on the electro-optical properties associated with the morphological and structural changes in this material system. By varying the elemental flux and novel heating method, we are able to stabilize the superlattice structure in a 2D growth regime. The ability to grow via MBE on transparent substrates allows us to incorporate the iPCMs into next-generation electronic and optical devices that may benefit applications such as computing, sensing and communications.

4:50 PM EL04.04.02
Spotlight Talk—Electrothermal Modeling of Interfacial Phase Change Memory Md Tashfiq Bin Kashem, Jake Scoggin, Ali Gokirmak and Helena Silva; University of Connecticut, United States

Chalcogenide alloys are the most common phase change materials used in phase change memory (PCM), which has entered the market as a high-speed non-volatile memory [1,2]. One of the main challenges for PCM is the large power required to heat the active region above crystallization or melting temperature. Lower energy and higher speed operations have been demonstrated with thin film superlattice stacks of phase change materials known as interfacial phase change memory (iPCM) [3-6]. The mechanisms behind the improved performance of iPCM are still under investigation but recent work indicates similar crystallization and melt-quench operation of these devices [5].

In this work, we perform electrothermal finite element simulations of reset and set operations on iPCM structures consisting of alternately stacked Ge2Sb2Te5 (GST) and GeTe layers using COMSOL multiphysics [7-10]. Electrical pulses are applied for reset and set processes utilizing an internal circuit model where a transistor is used as an access device. Coupled electric current and heat transfer physics are employed to incorporate Joule heating and thermoelectric effects (Thomson heat within a single material and Peltier heat at material interfaces) with temperature dependent Seebeck coefficients, thermal conductivities, electrical resistivities, heat capacities and thermal boundary resistances (TBR) for each material / material pairs. Latent heat of fusion is included in the amorphous-crystalline and solid-liquid transitions [10], giving rise to heat release at the crystal-amorphous boundaries during crystal growth and heat absorption at the grain boundaries during amorphization. Grain boundaries and material interfaces have high energy sites, making them easier to melt, described as heterogeneous melting [10].

iPCM [5] structures utilize engineered interfaces formed between nanometer scale thin-film stacks, promoting amorphization through increased number of material interfaces and reduced thermal conduction due to TBR. Furthermore, the melting temperature, electrical conductivity and Seebeck coefficient of the different materials within an iPCM device differ. Hence, such layered structures may have the advantage of melting of only one of the alternating layers assisted by local heating or cooling due to Peltier effect at the interfaces. Our results on iPCM and conventional PCM structures of same dimensions and geometry (20 nm wide, 150 nm high pore-cells) show ~ 50% reduction in reset times and more consistent set times for iPCM cells due to lesser variations in grain sizes and location of boundaries.

Chalcogenide Alloys Enable Reconfigurable All-Dielectric Metasurfaces Mikhail Y. Shalaginov1, Sensong An2, Tian Gu1, Yifei Zhang1, Claudia Goncalves1, Peter Su1, Clayton Fowler2, Vladimir Liberman3, Anuradha Agarwal1, Clara Baleine2, Kathleen Richardson3, Hualiang Zhang2 and Juejun Hu1; 1Massachusetts Institute of Technology, United States; 2University of Massachusetts Lowell, United States; 3University of Central Florida, United States; 4Lincoln Laboratory, MIT, United States; 5Lockheed Martin, United States

Material platform based on chalcogenide alloys, such as the recently emerged Ge-Sb-Se-Te, is uniquely poised for enabling new class of active meta-optical devices. Ge-Sb-Se-Te exhibits unique optical and structural properties, including high refractive index (3.3 - 4.7) in mid-infrared, low losses (k < 0.01), and the non-volatile phase-change ability with a significantly larger switchable thickness than the traditional Ge-Sb-Te alloys. Based on this material platform, we demonstrated all-dielectric phase-change metalens with a switchable focusing capability. This research finding opens up new avenues for further development of ultra-compact reconfigurable optical devices for thermal imaging and chemical sensing applications.

EL04.05.02
Cubic NaSbS2 as an Electrically Reconfigurable Semiconductor for Switchable Photovoltaic and Neuromorphic Devices Harikesh Padinhare Cholakkal, Abhijith Surendran, Biplab Ghosh, Rohit A. John, Arjun Moorthy, Natalia Yantara, Sudhanshu Shukla, Krishnamoorthy Thirumal, Subodh G. Mhaisalkar and Nripan Mathews; Nanyang Technological University, Singapore

In a bid to decouple the property-processing correlation which limits electronic materials' performance- we develop material systems that can be compositionally and electronically modulated by the application of electric fields. This requires the careful control of ionic insertion, transport and chemical transformation as well as a host materials system that is electronically fault tolerant and able to handle a wide composition variation. Highly connected and soft Ionic semiconductors such as halide perovskites serve as an archetype in this respect by allowing structural and compositional modulation without impeding the semiconducting property. This co-existence of ionic and electronic properties can be attributed to its defect tolerance – ie the ability of a semiconductor to retain its properties despite the presence of point defects. The presence of ns2 electrons, a high dielectric constant and the presence of the heavy element for strong spin orbit coupling effect are deemed the fundamental reasons for this effect. Based on these design rules, we evaluated Cubic NaSbS2 for similar properties utilising a combined experimental and theoretical approach.

First Principle Calculations indicate the presence of an antibonding valence band maximum eliminating deep traps at the Valence Band side. The cross gap hybridisation between Sb(p) and S(p) enable high dielectric constants and the p to p transitions enable high absorption coefficient in this material. The connected lattice with high ionic conductivity coupled with the above properties make it suitable for electronic and compositional reconfiguration by applied electric fields. We developed a novel solution processing strategy to form thin films of this class of compounds. The material possess a high absorption coefficient with an indirect band gap around 1.5 eV suitable for PV applications. In addition, it exhibits mixed electronic and ionic conductivity which can be modulated by the Na content and the ambient atmosphere. The material behaves as a superionic conductor on exposure to humidity enabling its application as humidity sensors and solid state electrolytes for thin film batteries. We also show for the first time, switchable photovoltaic effect in this Chalcogenide semiconductor by electrically re-configuring the material by ionic insertion. Furthermore, the Persistant photoconductivity of the material is utilised to demonstrate a reconfigurable photonic synapse with low energy consumption in an extremely simple architecture. Thus we report
a extremely versatile electrically reconfigurable Chalcogenide semiconductor with potential applications in Photovoltaics, battery, sensors and Neuromorphic devices.

**Resistance Switching in CdS by Donor-Level Switching** Han Yin and Rafael Jaramillo; Massachusetts Institute of Technology, United States

CdS exhibits large and persistent photoconductivity due to lattice relaxations associated with sulfur vacancies [1]. Sulfur vacancies are deep donors at equilibrium in the dark, but under photoexcitation they convert to shallow donors in a metastable state. This donor-level switching mechanism suggests a new way to control conductivity in electronic devices.

Here we demonstrate two-terminal electrical devices that exhibit donor-level switching. We fabricate and test vertical thin-film devices consisting of Ag/CdS/MoO₃/Au layer. MoO₃ is a hole-injection layer, due to its large electron affinity and nearly type-III alignment with CdS. We hypothesize that MoO₃ extracts electrons from the deep donor levels in CdS (possibly via the valence band), and thereby switches CdS into a highly-conductive state in a thin layer near the interface.

The hypothesis of electrically-stimulated donor-level switching ("photo"conductivity without photons) leads to several testable predictions, all of which are confirmed by device measurements. Our devices are in a high-conductivity state in equilibrium, and exhibit repeatable resistive switching with no electro-forming step. The active n-type layer is switched into a low-conductivity state by injecting electrons, and a high-conductivity state by injecting holes. These results support the hypothesis that the observed electrical switching behavior is due to donor-level switching, rather than mass transport (e.g. filament formation). We further support the donor-level switching hypothesis with numerical device simulations, pulsed electrical measurements, capacitance-voltage profiling, electron beam induced current (EBIC) measurements, X-ray absorption spectroscopy (XAS) mapping, and Raman microscopy. Spatially- and chemically-sensitive techniques suggest that no filaments are formed during switching.

Donor level switching represents a new mechanism for the design of electronic circuit elements such as variable resistors (e.g. for analog computing), ovonic switches, oscillators, and compliance limiters. We suggest that this mechanism is not unique to CdS, and can be found in any material with metastable charged defect states, including ZnO, CuInS₂, and AlGaAs. We end by discussing proposals to optimize defect level switching for particular applications by material selection and device design.

**Single-Shot Ultrafast Phase-Change Memory Materials** Desmond Loke¹, Jonathan Skelton², Tae-Hoon Lee³, Tow-Chong Chong¹ and Stephen Elliott³; ¹Singapore University of Technology and Design, Singapore; ²University of Bath, United Kingdom; ³University of Cambridge, United Kingdom

Although the combination of RAM chips and Flash memory have been leveraged widely in big data and artificial intelligence tasks, they usually fail to meet the commercial demands of either speed or scalability. Phase-change memory materials may overcome these limitations, yet the typical crystallization time is many times slower compared to the melting time, and as a result is insufficient for any real-world application. Here we demonstrate how the crystallization kinetics of a wide range of phase-change systems can be controlled by using a single-shot treatment via “initial crystallization” effects. Ultra-rapid and highly stable phase-change structures viz. conventional and sub-10 nm sized cells, stackable cells, and multilevel configurations have been demonstrated. Material measurements and thermal calculations also reveal the origin of the pretreatment-assisted increase in nucleation and growth time and the thermal diffusion in chalcogenide structures, respectively. This insight may accelerate the technological deployment of new types of phase-change memory.

Effect of the S-Shaped Negative Differential Conductance (SNDC) on the Switching of the GST- Based PCMs
Kazimierz J. Plucinski; Military University of Technology, Poland

In the switching of the Phase Change Memory based on the telluride chalcogenides, eg GST, the following two mechanisms can be recognized [1,2]:
- reversible switching mechanism between an electrical low conducting state and high conductive one, named as threshold switching or Ovonic Threshold Switching (OTS). This mechanism is associated with an S-Shaped Negative Differential Conductance (SNDC);
- thermally activated phase transition between high conductive crystalline and low conductive amorphous states – named as Ovionic Memory Switching (OMS).

OTS is a fundamental mechanism for PCM devices. Despite intensive research into the role of the OTS mechanism, the nature of the physical principle responsible for the conductance switching is still not fully understood [1,4]. One of the reasons for the lack of understanding of the OTS mechanism are deficiencies in the understanding of SNDC mechanism.

The critical analysis of the current state of knowledge in the field of SNDC, in particular the impact of SNDC-related effects on the OTS process will be presented based on the developed phase change algorithm.

EL04.05.06
Systematic Computational Study on Transition Metal-Based Ternary Tellurides for High-Endurance Phase Change Memory Applications
Yuta Saito1, Shogo Hatayama2, Yi Shuang2, Satoshi Shinoda2, Paul Fons1, Alexander V. Kolobov1,3, Keisuke Kobayashi4,5,6 and Yuji Sutou2; 1National Institute of Advanced Industrial Science and Technology, Japan; 2Tohoku University, Japan; 3Herzen State Pedagogical University, Russian Federation; 4Japan Atomic Energy Agency, Japan; 5Kouchi University of Technology, Japan; 6Nagoya University, Japan

Phase change random access memory (PCRAM) is a promising candidate for next-generation non-volatile memory applications, which rely on reversible electrical resistivity change in telluride-based phase change materials between the crystalline and amorphous phases. Ge-Sb-Te alloys have been the most studied phase change materials since they were discovered for rewritable optical disc applications in the 1990’s. Essentially, the same material has been used in conventional PCRAM applications, but it suffers from both thermal stability problems and a limited cycling due to the large changes in density (volume) occurring during the phase change processes. These were not serious issues for optical discs applications, but are for PCRAM. In this work, using an empirical relation linking the physical characteristics of phase change materials, we predict novel materials that are expected to exhibit small density changes upon the phase transition.

The optical properties of 18 different transition-metal-based ternary tellurides have been systematically examined by density functional theory simulations. On the basis of the aforementioned empirical law, which correlates density change with the optical contrast between the amorphous and crystalline phases of chalcogenides, the density changes occurring upon crystallization for hypothetical materials have been predicted. Cr₂Ge₂Te₆ was found theoretically to be one of the best materials for phase-change memory applications owing to its small density
change. This novel criterion will be useful in the screening of materials yet to be experimentally realized, and will help target promising materials for high-endurance phase-change memory applications [1].

Spotlight Talk—Growth of GeTe and Sb2Te3 Interlayer Structures for Interfacial Phase Change Devices via Molecular Beam Epitaxy
Adrian Podpirka, David Shrekenhamer, Christine Zgrabik, Jonathan Pierce, Jarod C. Gagnon and Andrew Strikwerda; Johns Hopkins University Applied Physics Laboratory, United States

Phase change memories (PCMs) are based on the bad glass forming ability and metastability of the thermodynamic and kinetic transition in chalcogenide materials. This relies on the electrical and optical properties changing substantially when the atomic structure of the materials is altered. This transition, between a significant electrical resistance in the amorphous phase and a highly conductive state in the crystalline phase, has lent itself to numerous applications that include optical storage (i.e. blue ray and CDs) to electronic devices (i.e. Intel x-point technology). A novel subset of these materials uses the superlattice structure in order to greatly reduce the switching current and total energy required, thereby overcoming the joule heating constraint common to conventional PCMs. These are known as interfacial phase change materials (iPCM). Though currently unsettled as to the origins of the mechanism, they have shown promise for use in microwave devices based on interlayer switching by reducing the thermal loads required. In this presentation, we investigate the growth of interfacial GeTe-Sb2Te3 structures via Molecular Beam Epitaxy (MBE) with differing orientations and various substrates (GaAs, Si, Al2O3) and report on the electro-optical properties associated with the morphological and structural changes in this material system. By varying the elemental flux and novel heating method, we are able to stabilize the superlattice structure in a 2D growth regime. The ability to grow via MBE on transparent substrates allows us to incorporate the iPCMs into next-generation electronic and optical devices that may benefit applications such as computing, sensing and communications.

EL04.05.08
Atomic Layer Deposition of GeSe Using GeIINMe2[(NiPr)2CNMe2] and Te(SiMe3)2 with NH3 Co-Reagent for Ovonic Threshold Switch
Manick Ha, Chanyoung Yoo, EuiSang Park, YoonKyeung Lee, Woohyun Kim, JeongWoo Jeon and Cheol Seong Hwang; Seoul National University, Korea (the Republic of)

Ovonic Threshold Switch (OTS) is a critical component for suppressing the sneak current in the cross-bar array (CBA) phase change random access memory (PcRAM), and GeSe is a feasible functional material of the OTS. The conventional method to grow GeSe OTS film is sputtering[1,2]. However, the sputtering is not suitable for the vertically integrated PcRAM (V-PcRAM), which must be the ultimate integration structure of the CBA-PcRAM. For this V-PcRAM fabrication, a growth method which guarantees the thickness and composition uniformities within the deep hole structure is necessary. Atomic layer deposition (ALD), therefore, must be the process of choice for such a purpose, and the authors’ group already reported high functionality of ALD-GeSe film as a feasible OTS material [3]. However, the previous work has a limitation of the growth process; the ALD-GeSe film must be grown at a low temperature of 70 oC due to the serious desorption of the precursors at higher temperatures. This might also hinder the achievement of the ultimate functionality of the same material.

In this work, therefore, the ALD process was improved to allow the growth of the ALD-GeSe films at much higher temperatures (up to 180 oC) by changing the Ge(II)-precursor from HGeCl3 to (Ge(iPrN)2CNMe2)NMe2 and co-injecting NH3 with the new Ge(II)-precursor. Under this condition, the (Ge(iPrN)2CNMe2)NMe2 was activated by accepting the lone pair electrons of NH3, which allowed the growth of the GeSe film at temperatures as high as 180 oC. The activated Ge(II)-precursor molecules feasibly reacted with the Se-precursor, (Si(CH3)3)2Se, resulting in the stoichiometric GeSe thin film deposition. The ALD process showed self-limiting growth behavior and produced highly uniform and stoichiometric GeSe films with the saturation growth rate around 39 ng*cm2*cy-1 at 70 oC substrate temperature (Figure 1). X-ray photoelectron spectroscopy analysis revealed that the composition ratio of Ge:Se was ~1:1 for all the ALD temperature from 70 to 180 oC. However, the N impurity level in the film varied depending on the substrate temperature; film grown at higher temperature contained lower N- impurity concentration (Figure 2 (a), (b)). This may cause discrepancies in the density and morphology of the deposited film. When the film was grown at 180oC, a high film density (4.23g*cm-3) and low N impurity content could be obtained. The presentation will also report the high electrical performance of the film as the OTS using an integrated cell structure of mushroom type, where the 10nm thick GeSe film was interposed between the planar-TiN top electrode and W-plug (diameter of 2um) bottom electrode.
Numerical Analysis of Mechanical Stress During Switching Operation in Phase-Change Memory
Hwanwook Lee and Yongwoo Kwon; Hongik University, Korea (the Republic of)

A chalcogenide material, Ge$_2$Sb$_2$Te$_5$ (GST), can undergo a fast nanosecond-transition between the amorphous and crystalline phases that have a resistivity difference of 1,000 times or more. This phase change can be controlled electrically and is used as phase change memory (PCM). However, amorphous and crystalline phases have a density difference of about 10% and cause a mechanical stress in the device due to the volume change during the switching operation. Repetitive switching operations between two phases lead to an open circuit failure, more specifically, the breakdown of the interface between GST and its contact electrode by the fatigue, which is called stuck reset. In this study, finite element analysis (FEA) was performed for several PCM cell architectures by combining electrothermal and solid mechanics models using COMSOL Multiphysics, a commercial FEA software. Simulation techniques and comparative study on the cell architectures will be presented.

TEM of GeSbTe Thin Films—Crystallization Dynamics, Void Formation and Elemental Segregation
Shalini Tripathi$^{1}$, Rongjung Wang$^{2}$, Paul Kotula$^{3}$, Gokhan Bakan$^{4}$, Helena Silva$^{1}$ and Barry Carter$^{3,1}$; $^{1}$University of Connecticut, United States; $^{2}$Applied Materials, Inc., United States; $^{3}$Sandia National Laboratories, United States; $^{4}$Atilim University, Turkey

Chalcogenide compounds show distinct properties in the amorphous and crystalline phases with orders of magnitude difference in electrical resistivity, making them prominent candidates for fast, non-volatile and high-density electronic memory devices. Adoption of this new technology has been hindered by the large power required to heat the active volume above crystallization or melting (for melt-quench amorphization), resistance drifts of the metastable phases, and void formation and elemental segregation during heating and cooling. We are using transmission electron microscopy (TEM) to study the changes that occur in these materials with the aim of relating microstructure findings to the physical and chemical properties.

GeSbTe (GST) thin films are deposited directly onto Protochips carriers by sputtering. The phase transformation is monitored in real time in the TEM using the Protochips heating holders. Materials characterization uses both a Tecnai F30 (operating at 200kV equipped with an EDS detector) and Titan ETEM (300kV Cs-image-corrected Titan) that can accept the same Protochips heating holders. The ETEM is equipped with a K3-IS direct electron detector camera allowing high-speed video recording (up to 1600 frames/s) of the structural changes in these materials upon heating and cooling. The aim is to observe the various phase transformations and other critical processes such as grain evolution, void formation and elemental segregation and study how these relate to the electronic behavior. High-resolution TEM images of GST films after heat treatment show coherent twin boundaries, which will be discussed together with the sensitivity of these films to the electron beam. Challenges associated with integrating results from different techniques will also be discussed.

Spotlight Talk—Electrothermal Modeling of Interfacial Phase Change Memory
Md Tashfiq Bin Kashem, Jake Scoggin, Ali Gokirmak and Helena Silva; University of Connecticut, United States

Chalcogenide alloys are the most common phase change materials used in phase change memory (PCM), which has entered the market as a high-speed non-volatile memory [1,2]. One of the main challenges for PCM is the large power required to heat the active region above crystallization or melting temperature. Lower energy and higher speed operations have been demonstrated with thin film superlattice stacks of phase change materials known as interfacial phase change memory (iPCM) [3-6]. The mechanisms behind the improved performance of iPCM are
still under investigation but recent work indicates similar crystallization and melt-quench operation of these devices [5].

In this work, we perform electrothermal finite element simulations of reset and set operations on iPCM structures consisting of alternately stacked Ge$_2$Sb$_2$Te$_5$ (GST) and GeTe layers using COMSOL multiphysics [7-10]. Electrical pulses are applied for reset and set processes utilizing an internal circuit model where a transistor is used as an access device. Coupled electric current and heat transfer physics are employed to incorporate Joule heating and thermoelectric effects (Thomson heat within a single material and Peltier heat at material interfaces) with temperature dependent Seebeck coefficients, thermal conductivities, electrical resistivities, heat capacities and thermal boundary resistances (TBR) for each material / material pairs. Latent heat of fusion is included in the amorphous-crystalline and solid-liquid transitions [10], giving rise to heat release at the crystal-amorphous boundaries during crystal growth and heat absorption at the grain boundaries during amorphization. Grain boundaries and material interfaces have high energy sites, making them easier to melt, described as heterogeneous melting [10].

iPCM [5] structures utilize engineered interfaces formed between nanometer scale thin-film stacks, promoting amorphization through increased number of material interfaces and reduced thermal conduction due to TBR. Furthermore, the melting temperature, electrical conductivity and Seebeck coefficient of the different materials within an iPCM device differ. Hence, such layered structures may have the advantage of melting of only one of the alternating layers assisted by local heating or cooling due to Peltier effect at the interfaces. Our results on iPCM and conventional PCM structures of same dimensions and geometry (20 nm wide, 150 nm high pore-cells) show ~ 50% reduction in reset times and more consistent set times for iPCM cells due to lesser variations in grain sizes and location of boundaries.

Synthesis of Segregating Binary Alloy for Nanowire-Like Phase-Change Materials and Memory

Desmond Loke¹, Griffin Clausen², Jacqueline Ohmura², Tow-Chong Chong¹, Natasa Bajalovic¹ and Angela Belcher²;
¹Singapore University of Technology and Design, Singapore; ²Massachusetts Institute of Technology, United States

Non-volatile memories are pivotal components for emerging opto- and nanoelectronic applications such as smart displays and brain-inspired neuromorphic computing. Flash memories are currently the key player in the field, yet they fail to meet the commercial demands of scalability and speed. Phase-change materials (PCM), based on reversible switching between the crystalline state and amorphous state of a chalcogenide material, showing fast switching on 10 ns time scale, are promising alternatives explored by the industry. However, segregating-binary-alloy (SBA)-based PCM tends to show high consumption of energies and segregation of elemental components. Nanowire-like PCM has so far evolved as the most ideal candidate to achieve low-energy consumption PCM, however they are often synthesized by vapor-liquid-solid methods above 720 K, which would cause irreversible corruption of SBA-based PCMs. Here we leverage M13 bacteriophage as biological template to control the structure and assembly of SBA PCMs. We demonstrate a biologically templated, low temperature, wire-like PCM simply by leveraging the binding affinity of the negatively-charged amino acids on M13 bacteriophage surface to the precursor components of SBA-type germanium-tin-oxide systems. This study may open intriguing perspective for realizing
genetically-engineered PCM with tunable, reliable and fast switching characteristics.

**Plasma-Assisted Atomic Layer Deposition of GeSb Films Using Non-Halide Organo-Metallic Precursors for Phase-Change Electronic Devices**

Saidjafarzoda Ilhom, Adnan Mohammad, Deepa R. Shukla, Brian Willis, Helena Silva and Necmi Biyikli; University of Connecticut, United States

Germanium-antimony-telluride compound (GST) is one of the most widely known chalcogenide materials which has been heavily commercialized in phase-change memory (PCM) devices including the recently announced cross-bar memory architectures. Besides the ternary GST, binary versions (GeSb, SbTe, and GeTe) of this compound family show also interesting properties including phase transitions. Compared to more conventional deposition methods including rf-magnetron sputterin and pulsed laser deposition, atomic layer deposition (ALD) has recently attracted significant interest mainly due to its precision thickness control and ultimate conformal deposition capability, which becomes more and more critical as device sizes shrink down to single digit nanometers and device architectures become highly three-dimensional with increased complexity. Currently, most of the successful works towards the ALD growth of phase-change (PC) materials have been focusing on utilizing corrosive chemical compounds such as metal-halides and alkyl-silyls as the precursors and co-reactants. In this work we aim to produce highly uniform and void-free binary phase-change GeSb films using non-halide organo-metallic precursors at relatively low substrate temperatures. Towards this goal, GeSb films are grown on Si(100) and glass/quartz substrates via inductively-coupled plasma-enhanced atomic layer deposition using tetramethyl-germane ((CH₃)₄Ge) and tris(dimethylamino)-antimony ((CH₃)₂N)₃Sb as germanium (Ge) and antimony (Sb) precursors, respectively. Ar/H₂ plasma gas mixture was employed to remove the precursor ligands at each intermediate reaction steps. Growth experiments have been performed within 100 - 250 °C substrate temperature at 300 W rf-plasma power. *Ex-situ* materials characterizations are carried out to identify structural, chemical, optical and electrical properties of the grown GeSb films. Detailed temperature-dependent electrical characterization is performed to measure the phase-change transition properties of the ALD-grown GeSb layers.

**Direct Phase Transition of the Few Layer MoS₂ from 2H to 1T' State by Using 2D Electride: Ca₂N**

Krishna P Dhakal, Ganesh Ghimire, Kyungwha Chung, Sung W. Kim and Jeongyong Kim; Sungkyunkwan University, Korea (the Republic of)

The lattice engineering of the sulfide based transition metal dichalcogenide (TMDs) is difficult compared to selenide and telluride materials.1 Here, we report on the continuous phase transition of the few layers to bulk molybdenum disulfide (MoS₂) system by realizing the hetero-structures with the low work function (2.6 eV) two dimensional electrode (2D-Ca₂N) that contain highly mobile electrons, where the large work function differences (>2 eV) between them is the key of the degenerate electrons doping that is distributed over a distance of few tens of nanometer from the contact interface in contrast to the other surface limited (~1 nm) chemical functionalizations or ionic gating approaches.3 An electron doping density of ~10¹⁴ cm⁻² was estimated on the MoS₂ layers that performed exceptional thickness dependent lattice symmetry change from the 2H to 1T' phases until a few-layer (~10 nm) and then strong doping effect to the bulk samples resulting a giant band gap re-normalization by ~200 meV along with the softening of the commonly observed Raman modes by the Δω=10 cm⁻¹. As the MoS₂ thickness was decreased, well defined Raman peaks of 2H crystal were gradually disappearing along with the
emergence of other 1T' phase Raman modes, thus elucidating the symmetry change feature due to concentrated charge density in a thinner film. Additionally, a hetero-structure of the few-layer MoS2 demonstrated multiple in-plane anisotropic Raman modes, including those of metallic phases Raman modes along with the presence of the hugely shrunk (250 meV) optical gap and enhanced PL intensity than a pristine monolayer MoS2; a realization of the few-layer 2H-MoS2 crystal with distorted symmetry and direct band gap structure when placed on the top of the Ca2N. This is attributed to the long-range electron doping induced structural change across the K-Γ line, hence provided an opportunity to discover various kinds of 2D materials using a single 2D-dopant suitable for the future optoelectronic application.

KEYWORDS: MoS2, electride, doping, long range, phase-transition, direct band gap structure

Energy-Efficient Neuromorphic Computing through the Control of the Density, Location and Properties of Conducting Filaments in TiO2
Nicolas Emond and Bilge Yildiz; Massachusetts Institute of Technology, United States

Improvements in actual computing performance, which is based on von Neumann architecture, requires designing novel scalable, fast and energy-efficient technologies with both processing and storage capabilities. A typical example of systems with such capabilities is the human brain. Indeed, it has major advantages over supercomputers in terms of energy efficiency and adaptability due to its complex processing capability, made possible by the interconnection between \(10^{11}\) neurons and \(10^{15}\) synapses. The current "holy grail" of neuromorphic computing technology is thus to mimic brain performance for the development of superior computational systems. Among the proposed next generation device candidates to reproduce neuromorphic core architectures for pattern recognition and machine learning, redox-based resistive switching (RS) random access memories (RRAM) are particularly highly regarded due to their predicted high memory density, energy efficiency and speed. Within their metal–insulator–metal architecture, these devices store binary code information using the electric field-induced resistance change of the insulating oxide layer by conductive filament (CF) formation and rupture at chemical and structural defects. Despite such very attractive properties, a lack of control on the location and spacing of CFS formation, as well as on their properties, results in stochasticity and randomness of CFS formation in these devices, which in turns leads to detrimental variation in device performance and lack of reliability in training processes. Unfortunately, there is actually a lack of fundamental knowledge connecting these defects to their nucleation and evolution. Within this context, we initiated a study on the effect of strain on the microstructure, chemistry and RS properties of TiO2 thin films to resolve the thermodynamic and kinetic relations of heterogeneities to their intrinsic and local RS properties.

Epitaxial TiO2 films with varying thicknesses were pulsed laser deposited on Nb-SrTiO3 and Nb-TiO2 single-crystal substrates to investigate the effect of phase, strain, crystallinity and defects concentration on the nature of the CFS and the local RS properties of the films. The fabrication and characterization of TiO2-based two-terminal devices was also carried out to get information about their RS properties, mainly in terms of switching consistency and reproducibility. Such studies will not only allow gathering insights into defects location of formation but will further serve as a guideline while looking to introduce chemical disorder at specific locations into the TiO2 matrix. Such a selective doping along defects is expected to locally decrease the reduction enthalpy and provide preferential sites for CF formation. The objective here is to achieve proper control of CFS formation and properties to accordingly reduce the variability among RRAM devices and improve their switching symmetry.

EL04.05.16
Controlling Conductive Filaments in Resistive Switching Oxides by Controlled Chemical Disorder
Kevin J. May1, Yu Ren Zhou1, Vijay Naranyanan2, Takashi Ando2, Harry L. Tuller1 and Bilge Yildiz1;1 Massachusetts Institute of Technology, United States; 2IBM T.J. Watson Research Center, United States

There has been a growing interest in using specialized neuromorphic hardware to implement artificial neural networks for use in applications such as image and speech processing. These neuromorphic devices show promise
for meeting the significant parallel computing demands of such applications with higher speed and lower power consumption than software-based implementations. One approach to achieving this goal is through oxide thin film resistive switching devices arranged in a crossbar array configuration. Resistive switching can mimic several aspects of neural networks, such as short- and long-term plasticity, via the dynamics of switching between multiple analog conductance states—dominated by the creation, annihilation and movement of ionic species within the film (such as oxygen vacancies). These processes can be stochastic in nature and contribute significantly to device variability, both within and between individual devices.

This study focuses on reducing the variability of the set/reset voltages using model systems of HfO₂ grown on Nb: SrTiO₃ and Si/TiN substrates. We control the oxide microstructure via growth parameters and thermal treatment, to compare amorphous HfO₂ films with nanocrystalline columnar-grained films with both single (-111) texture and multiple orientations and selectively dope grain boundaries using thermal diffusion. By statistically comparing the electrical characteristics of at least 10 devices from each processing condition, film microstructure and dopants may be optimized for maximum resistive switching repeatability. Because the device requirements for practical resistive switching arrays are significant, controlling the variability of individual devices will likely be a consideration for every fabrication and processing step. This work provides a significant step towards understanding the mechanisms behind device variability and achieving devices that meet the strict requirements of neuromorphic computing.

EL04.05.17
Electrochemical Proton Intercalation Synapse for Analog Resistive Switching Xiahui Yao, Wenjie Lu, Nicolas Emond, Jesus A. del Alamo, Ju Li and Bilge Yildiz; Massachusetts Institute of Technology, United States

Analog resistive switching processor arrays are promising as in-memory computing hardware and to construct physical neural networks capable of implementing machine learning algorithms at higher operating speed and lower energy cost than conventional von-Neumann architectures. State-of-the-art analog resistive switches rely on the mechanism of either forming conductive filaments or inducing a phase change. These processes suffer from poor repeatability or high energy consumption, respectively. A fundamentally different mechanism is desired to address these challenges.

Herein we demonstrate proton intercalation induced resistive switching, that can be applied on a variety of layered or channeled materials including chalcogenides and metal oxides. A prototypical three-terminal resistive switching device was designed, with a channel of active material probed by two terminals (source and drain), a proton reservoir layer as gate terminal, and a proton conducting solid electrolyte separating the two. The electrical conductivity of the active material can be modulated by the precise control of proton intercalation, providing a highly reproducible resistive switching behavior. As the lightest cation, the shuffling of protons between the reservoir and the active material requires minimal energy.

A proof-of-concept device has been fabricated. 50 nm WO₃ was deposited by reactive sputtering as the active material, with a channel size of 100 μm x 500 μm. A 400 nm Nafion polymer electrolyte layer was deposited by spin coating. A 50 nm Pd electrode serving as both gate and solid proton reservoir was sputtered on top and later hydrogenated to palladium hydride. The energy consumption is only 3.5 fJ/μm² per state per potentiation and depression operation, comparable with state-of-the-art demonstrations. Extreme on/off ratio of more than 10⁷ in conductance was observed and more than 1000 distinct conductance states were demonstrated. Most important of all, a symmetric potentiation and depression behavior was achieved in a constant current pulse mode. Further, insight into the switching mechanism involving protons has been obtained through a combined examination of crystal and electronic structure using synchrotron X-ray absorption spectroscopy and in-situ X-ray diffraction. It is found that protons serve as donors to reduce the metal oxidation states in the active material and create gap states. The continuous filling of electrons into the empty d-orbital of W metal increase the charge carrier density and conductivity. Additionally, proton intercalation induced lattice distortion of the active material is found to result in higher crystal symmetry and better alignment of W-O₆ octahedrals. This also contributes to the enhanced conductivity after proton intercalation.

In summary, we successfully proved the feasibility of utilizing proton intercalation chemistry to induce the modulation of resistivity and prototyped an all-solid three-terminal analog resistive switch. The advantages of this switching mechanism, namely, low energy dissipation, good operating symmetry and multi-state capability, are demonstrated.
Lanthanide elements offer a versatile platform for the design of new magnetic and optical materials. The use of soft chalcogenide ligands introduces tunability of the crystal electric field of the lanthanide cations, which can result in new classes of materials with various potential applications. Exploratory crystal growth of these compounds is an important tool for creating new compounds, and the development of new synthetic routes is highly desirable to achieve the intentional synthesis of new chalcogenide materials.

One well-developed technique for obtaining crystals is flux crystal growth. Unlike solid state synthesis, which is usually performed at higher temperatures and which typically results in thermodynamic products, flux crystal growth enables access to kinetically stabilized phases by using fluxes with low melting points. Focusing on the synthesis of new magnetic materials, specifically those containing f-elements, we employed alkali iodide fluxes to obtain single crystals of new thiophosphate and thiosilicate compounds with incorporated lanthanide and uranium cations. A targeted synthesis of first two uranium(IV) thiosilicates was achieved by using CsI and CsI/NaI eutectic fluxes. We showed that different products can be achieved by using either SiS₂ or an equivalent mixture of Si and S. This highlights the complex reaction pathway that results in single crystals of Cs₂Na₄[U₂(SiS₄)₂(Si₂S₈)], in the case of SiS₂ starting material, or a polycrystalline product that was obtained when elemental sulfur and silicon were used. The use of alkali iodide fluxes has enabled us to synthesize over 20 new lanthanide thiophosphate compounds as high quality single crystals. The structures and physical properties of several of these phases will be discussed.

The charge transfer and spin coupling effects are explored at the interface of two-dimensional (2D) superconducting FeSe nanosheets and one-dimensional (1D) molecular photochromic potassium-7,7,8,8-tetracyanoquinodimethane (KTCNQ).[1] 2D superconducting FeSe layer is obtained in a large scale by liquid exfoliation and maintains the characteristics of its bulk counterpart.[2] Light-induced current density in 2D FeSe nanosheets device is enhanced by the electron doping from KTCNQ by the destabilized spin-Peierls phase[3] through their interface. The spin coupling at the interface of FeSe and KTCNQ shifts the dimerization transition temperature of KTCNQ from 389 K to 395 K. Our results suggest 2D exfoliated FeSe nanosheet as a versatile strongly correlated platform for the electron doping and inorganic-organic interface studies.

Chalcogenide perovskite-type materials have recently been investigated as alternative solar absorbers to the familiar oxide ferroelectric and halide perovskite families. In particular, Ba₃Zr₂S₇ (BZS) is a Ruddlesden-Popper chalcogenide, which was shown to exhibit a band gap of approximately 1.3 eV [1] that is ideally suited for solar absorption, and thermal stability up to at least 550 °C [2]. Knowledge of the thermal expansion of Ba₃Zr₂S₇ is also important during operation and fabrication of a photovoltaic device based on this material. Here we compute the temperature-dependent structural, lattice dynamical, and thermal expansion properties of Ba₃Zr₂S₇ using the self-consistent quasi-harmonic approximation [3] within the framework of density functional theory. We explain the mechanism of thermal expansion, report its effect on the band gap, and compare this behavior to other perovskite-structured oxides and chalcogenides materials.

Dielectric Response of Highly-Polarizable Complex Chalcogenide Semiconductors BaZrS3 and Ba3Zr2S7

Stephen Filippone1, Ignasi Fina2, Shanyuan Niu3, Boyang Zhao3, Jayakanth Ravichandran3, Dino Klotz1, Harry L. Tuller1 and Rafael Jaramillo1; 1Massachusetts Institute of Technology, United States; 2Universitat Autònoma de Barcelona, Spain; 3University of Southern California, United States

Complex oxides in perovskite and Ruddlesden-Popper crystal structures often have large, interesting, and useful dielectric response. Complex sulfides in similar structures may feature similarly large dielectric response while also featuring band gap in the visible and infrared, and likely have higher charge transport mobility than complex oxides. Complex chalcogenides may therefore be an uncommon class of highly-polarizable semiconductors.

We report measurements of the dielectric susceptibility of single crystal samples of BaZrS3 (BZS-113) and Ba3Zr2S7 (BZS-327). BZS-113 has a distorted-perovskite structure and a band gap of 1.8 eV. BZS-327 is a Ruddlesden-Popper variant and has a band gap of 1.3 eV. We use impedance spectroscopy to measure the complex dielectric response of single crystal and cold-pressed pellets over the frequency range 0.1 Hz – 1 MHz. We find that both phases are highly-polarizable, with room-temperature static dielectric constant (ε0) over 50 and dielectric loss tangent below 0.05. We also report temperature-dependent susceptibility and electrical resistivity and discuss the effects of incipient ferroelectricity, predicted for chemically-adjacent Sr-Ba-Zr-S compounds. The combination of strong and low-loss dielectric response and band gap in the VIS-NIR spectral range may be unique for inorganic semiconductors and is interesting for applications including photonics and solar energy conversion.

**EL04.05.22**

pi-Phase Tin and Germanium Monochalcogenide Semiconductors—An Emerging Materials System

Ran E. Abutbul1,2, Elad Segev1,2, Uri Argaman1, Guy Makov1,2 and Yuval Golan1,2; 1Ben-Gurion University of the Negev, Israel; 2Ilse Katz institute for Nanoscale Science & Technology, Israel

Cubic pi-phase monochalcogenides (MX, M = Sn, Ge; X = S, Se) are an emerging new class of materials that have recently been discovered. Here, their thermodynamic stability, progress in synthetic routes, properties, and prospective applications are reviewed. The thermodynamic stability is demonstrated through density functional theory total energy and phonon spectra calculations, which show that the pi-phase polytype is stable across the monochalcogenide family. To date, only pi-phase tin monochalcogenides have been observed experimentally while pi-phase Ge-monochalcogenides are predicted to be stable but are yet to be experimentally realized. Various synthetic preparation protocols of pi-SnS and pi-SnSe are described, focusing on surfactant-assisted nanoparticle synthesis and chemical deposition of thin films from aqueous-bath compositions. These techniques provide materials with different surface energies, which are likely to play a major role in stabilizing the pi-phase in nanoscale materials. The properties of this newly discovered family of semiconducting materials are discussed in comparison with their conventional orthorhombic polymorphs. These could benefit a number of photovoltaic and optoelectronic applications since, apart from being cubic, they also possess characteristic advantages, such as moderately low toxicity and natural abundance.
Sequential Structural and Antiferromagnetic Transitions in BaFe$_2$Se$_3$ under Pressure Yang Zhang; Southeast University, China

The discovery of superconductivity in the two-leg ladder compound BaFe$_2$S$_3$ has established the 123-type iron chalcogenides as a novel and interesting subgroup of the iron-based superconductor family. However, in this 123 series, BaFe$_2$Se$_3$ is an exceptional member, with a magnetic order and crystalline structure different from all others. Recently, an exciting experiment reported the emergence of superconductivity in BaFe$_2$Se$_3$ at high pressure [J. Ying et al., Phys. Rev. B 95, 241109(R) (2017)]. Here, our analysis unveils a variety of qualitative differences between BaFe$_2$S$_3$ and BaFe$_2$Se$_3$, including in the latter an unexpected chain of transitions with increasing pressure. First, by gradually reducing the tilting angle of iron ladders, the crystalline structure smoothly transforms from Pnma to Cmcm at $\sim$6 GPa. Second, the system becomes metallic at 10.4 GPa. Third, its unique ambient-pressure Block antiferromagnetic ground state is replaced by the more common stripe (so-called CX-type) antiferromagnetic order at $\sim$12 GPa, the same magnetic state as the 123-S ladder. This transition is found at a pressure very similar to the experimental superconducting transition. Finally, all magnetic moments vanish at 30 GPa. The information obtained in our calculations suggests different characteristics for superconductivity in BaFe$_2$Se$_3$ and BaFe$_2$S$_3$: in 123-S pairing occurs when magnetic moments vanish, while in 123-Se the transition region from Block- to CX-type magnetism appears to catalyze superconductivity.

An Ab Initio Study of Compressed Palladium Sulfide Isaías Rodríguez$^1$, David Hinojosa-Romero$^2$, Renela M. Valladares$^1$, Alexander Valladares$^1$ and Ariel A. Valladares$^2$; $^1$Faculty of Science, UNAM, Mexico; $^2$IIM-UNAM, Mexico

Recent experimental results indicate that palladium chalcogenides present interesting electronic behavior. In particular, superconductivity appears at 4.5 K in PdTe at ambient pressure. Similarly, PdS becomes a superconductor ($T_C = 1.8$ K) for pressures starting at 19.5 GPa [1]. As the pressure increases so does the $T_C$ reaching a value of 7 K at a pressure of 41.3 GPa. Recently we have predicted the superconducting transition temperature ($T_C$) of the Wyckoff phase of bismuth as 1.5 mK or below [2], and this was later experimentally corroborated. Afterwards we calculated $T_C$ for all bismuth solid phases under pressure and our results agree with experiment [3]. Here, we report an ab initio computational study of the effects of pressure on palladium sulfide (PdS), maintaining the original crystalline structure and compressing a 108-atom crystalline supercell computationally, as previously conducted for bismuth [4]. We calculate the electronic and vibrational density of states for the PdS system under pressure and relate them with its superconducting properties. We compare our results with the experimental ones reported in the literature.

Ab Initio Study of the BiS$_2$ Chalcogenide David Hinojosa-Romero$^1$, Isaías Rodriguez$^2$, Alexander Valladares$^2$, Renela M. Valladares$^2$ and Ariel A. Valladares$^1$; $^1$IIM-UNAM, Mexico; $^2$Faculty of Science, UNAM, Mexico

Bismuth, as a pure monatomic material, is a semimetal which possesses several interesting physical properties, not all of them well understood. The prediction of a critical superconducting temperature for its crystalline form at ambient pressure by our group [1] and its experimental verification several months later, have led us to ab-initio study bismuth in different conditions: amorphous [1], bi-layered [2], under-pressure phases [3] and mixed with copper [4]. In all of these systems, bismuth seems to contribute to their superconductive behavior and the modification of their critical temperature. Here we study the bismuth-sulphur chalcogenide which is known to contribute to superconductivity in the layered compound LaO$_{1-x}$F,BiS$_2$ which has a $T_C$ as high as 10.6 K. Using ab initio molecular dynamics and the undermelt-quench method, we generate layered and amorphous structures of the
BiS$_2$ system to study its electronic and vibrational properties and then relate them to possible superconducting properties. We shall report these results and study similarities and differences for the amorphous and layered structures and infer its relevance for superconductivity. We shall compare these results with those found for the bulk amorphous bismuth, the bi-layered, the under-pressure phases and mixed with copper, that we have recently calculated and reported.

Compositionally Modulated Telluride Heterostructure Nanowires Debadarshini Samantaray and Ravishanak Narayan; Indian Institute of Science Bangalore, India

Semiconductor nanostructures with modulated shape and size can be potential candidate for various applications in fields of nanoelectronics, photonics and thermoelectric. In this respect, Te (low band gap semimetal) and Te based nano structures have gained popularity due to their superior thermo-electric property. These properties get manifold when suitable material is incorporated into these systems; one e.g. could be having periodic arrangement of two different nanostructures (superlattice) (SL). But a general and simple scheme to obtain such superlattice 1-D heterostructure with clear and coherent interface is still challenging. In the current study, we have come up with a synthetic design to obtain telluride based compositionally modulated 1D- hetero-structure. Moreover, earlier theoretical studies suggest that SL nanowires can make huge impact on the thermo-electric conversion efficiency by minority carrier blocking.

Several gas phase reactions have resulted in vertical/ radial heterostructure. But we have come up with simple wet chemical synthesis method to obtain single crystalline SL nanowire. In this study, reactive dewetting phenomena has been exploited to obtain periodically arranged PbTe beads along the length of Te nanowire. Using this nanowire as template, the exposed part of the nanowire has been converted to either Ag$_2$Te or Cu$_2$Te to form PbTe-Ag$_2$Te or PbTe-Cu$_2$Te SL nw. TEM analysis shows, these nanowires are single crystalline in nature and having diameter of 60 nm and lengths in micron. Further characterization has been done using STEM-HAADF-EDAX and tomography to understand the morphology and composition. Thermal and electrical conductivity measurements have been carried out on these SL nanowires by Raman and two probe measurement respectively. Further, optical measurements in these system shows intricate nature, which can be attributed to quantum confinement in these SL structures.

EL04.05.27
Earth Abundant, Cation Mutated Delafossites Cu$_3$M$_2$SbO$_6$ Ethan Rubinstein and David O. Scanlon; University College London, United Kingdom

The electronic and optical properties of CuM$_3^{3+}$O$_2$ delafossites have been thoroughly investigated for numerous applications. A notable feature of these materials is a symmetry disallowed VBM to CBM transition often resulting in an optical band gap significantly larger than the smallest direct band gap [1]. CuGaO$_2$ has application potential as a hole transport layer for perovskite solar cells [2], and as part of hybrid electrodes for various photoelectrochemical cells [3][4]. CuInO$_2$ is known for its unusual bipolar dopability considering its wide optical band gap [1].

R. Nagarajan *et al.* successfully synthesized a set of 2+/5+ mixed B-site antimony based analogues [5] opening up a new materials space free of the relatively scarce and increasingly in demand gallium and indium. Of these analogues two earth abundant variants, Cu$_3$Mg$_2$SbO$_6$ and Cu$_3$Zn$_2$SbO$_6$, were found to have ordered crystal structures. In this study hybrid density functional theory with the HSE06 functional is used to predict the electronic structure, optical properties, and band alignments of the Mg and Zn variants. We compare and contrast these results with those of the
known Ga and In based delafossites, and speculate on their potential applications.

Atomically Thin TMD Wafers for Technology in the 21st Century Jiwoong Park; University of Chicago, United States

Manufacturing of paper, which started two thousand years ago, simplified all aspects of information technology: generation, processing, communication, delivery and storage. Similarly powerful changes have been seen in the past century through the development of integrated circuits based on silicon. In this talk, I will discuss how we can realize these integrated circuits thin and free-standing, just like paper, using two-dimensional materials based on transition metal dichalcogenides and how they can impact the modern information technology.

In order to build these atomically thin circuits, we developed a series of chemistry-based approaches that are scalable and precise. They include wafer-scale synthesis of three atom thick semiconductors and heterojunctions (Nature, 2015; Science 2018), a wafer-scale patterning method for one-atom-thick lateral heterojunctions (Nature, 2012), and most recently, atomically thin films and devices that are vertically stacked to form more complicated circuitry (Nature, 2017). Once realized, these atomically thin circuits will be foldable and actuatable, which will further increase the device density and functionality.

9:00 AM EL04.06.02
Facile Synthesis of Non-Stoichiometric Modulated Copper Selenide (Cu2−xSe) Using Chemical Vapor Deposition for Electronic and Electrochemical Applications Konar Rajashree1, Gili Yaniv2, Eti Teblum1, Madina Telkhozhayeva1, Gilbert D. Nessim1 and Louisa Meshi2; 1Bar Ilan University, Israel; 2Ben-Gurion University of the Negev, Israel

Two-dimensional architectures are considered excellent candidates for electronics and electrochemical applications. Some of the most commonly researched 2D layered materials are: graphene, boron nitride, black phosphorous, and transition metal chalcogenides (TMCs). TMCs are promising high-performance materials for next-generation energy storage systems because of their high theoretical capacity, high energy density, and high voltage. Among them, copper-based chalcogenide nanocrystals and related alloys have been widely investigated due to their non-toxicity, low cost, and ability to achieve band-gap energies of 1.0–1.5 eV [1-2].

Copper selenide has attracted a lot of attention because of its abundant applications in photoelectric devices, medical treatments, gas sensors, and catalysis. Copper selenides exist as a variety of stoichiometric and nonstoichiometric phases such as CuSe, Cu₂Se₃, Cu₃Se₄, Cu₅Se₄, Cu₁.₈Se, Cu₂Se, Cu₅Se₄, and Cu₂₃-Se [4]. Among them, Cu₂−x-Se shows unique structures and properties. Cu₂−x-Se has Se atoms in a simple face-centered cubic (FCC) structure with the space group Fm-3m, but the superionic Cu ions are kinetically disordered throughout the structure, resulting in a quite high electrical conductivity. Thus, researchers concentrated their synthesis of Cu₂−x-Se with different sizes and shapes through various techniques.

Here, we report the synthesis of bulk 2D layered copper selenide using atmospheric pressure chemical vapor deposition (AP-CVD), with elemental selenium as a precursor. Using top-down approaches (drop casting, etc.), we deposited mono/few-layer flakes on substrates. The layered material was characterized using XRD, HRSEM, TEM, UV-VIS, and AFM to confirm its morphology and stoichiometry. We identified our material as a modulated
structure based on the FCC basic structure (Fm-3m), similar to reported in [5]. It should be noted that due to structural modulation, structure characterization was possible here through electron diffraction only which allowed to conclude modulation vector. AFM measurements demonstrated that the single flakes had a lateral size of approximately 3-6 μm. HRSEM images of the dropcasted material on Si/SiO2 wafer showed copper selenide flakes on top of each other and the presence of layers has also been confirmed by TEM. We will show that this material is a potential candidate for electronic and electrochemical applications.

Epitaxial Growth of Layered Metal Chalcogenides via Metalorganic Chemical Vapor Deposition Xiaotian Zhang, Mikhail Chubarov, Tanushree H. Choudhury, Anushka Bansal and Joan M. Redwing; The Pennsylvania State University, United States

2D metal chalcogenide semiconductors have received considerable attention due to their compelling properties and layered crystal structure. Much of this work has focused on transition metal dichalcogenides (TMDs, MX2 where M=Mo, W and X=S, Se, Te), but there is growing interest in group III (Ga, In) and group IV (Sn, Ge) chalcogenides to expand the suite of layered materials. Much of the research to date has been carried out using flakes exfoliated from bulk crystals but techniques for wafer-scale epitaxial growth of single crystal monolayer and few layers films are rapidly developing.

Our work has focused on the epitaxial growth of 2D layered chalcogenides using gas source chemical vapor deposition (CVD) also referred to as metalorganic CVD (MOCVD). The process is carried out in cold wall reactor geometries at moderate pressures (100-700 Torr) using hydrides (H2Se, H2S) as the chalcogen source in a H2 carrier gas. In the case of TMDs, a multi-step method involving modulation of the metal hexacarbonyl precursor source flow rate was developed to independently control nucleation and lateral growth of domains at elevated temperature (>700°C) which is beneficial to enhance the surface diffusivity of transition metal adatoms. Using this approach, uniform, coalesced monolayer and few-layer TMD films (MoS2, WS2, MoSe2 and WSe2) were obtained on 2” sapphire substrates at growth rates on the order of ~1 monolayer in 10-60 minutes. In-plane X-ray diffraction demonstrates that the films are epitaxially oriented with respect to the sapphire. Post-growth dark-field transmission electron microscopy carried out on monolayers transferred from the sapphire reveals that the films consist of highly ordered micron-sized single crystal regions bounded by low angle grain boundaries. Epitaxial growth of indium selenide was also investigated using trimethyl indium (TMIn) and H2Se in H2. In this case, lower growth temperatures (<500°C) and lower reactor pressures (100 Torr) were necessary to reduce the extent of gas phase pre-reaction of precursors and obtain a stoichiometric film. Under these conditions, epitaxial growth of beta-In2Se3 was demonstrated on c-plane sapphire and (111) Si substrates with both island growth and step-flow growth modes observed. Prospects for utilizing MOCVD for the growth of epitaxial 2D heterostructures will also be discussed.

9:45 AM EL04.06.04
Substrate Directed Synthesis of MoS2 Nanocrystals with Tunable Dimensionality and Optical Properties Tomojit Chowdhury1, Jungkil Kim1, Erick Sadler1, Chenyang Li1, Tim Mueller1, Todd Brintlinger1, Hong-Gyu Park1 and Thomas J. Kempa1, 1Johns Hopkins University, United States; 2U.S. Naval Research Laboratory, United States; 3Korea University, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have demonstrated enormous potential in optoelectronic, catalytic, and device studies. Although “top-down” approaches can be used to define crystal morphologies and dimensions, the ability to tailor the physical properties of TMD crystals through explicit synthetic control is a major challenge. We introduce a gas-phase synthesis method that significantly transforms the structure and dimensionality of MoS2 crystals without lithography. Synthesis of MoS2 on Si (001) surfaces pre-treated with phosphine (PH3) furnishes high aspect ratio (~1:20) nanoribbons of crystalline 2H phase MoS2. The widths of the MoS2 nanoribbons can be systematically controlled in the range of 70 – 500 nm by varying the concentration of PH3 gas introduced during the Si (001) surface treatment step. Detailed kinetic studies along with adsorption energy
calculations indicate that the nature and concentration of the underlying Si–phosphide moieties are instrumental in transforming growth of MoS\textsubscript{2} from a conventional 2D triangular to quasi-1D morphology. Notably, the room temperature photoluminescence (PL) of 1D MoS\textsubscript{2} crystals exhibits an emission peak which is blue-shifted by 50 meV relative to that of 2D MoS\textsubscript{2} nanocrystals. Extensive structural, electronic, and optical characterization of these new materials was carried out through a combination of electron microscopies (ac-STEM, HAADF, EELS), scanning probe microscopies (AFM, NSOM), optical spectroscopies (confocal Raman, PL), and electrical transport measurements.

10:00 AM BREAK

10:30 AM *EL04.06.05
Growth of Chalcogenide Based Layered Materials by Molecular Beam Epitaxy Roman Engel-Herbert; The Pennsylvania State University, United States

Two dimensional layered materials offer remarkable properties that are not found in their three-dimensional counterpart. Given its simplicity mechanical exfoliation is conventionally applied to prepare these material systems in the monolayer limit. However, since the materials are not very robust, but rather mechanically soft and chemically reactive in ambient atmosphere – making them prone to a sizeable defect formation during the top-down preparation method – the utilization of a bottom-up approach is highly desirable to study the intrinsic properties in the monolayer limit. Molecular beam epitaxy (MBE) is an ideal method of choice; however the nucleation and growth of layered chalcogenide materials encompasses a specific set of challenges.

In this talk the growth kinetics specific to chalcogenide thin films is discussed and contrasted to the growth of other materials by MBE. Emphasis is placed on experiments to determine the temperature dependent sticking coefficient of the volatile chalcogenide element using a heated quartz crystal monitor to derive growth conditions to access self-regulated growth. Strategies to suppress the formation of twin domains during the layer nucleation stage and strategies to promote the growth of large single domains to achieve high quality monolayer and few layer materials are discussed using the specific examples of PtSe\textsubscript{2} on sapphire, Te on TiO\textsubscript{2} and FeSe on SrTiO\textsubscript{3}. Emphasis will be placed, how in-situ spectroscopic ellipsometry can be used as complimentary diagnostic tool to RHEED to optimize growth conditions and achieve high quality layered chalcogenide-based materials.

11:00 AM EL04.06.06
Growth and Characterization of Large-Area Ultrathin InSe Hadallia Bergeron, Linda M. Guiney, Megan E. Beck, David Lam, Chi Zhang, Silu Guo, Katherine Su, Vinayak Dravid and Mark C. Hersam; Northwestern University, United States

The lack of large-area synthesis methods for emerging 2D materials presents a significant challenge for nanoelectronic devices and systems. In particular, InSe is a semiconducting van der Waals (vdW) material that possesses exceptional band-gap tunability as a function of thickness in the ultrathin limit. Despite its desirable electronic properties, InSe is a relatively under-investigated 2D material, primarily due to the fact that high-quality samples have only been achieved via mechanical exfoliation as opposed to large-area ultrathin-film growth. While many of the extensively studied and synthesized vdW 2D material systems have relatively simple phase diagrams (e.g., MoS\textsubscript{2}), the complex phase diagram for InSe has hindered the development of large-area films, thus motivating more fundamental studies aimed at characterizing and understanding growth mechanisms.

Towards that end, we use diverse surface characterization techniques (e.g., X-ray photoelectron spectroscopy, Raman spectroscopy, atomic force microscopy, transmission electron microscopy, and selected area electron diffraction) and in operando X-ray diffraction to study the structural and compositional evolution of ultrathin InSe films grown by pulsed laser deposition with subsequent vacuum thermal annealing. By monitoring the post-deposition annealing temperatures, we rationally determine the synthesis conditions to realize ultrathin InSe films with high uniformity over large areas, controlled thickness, and no detectable impurities. Using this optimized method, ultrathin InSe films are patterned for the fabrication of top-gated field-effect transistors that demonstrate homogenous device behavior. Thus, our work provides a pathway to large-area ultrathin InSe films with high crystalline quality, thickness tunability, and generalizability to a wide range of substrates suitable for nanoelectronic applications.
Temperature-Controlled Phase Selection in Pulsed-Laser Deposited Gallium Sulfide Thin Films

Kazutaka Eriguchi1,2,3, Petra Specht1, Junqiao Wu1,2 and Oscar D. Dubon1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States; 3SUMCO Corporation, Japan

Gallium sulfide is a III-VI semiconductor with multiple stable phases including (layered) hexagonal and monoclinic, GaS and Ga2S3, respectively. The layered GaS crystal structure is composed of Ga-Ga and Ga-S covalent bonds that extend in two dimensions while interlayer bonding occurs by van der Waals interaction. With a room-temperature band gap of 2.6 eV, GaS has been used for a variety of applications requiring ultrathin layers including transistors and photodetectors and is an attractive candidate for flexible electronics. On the other hand, Ga2S3 exists mainly in the monoclinic form with covalent bonds in three dimensions (i.e., not layered) and a reported band gap of ~3.0 eV.

Thin films of GaS and Ga2S3 have been grown by a variety of methods including chemical vapor deposition, chemical vapor transport, chemical bath deposition. Each method has advantages and challenges. Until now, pulsed-laser deposition (PLD) has been considerably less explored, yet possesses characteristics that are attractive for the synthesis of layered materials. Specifically, PLD is a physical vapor process that enables the “digital” deposition of target materials due to the use of a pulsed laser as an energy source for the evaporation of source materials.

We demonstrate the selective, pulsed-layer deposition of hexagonal GaS and monoclinic Ga2S3 epitaxial films on sapphire substrates from a single Ga2S3 target under high vacuum conditions. Growth with substrate temperatures between 400 °C and 550 °C results in the formation of GaS films, indicating non-stoichiometric transfer from target to film (i.e., loss of sulfur presumably due to its high vapor pressure). Surprisingly, the stoichiometric transfer occurs for substrate temperatures above 650 °C but with a lower growth rate under otherwise the same growth conditions as those used to grow GaS. In the temperature window between 550 °C and 650 °C, films displayed a mixture of phases which is consistent with a monotonic decrease in the Ga:S ratio in films from 1:1 to 2:3. By changing the substrate temperature in this narrow growth range, we are able to synthesize heterostructures of GaS and Ga2S3, thereby providing the unprecedented opportunities to realize heterojunctions from a single materials system in a single growth process and to investigate the heteroepitaxy of two-dimensional crystals on three-dimensional crystals and vice versa.

Materials synthesis and characterization were supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division, under contract DE-AC02-05CH11231 within the Electronic Materials Program (KC1201). K.E. acknowledges support from SUMCO Corp., Japan.

Intergration Challenges for Transition Metal Dichalcogenides

Peter Litwin, Keren Freedy, Maria Sales, David Olson, Samantha Jaszewski, Shelby Fields, Jon Ihlefeld, Patrick Hopkins and Stephen J. McDonnell; University of Virginia, United States

The last 15 years has seen a renewed interest in layer materials with a new focus on their potential in nanoelectronic applications. These materials have a long history of use as dry lubricants and have been previously studied for their photoelectrochemical and photovoltaic properties. While there have been prior reports on monolayer 2D materials including ‘a single carbon hexagonal layer’ and ‘single-layer MoS2’, it was the seminal work of Novoselov and Geim that triggered this remarkable interest in monolayer 2D for nanoelectronics and it was the demonstration of a monolayer MoS2 based transistor in 2011 that sparked an exponential rise in publications on MoS2 and the subsequent increased interest in the transition metal dichalcogenide (TMDC) family in general.

The focus of this presentation will be on various integration challenges for TMDCs. These include the synthesis of TMDC thin films, the formation of metal contacts on these films, the deposition of high-k dielectrics on the TMDCs, and the synthesis of TMDCs on novel substrates. The presentation will include a summary of our parametric studies of WSe2 molecular beam epitaxy graphite which demonstrates that substochiometric is difficult to completely avoid without the use of seeding layers. We demonstrate the seeding layers not only prevent the formation of substochiometric material, but also dramatically improve the reproducibility of our growths.

In our metal-TMDC interface studies we build on prior work showing interface reactions with Ti and MoS2, to...
demonstrate how thin oxide layers can be used to engineering the interface, preserving a sharp interface while having a minimal impact on the thermal properties of the structures. We find that similar results are observed for WSe$_2$, but that some reaction with TiO$_x$ and WSe$_2$ is observed.

In our prior work we demonstrated the importance of functionalizing TMDCs prior to atomic layer deposition (ALD) of metal oxides to ensure a uniform layer. However in the present work we extend these studies to consider the thermal stability of the HfO$_2$-MoS$_2$ and HfO$_2$-WSe$_2$.

Finally we will present a summary of our growths of TMDC on a range of substrates, with a particular focus on the interface chemistry formation between WSe$_2$ and Ferroelectric hafnium zirconium oxide.

SESSION EL04.07: Layered Chalcogenides—Solid State Fundamentals

1:30 PM EL04.07.01
Imaging Structure-Directed Phonon Dynamics in MoS$_2$ with Ultrafast Electron Microscopy Yichao Zhang and David J. Flannigan; University of Minnesota, United States

The large elastic strains that can be sustained by van der Waals bonded layered materials (e.g., TMDs) cause significant modification of the electronic band structure through modulation of bond distances and crystal symmetries. This manifests as measurable variations in the electronic and optical properties [1,2]. In addition to static (i.e., time-invariant) strain, ultrafast transient strains can be induced in such materials via femtosecond (fs) photoexcitation. For example, in-plane atomic motions and out-of-plane interlayer coupling in MoS$_2$ have been studied with ultrafast reciprocal-space electron and X-ray diffraction [3,4]. Similarly, bright-field imaging in ultrafast electron microscopy (UEM) has been used to study the nucleation, propagation, and relaxation of coherent elastic strain waves in a number of TMDs arising from the release of impulsive local strain mediated by defects [5-7].

Here, we report the direct imaging with UEM of photoexcited localized anisotropic coherent acoustic-phonon dynamics in single, freestanding, multilayer MoS$_2$ flakes. Combining picosecond temporal resolution and nanometer spatial resolution in bright-field imaging, we observe and quantify both the in-plane nucleation and propagation of acoustic phonons and an interlayer low-frequency breathing mode spatially isolated and localized within two regions of different layer number and along two distinct crystallographic zone axes. Transient structural information induced via fs photoexcitation was extracted by monitoring Bragg diffraction-contrast motion within discrete, nanoscale regions. Propagating and stationary coherent contrast motion occurring within differently-oriented crystal regions occurs via excitation of both intralayer and interlayer phonon modes. The distinct dynamics are resolved within a single field of view and along a single incident electron wavevector. Isolation of the strongly-scattering coherent dynamics reveal a response delay of a few ps for the intralayer mode, indicating a coupling to, and excitation of, the low-frequency interlayer breathing mode. Further, the sensitivity of the measurement is such that a rapid dephasing of the breathing mode relative to an adjacent nanoscale crystal region is observed, indicative of a difference of one to three MoS$_2$ layers and a lag in energy transmission between the crystal boundaries. These results provide new insights into the microscopic nature of intra and interlayer acoustic-phonon dynamics and mode coupling in MoS$_2$ and layered materials in general, especially with respect to the dramatic influence of nanoscale morphology on photoinduced strain [8].

[8] This material is based upon work supported by the National Science Foundation under Grant No. DMR-1654318. Partial support was provided by the Arnold and Mabel Beckman Foundation in the form of a Beckman Young Investigator Award.

1:45 PM EL04.07.02
Sub-Nanosecond Crystallization of Melt-Quenched MoS₂—An Ab Initio Molecular Dynamics Study
Paul Fons¹², Alexander V. Kolobov³¹, Yuta Saito¹, Yuji Sutou⁴ and Muneaki Hase⁵; ¹National Advanced Institute of Science and Technology, Japan; ²Japan Synchrotron Radiation Institute (SPring-8), Japan; ³Herzen State Pedagogical University, Russian Federation; ⁴Tohoku University, Japan; ⁵University of Tsukuba, Japan

MoS₂ is a two-dimensional transition metal dichalcogenide that has gathered much attention with the shift in the research community’s focus from metallic graphene to alternative two-dimensional materials with semiconducting properties. With the lifting of inversion symmetry, monolayer MoS₂ has a direct bandgap of 1.8 eV leading to strong light-matter interaction. In addition, the 2D character of the monolayer leads to reduced dielectric screening and the resulting enhancement in Coulomb interaction leading to large excitonic effects. The high melting point of MoS₂ of more than 1450 K, however, has led to challenges in the growth of thin films. In particular, the large vapor pressure of Sulphur in combination with the high growth temperatures required for film growth have been problematic underscoring the need for a non-conventional approach to growth. In this presentation, ab-initio molecular dynamics is used to show that crystalline MoS₂ can be grown from the amorphous phase on sub-nanosecond time scales with the van der Waals (vdW) gaps serving to strongly orient the resulting structure. The plane wave Vienna ab-initio simulation package (VASP) was used to first form a melt-quenched amorphous phase. The amorphous phase was then heated to just below the melting point and the dynamics of the system were studied. The formation of ABAB rings of Mo-S bonds was observed to precede the emergence of vdW gaps leading to the formation of well defined lattice planes. In the presentation, we will explore details of growth process and probe critical interactions that allow the formation of the crystalline phase on sub-nanosecond time scales using confined thin film amorphous opening up new avenues for large scale growth of 2D MoS₂.

2:00 PM EL04.07.03
Thermal Degradation of Monolayer MoS₂ on SrTiO₃ Supports
Wenshuo Xu¹₂ and Jamie Warner¹; ¹University of Oxford, United Kingdom; ²Beijing Institute of Technology, China

Monolayer MoS₂ is a wide-bandgap semiconductor suitable for use in high-temperature electronics. It is therefore important to understand its thermal stability. We report the results of a study on thermal degradation of MoS₂ monolayers supported on SrTiO₃ substrates in ultrahigh vacuum (UHV). Our studies were carried out on the (111), (110), and (001) terminations of SrTiO₃ substrates, but MoS₂ was found to degrade on all of these surfaces in a similar way. By scanning tunneling microscopy, we show that MoS₂ monolayer crystals maintain their structure up to 700 °C under UHV, at which point triangular etch trenches appear along the 〈2-1-10〉 lattice directions (i.e., sulfur-terminated edge directions) of the MoS₂ crystals. The trenches are due to the preferential loss of sulfur, allowing molybdenum to be oxidized by oxygen originating from the SrTiO₃ substrate. The intensity of the A-exciton photoluminescence (PL) peak and the E₂g¹ and A₁g Raman signals reduced significantly following treatment at this temperature. The crystals continue to degrade at higher annealing temperatures in UHV until they transform into MoO_x (x = 2–3) particles at 900 °C, and the optical properties characteristic of MoS₂ are lost entirely in PL and Raman spectra. The initial sulfur loss and the formation of MoO₃ are confirmed by X-ray photoelectron spectroscopy. The macroscopic triangular shapes of the MoS₂ crystals are retained until the residual particles evaporate at above 1000 °C. The optical properties of the 700 and 800 °C UHV-annealed samples can be partially recovered upon sulfur annealing. This work establishes a pathway of the thermal degradation of SrTiO₃-supported monolayer MoS₂ in vacuum from smooth MoS₂ crystals to crystals with sulfur vacancies (etch trenches), followed by MoO₃ and finally MoO₃ particles. We also demonstrate how sulfur annealing can be used to heal the defects.

Electronic and Photonic Properties of Emerging Low-Dimensional Chalcogenides Materials \textit{Han Wang};
University of Southern California, United States

In this talk, I will discuss our recent work in studying the electronic and photonic properties of emerging low-dimensional chalcogenides materials, and in developing them for novel semiconductor device applications. The first part of the talk will focus on discussing our recent research on the phonon-spin and phonon-electron coupling in chalcogenides ferromagnetic monolayer materials and its electronic device applications. In the second part of the talk, I will discuss our work on studying the unique optical properties of chalcogenides perovskite BaTiS$_3$ over a broad wavelength range from mid-IR to visible, and the new non-linear photonic device applications it can enable. I will conclude with remarks on promising future research directions of low-dimensional chalcogenides materials, and how these newly developed low dimensional materials may enable new functional electronic and photonic devices for sensing, communication, and computing applications.

3:15 PM EL04.08.02
2D Rules—Band Gap Engineering in Weakly Interacting van der Waals Heterostructures \textit{Francis H. Davies,}
Ned T. Taylor, Conor J. Price, Shane G. Davies and Steven P. Hepplestone; University of Exeter, United Kingdom

The band gap is of paramount importance to almost all of the electronic and optical properties of semiconducting materials. By controlling the size of the band gap and their electronic structure, we can control both the transport properties and the optical interactions of such materials. The ability to energetically control electrons in solid-state devices is pivotal in the fields of sensing, renewable energy [1], information processing and communications technology [2]. Here we present the rules of 2D band gap engineering in 2D heterostructures. Our insights offer the potential of engineering not just the band gap, but the electronic dispersion itself; making it far more versatile than strain engineering of band gaps.

The field of 2D semiconductors has been of growing research interest in recent years, but 2D heterostructures have only recently become experimentally viable [3]. We have performed a large scale first principles study of many transition metal dichalcogenides and other 2D semiconductors using density functional theory. These 2D layered heterostructures demonstrate weak inter-layer interactions. Due to this, the band structures of individual layers of a heterostructure have a high fidelity to their isolated counterparts. We show that a layered heterostructure will, therefore, have a dispersion which consists of an overlay of its components’ band structures with one key change due to interlayer interaction which we discuss at length. We determine that the electronic dispersions of 2D layered heterostructures can be tailored by layer composition, and demonstrate a wide range of potentially attainable tunable band structures.

Anisotropic Optical Properties of 2D Silicon Telluride \textit{Romakanta Bhattarai, Jiyang Chen, Thang B. Hoang,}
Jingbiao Cui and Xiao Shen; University of Memphis, United States

Silicon Telluride (Si$_2$Te$_3$) is layered semiconductor material with a unique crystal structure where Si atoms form dimers to fill the sites between the hexagonally close-packed Te atoms.\textsuperscript{1} Theoretical investigations showed that Si dimers can rotate between four possible orientations within the Si$_2$Te$_3$ layer, giving rise to a unique structural variability that could have potential new applications in electronic and optoelectronics devices.\textsuperscript{2} Recently, two-dimensional Si$_2$Te$_3$ multilayers, along with nanoplate and nanowires have been reported.\textsuperscript{3} Combining the reduced dielectric screening from low dimensionality and the structural variability from Si dimer rotation, the optical

Final Program 1/13/2020  243
properties of 2D Si\(_2\)Te\(_3\) is particularly interesting. In this study, we report a combined computational and experimental investigation of the optical properties of 2D Si\(_2\)Te\(_3\). Using many body GW approximation and Bethe-Salpeter equation (BSE), we obtain the dielectric constants of bulk and monolayer of Si\(_2\)Te\(_3\). A strong optical anisotropy is discovered. The imaginary dielectric constant in the direction parallel to the Si-Si dimers is half of the value perpendicular to the dimer. We show this effect originates from the particular compositions of the wavefunctions in the valence and conduction bands. The optical measurement of the absorption spectra of 2D Si\(_2\)Te\(_3\) nanoplates shows modulation of the absorption coefficient under 90-degree rotation, confirming the computational results. We also found that the BSE calculations reduce GW quasiparticle band gap by 0.3 eV in bulk and 0.9 eV in the case of a monolayer, indicating a large excitonic effect in Si\(_2\)Te\(_3\). Furthermore, including the excitonic effect in bulk calculations significantly reduces the imaginary dielectric constant in the out-of-plane direction, indicating a strong effect of Coulombic interaction of the out-of-plane excitons in the case of Si\(_2\)Te\(_3\) multilayers. The results show rich features and tunability in the optical properties of 2D Si\(_2\)Te\(_3\).

A Physical MoS\(_2\) Sensor Simulation Using Scanned Gate Microscopy Steven G. Noyce, James Doherty and Aaron D. Franklin; Duke University, United States

The field of nanoelectronic chemical sensors faces a gap between theory and observation in applied sensor demonstrations. For example, theoretical predictions of the operating point at which maximal signal-to-noise ratio (SNR) will be obtained are at odds with trends of measured SNR versus gate voltage. This work seeks to bridge this gap for the case of molybdenum disulfide (MoS\(_2\)) chemical sensors by studying a MoS\(_2\) device that is influenced by a controlled local charge, which simulates an analyte. The extensive control available in this physical sensor simulation provides pathways to explore and resolve discrepancies between computational sensor simulations and demonstrated sensors. Realizing this level of control with sub-nanometer and pico-amp precision required the development of an advanced characterization system (a customized scanning gate microscopy setup), which was then utilized to test the response of MoS\(_2\) field-effect transistors (FETs) in a variety of configurations. Sensitivity of the device to a local charge was mapped across locations near the device surface, revealing localized sensitive “hot spots” within the 2D channel. Similar maps were taken across a range of operating points and charge-to-surface distances, allowing for the extraction of sensor metrics. For instance, the SNR was shown to peak in the transistor subthreshold regime, reaching over 4 times its value in the linear regime. The comparison of these controlled measurements with electrostatic and 2D current flow models leads to increased understanding of the behavior of MoS\(_2\) FETs in sensors, indicating directions for the optimization of future sensor design and operation.

Controlling Light-Matter Interactions in Chalcogonede-Based Topological Semimetals—Novel Physics to Devices Ritesh Agarwal; University of Pennsylvania, United States

Can one control photoresponse in materials via patterning optical intensity distribution and polarization? In this talk, we explore this idea on a new class of topological material, Weyl semimetals (WSMs). WSMs are a family of gapless topological materials with broken inversion and/or time reversal symmetry in which the conduction and valence bands cross at single points in momentum space, which are called the Weyl nodes. The electronic bands are topologically nontrivial and display linear dispersion around the Weyl nodes, hosting unique quasiparticles called the Weyl fermions with interesting properties. The optical excitation properties of WSMs are only starting to be explored. We will introduce a new second order nonlinear optoelectronic probe, which we call spatially dispersive circular photogalvanic effect (s-CPGE) and demonstrate its sensitivity to detailed band features owing to its unique excitation mechanism. In WSMs such as MoTe2 and MoW1-xTe2 (x=0.3, 0.9) in the inversion symmetry broken...
For the total energy calculations using DFT, we use the Hubbard temperature for the configurations that yield a ferromagnetic ground state. We simulate their magnetic phase change using lattice Monte-Carlo simulations. Finally, we extract the Curie temperature of iron (Fe) doped WSe$_2$ as high as 307 K and manganese (Mn) doped WSe$_2$ as high as 232 K.

Clusters of dopant atoms in monolayer WSe$_2$ have attracted immense attention in the recent past for their possible use in future, energy-efficient, spintronic devices. A class of 2D-DMS candidates are transition-metal dichalcogenides (TMDs), substitutionally doped with magnetic-transition-metals (Cr, Fe, Mn, etc.). Especially promising are TMDs based on heavy elements like tungsten (W) and selenium (Se). Thanks to their strong spin-orbit interaction, they easily mediate magnetic interactions among the dopant transition-metal atoms.

In this work, we investigate magnetism in magnetically doped WSe$_2$ monolayers using Density Functional Theory (DFT). We investigate various doping concentrations and various configurations with different relative positions of the dopant atoms. Specifically, we investigate the effect of clustering of the dopant atoms on the magnetic properties of doped monolayer WSe$_2$. In our computational model, we first determine the magnetic ground state of the doped WSe$_2$ monolayers by comparing the total energies of various magnetic configurations calculated using DFT. Next, we simulate their magnetic phase change using lattice Monte-Carlo simulations. Finally, we extract the Curie temperature for the configurations that yield a ferromagnetic ground state.

For the total energy calculations using DFT, we use the Hubbard $U$ model within DFT+$U$ to take into account the enhanced electron-correlation energy of the dopant atoms. The electron-correlation energy in the $d$ orbitals of the magnetic-transition-metals significantly impacts the magnetic order of the material system. To correctly account for the electron-correlation energy of the dopant magnetic transition-metal atoms, we first calculate the Hubbard $U$ parameter for each configuration using the linear-response method. Next, we use the calculated Hubbard $U$ parameters for subsequent total energy calculations using DFT+$U$.

For structures with a ferromagnetic ground state, we quantify the magnetic order of doped WSe$_2$ with different doping configurations by calculating their Curie temperature using a two-step approach. In the first step, we build the classical Heisenberg Hamiltonian by obtaining the exchange interactions among the dopant transition-metal atoms. To account for the long-range interactions, we use a parameterized function to define the exchange interactions with asymptotic decaying exponential behavior. We optimize the parameters of the functional form representing the exchange interactions by least square fitting the Heisenberg Hamiltonian to the total energy difference between the magnetic and the non-magnetic configurations obtained from the DFT+$U$ calculations. In the next step, we simulate the magnetic phase change of the classical Heisenberg Hamiltonian using the lattice Monte-Carlo method to obtain the Curie temperature.

From our DFT+$U$ calculations, we additionally extract formation energies, showing that the clustering of the dopant atoms is energetically favorable in monolayer WSe$_2$. Further, we find that the magnetic order strongly depends on the type of dopant transition-metal atoms and their relative position in the monolayer WSe$_2$. The strong positional dependence of the dopant atoms on the magnetic order is the result of a trade-off between the minimization of the kinetic energy and the exchange energy. Finally, we conclude by calculating the Curie temperature for various doped structures with ferromagnetic ground states. We predict the optimum doping conditions necessary for obtaining a Curie temperature which exceeds room temperature in transition-metal doped monolayer WSe$_2$. Among our studied magnetic configurations, we find a Curie temperature of iron (Fe) doped WSe$_2$ as high as 307 K and manganese (Mn) doped WSe$_2$ as high as 232 K.
Electron-Phonon Interactions in Defective Germanium Selenide  
Tianlun Huang, Arielle Cohen, David K. Lewis and Sahar Sharifzadeh; Boston University, United States

We utilize first-principles density functional theory (DFT) and many-body perturbation theory (MBPT) to study the optoelectronic properties of monolayer germanium selenide (GeSe), emphasizing the role of point defects and electron-phonon interactions; two phenomena that will be present in and can dominate the properties of real materials. We systematically study a series of charged vacancies, their trap state energies, and their impact on optical absorption. Additionally, by approximating the role of electron-phonon interactions, we determine how the defect-induced trap states are modified by the presence of phonons at finite temperature. We determine that the excitonic properties of the material are significantly affected by the presence of defects and phonons, with implications for devices fabricated using this material system.
it is extremely important to understand the key features behind such subtle sources of structural defects. Distinguishing features related to the weakness of vdW forces, and hence relevant to most systems based on vdW epitaxy, and features specifically related to some particularities of the system under investigation.

Here, several x-ray diffraction tools are combined to investigate defects in bismuth telluride films grown by molecular beam epitaxy on BaF2 (111) substrates. Intrinsic topological surface states have already been observed in such films [1], making them good candidates for applications in spintronics or quantum computing. Compositional fluctuation, twinned domains, and bulk free carriers are among the main problems reported in these films [2]. Desorption of tellurium is the root of compositional fluctuation. But, from tellurium vacancies to bismuth rich phases there are a whole gamut of possible processes involved. Antisite occupation can follow the introduction of vacancies in the vdW gaps, promoting films full of point defects detrimental to lattice perfection. At some instant, lattice energy is minimized by turning point defects into bismuth bilayers (BLs). This is a critical instant in terms of free carriers since films with only point defects, only BLs, or coexisting point defects and BLs may have completely different behaviors. Twinned domains can be a simple consequence of low degree of lateral ordering in vdW epitaxy, or of any other source of lateral inhomogeneities still to be identified. Moreover, lattice misfit can be slightly different in bismuth rich films [3], giving the opportunity to study the actual impact of lattice misfit in vdW epitaxy.

EL04.09.03 Polariton Propagation and Exciton Phase Correlations in an Optical Microcavity with Embedded Topologically-Disconnected Transition Metal Dichalcogenide Microflakes Yamuna Paudel¹, Shaina Raklyar¹, Yuri Lvov², David W. Snoke³ and German V. Kolmakov⁴; ¹NYC College of Technology CUNY, United States; ²Rensselaer Polytechnic Institute, United States; ³University of Pittsburgh, United States

Due to strong light-matter interactions and exciton stability, transition-metal dichalcogenides (TMD) provide a platform for optoelectronic applications at room temperatures. By considering coupled dynamics of cavity photons and TMD excitons, we studied exciton-polariton propagation in an optical microcavity with an embedded TMD layer. Specifically, we considered the case where the TMD layer is non-uniform and consists of a set of separate, topologically disconnected microflakes. Via numerical simulations we demonstrated that polaritonic modes can propagate in the system if the TMD coverage is high enough. However, the polaritonic excitation spectrum is broadened compared to that in the case of an ideal homogenous embedded TMD layer. We also found that although the TMD flakes are disconnected, the phases of the excitonic wave functions in different flakes are strongly correlated. We attribute the latter to the exchange by cavity photons emitted and re-absorbed by the TMD excitons. Finally, we discuss the possibility to use the TMD polaritonic system in optoelectronic applications. This work was supported in part by the Department of Defense under grant No. W911NF1810433.

EL04.09.05 Resistless Patterning Techniques for Transition Metal Dichalcogenides Jian-An Ke, Kevin Bogaert and Silvija Gradečak; Massachusetts Institute of Technology, United States

Two-dimensional (2D) materials such as graphene and transition metal dichalcogenides (TMDs) exhibit many interesting properties that make them promising materials for novel electronic and optical applications. The application space could be further broadened by having the ability to combine these materials into more complex heterostructures. Conventional patterning methods rely on coating a polymer-based resist that is then exposed (by light or electron beam), developed, and selectively removed. Each of these steps adds to the process complexity, and in the case of 2D materials, potential materials damage. A resistless patterning technique is therefore desirable, due to fewer potentially damaging processing steps, which naturally improves yield and is more cost-efficient.

In this work, we demonstrate two distinct direct-write patterning methods for 2D TMD heterostructures grown by chemical vapor deposition (CVD). The first approach is based on laser-induced method for controlling the location
of MoS2 nucleation within patterned WS2. We investigate WS2 defect formation as a function of the laser power and wavelength and demonstrate the site selectivity of subsequent MoS2 growth. In an effort to push the patterning resolution, the second resistless technique uses electron beam to directly pattern MoS2 on Si/SiO2 substrates. By exposing the substrate by electron beam, we show that CVD-grown MoS2 preferentially nucleates at the exposed patterns. We will discuss the underlying mechanisms that govern both patterning methods, properties of the resulting TMD materials, resolution limits, as well as the application for more complex TMD heterostructures. These direct-write technique will simplify the process of heterostructure patterning and enable the routine fabrication of complex device architectures.

**Feasibility of Layer-Number Determination of Few to Monolayer MoS2 via Combined Simulation and Electron Diffraction Experiments**

Yichao Zhang and David J. Flannigan; University of Minnesota, United States

Properties of transition metal dichalcogenides (TMDs) are sensitively dependent upon a number of structural and morphological features within the few to monolayer limit. For example, the electronic and optical properties of MoS2 can be tuned via variation in single layer number and applied elastic strain [1,2]. Owing to this sensitive dependence at the single-layer level, development of methods for precisely and accurately determining local layer number is important for unambiguously determining the relationship between function and structure. Among other viable methods (e.g., Raman spectroscopy and atomic force microscopy), transmission electron microscopy (TEM) is an especially attractive platform for such measurements, as it enables combined comprehensive characterization and correlative in situ measurements of the electronic and structural properties, with atomic- to millimeter-scale spatial resolution. For layered materials, a practical approach in TEM for determining layer number involves analysis of relative Bragg-spot intensities in parallel-beam electron diffraction (PBED) patterns over a range of specimen tilt angles [3]. Such an approach has been explored via simulations for few and monolayer MoS2 [4], while experimental methods aided by prior knowledge of layer number have been applied [5]. Accordingly, systematic experimental measurements employing PBED in TEM on MoS2 specimens with initially unknown thicknesses, as directly compared to simulations, are needed to establish the practical feasibility, accuracy, and precision of such an approach.

Here, we combine PBED experiments in TEM with simulations to systematically study the robustness of the specimen tilt-angle approach for determination of layer number at the single-layer level in MoS2. Bragg-spot intensities as a function of tilt angle were simulated through calculation of the associated crystal shape function of the reciprocal-space rods and the structure factors, following Mkhoyan and co-workers [4]. Few and monolayer specimens were prepared using mechanical exfoliation, with subsequent mounting onto holey SIN TEM membranes. Bragg-spot intensities for the \{100\} and \{110\} families of planes were mapped over a wide range of tilt angles and for different tilt axes (with respect to a particular in-plane crystallographic direction). Overall, agreement between experiments and simulations were good for an MoS2 monolayer, indicating the method may be practically useful for identifying such specimens. However, deviations ranging from subtle to severe were observed with increasing layer number, indicating the approach becomes increasingly limited as sensitivity of Bragg-spot intensities and tilt angle to layer number decreases with increasing thickness. Potential sources of error and deviation from simulated results will be discussed [6].

[6] This material is based upon work supported partially by the National Science Foundation under Grant No. DMR-1654318 and partially by the National Science Foundation through the University of Minnesota MRSEC under Award Number DMR-1420013. Partial support was also provided by the Arnold and Mabel Beckman Foundation in the form of a Beckman Young Investigator Award
We demonstrate, for the first time, wafer-scale graphene/MoS$_2$ heterostructures prepared by chemical vapor deposition (CVD) and their application in vertical transistors and logic gates. A CVD-grown bulk MoS$_2$ layer is utilized as the vertical channel, whereas CVD-grown monolayer graphene is used as the tunable-work-function electrode. The short vertical channel of the transistor is formed by sandwiching bulk MoS$_2$ between the bottom indium tin oxide (ITO, drain electrode) and the top graphene (source electrode). The electron injection barriers at the graphene-MoS$_2$ junction and ITO-MoS$_2$ junction are modulated effectively through variation of the Schottky barrier height and its effective barrier width, respectively, because of the work-function tunability of the graphene electrode. The resulting vertical transistor with the CVD-grown MoS$_2$/graphene heterostructure exhibits excellent electrical performances, including a high current density exceeding 7 A/cm$^2$, a subthreshold swing of 410 mV/dec, and a high on-off current ratio exceeding 10$^3$. The large-area synthesis, transfer, and patterning processes of both semiconducting MoS$_2$ and metallic graphene facilitate construction of a wafer-scale array of transistors and logic gates such as NOT, NAND, and NOR.

**Spray-Deposited Molybdenum Disulfide Nano flakes Aiming Energy Storage Devices**

Maykel d. Klem, Gabriel Nogueira, Caroline Sousa and Neri Alves; São Paulo State University (UNESP), School of Technology and Sciences, Brazil

Among a variety of 2D graphene-like materials, molybdenum disulfide (MoS$_2$) has attracted much attention due to its remarkable physical, electrical and optical properties [1]. MoS$_2$ is a layered material member of the transition metal dichalcogenides family and presents a direct bandgap of 1.8 eV when in monolayer. Furthermore, MoS$_2$ can produce high specific area nanostructures and presents great electrochemical performance [2]. These are desirable features for application in energy storage devices. However, the mass production of large-area electrodes based on MoS$_2$ is a major problem. Here we present the synthesis and characterization of MoS$_2$ nano flakes deposited over stainless steel substrates by spray. We obtained the MoS$_2$ by hydrothermal synthesis, using thiourea and sodium molybdate dihydrate as precursors. The resulting black powder was collected by centrifugation and washed several times with water and ethanol. The obtained material was exfoliated in a solution of water and isopropanol (30%wt.) assisted by sonication. After 3 h of sonication, the dispersion was centrifuged at 5000 rpm over 1 h and the supernatant was collected. The film deposition was carried out by transferring the as-prepared dispersion (supernatant) to an airbrush coupled to a modified 3D printer base with in-line displacement. We produced a supercapacitor with the spray-deposited MoS$_2$, using the stainless-steel substrate as the current collector. We used a gel-like electrolyte based on Poly (vinyl alcohol) (PVA) and phosphoric acid (H$_3$PO$_4$). SEM images showed a flower-like structure for the MoS$_2$ black powder collected from the autoclave, which is broken into nanoflakes during the exfoliation process. XDR analyses showed that the sprayed films are highly crystalline, presenting the characteristics peaks of the hexagonal semiconducting microstructure (2H-MoS$_2$). Preliminary tests showed a specific capacitance of 18 F/g for the supercapacitor. The device also exhibited a good electrochemical behavior over cyclic voltammetry (C-V) measurements. In conclusion, here we demonstrated the production and characterization of spray-deposited films based on MoS$_2$ nanoflakes and its application as an energy storage device electrode.

**Atomic and Electronic Structure of the Edges of Bulk and Monolayer Tin disulfide (SnS$_2$)**

Tao Yan, Pratap M. Rao and Aaron Deskins; Worcester Polytechnic Institute, United States

Because of its two-dimensional structure and semiconducting properties, tin disulfide (SnS$_2$) is of interest for applications in electrochemical catalysis and sensing, as an electron transport layer for photovoltaics, and as an active material in photodetectors and thin film transistors. While the atomic and electronic structure of the basal planes of bulk and monolayer SnS$_2$ are well known, the same is not known for the edges, which could have a major influence on the performance of SnS$_2$ in the aforementioned applications. This paper reports on density functional...
theory (DFT) simulations and experimental measurements of the atomic and electronic structure of the edges of bulk and monolayer SnS₂ under different chemical conditions. We found that, with increasing sulfur coverage, the band gap of SnS₂ edges becomes smaller and there’s a transition from indirect to direct bandgap of bulk SnS₂ edges and form indirect to direct to indirect bandgap of monolayer SnS₂ edges. These results thereby determined the influence of chemical synthesis conditions on the electronic structure of the edges.

EL04.09.10
2D Chalcogenide Perovskites—Atomic and Electronic Structures Chen Ming and Yi-Yang Sun; Shanghai Institute of Ceramics, Chinese Academy of Sciences, China

Perovskite materials are intrinsically two dimensional, as any termination along two parallel (100) surfaces with a finite thickness could produce a self-passivated slab, which is not too different from the widely studied transition-metal dichalcogenides. The stacking of such slabs gives rise to the so-called Ruddlesden-Popper phase. In this work, we perform a systematic study on the atomic and electronic structures of such slabs (or 2D chalcogenide perovskites) following a generalized Glazer’s notation used for bulk perovskites. The pattern of the octahedron distortion in thin slabs is found to be distinctly different from that in bulk, which in turn affects the electronic structures. The thermodynamic stability and the effect of strain (in the case of freestanding slabs) and substrate (in the case of epitaxial growth) are studied based on density functional theory calculations. Comparison with halide and oxide perovskites will also discussed in this talk.

EL04.09.11
Heterojunction of 2D-MoS₂ with p-Type MnO Quantum Dots for Improved Photoresponse Somak Mitra, Yusin Pak, Naresh Alaal, Bin Xin and Iman Roqan; King Abdullah University of Science and Technology, Saudi Arabia

Photodetection characteristics can be improved by optimized heterojunction architecture in photodetector device. A two-dimensional (2D) platform material can be used for stably transferring the photogenerated signals into circuitry with a quantum confined nanostructure material from which photonics aspects and enhanced absorption can be exploited. In this work, we will present a heterojunction device structure of 2D molybdenum disulfide (2D-MoS₂) and manganese oxide quantum dots (MQDs). Solution-processed P-type manganese oxide quantum dots (MQDs) with a mean diameter of 4.9 nm are synthesized by femtosecond laser ablation (FLA). MQDs were uniformly spray-coated onto the 2D-MoS₂ to fabricate the active layer. The p-n junction structure of n-type 2D-MoS₂ and p-type MQDs reveal a significantly enhancement in the photoresponse of the photodetector by 2-5 folds. At the same time the photoresponse in the ultraviolet region has been improved due to MQDs. The dark current of the photodetector device is reduced by heterojunction structure compared to bare 2D-MoS₂ photodetector. This work revealed that solution-processed quantum dots hybridized with 2D material can lead to different high-performance flexible and cost-effective optoelectronic, sensor devices for large scale.

EL04.09.12
Building an All-Sulfide TaS₂/Cu₂-II-Sn-S₄/CdS Solar Cell and Putting it on Silicon Andrea Crovetto, Rasmus Nielsen, Alireza Hajijfarassar, Ole Hansen, Brian J. Seger, I.B. Chorkendorff and Peter Vesborg; Technical University of Denmark, Denmark

A few transition metal dichalcogenides are high work-function metallic compounds and could therefore be effective hole contacts in a variety of (opto)electronic devices. Nevertheless, when considering - for example - the field of photovoltaics, it is difficult to find reports of conductive contacts that are not elemental metals or transparent conductive oxides. Here, we incorporate the metallic compound TaS₂ into the device structure of emerging photoabsorbers (Cu₂BaSnS₄ and Cu₂SrSnS₄) and fabricate all-sulfide solar cells. Compared to reference cells built with a standard elemental metallic contact (Mo), the all-sulfide solar cells are more efficient by about 10% relative. We will discuss some of the properties of the TaS₂ hole contact, its stability, and the possible reasons for the efficiency improvement.

For the growth of Cu₂BaSnS₄ and Cu₂SrSnS₄ we propose an oxide precursor route involving thermal conversion of sputtered oxide films (Cu₂BaSnO₄ and Cu₂SrSnO₄) in an H₂S atmosphere at the same temperature normally used for the more common non-oxide precursors. Interestingly, Cu₂BaSnS₄ and Cu₂SrSnS₄ crystallize in a trigonal structure where Cu, Ba(Sr), and Sn have distinct coordination environments. This major structural difference from the well-studied tetrahedrally-coordinated kesterite Cu₂ZnSnS₄ implies that substitutional defect formation is in general
unfavorable in Cu$_2$BaSnS$_4$ and Cu$_2$SrSnS$_4$. In fact, both compounds are found to have sharper absorption and emission edges than kesterite, and their room-temperature photoluminescence peak is well aligned to their band gap. Finally, there is a long-standing dream of depositing sulfide semiconductors as wide band-gap absorbers on silicon solar cells, in order to realize highly efficient double-junction (tandem) cells. Progress towards this ambitious goal has been hampered by the relatively low efficiency of sulfide absorbers, and by integration issues with the Si bottom cell due to the relatively high temperatures needed to grow and crystallize many sulfides. Here we attempt to address the second issue by incorporating a very thin TiN diffusion barrier between the two sub-cells, which helps preserve the silicon cell during a sulfurization process at 550°C. Efficiencies up to 3.3% for Cu$_2$ZnSnS$_4$/Si tandems have been reached so far when incorporating the TiN barrier layer.

EL04.09.13
Spontaneous Nanopattern Development Directed by Interfacial Light Absorption Anisotropy
Azhar I. Carim, Nicolas A. Batara, Anjali Premkumar, Madeline C. Meier, Kathryn R. Hamann, Harry A. Atwater and Nathan S. Lewis; California Institute of Technology, United States

Photoelectrodeposition of Se-Te alloys using unstructured illumination spontaneously generates nanopatterned films with significant long-range order. The feature sizes, periodicities, anisotropies, and orientations of the nanoscale pattern can be selected by manipulating the input optical excitation. Isotropic morphologies consisting of ordered arrays of nanopores were generated using unpolarized and circularly-polarized illumination whereas linearly-polarized light resulted in highly-anisotropic lamellar-like morphologies with the in-plane orientation of the patterns controlled by the direction of the light polarization. Elliptical polarization inputs effected additional morphological complexity. The pattern periodicity was encoded by the illumination spectral profile. A single periodicity in single spatial direction was only generated even with the use of broadband and multimodal spectral profiles and the periodicity was found to be sensitive to all investigated tuning of such profiles. Structures with nonequal periodicities in the two orthogonal in-plane directions could also be generated and both periodicities could be independently controlled. The deposition process was assessed computationally using a two-step iterative model wherein a finite-difference time domain method was first used to calculate the spatially-varying levels of light absorption in the growing structure. This instructed a Monte Carlo method in which deposition was simulated to occur preferentially near areas of high localized light absorption. These computational results matched the experimentally observed patterns indicating that pattern development was directed by evolution of interface to maximize anisotropic light collection.

Systematic Prediction of the Electronic and Magnetic Properties of Vacancy, Antisites and Defect-Complexes of Monolayer CrS$_2$, MoS$_2$ and WS$_2$
Emmanuel Igumbor, Guy M. Dongho-Nguimdo, Evans M. Benecha, Abdulrafiu Raji and Enrico B. Lombardi; University of South Africa, South Africa

Graphene is one of the first two-dimensional (2D) materials to be experimentally synthesized. Since then, 2D materials have attracted great attention because of their unique physical properties: ability to be used for future nano-electronic, optoelectronics and other industrial applications. However, graphene has a major deficiency due to its gapless band structure, which limits its use for applications in semiconductor devices. Recently, 2D transition metal dichalcogenides (TMDs) materials have attracted significant interest. Research has shown that novel electronic and photonic devices have been demonstrated using 2D TMDs. This discovery paved the way for intense scientific consideration of 2D mono layers CrS$_2$, MoS$_2$ and WS$_2$. Point defects are inevitable in in chemically grown 2D materials due to the imperfection of the growth process. Defects are inevitably introduced during the synthesis of TMDs by means of chemical vapor deposition. Point defects including sulphur vacancies, transition metal vacancy, antisites and defect-complexes as well as how they influence the electronic and optical properties of CrS$_2$, MoS$_2$ and WS$_2$ are not well known. In this report, we predicted the electronic, magnetic and structural properties of intrinsic point defects in CrS$_2$, MoS$_2$ and WS$_2$ that may be observed under certain conditions. Density functional theory calculations were performed to model the structural and electronic properties of defects in CrS$_2$, MoS$_2$ and WS$_2$. The ultrasoft psuedopotential was used to separate the valence electron from the core electrons and the generalized gradient approximation was used as the exchange correlation functional.

Whereas sulphur vacancy is predominant energetically favorable in the S-poor chemical condition, the transition metal (TM) vacancy is energetically more favorable in the S-rich chemical condition. While the antisites of the CrS$_2$
and WS$_2$ are energetically more favorable when a chalcogen atom is replace by a TM atom of the host, the antisites of the MoS$_2$ on the other hand, is energetically more favorable when a Mo is replaced by an S atom. The antisites show that they are sensitive to chemical rich environment. The S$_{TM}$ and TM$_S$ are desirable in the S-rich and TM-rich chemical limit conditions, respectively. While the V$_{CS}$, V$_{MoS}$ and V$_{WS}$ are stable complexes with respect to their binding energies, the V$_{TM}M_S$ and V$_{VS}M_T$ are more energetically favorable in the N configurations. Introduction of defects in CrS$_2$, MoS$_2$ and WS$_2$ modulated their wide band gaps. While sulphur vacancies in CrS$_2$, MoS$_2$, and WS$_2$ behave as $p$-type semiconductor, the Cr$_S$ on the other hand, behaves as an $n$-type semiconductor. Defect-complexes; $V_WW_S$, $V_SM_S$ and $V_CSS$ induced higher magnetic moment, relatively to other defects. The $V_WM_S$, $V_{MoMoS}$, $V_{Mo2}$ and $V_{W2}$ induced several occupied defect states in the band gap of their host, exhibiting metallic character and are highly spin polarized relative to other defects. The delocalized disorder antisites in CrS$_2$, MoS$_2$ and WS$_2$ are important centers of carriers, which may reduce the mobility of charge carriers. Furthermore, whereas all the defects in WS$_2$ enhance the spin orientation of the host, for the MoS$_2$, the complexes distorted its spin orientation and induced magnetic moment. The spin polarized induced defects could be useful for spintronics application.

Magnetic, Electrical and Magnetocaloric Properties of Fe$_{90}$Ta$_{10}$ Thin films

Surabhi Shaji$^1$, Nikhil R. Mucha$^1$, Prakash Giri$^2$, Manosi Roy$^1$, Christian Binek$^2$ and Dhananjay Kumar$^1$; $^1$North Carolina A&T State University, United States; $^2$University of Nebraska–Lincoln, United States

Fe$_{90}$Ta$_{10}$ (Fe-Ta) thin films, deposited using a pulsed laser deposition (PLD) method, have been found to exhibit characteristics of a soft ferromagnetic material with very low coercivities (1-10 mT) and saturation magnetization ~ $16 \times 10^5$ A/m. Our field dependent magnetization data (MH) at various temperatures (20 K - 250 K) were used for the indirect measurement of magnetocaloric effect (MCE) to determine the entropy change in the material. An MCE is reported for the first time in rare-earth free Fe$_{90}$Ta$_{10}$ (Fe-Ta) thin films. This material system in thin film has shown a crystallographic transition from regular body centered cubic (BCC) crystal structure to an iron rich hexagonal laves phase structure which is isomorphous with the structure type, MgZn$_2$ (C14). Applying the Maxwell relation to the MH curves at various temperatures, we have numerically calculated $\delta M/\delta T$ vs H the integration of which provides quantitative information about the isothermal entropy change. We have observed a positive MCE with maximum entropy change of 6.9 J/K-m$^3$ for the magnetic field changing from 0.05-0.5 T in Fe-Ta system. Although the maximum of the mass specific entropy change is rather small in comparison with existing magnetocaloric material, the entropy change saturates for moderate applied magnetic fields around 0.15 T. This is more than an order of magnitude lower than the magnetic fields generally used to realize a large MCE effect. Efforts have been made to improve the mass specific entropy change by optimizing the deposition parameters and by varying the levels and types of dopants in the FE host.

Metal-Insulator Transition in Quasi-One-Dimensional HfTe$_3$ in the Few-Chain Limit

Scott Meyer$^{1,2}$, Thang Pham$^3$, Sehoon Oh$^{1,2}$, Marvin Cohen$^{1,2}$ and Alex Zettl$^{1,2}$; $^1$University of California, Berkeley, United States; $^2$Lawrence Berkeley National Laboratory, United States; $^3$Massachusetts Institute of Technology, United States

Constraining the physical size of solids can dramatically influence their electrical, optical, magnetic, thermal, and mechanical properties. Intrinsically low-dimensional materials, including van der Waals (vdW) bonded quasi-two-dimensional compounds (exemplified by graphite, hexagonal boron nitride, and transition metal dichalcogenides (TMD)) and quasi-one-dimensional vdW compounds (exemplified by transition-metal trichalcogenides (TMT)), are particularly intriguing, in that the bulk state already presents weakened inter-plane or inter-chain bonding, which leads to strong structural, electronic, and phononic anisotropy. Constraining the dimensions of these 2-D vdW materials down to “atomic thinness” can result in various degrees of additional size quantization with profound consequences. Therefore, it is a reasonable expectation that the 1-D vdW TMT materials would exhibit additional
size quantization phenomena with novel and unexpected properties when isolated down to the few- and single-chain limit. Here we report the successful synthesis and structural characterization of HfTe$_3$ within the hollow cores of multiwall carbon nanotubes (MWCNT). The selectable inner diameter of the MWCNT constrains the transverse dimension of the encapsulated HfTe$_3$ crystal and thus, depending on the inner diameter of the nanotube, HfTe$_3$ specimens with many chains (~20), down to few chains (3 and 2), and even single isolated chains, are obtained. The MWCNT sheath simultaneously confines the chains, prevents oxidation in an air environment, and facilitates characterization via high resolution transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM). Together with complementary density functional theory (DFT) calculations, we find a coordinated interchain spiraling for triple and double chain HfTe$_3$ specimens. Additionally, HfTe$_3$ shows a structural transition via a trigonal prismatic rocking distortion to a new, unreported crystal phase, concomitant with a metal-insulator transition, as the number of chains is decreased below four.

8:15 AM EL04.10.02
Extrinsic Doping of Antimony Selenide for Photovoltaics Laurie J. Phillips$^1$, Oliver Hutter$^1$, Theo Hobson$^1$, Christopher Savory$^{2,2}$, David O. Scanlon$^{2,2,3}$, Ken Durose$^1$ and Jonathan Major$^1$; $^1$University of Liverpool, United Kingdom; $^2$University College London, United Kingdom; $^3$Harwell Science and Innovation Campus, United Kingdom

Control of the doping in antimony selenide (Sb$_2$Se$_3$), both native and extrinsic, remains a key challenge for the material if it is to reach its full potential as a high-efficiency photovoltaic absorber. Carrier concentrations in Sb$_2$Se$_3$ are often low, with most reports of the material finding quasi-intrinsic or light p-type doping. Several studies have already shown the complicated defect chemistry of Sb$_2$Se$_3$, however, there is a paucity of studies into the deliberate doping of the material. In this study, we identify suitable doping strategies to achieve both n-type, and p-type material, first in single crystals and then apply this knowledge to create thin-film devices using a simple post-growth diffusion process. We investigate native defects and extrinsic doping in single-crystal Sb$_2$Se$_3$ through a combination of deep-level transient spectroscopy, density functional theory calculations, hot-probe, hall effect and secondary ion mass spectrometry techniques. We show that stoichiometric Sb$_2$Se$_3$ is an intrinsic semiconductor and identify tin and chlorine as effective extrinsic dopant species. We then discuss routes to achieve controlled doping profiles and high carrier concentrations in Sb$_2$Se$_3$ thin films. This study provides a greater understanding of doping in Sb$_2$Se$_3$, and offers a roadmap to high efficiency devices through extrinsic doping processes.

8:30 AM EL04.10.03
Dopability in Antimony Selenide—Suppressing Amphoteric Antisites Christopher Savory$^1$, Laurie J. Phillips$^2$, Jonathan Major$^2$ and David O. Scanlon$^1$; $^1$University College London, United Kingdom; $^2$University of Liverpool, United Kingdom

With the global demand for energy increasing year on year, diversification beyond current technologies and materials is crucial to meeting this demand by accessing more sustainable materials in a wider variety of device architectures and applications. In photovoltaics, while silicon is the dominant technology, its poor absorption puts upper bounds on device thinness, while established ‘thin-film’ materials such as CdTe allow strong absorption from nanometre-thin films and flexible devices but suffer from toxicity and low abundance of constituent elements. Antimony Selenide, on the other hand, is a highly promising candidate chalcogenide photovoltaic absorber, possessing a very high absorption coefficient, near-ideal band gap and relatively abundant constituents. Solar cells utilising it as the absorber layer are nearing 10% in efficiency, and the pseudo-1D nature of the material, with van der Waals interactions, has been highlighted as a potential reason for benign grain boundaries. Our recent theoretical work, however, has found that despite a high dielectric constant and a ns$^2$ ‘lone-pair’ cation configuration, both characteristics that have been associated with the concept of defect tolerance, Sb$_2$Se$_3$ possesses multiple low formation energy intrinsic defects with mid-gap transition levels that could severely hinder future improvements in open circuit voltage. In this study, we discuss these hybrid density functional theory calculations on the intrinsic defects of Sb$_2$Se$_3$ with focus on examining how the amphoteric behaviour of selenium allows for such low formation antisite defects, which may pin the Fermi level. Further, we examine the carrier capture behaviour of these defects and which defect levels may be responsible for the trap states seen in experimental DLTS measurements. Finally, we have also performed calculations on numerous extrinsic dopants to assess possible routes to doping in Sb$_2$Se$_3$, including passivation of deep intrinsic levels, and, in collaboration with colleagues at the University of Liverpool, potential contaminants that may affect current and future devices. Through these results, our study examines the specific effects at play within
Sb\textsubscript{2}Se\textsubscript{3} but also explores the consequences on the applicability of ‘defect tolerance’ within post-transition metal chalcogenide materials.

8:45 AM EL04.10.04
Adjusting Interfacial Chemistry and Electronic Properties of Photovoltaics Based on a Phase-Pure Sb\textsubscript{2}S\textsubscript{3} Light Absorber by Atomic Layer Deposition
Ignacio Minguez Bacho\textsuperscript{1}, Pascal Büttner\textsuperscript{1}, Craig Pointer\textsuperscript{2}, Florian Scheler\textsuperscript{1}, Dirk Dohler\textsuperscript{1}, Maïssa Barr\textsuperscript{1}, Dmitrii Pankin\textsuperscript{3}, Stefan Fliege\textsuperscript{4}, Ruriko Hatada\textsuperscript{4}, Alina Manshina\textsuperscript{3}, Elizabeth Young\textsuperscript{2} and Julien Bachmann\textsuperscript{1}; 1Friedrich-Alexander University Erlangen-Nürnberg, Germany; 2Lehigh University, United States; 3St. Petersburg State University, Russian Federation; 4Technische Universität Darmstadt, Germany

The combination of oxide and heavier chalcogenide layers in thin film photovoltaics suffers limitations associated with either oxygen incorporation into the chalcogenide layer or a chemical incompatibility which results in dewetting issues and defect states at the interface. Here, we establish atomic layer deposition (ALD) as a tool to achieve three goals in this field. Firstly, it allows one to obtain highly pure Sb\textsubscript{2}S\textsubscript{3} light absorber layer. Secondly, it provides high precision in the tuning of its thickness, demonstrated here between 30 and 160 nm. Thirdly, it is exploited to generate an ultra-thin adhesion layer of ZnS between 0.2 and 2.0 nm that simultaneously resolves dewetting and passivates defect states at the interface, thereby slowing down interfacial charge recombination. The materials stack is characterized by XPS, Raman, and SIMS, and its (photo-)physical properties are measured by UPS and transient absorption spectroscopy. The comparison of solar cells with and without oxide incorporation in Sb\textsubscript{2}S\textsubscript{3}, with an optimum ultra-thin ZnS interlayer below 1.0 nm, and with systematically varied Sb\textsubscript{2}S\textsubscript{3} thickness provides a complete picture of the physical processes at work in devices with optimized power conversion efficiency beyond 5.0 %.

9:00 AM EL04.10.05
Electrochemical and Photoelectrochemical Stability of Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} and Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} Based Photocathodes for Solar Water Splitting
Yihao Zhou, Betul Teymur, Edgard Ngaboyamahina, Charles Parker, David B. Mitzi and Jeffrey Glass; Duke University, United States

During the last decade, various chalcogenide materials (Cu(In,Ga)(S,Se)\textsubscript{2}, CuGa(S,Se)\textsubscript{2} and Cu\textsubscript{2}ZnSn(S,Se)\textsubscript{4}) have been studied as photocathodes for solar water splitting because of their high optical absorption, suitable band position and tunable bandgap. However, concerns including Zn-Cu antisite disordering and element scarcity/toxicity (In, Ga) remain as obstacles for their further performance improvements and practical applications. Most recently, Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} has attracted considerable attention as emerging chalcogenide materials with all earth-abundant elements and less tendency for antisite disordering compared to Cu\textsubscript{2}ZnSn(S,Se)\textsubscript{4} while maintaining the desirable electronic and optical properties for solar energy conversion applications. Previously, studies of Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} photocathodes focused on improvements of photocurrent density and onset potential. However, the stability of the Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} was not fully understood and stability beyond 10 hours (a concern for its practical application) was not yet demonstrated. The current study investigates the electrochemical and photoelectrochemical stability of bare Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} based photocathodes from both experimental and theoretical viewpoints. Additionally, long term stability of Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} with overlayers and catalyst was examined.

The stability of the bare Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} was found to significantly degraded at both positive and negative potentials but remains relatively stable in the middle potential range (e.g., 0 V/RHE to 0.4 V/RHE). Careful SEM, XPS, EDS and XRD measurements reveal different degradation mechanisms of Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} electrodes at different potentials. For positive potential, an electrochemically induced mechanical delamination was observed to cause the device performance to degrade. When a more negative potential was applied (e.g., -0.4 V/RHE,), photoelectrochemical corrosion was found to be responsible for the photocurrent decrease. Self-reduction and
oxidation potentials of Cu₂BaSn(S,Se)₄ was calculated thermodynamically and compared with the experimental results. Combining the theoretical and experimental results, the S/Se self-oxidation and Cu/Sn self-reduction were proposed to explain the degradation at positive and negative potentials respectively. Long term stability of Cu₂BaSn(S,Se)₄ photocathodes with TiO₂/CdS overlayers and Pt catalyst was tested for more than 100 hours continuously with AM 1.5G solar simulator at 0 V/RHE. It was found that more than 50% of the photocurrent was retained after 100 hours of testing. The decrease of photocurrent was attributed to Pt catalyst delamination and verified by EDS and SEM images. The present results elucidate the potential dependent stability and degradation mechanism of the Cu₂BaSn(S,Se)₄ system. Results of protected Cu₂BaSn(S,Se)₄ photocathodes highlight the possibility of practical Cu₂BaSn(S,Se)₄ solar water splitting devices with high efficiency (>10 mA/cm² at 0 V/RHE) low cost (solution-processed) and considerable stability (appropriate catalyst). The above results are also instructive for studying the stability of other existing chalcogenide materials and designing new chalcogenide materials with higher stability.

9:15 AM *EL04.10.06
Accelerated Discovery of Metal Oxides and Chalcogenides for Solar Energy Conversion Aron Walsh; Imperial College London, United Kingdom

The design criteria for sustainable thin-film photovoltaic devices includes the chemical (e.g. abundance, toxicity, stability, scalability) and physical (e.g. band gap, absorption, doping density, contact behaviour) properties of the underlying materials. Many non-conventional inorganic materials are currently being investigated including oxides (e.g. Cu₂O) and sulphides (e.g. SnS); however, none are close to reaching their theoretical potential as defined by the Shockley–Queisser limit [1].

I will discuss the latest advances in materials modelling [2] for the discovery of new materials for solar energy conversion. The role of predictive simulations can vary from high-throughput screening of candidate compounds, rigorous assessment of physical responses, to the optimisation of device architectures. Particular attention will be paid to what can learned from the high-performance of perovskite solar cells and the reduction of non-radiative electron-hole recombination that limits the performance of many new technologies. Examples will be taken from our exploration of kesterite (e.g. Cu₂ZnSnS₄), matlockite (PbFCl type), herzenbergite (SnS), and antimonselite (Sb₂Se₃) systems [3-5].

9:45 AM EL04.10.07
First-Principles Simulations of Stability, Optical and Electronic Properties of Competing Phases in Chalcopyrite-Based Photoelectrodes Joel B. Varley¹, Abhishek Sharan², Fernando P. Sabino², Anderson Janotti², Tadashi Ogitsu¹ and Nicolas Gaillard³; ¹Lawrence Livermore National Laboratory, United States; ²University of Delaware, United States; ³University of Hawaii, United States

One promising approach to economical and sustainable fuel production is through photoelectrochemical (PEC) hydrogen production. However, the widescale deployment of existing state-of-the-art photoelectrodes has been hampered by issues with durability, efficiency and cost. Chalcopyrite-based tandem photoelectrodes are attractive candidates in that they offer a great flexibility in the choice of component materials necessary that drive the
reactions for different device designs, offering ways to reduce the cost and to improve the performance. The synthesis of low-band gap chalcopyrites like CuInSe2 and alloys with CuGaSe2 (CIGSe) are known to exhibit a variety of Cu-poor phases (ordered-vacancy compounds or OVCs) that can greatly influence the resulting properties of fabricated devices, while the existence and properties of these phases in wider-band gap chalcopyrite compounds and alloys remains largely unexplored. Using hybrid functional calculations, we discuss the stability, optical and electrical properties of OVCs in a number of other chalcopyrite chemistries beyond CIGSe. We discuss the influence of such phases on the resulting absorption and band offsets that would result upon their formation, which have implications in device design. We additionally discuss experimental fingerprints that could be used to identify the existence of such phases in synthesized material.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and funded by the HydroGen Consortium within the Department of Energy Office of Energy Efficiency & Renewable Energy (EERE) and Fuel Cell Technologies Office.

Interfaces between PbSnSe and III-V Semiconductors Brian B. Haidet, Eamonn T. Hughes and Kunal Mukherjee; University of California Santa Barbara, United States

Group-IV chalcogenides are a fascinating material system with rare properties that arise from the nature of their bonding. The rocksalt alloys of PbSn1-xSe have important mid-infrared optoelectronic properties, with certain compositions host topologically non-trivial states. We explore the epitaxial integration of PbSnSe alloys with zincblende III-V materials for control over these unique electronic properties via hybrid interfaces to a mature materials platform. Here, we use PbSe as a model material to explore how IV-VI materials nucleate and grow on III-V materials. The thin films in our study are synthesized by molecular beam epitaxy from compound IV-VI sources. We show how to independently tune the substrate surface chemistry and lattice mismatch using buffer layers of (In,Ga)(As,Sb) alloys; finding that both influence the growth behavior of PbSe. Characterization of the (001) rocksalt/zincblende interface by electron microscopy reveals a unique arrangement of atoms that mediates dissimilarity in atomic identity, crystal structure, and valence.

With these tools in hand, we demonstrate routes to create atomically sharp and uniform interfaces between these material systems, paving the way to the measurement of the band alignment. The growth mode and lattice-mismatch also results in the generation of dislocations at the interface of PbSnSe and III-V materials that propagate into the film. We do not fully understand the properties of these dislocations, their relationship to interface preparation, and their impact on electronic properties. To this end, we present results from atom probe tomography and electron microscopy to provide a detailed microstructural description of these features. We see evidence for strong deviation in composition at these defects. Finally, dislocations are not always harmful and here we show that the glide of these dislocations can be used to our advantage to grade across composition in PbSnSe in (111) oriented films to explore the growth of metastable cubic SnSe-rich phases. These growth studies are now guiding our designs of hybrid heterostructures to understand and control the unique properties of IV-VI materials.

10:45 AM EL04.11.02
Electronic Structure and Defect Physics in Emerging Quasi-1D Antimony Chalcogenide Optoelectronic Materials Baiyu Zhang and Xiaofeng Qian; Texas A&M University, United States

Low dimensional chalcogenides become very attractive for electronic and optical applications, largely owing to their unique physical and chemical properties strongly augmented by low-dimensionality. The low dimensionality reduces dielectric screening and enhances Coulomb interaction, resulting in pronounced optoelectronic response and
forming quasiparticles such as excitons and polaritons. Here we present our first-principles theoretical study of quasi-1D antimony chalcogenides, an emerging class of optoelectronic materials possessing intermediate bonding between weak van der Waals and strong covalent interactions. We show that this unique quasi-1D structure mediates its dielectric screening environment, giving rise to highly anisotropic electronic and optical properties that are promising for low-cost photovoltaics and novel optoelectronics. We will further discuss the defect physics in antimony chalcogenides including both intrinsic and extrinsic point defects as well as their impact on relevant device performance. Our results provide valuable theoretical insights on the emerging antimony-chalcogenide based non-toxic and earth-abundant photovoltaics and open exciting avenues for optoelectronic applications of quasi-1D chalcogenides.

11:00 AM EL04.11.03
Investigating the Mechanisms Behind the Emergence of Magnetic Properties in Nominally Nonmagnetic Metal Chalcogenide Semiconducting Nanocrystals Alex Khammang and Robert W. Meulenberg; University of Maine, United States

Metal chalcogenide semiconducting nanocrystals (NCs), such as CdSe, possess striking size-dependent optical properties and have been shown to have applications as both optoelectronic (i.e. solar cells and laser emitting diodes) and biomedical devices (i.e. biological markers) [1]. These types of materials typically consist of an inorganic core, which dictates most of the physical properties, and an organic layer on the surface, which helps dictate chemical stability. While much work has been performed towards understanding the fundamental physics of the core NC, the surface science of these materials remains relatively unexplored. Although it is believed that the surface of NCs are primarily responsible for chemical stability, recent reports have suggested that the surface layer does much more, including affecting photoluminescence (PL) quantum yields and PL lifetimes [2]. Quite remarkably, the surface layer even has been shown to convert nominally non-magnetic materials, such as CdSe, into “magnetic NCs” [3]. This result is curious, as the bulk state of these materials exhibit diamagnetic properties. These exciting results suggest that is may be possible to pair these induced magnetic properties with the inherent PL properties of these materials without introducing chemical dopants. The multi-functionalization of CdSe and ZnO semiconducting magnets may lead to better biomedical applications such as targeted drug delivery, targeted organelle extraction, and magnetic hyperthermia treatments.

To gain further insight on how the surface layer affects the magnetic properties, our current work focuses on altering the NC surface chemistry by controllably varying the surface ligand concentrations and by systematically varying the types of ligands (i.e. headgroup) on the surface of spherical CdSe and ZnO NCs. Our work reveals that CdSe NCs exhibit weak paramagnetic (PM) properties in the presence of an external magnetic field as previously reported [3]. Sequential ligand removal does not yield a proportional response to the magnetic properties, but in general the PM properties are enhanced with fewer surface ligands attached. We hypothesize that after the removal of ligands the surface of the NC restructures by forming Se-Se bonds. DFT calculations suggest that removal of a full surface layer can result in a Se-Se triplet state that is energetically favorable compared to the singlet state and may be the source of magnetism in this system [4].

Similarly, ZnO NCs become paramagnetic or ferromagnetic at the nanoscale and it is generally accepted that the mechanism behind the magnetic phenomenon in ZnO results from interstitial point defects near the surface of the NC [4]. It has been shown that by variation of both the size and type of surface ligands, ZnO NCs can exhibit differences in the magnetic responses. Preliminary results suggest that ZnO NCs on the order of 30 nm exhibit PM behavior and while 4 nm ZnO NCs exhibit ferromagnetic behavior. The size dependencies are suggestive of surface defects, as the aspect ratio increases as NCs decrease in size. Very little is known about how the magnetic properties are affected when altering the surface ligand concentration and while surface reconstruction could be the source of the magnetism, reconstruction alone may not be the only source of magnetic properties.

1 N. Sahu, N. Brahme, and R. Sharma, Luminescence 31, 1400 (2016)
The search for new thermoelectric materials requires optimizing a set of interrelated, complex, and often conflicting material properties. Amongst the many desirable features needed to achieve good thermoelectric performance in semiconductors, two critical ones are low thermal conductivity and high carrier concentrations (dopability). This presentation will highlight recent combined computational and experimental efforts to tailor and understand thermal and electronic properties of a chemically-diverse set of telluride-based diamond-like semiconductors (DLS) within the Cu₂III₁IV₄Te₄ (III = Zn, Cd, Hg, IV = Si, Ge, Sn) material space and other related compounds. We use combined computational first-principles methods, synthesis, and characterization to comprehensively assess this space for thermoelectric performance. To address thermal properties, first-principles modeling together with thermal transport measurements together suggest that substantial site disorder arising from the prevalence of IIIB$_{\text{Cu}}$ and CuIIIB antisite defects gives rise to ultra-low thermal conductivities. The measured trend in the thermal conductivities corresponds well to the spectral mismatch of the Cu and group IIIB species in the phonon spectrum, suggesting the key role of these antisite defects in scattering thermal carriers. To address dopability, we use density functional theory to investigate the intrinsic defect chemistry of several telluride DLS including Cu₂HgGeTe₄ and the related ordered oxygen-vacancy compound Hg₂GeTe₄, and predict achievable carrier concentrations. Experimentally, carrier density control has been demonstrated within the Cu₂HgGeTe₄-Hg₂GeTe₄ solid solution. Our first-principles analysis shows that Cu₂HgGeTe₄ can range from degenerate p-type to highly n-type under different thermodynamic environments. In agreement with high-temperature x-ray diffraction and resonant spectroscopy experiments, the predominant defects in the quaternary are found to be antisite defects with Cu and Hg. On the other hand, as Hg₂GeTe₄ does not contain Cu-related antisites, native defects exhibit relatively high defect formation energies, and Hg₂GeTe₄ is predicted to have an equilibrium Fermi energy near mid-gap for all growth environments and a wide dopability window. To overcome the small intrinsic carrier concentrations in Hg₂GeTe₄, we use first-principles to screen and recommend a set of extrinsic dopants that can be used to tune the carrier type from p-type to n-type.

SESSION EL04.12: Quantum Dot Synthesis and Optoelectronics
Session Chairs: Vladan Stevanovic and Vanessa Wood
Wednesday Afternoon, December 4, 2019
Hynes, Level 1, Room 104

1:30 PM *EL04.12.01
Chalcogenide Nanocrystals as Optoelectronic Materials Dmitri V. Talapin; University of Chicago, United States

Development of nanostructured materials has introduced revolutionary approaches for materials processing and electronic structure engineering. These materials can offer the advantages of crystalline inorganic solids combined with inexpensive solution-based device fabrication. Along these lines, semiconductor quantum dots are explored as the functional elements for printable electronics, light emitting devices, photodetectors, solar cells and lasers. All these applications require efficient coupling between individual nanostructured components. The advances in the surface chemistry of semiconducting nanostructures are poised to enable advances in additive manufacturing of semiconducting and multifunctional materials. Specifically, I will discuss inorganic linkers that permit electronic coupling between the nanocrystals and composition-matched molecular semiconductor "solders" that convert nanocrystals in the high quality inorganic semiconductors. I will also introduce a general chemical approach for photoresist-free, direct optical lithography of functional inorganic nanomaterials (DOLFIN). Examples of patterned materials include metals, semiconductors, oxides, and magnetic and rare earth compositions. No organic impurities are present in the patterned layers, which helps achieve good electronic and optical properties. The conductivity, carrier mobility, dielectric, and luminescence properties of optically patterned layers are on par with the properties of state-of-the-art solution-processed materials. The ability to directly pattern all-inorganic layers using a light exposure dose comparable to that of organic photoresists opens up new opportunities for thin-film device manufacturing.

2:00 PM EL04.12.02
Composition-Dependent Properties of Multicomponent Chalcogenide Nanocrystals—Old Concept Enables New Opportunities Maksym Yarema, Olesya Yarema and Vanessa Wood; ETH Zurich, Switzerland

Colloidal chalcogenide nanocrystals comprise an important class of materials with a plethora of uses in photovoltaic, thermoelectric, catalytic, phase-change memory and other applications. Traditionally, the properties of such chalcogenide colloids are tuned by accurate control over their size, exploiting quantum confinement phenomena. Multicomponent chalcogenide nanocrystals provide an extra tuning knob: composition-dependent effects (i.e., tunable ratio between constituent cations) are superimposed on nanoscale size dependences. Synthesis of multicomponent nanocrystals, however, remains a synthetic challenge, due to side reactions and difference in reactivity of starting elemental precursors. In this talk, I will summarize our recent work, regarding ternary and quaternary chalcogenide nanomaterials. Taking example of I-III-VI group nanocrystals, I will highlight an amide-promoted synthetic approach that enables
independent control over nanocrystal size and composition. The method is based on addition of amide superbase, which accelerates the nucleation rate of nanocrystals and, ultimately, diminishes the reactivity difference between M\(^+\), M\(^{2+}\), and M\(^{3+}\) ions. We will demonstrate a generality of amide-promoted synthetic approach for various chalcogenide nanocrystals and discuss the limitations of the method.

In the following, we will focus on quaternary Cu-Zn-In-Se nanocrystals, for which we develop a predictive model for the synthesis in broad range of Indium-rich compositions. We will discuss an interplay between size and composition effects on structural and optical properties of Cu-Zn-In-Se nanocrystals. We will detect optimal ternary and quaternary compositions with enhanced luminescence efficiencies, which can be associated with structural ordering of cations and cationic vacancies. These results can provide better understanding of structure-property relationships for multicomponent nanocrystals and ultimately guide the development of multicomponent nanomaterials with optimized optical and electronic properties.

2:15 PM EL04.12.03  
**Polymer Guided Formation of Metal Chalcogenide Nanocrystal Networks**  
Paul D. McNaughter, Stephen Yeates and David J. Lewis; University of Manchester, United Kingdom

The ability to control the assembly of inorganic nanocrystals within polymer hosts is an important requirement for the use of metal chalcogenide nanocrystals in optical, energy capture and electrical devices. A popular route to the forming polymer-inorganic nanoparticle mixtures is to synthesis the particles and then mix with the polymer. This has disadvantage that when removing the solvents typically used that the conformational entropic penalty of the polymer existing at the nanoparticle surface and the enthalpic interactions between polymer and particle cause the particles to become immiscible with the polymer.

A route that has been explored to tip the balance to better mixtures of polymers and particles is to synthesise the particles within the undissolved polymer, *i.e. in situ*. The polymers of interest are solution processed in the same solution as the precursors for the desired metal chalcogenide.\(^1,2\) In particular, metal xanthates have proven to have the solubility in compatible processing solvents and also breakdown at relatively low temperatures, avoiding the decomposition of the polymer matrix. Our group has used this technique to form randomly ordered mixtures of polymer and lead chalcogenide nanocrystals where we reintroduced size control of the synthesised nanocrystals.\(^3–5\)

In this work we use electrospinning and electrospray techniques to form fibres containing highly aligned polymer chains and the required metal xanthate complexes. Upon heating the aligned polymers act as the environment the nanocrystals form within and direct the location of the resulting nanocrystals.

3:30 PM *EL04.12.04  
**Synthesis of Unnatural Polytypes of the Copper Chalcogenides**  
Emil Hernández-Pagán\(^1\), Suresh Sarkar\(^2\), Alice Leach\(^3\), Christopher Sharp\(^3\), Evan Robinson\(^3\), Andrew LaCroix\(^4\), Yilun Zhao\(^3\) and Janet E. Macdonald\(^4\); \(^1\)The Pennsylvania State University, United States; \(^2\)The University of Chicago, United States; \(^3\)Vanderbilt University, United States; \(^4\)Lander University, United States

Geology has the advantages of extreme temperatures, pressures, and cooling rates to achieve a dizzying array of diverse crystalline phases of metal chalcogenides. As solution phase chemists, we alternatively have access to diverse organochalcogenide precursors and chemistries with distinctive reactivities both in rate and mechanism. These precursors provide new methods to control crystalline phase in colloidal nanocrystal synthesis. At times, solution phase chemistry is even more powerful than geology as new “unnatural” polytypes of binary and ternary
compounds not present in the geologic record can result. These new polytypes present an emerging class of materials with new optical, electronic, and chemical properties. Here we will present examples from our research along with a study of the mechanism of formation that will provide the basis for further discovery of new materials. CuInS₂ has a band gap of 1.5eV and is a potential replacement for CdSe and CdS semiconductors in optoelectronic applications. While the favored thermodynamic structure is chalcopyrite, in some nanocrystal syntheses, a metastable wurtzite-like polymorph forms. We will show how the chalcogenide precursor reactivity influences the preferential formation of one of two binary intermediates, either pseudo-hexagonal Cu₂S or othorhombic In₂S₃. These binaries provides the anionic substructure which dictates the final phase of the ternary product after a second step of partial cation exchange.

With this mechanistic understanding, the class of hexagonal ternary copper sulfides has been expanded to now included the synthesis of wurtzite-like CuFeS₂, another rare, unnatural polymorph, instead of chalcopyrite. In this case, Cu₂S nanocrystals are intentionally prepared and used as a reagent. However, the exchange process itself can be disruptive, and there is a ligand dependence of the retention of structure even in cation exchanges at moderate temperatures.

The syntheses of hexagonal ternary copper sulfides are facilitated by the facile synthesis of pseudo-hexagonal Cu₂S, which is the thermodynamic phase. Similar intentional two step syntheses to hexagonal ternary copper selenides is hampered because the thermodynamic phase of Cu₂Se is cubic. Indeed, the hexagonal phase is not known to the geologic record, and it was synthesized only once before through cation exchange from CdS nanocrystals. We will present the first known direct synthesis of hexagonal Cu₂Se: a product that is facilitated by a didodecylselenidenidenprecursor. Similar syntheses that use dodcecylselenol or include phosphine precursors produce the thermodynamic cubic phase. Details of the relationship between precursors used and phase selection is revealed by in situ ⁷⁷Se NMR of nanocrystal syntheses.

Effects of a Lead Chloride Shell on Lead Sulfide Quantum Dots Sarah Brittman¹, Adam Colbert¹, Todd Brintlinger¹, Paul D. Cunningham¹, Michael Stewart¹, William Heurer², Rhonda Stroud¹, Joseph Tischler¹ and Janice Boercker¹; ¹U.S. Naval Research Laboratory, United States; ²U.S. Naval Academy, United States

PbS quantum dots are already commercialized in short-wave infrared (SWIR) photodetectors and are under development for single-photon sources, photovoltaics, and light-emission applications. Nevertheless, key aspects of their fundamental physics such as their excitonic fine structure, exciton-phonon coupling, and exciton dynamics are still not well understood. Using a popular synthesis from the literature,¹ we find that these PbS nanocrystals are coated in a previously unnoticed shell that is measurable in transmission electron micrographs.² The shell contains lead and chlorine, beyond the monoatomic chlorine termination previously proposed. Identifying this shell and its influence on the nanocrystals’ excitonic structure is a crucial first step toward understanding the physics of PbS quantum dots.

Earlier work has correlated the diameters of PbS nanocrystals to their excitonic absorption; however, we observe that PbS quantum dots synthesized in saturated dispersions of PbCl₂ can deviate from the previous 1Sₓ-1Sᵧ energy vs. diameter curve by 0.8 nm. In addition, their surface differs chemically from that of PbS quantum dots produced via other syntheses, which affects their excitonic absorption spectrum.

This result has important implications for understanding the growth mechanism of this reaction, the linewidth of these quantum dots’ photoluminescence, and electronic transport within films of these nanocrystals. Such fundamental knowledge is critical to further our understanding of PbS quantum dots and their development into optoelectronic devices.

Delayed Luminescence and Memory Functionality in CdS/ZnS Ligand Capped QLEDs Christian Blauth¹,², Paul Mulvaney¹ and Tadahiko Hirai²; ¹University of Melbourne, Australia; ²CSIRO, Australia
Quantum dot light-emitting diodes (QLEDs) emitting at 410 nm were studied by time-resolved electroluminescence measurements. A novel transient device current overshoot after voltage turn-off was observed which is attributed to the accumulation and storage of charge carriers at the ligand-quantum dot interface. Short ligands produced short rise times and prevented current overshoots, whereas longer ligands caused a storage of charge carriers, a slower response and notable current overshoots. This overshoot can be attributed to the internal electric field between the injected, and stored and trapped electrons and holes upon switching-off of the external voltage. Thereby, trapped charges at the quantum dot/ligand interface recombine and produce an electroluminescence spike. Applying a dual step voltage pulse, prevents this overshoot, and instead a delayed luminescence is found. As the accumulated charge carriers are immobile and trapped in shallow states at the ligand/quantum dot interface, a reverse pulse was applied to fully deplete the emissive layer. With the transient overshoot disappearing after the device has been turned on and operated, a measure for degradation of QLEDs has been identified.

Upon using a 5nm thick Al interlayer under the hole transport layer, accumulated charge carriers can increase the conductance of the active layer during the forward voltage sweep. This introduces a memory window, a new device functionality, with ON/OFF states that can be reversed by applying a negative bias. The height of the memory window depends on the length of ligand passivating the chalcogenide quantum dot. During backward voltage sweeps, previously injected charge carriers recombine until the active layer is free of charge carriers and show a low conductance state. Voltage-capacitance measurements confirm the changes in charge carrier population within the active layer that depend on both the direction of the bias sweep as well as the ligands surrounding the quantum dots. A complete memory cycle with read, write, erase and re-read modes has been demonstrated.

Beneficial Impurities in Surfactant Assisted Synthesis of Colloidal Nanoparticles Yuval Golan; Ben-Gurion University of the Negev, Israel

While surfactant assisted synthesis is the most common technique used for the preparation of colloidal nanoparticles, researchers in the field often encounter serious irreproducibility issues. In this talk, we will present several examples for the role of ‘beneficial impurities’ in nanoparticle syntheses.[1-5] Specifically, controlled amounts of alkylammonium-alkylcarbamate surfactants were shown to strongly affect alkylamine-assisted synthesis of anisotropic colloidal ZnS nanoparticles.[4,5] Furthermore, a new cubic semiconducting binary phase (denoted as the π-phase) has been discovered in recent years in the form of colloidal nanoparticles. The first π-phase materials to be discovered were tin mono-sulfide, π-SnS [6,7] followed by tin mono-selenide, π-SnSe [8], and density functional theory calculations predict additional π-phase compound semiconductors.[9] Increasing experimental and computational evidence points out that ‘beneficial impurities’ can be used for achieving phase control in the tin mono-chalcogenide system.

Maximum Efficiency of Kesterite Solar Cell Limited by Nonradiative Recombination Sunghyun Kim¹ and Aron Walsh¹,²; ¹Imperial College London, United Kingdom; ²Yonsei University, Korea (the Republic of)

The theoretical maximum efficiency of a solar cell such as Shockley-Queisser limit has mainly focused on the radiative recombination as the limiting factor. However, in practical solar cells, the nonradiative recombination is unavoidable due to the formation of native point defects and often the dominant recombination mechanism [1]. We will predict the theoretical maximum efficiency of kesterite solar cells (Cu₂Zn(Ge,Sn)(S,Se)₄), taking into account both radiative recombination and non-radiative carrier recombination mediated by the native point defects. We calculate the thermal equilibrium concentrations of native defects and their capture cross-sections. We find that the sulfur vacancy (VS), sulfur vacancy-donor complex and Sn antisites (SnZn) produce deep levels and large capture cross-sections resulting in the low open-circuit voltage and the low solar-to-electricity conversion efficiency [2, 3]. The predicted upper limit is compared to the current generation of best performing kesterite solar cells. We suggest that the codoping and alloying may improve the efficiency of kesterite solar cells.

EL04.13.02
Effects of Aluminium Doping on Kesterite Cu₂ZnSnS₄ Thin-Films Ahmet S. Nazligul, Mingqing Wang and Kwang-leong Choy; University College London Institute for Materials Discovery, United Kingdom

In recent years Cu-based chalcogenide Cu₂ZnSnS₄ (CZTS) has attracted a lot of attention as an earth-abundant alternative for CIGS solar cells. To date, the research in this field has been focused on solar cell applications. However, the efficiency of CZTS solar cells has not experienced a real improvement in the past five years. Therefore, research is beginning to explore new applications for this material such as sensors, water-splitting and charge-extraction layers. In this project, aluminium doping has been introduced to CZTS thin-films for the first time. CZTS films were deposited in atmospheric conditions via a low-cost and environmentally friendly solution-based method. The effects of up to 3 % Al doping in a range of different annealing temperatures from 350 °C to 550 °C without any sulfurization/selenization were examined. Our results show that Al has no significant effect for the samples heat-treated at 350 °C. On the other hand, we observed successful doping for the samples heat-treated above 450 °C. Our EDS, XRD and Raman results suggest that Al is replacing Sn sites in these samples. The Al doping caused a drop in resistivity while increasing the charge-carrier concentration, bandgap and grain sizes. The biggest reduction in resistivity was observed for 2% doped and heat-treated at 450 °C samples. In these samples the resistivity reduced from 13.34 Ω.cm to 0.42 Ω.cm while charge-carrier concentration increased from 7.85×10¹⁷ to 1.74×10²⁰ cm⁻³. Such improvement in charge-carrier concentration is promising for using Al-doped CZTS thin-films as hole transport layers in Perovskite solar cells, while an increase in the bandgap is advantageous for water-splitting applications.

EL04.13.03
Impact of Ag-Doping on Cu₂ZnSnS₄ (CZTS) Thin-Film Solar Cell Heydar Honarvar Nazari¹,² and Tara P. Dhakal¹,²; ¹Binghamton University, The State University of New York, United States; ²Center for Autonomous Solar Power (CASP), United States

CZTS-based solar cell is one of the most attractive p-type solar absorbers due to its low cost and earth-abundant elements. In addition, CZTS has a band gap of 1.5 eV and high absorption coefficient (10⁴ cm⁻¹) required to be a near ideal solar cell absorber. We report the impact of silver (Ag) doping on CZTS solar cell and how the dopant mitigated the defect density. We
deposited 10 to 20 nm thick Ag layer on top of the CZTS precursor before annealing in sulfur environment for crystallization of the Ag-doped CZTS (ACZTS) film. Ag-doping has shown to improve $V_{oc}$, but we observed it is important to control the Ag for optimal p-type conductivity. Although $V_{oc}$ improvement was achieved, Ag doping of CZTS increased series resistance due to more defects in the crystalline structure. Our recent study showed that by doping a small amount of Ag could improve $V_{oc}$ up to 0.65 (V), compared to bare CZTS which was 0.605 (V). It improved by 10% compared to the cell with no Ag ions. The formation Ag$_2$S which has a higher formation energy compared to other defects is expected, which in turn may have it lowered the number of Cu$_{Zn}$ antisite defects. Moreover, Ag ion has large atomic radius improving grain sizes of ACZTS and lowering GB effect. The highest efficiency based on Ag-doping of CZTS showed 6.4% in our lab compared to the CZTS cell with ~6% efficiency due to the gain in $V_{oc}$. Jsc also improved due to lowering Cu$_{Zn}$ antisite defects.

**High Performance CZTSSe Solar Cells by Using Cadmium-Free Non-Toxic Zn(O, S) Buffer Layers** Cheng-Ying Chen$^{1,2,3}$, Yun-Fu Chen$^{1,2}$, Wei-Hao Chen$^{1,2}$, Fang-Yu Fu$^{1,2}$, Narmatha Koothan$^4$, Yu-Hsuan Yu$^4$, Kuei-Hsien Chen$^2$ and Li-Chyong Chen$^{1,3}$; $^1$National Taiwan University, Taiwan; $^2$Institute of Atomic and Molecular Science, Academia Sinica, Taiwan; $^3$Center of Atomic Initiative for New Materials, National Taiwan University, Taiwan; $^4$Taiwan Instrument Research Institute, National Applied Research Laboratories, Taiwan

The future deployment of photovoltaics demands stable, abundant, non-toxic materials. Kesterite Cu$_2$ZnSn(S,Se)$_4$ (CZTSSe) has attracted attention due to its non-toxicity, low cost, earth-abundant elements and its band gap can be tuned easily. However, efficiency of CZTSSe (12.6%) is much lower than CIGS (22.9%), mainly due to a large $V_{oc}$ deficit. Several factors have been suggested for this $V_{oc}$ deficit, including large amount of defects, undesirably thick MoS$_2$ layer at the rear of the CZTSSe cell, coexistence of secondary phases and unfavorable band alignment at the CZTSSe/CdS heterojunction interface. The importance of the conduction band offset (CBO) at the absorber/buffer interface is well known. A cliff structure (CBO<0) can increase interface recombination, while a spike (CBO>0) results in blocking of the photocurrent and reduce fill factor. Commonly, it is assumed that a small cliff is present at the CZTSSe/CdS interface, which highlights the need to replace CdS with materials with a lower conduction band in order to avoid an unfavorable band alignment. Furthermore, this CdS-based solar cell is desirable to replace with a more environment-friendly highly effective n-type buffer layer.

In this work, we have demonstrated the non-toxic Zn(O,S) as an alternative buffer layer for CdS by chemical bath deposition (CBD) and atomic layer deposition (ALD). One is chemical bath deposition (CBD) that is simple and well prepared. The other is atomic layer deposition (ALD) that can deposit uniformity for atomic level as well as the conformal coverage over large-scale areas. The Zn (O, S) buffer layer band gap (3.5eV) is wider than CdS (2.4eV) which can achieve higher short-circuit current density (Jsc) due to the enhanced transmission of the wavelength region between 350 nm and 550 nm.

Finally, we obtained 5.4% efficiency of CZTSSe solar cell with open circuit voltage ($V_{oc}$) of 440 mV, short-circuit current density ($J_{sc}$) of 25 mA/cm$^2$, and fill factor (FF) of 50.2% by chemical bath deposition (CBD) ZnO. Subsequently, we got 9.77% (~ 10.75% in the cell effective area) efficiency with open circuit voltage ($V_{oc}$) of 460mV, short-circuit current density ($J_{sc}$) of 36.07 mA/cm$^2$, and fill factor (FF) of 58.06 % by atomic layer deposition (ALD) ZnO, which is the highest reported efficiency of CZTSSe with a Cd-free buffer layer. Apart from this, we successfully established the number of precursor cycles using the ALD process to control the O/S ratio and thickness. It helps us adjust the appropriate conduction band offset (CBO) to avoiding an unfavorable band. The morphology, elemental composition, and distribution of the absorber layers are being examined by X-ray diffraction (XRD), X-ray fluorescence spectrometry (XRF), scanning electron microscopy (SEM), Transmission electron microscope (TEM), and X-Ray Photoelectron spectroscopy (XPS).

**Vapor-Phase Selenization of Powder-Fabricated Cu$_2$GeS$_3$ Thin Films** Hak-Young Ahn$^{1,2}$, Jong-Ku Park$^2$, Seung
Yong Lee2,3, Byeong-Kwon Ju1 and So-Hye Cho2,3; 1Korea University, Korea (the Republic of); 2Korea Institute of Science and Technology, Korea (the Republic of); 3Korea University of Science and Technology, Korea (the Republic of)

Selenization is a process of supplying selenium (Se) in gas phase typically at the elevated temperature. The process has been applied for the formation of chalcogenide thin films for electronic, optical and thermoelectric devices. However, the commonly used method for selenization has limitations such as using toxic gas H2Se gas, high temperature and high equipment cost due to the necessity of two zone furnace system. Therefore, a low-cost and facile method of selenization with a precise control of Se supply is needed.

Herein, we demonstrate one-step and one-zone selenization process of chalcogenide thin films by a new Se source which is a mixture of inert Al2O3 and Se. It was found that Al2O3 in the mixture plays a role as a controller of Se vaporization and therefore by adjusting ratios of Al2O3 vs. Se, we were able to control selenization vapor supply. And mechano-chemical synthesis of Cu2GeS3 particles and the transformation of a thin film of Cu2GeS3 to that of Cu2GeSe3 through selenization will be discussed. During our synthesis of Cu2GeSe3, only elemental Cu, Ge and S were used without any solvent and the thin film of Cu2GeS3 was fabricated by the solution phase, ink printing method followed by the annealing under Se environment. When the selenization method was used for Cu2GeS3 semiconductor thin film, we found resulting selenized thin film has better morphology and electrical properties than that selenized with Se powder alone. This alternative method consumes much less Se than previous methods so that it can be considered environmentally less toxic and has a benefit of low-cost and facile process. And also, this process can broaden applicability by easily controlling the band gap of various chalcogenide materials and thin films.

EL04.13.06
Cesium-Related Compound—An Emerging Chalcogenide Material and Its Influence on CIGS Thin-Film Solar Cells Ishwor Khatri, Tzu-Ying Lin, Mutsumi Sugiyama and Tokio Nakada; Tokyo University of Science, Japan

Current world record CIGS solar cells are achieved by post-deposition treatment (PDT) of heavy alkali metal fluorides (such as KF, RbF and CsF). These alkali-PDT processes are predicted to form alkali-containing compounds such as K-In-Se and Rb-In-Se. The structure and chemistry have intensively been investigated so far. However, the properties of Cs-containing compounds formed by CsF-PDT have not yet been widely discussed. We thus investigated the influence of CsF-PDT on the formation of Cs-related compounds, and its beneficial and detrimental effects on solar cell performance.

CIGS thin films were deposited using three-stage deposition process on Mo-coated SLG substrates. CsF-PDT was performed at a substrate temperature of 350 °C for 2 minutes. The CIGS solar cells were fabricated with MgF2(105nm)/Ni/Al (2-2.5μm)/ZnO: Al(300nm)/ZnO(100nm)/CBD-CdS/CIGS (2.5-3μm)/Mo (700nm)/SLG (1.8mm) structure. TEM and SAD analyses revealed that the Cs-related secondary compounds are present on the surface of CIGS thin film after CsF-PDT. XPS narrow scan spectra confirmed Cu depleted regions at the surface area with a few tens of nanometers, whereas SIMS and EDS-line scan showed that Cs was distributed throughout the CIGS absorber. We noticed that CsF-PDT modifies CIGS surface and formed Cs-related compounds such as Cs-In-Se or Cs-In-Ga-Se. These Cs-related compounds provide several beneficial electronic effects. Presence of Cs-related compounds at the surface of the CIGS thin film reduce interfacial recombination, thereby, improving open-circuit voltage and efficiency. Recombination mechanisms in the devices were characterized using temperature dependent current density-voltage measurements and time-resolved photoluminescence based on different Cu/(In+Ga) and Ga/(In+Ga) ratios. CsF-treated CIGS thin films with near-stoichiometric (Cu/(In+Ga)) yields higher efficiencies. Furthermore, we found the important role of Cs-related compounds in heat-light soaking (HLS) and heat-bias soaking (HBS).

EL04.13.07
A Study of Potential Induced Degradation (PID) and Recovery Mechanisms in CIGS Solar Cells Solhee Lee1, Soohyun Bae1, Se Jin Park1, Yoonmook Kang2, Hae-Seok Lee2 and Donghwan Kim1,2; 1Korea University, Korea (the Republic of); 2KU-KIST Green School, Korea (the Republic of)

CIGS solar cell is a high-efficiency cell with more than 22% efficiency, and can also be modularized in a large area. CIGS module efficiency is approaching the multicrystalline silicon module efficiency. For safety and supporting reasons, photovoltaic (PV) modules have to be grounded and PV modules are serially connected to generate high
voltage and power. When several hundreds of volts induced to modules, degradation is occurred. This is called potential induced degradation. The term ‘potential induced degradation (PID)’ was first introduced by S. Pingel and coworkers in 2010 [1]. Efficiency deterioration by PID phenomenon has been reported in large capacity photovoltaic systems. In c-Si solar cells, decrease in shunt resistance by Na+ ion immigration is known as the cause of PID. However, the mechanism during PID in CIGS solar cells is not known yet. For commercialization of CIGS thin film solar cells, PID study in CIGS solar cell is important. Since PID is known to be common in modules, in this research, an experimental structure was designed to replicate PID in cell level. As an experimental method, the cell was degraded with 600 V bias at 65 °C in darkness. Light I-V, dark I-V and external quantum efficiency (EQE) were performed to investigate the degree of degradation. To image the position of PID by electroluminescence (EL) and lock in thermography (LIT) measurements were also performed. We tried to extract the mechanism of PID in CIGS solar cells through the change of element or doping concentration. Furthermore, recovery was confirmed with no bias at room temperature in darkness.

**EL04.13.08**
**Potassium Treatments for Solution-Processed Cu(In,Ga)(S,Se)2 Solar Cells** Essam AlRuqobah and Rakesh Agrawal; Purdue University, United States

Cu(In,Ga)Se2 (CIGSe) has emerged as an attractive thin-film solar cell material owing to its high light absorption coefficient and tunable bandgap. In CIGSe processing and fabrication, the use of alkali treatments has been implemented extensively. Sodium treatment is considered a requirement for high efficiency CIGSe solar cell as it was found to improve the performance and growth of CIGSe absorber films. However, one of the more significant developments in recent years has been the discovery of the beneficial effects that potassium treatments have on CIGSe solar cells, particularly on the absorber surface. When applied, it was found that potassium induces copper and gallium depletion from the surface of CIGSe films. Moreover, a high-bandgap K-In-Se phase also forms on the surface of films subjected to potassium treatments. In practice, these two phenomena lead to an improved CIGSe device by mainly improving the quality of CIGSe/CdS p-n heterojunction.

Despite these significant beneficial effects, the use of potassium has been limited to expensive vacuum-based CIGSe processing. Here, we develop a route to apply potassium treatments to low-cost solution-processed CIGSe films grown from colloidal sulfide-based nanoparticle inks. By adding potassium through e-beam evaporation of KF prior to growth, we find that the grain growth of CIGSe is enhanced with potassium addition and that a larger-grained thicker coarsened film results compared to untreated selenized CIGSe film, similar to what is observed in sodium-treated films. We also observe via XPS that films treated with potassium show depletion of gallium from the surface, and that the amount of gallium depletion correlates with the amount of potassium added. Similar effects on film surface were also observed for films that have undergone potassium treatment through a soak in KCl solution prior to selenization. Furthermore, it was also observed through XPS that films treated with KF showed the presence of a different Se chemical state on the surface, which is attributed to a K-In-Se phase. Devices that were fabricated with potassium treatments were found to have enhanced optoelectronic performance which was mainly manifested in higher open-circuit voltage and higher fill factor, compared to films that are untreated or treated with sodium only.

In conclusion, we purpose a route to apply potassium treatments for solution-processed CIGSe devices. We also conduct a systematic study on the effects of potassium on CIGSe film growth, surface environment, and optoelectronic properties.

**EL04.13.09**
**Heavy-Metal-Free Quantum Dot Inks for Thin-Film Tandem Solar Cells** Filip Dinic, Larissa Levina, Edward H. Sargent and Oleksandr Voznyy; University of Toronto, Canada

Tandem solar cells are a promising route to increase the efficiency of solar cells. They require semiconductor materials with a bandgap wider than that of silicon, e.g. GaAs, GaInP, CuInGaSe. However, due to vacuum processing of these materials, their price remains an order of magnitude higher than that of silicon. We propose to utilize chalcogenide based colloidal quantum dot (CQD) inks to achieve scalable and low-cost solution processing of the state-of-the-art photovoltaic materials. Films are prepared by thermally annealing and sintering the QDs, resulting in bulk direct bandgap semiconductors, which have been demonstrated to be highly efficient light absorbing layers. The key challenges in this field revolve around improving CQD packing and further reducing the
defect densities. We will demonstrate that inorganic atomic ligands can eliminate the need for organic long chain ligands required for colloidal stability, and at the same time can be used as abundant passivating agents in the resulting films. We will demonstrate the proof-of-principle results based on lead-free chalcogenide based CQDs, primarily CdTe and CuInS.

**EL04.13.10**

**Controlling Magnetism in Boron-Doped Cadmium Sulfide with Light** Bilal Azhar and Rafael Jaramillo; Massachusetts Institute of Technology, United States

The large and persistent photoconductivity displayed by some semiconductors provides a way to control magnetism with light, through illumination-control of free carrier concentration and thereby magnetic interaction in dilute magnetic semiconductors. CdS is a wide band-gap semiconductor that displays large and persistent photoconductivity, and is predicted to become magnetic when doped with certain non-magnetic dopants including Boron [1]. In this work, we experimentally test the prediction of magnetic CdS:B, and the hypothesis that magnetism can be controlled by photoconductivity. We make CdS:B nanoparticulate powders by co-precipitation [2]. We use X-ray diffraction and plasma optical emission spectroscopy to quantify boron doping, and we characterize the effect of doping on electronic structure using optical spectroscopy. We use nuclear magnetic resonance (NMR) and magnetometry to confirm the presence of magnetic B, and to study the position of B in the CdS lattice. Finally, we report the effect of above- and below-band gap illumination on the magnetism of B sites and the magnetic order of CdS.

**EL04.13.11**

**Copper Chalcogenide Thin Films Proposed for UV-Inhibited, Nutrition-Conserving Solar Dehydration of Fruits** P. Karunakaran Nair, Angélica Lizbeth Espinosa Santana, Anabel López Ortiz and M. T. Santhamma Nair; Universidad Nacional Autonoma de Mexico, Mexico

Degenerate n-type semiconductors such as SnO\(_2\):F, In\(_2\)O\(_3\)::Sn or ZnO:Al, and of p-type, Cu\(_{2-x}\)S, Cu\(_{2-x}\)Se, Cu\(_{2-x}\)O of electrical conductivity superior to 10\(^3\) \(\Omega^{-1} \text{ cm}^{-1}\) and carrier concentrations of 20\(^{21}\) \(\text{cm}^{-3}\) make use of degeneracy of energy levels, the same way as metals do. They behave as conductors at wavelengths of electromagnetic radiation above 1500 nm, with high reflectance and low transmittance. In the case of thin films (150 – 200 nm) of copper chalcogenides, with optical bandgap of 1.3 to 2.5 eV, this leads to a bell-shaped transmittance curve, with near-zero transmittance at wavelengths below 500 nm and very low as well as wavelengths above 2000 nm. The overall optical transmittance of 25 – 30 % has a maximum at 550 – 650 nm, absorptance of 60 – 70 % and reflectance of 15 – 20 % for solar radiation. We deposited copper sulfide selenide thin films on the outer wall of on one side of cellular polycarbonate sheet by floating it on a chemical deposition solution of copper nitrate, thiourea, and sodium selenosulfate. This film, protected with food-safe adherent polyethylene sheet, is fixed at 2 cm from a layer of sliced fruit (strawberry) or fruit pulp (blackberry) placed under the sun. Due to the high solar absorptance of 60 %, the device acts as a 600 W/m\(^2\) heater and raises the temperature of the fruit layer to 60 \(^\circ\)C, which is optimum to conserve food value during drying and also to assure a viable drying rate. The cellular structure inhibits convectional heat loss to the ambient from the top (exposed) side of the sheet, without the copper chalcogenide coating. Further, the absence of UV radiation notably retains the antioxidant nutritional value of the product. This advantage is detected in free radical (DPPH) aided spectrophotometric characterization. The UV-inhibited drying also retains the appearance of the product. This approach is may be directly applicable in a rural setting, where a timely drying of fruit products during harvest reduces large-scale loss.

**EL04.13.12**

**Functional Antimony Sulfide Selenide Photovoltaic Prototype Modules via Chemical Deposition** Jesús Alberto González Iñiguez, José Diego Gonzaga Sánchez, Carolina Senaí Avendaño Peréz, Angélica Lizbeth Espinosa Santana, M. T. Santhamma Nair and P. Karunakaran Nair; Universidad Nacional Autonoma de Mexico, Mexico

Final Program 1/13/2020  267
Can we build in “our” laboratory a functional photovoltaic prototype module, which is stable under the sun and is open to innovation to achieve technological viability? Yes. We present the prototype module, FTO/CdS/Sb₂SₓSe₃/C-Ag, which is stable, functional to light up 20 mW blue light emitting diode and open to innovation in any laboratory. It is build on commercial F-doped SnO₂ (FTO) substrate of 7.5 cm x 2.5 cm in area, with an 80 nm CdS thin film deposited in 1 h form a chemical bath at 80 °C. Subsequently four sequential depositions of Sb-S-Se are made on it in a total of 10 h at 80 °C from chemical bath containing potassium antimony tartrate, thioacetamide and sodium selenosulfate. This film is of 350 nm in thickness, and amorphous. The sun appears deep red when viewed through it. Seven graphite electrodes of 2 cm x 0.5 cm at a separation of 0.4 mm are placed on it by hand painting colloidal acrylic based graphite suspension. This structure now goes into an oven at 250 - 290 °C for 05 – 1 h, under a nitrogen flow. The Sb-S-Se film surrounding the cell is etched-off with NaOH solution, and the underlying CdS with dilute HCl. Using a SiC scribe the cells are isolated. The heating renders the graphite electrodes of sheet resistance 25 Ω and the underlying layer is transformed to a carbon-doped p-absorber. The Sb-S-Se film is crystallized, with the composition, Sb2S0.9Se2.1 with a bandgap of 1.42 eV, and electrical conductivity 10⁻⁵ Ω⁻¹ cm⁻¹ under light. An estimated light generated current density, 28 mA/cm² under the sun should be available in a solar cell. The prototype module is completed by applying colloidal silver paint on the graphite electrode and interconnecting it to the silver-paint electrode on the FTO base of the neighboring cell. A commercial acrylic lacquer encapsulates the module. The prototype is of Voc 3.1 V, Jsc 22 mA, maximum power 30 mW. Innovation is possible with modification/ replacement of the CdS window, compositional (bandgap) variation along the thickness and heat-processing of the absorber film, and in the application of back contact. We also present results on module produced by combining chemical deposition and thermal evaporation in the production of the absorber film, whereby bandgap is modified along the absorber thickness.

**Effects of Substrate Material and Substrate-Assisted Laser Patterning on Material Properties of CdSe Thin Films**

Hasan H. Gullu¹, Ozge Bayrakli Surucu², Makbule Terlemezoglu³,⁴, Cansu Emir² and Mehmet Parlak³,⁴

¹Atilim University, Turkey; ²Kirsehir Ahi Evran University, Turkey; ³Middle East Technical University, Turkey; ⁴Tekirdag Namık Kemal University, Turkey

II-VI semiconducting chalcogenides have become a great part of research interest due to their possibility to use in a wide range of device applications with their remarkable optoelectronic properties as ideal direct band gap, high absorption coefficient and photosensitive behavior in the visible region of spectrum. Based on these optical and electrical properties, these compounds have been investigated as an alternative material system in the fabrication of low cost optoelectronic devices and used as promising materials for the development of current technological devices. Among these compounds, cadmium selenide (CdSe) thin film has long been popular in the field of optoelectronics due to their high transparency in visible region, direct and wide band gap value, photoconductivity, high electron affinity and n-type semiconducting behavior. Although this type of films have potential applications in fabrication of light emitting diodes, thin film transistors, gas sensors, photodetectors and solar cells, in recent years, attention has been directed to alternative methods as variations in chemical constituents, doping, formation of ternary analogues, surface patterning in order to manipulate the material characteristics of thin films to improve the performance of the devices. In this study, CdSe thin films were deposited on a soda-lime bare glass and indium tin oxide (ITO) coated glass substrates using direct evaporation of high purity and stoichiometric CdSe powder at room temperature. Bare glass substrates were used in thin film characterization processes and ITO coated glass substrates was employed to create transparent conducting oxide layer for possible device applications. For the deposited CdSe thin films, energy dispersive X-ray (EDS) analysis showed an average atomic percentage of CdSe is near to stoichiometric composition of the source material as Cd:Se ratio (50:50). The X-ray diffraction profile of the samples was indexed according to JCPDS files and the characteristics diffraction peaks were observed in a good agreement with the literature without any formation of secondary phase in the structure. The surface imaging using scanning electron microscopy (SEM) and detailed surface morphology analysis by using atomic force microscope (AFM) showed that the deposited CdSe thin films are dense and compact in nature. From the optical transmission studies, films were found in direct optical transition characteristics and the band gap values of the samples were calculated using Tauc plots. In addition to the film analysis on different substrates, substrate-assisted laser patterning was investigated as an alternative technique to create functional structures for possible optoelectronic applications. The straight and continuous line patterns on bare and ITO coated glass substrates were optimized in terms of pulse repetition rate, laser power, pulse energy and the feeding speed of the nanosecond pulsed Nd:YAG laser system. Uniform periodic pattern without any damage to the glass substrates were achieved with a wavelength in the infrared region. It was observed from EDS spectrum of the films that the stoichiometric transfer of material from source.
powder to the deposited films on different substrates with different line patterns was achieved. In the case of surface morphology, the effects of laser patterning on characteristics of the CdSe thin films deposited on bare and coated glass substrates were investigated by SEM and AFM images. UV/Vis spectrophotometer was used to discuss the transmittance and reflectance characteristics of these patterned samples.

EL04.13.14
Synthesis, Characterization and Optical Properties of Copper Antimony Sulphide (CAS) Thin Films for Low Cost Photovoltaics Kimberly A. Weston and Richard A. Taylor; University of the West Indies, St Augustine, Trinidad and Tobago

An attractive class of semiconducting materials with non-toxic, low-cost and highly efficient characteristics have emerged as promising alternatives for applications in solar cell technologies. Novel materials or structures with properties that match the spectral distribution of the solar spectrum are therefore required to produce materials of high efficacy. One copper-based semiconductor metal chalcogenide, copper antimony sulphide (CAS) as thin films, is an excellent candidate for potential photovoltaic (PV) applications, since, in addition to the elements’ abundance, low toxicity and simple inexpensive processing protocols, bulk CAS has a strong absorption coefficient of $10^5$ cm$^{-1}$ and a band gap between 0.5 and 2.0 eV, matching well with the solar spectrum as well as excellent photostability. Interestingly, there are sparse reports of tuning the optoelectronic properties with metal dopants for the CAS material and few reports have been written for the synthesis of CAS thin films via the aerosol assisted chemical vapour deposition (AA-CVD) method. As-synthesized thin films of CAS microstructures have various morphologies and stoichiometries which are dependent on AA-CVD parameters of deposition temperature and time.

Homogeneous films of deposition temperatures 500, 550 and 600 °C, synthesised at 30 minutes and 1 hour are non-stoichiometric with mixed morphologies and particle sizes range from 0.3 to 1 µm. Consequently, the optical properties indicate that as-synthesized CAS thin films absorb near the end of the ultra-violet region but mainly in the visible portion of the spectrum. Indirect transitions occur between 0.89 to 3.40 eV. With detailed elucidation from powder X-ray diffraction, Raman spectroscopy, scanning electron microscopy, atomic force microscopy, energy-dispersive X-ray spectroscopy, X-ray photoelectron spectroscopy, steady-state and time-dependent electronic spectroscopy we have been optimizing AA-CVD protocols to effectively control the materials properties, and if achieved, this will provide possible enhancement of photocurrentivity and furthermore, PV efficiency of thin films.

EL04.13.15
Basic Improvements in Antimony Chalcogenide Thin Films to Build Efficient and Stable Solar Cells Fabiola De Bray Sánchez, Angélica Lizbeth Espinosa Santana, M. T. Santhamma Nair and P. Karunakaran Nair; Universidad Nacional Autonoma de Mexico, Mexico

Of orthorhombic crystalline structure, Sb$_2$S$_3$ and Sb$_2$Se$_3$ with optical bandgap ($E_g$) of 1.88 and 1.1 eV respectively can produce solar cell absorbers with $E_g$ of 1.3 – 1.6 eV, which can offer short circuit current density of 25 – 35 mA/cm$^2$. Antimony sulfide selenide thin film solar cells reported from our group has conversion efficiency ($\eta$) of 5 – 6 % [1]; and from other groups, it had touched 9 %. To be commercially viable, this value should move toward 20 %.

We present methodologies to improve material properties in antimony sulfide selenide thin films produced by thermal evaporation of chemical precipitate or commercial powders of the binary compounds and their mixtures. Chemical precipitates are produced in our laboratory from solution mixtures of potassium antimony tartrate, thiocacetamide and sodium selenosulfate. To improve the crystalline grain diameter, SbCl$_3$(melting point, 94 °C) is added to the evaporation source mixture. To prevent Sb$_2$S$_x$Se$_{3-x}$ film becoming n-type, Se powder is added to the mixture. The material produced this way has the mobility-lifetime product improved by an order of magnitude, to $10^{-6}$ cm$^2$ V$^{-1}$ s$^{-1}$ superior to that in the other two chalcogenides and a higher p-type electrical conductivity in it due to the low activation energy for Sb-vacancy creation. The $E_g$ of the materials produced is 1.48 – 1.54 eV. All these modifications have led to the development of solar cells with 6.5 % efficiency at absorber thickness 350 – 400 nm and in cell area, 0.5 cm$^2$. In prototype modules of area 7 cm$^2$, it is 4.8%. These cells are encapsulated with commercial resin, for keeping them stable under the sun over many days of operation.

Efficient 1D-Sb₂Se₃ Based Solar Cells in Substrate Configuration
Pedro Vidal-Fuentes¹, Yudania Sánchez¹, Marcel Placidi¹, Victor Izquierdo-Roca¹, Alejandro Perez-Rodriguez¹² and Edgardo Saucedo¹; ¹IREC, Spain; ²Universitat de Barcelona, Spain

One of the most attracting applications for emerging chalcogenide electronic materials is the use of low-dimensional/quasi-covalent compounds as absorbers for direct solar energy conversion into electricity. In this sense, 1D-Sb₂(S,Se)₃ is becoming a relevant thin film chalcogenide semiconductor. In particular, 1D-Sb₂(S,Se)₃ has shown remarkable improvements in the last few years, demonstrating solar cells in superstrate configuration with power conversion efficiencies higher than 7%. In fact, and similarly to CdTe, most of the devices reported in the literature so far have been prepared using this configuration, whiles the substrate configuration option is being marginally used. Additionally Sb₂(S,Se)₃ has shown a high degree of flexibility thanks to the relatively low temperatures required for the synthesis and crystallization of this compound (300-400 °C), being fully compatible with polymeric, steel, ceramic and TCO/glass substrates. This versatility makes this compound very promising for ubiquitous applications such as building integrated photovoltaics, wearables, or autonomous IOT applications among others. Nevertheless, all these technological applications require the urgent development of efficient devices in substrate configuration.

In this work we present a systematic optimization of the synthesis of 1D-Sb₂Se₃ thin films onto conventional Glass/Mo back contact using standard substrate configuration. For the synthesis of 1D-Sb₂(S,Se)₃, an innovative sequential process based on reactive annealing under Se atmosphere of thermally evaporated Sb layers was developed. The study is centered in the analysis of the reactive thermal annealing conditions (temperature, time, pressure) on the compositional, structural and morphological properties of the 1D layers. By adjusting the annealing parameters, we obtain continuous layers with large and homogeneous grains, excellent crystalline quality, and 1D preferential orientation perpendicular to the substrate. We will show that the annealing temperature and Se quantity control in the layer, are the key parameters for controlling the morphology, as well as the structural, optical and electrical properties.

After a first optimization, we report a 1D-Sb₂(S,Se)₃/CdS heterojunction with a promising power conversion efficiency of 5.3% in substrate configuration, demonstrating a Voc of 403 mV (the highest reported value for this configuration to the best of our knowledge).

Additionally, this study is complemented with a wide range of fundamental characterization techniques including photoluminescence, Raman, SEM, XRF, XRD, and with a complete analysis of the impact of the absorber stoichiometry under different regimes (Se-rich, Se-poor, Sb-rich and Sb-poor conditions). All this will be correlated with the optoelectronic characterization (JV, IQE, CV) of the solar cells. Finally, the main urgent challenges to develop Sb₂Se₃ type solar cells in substrate configuration will be presented and discussed.

Tin Chalcogenide Thin Films—Essential Resource for Direct Conversion of Energy
Enue Barrios Salgado¹², Rohini Neendoor Mohan¹, Diana Eréndira Lara Llanderal¹, Fabiola De Bray Sánchez¹, M. T. Santhamma Nair¹ and P. Karunakaran Nair¹; ¹Universidad Nacional Autonoma de Mexico, Mexico; ²Universidad Autónoma de Nayarit, Mexico

Among SnS-CUB, SnS-ORT, SnSe-CUB and SnSe-ORT of cubic and orthorhombic crystalline structures, tin chalcogenides offer an interval of bandgap (Eg) of 1 – 1.74 eV of p-type conductivities owing to the relative abundance of Sn(II) vacancies in them, acting as acceptors. These convert to n-type semiconductors, SnS₂ or SnSe₂ of Eg 1.7 – 2.2 eV when heated at 350 – 420 °C in presence of sulfur or selenium vapor – in which donor centers created due to S – or Se vacancies dominate. We find that heating SnS-Se-CUB films at 350 °C leads to SnSe-ORT and when the heating is done in presence of Se, it forms n-type SnSe₂, both of conductivity 0.01 Ω⁻¹ cm⁻¹ allowing us to build thermoelectric couple with a Seebeck coefficient of 1 mV/K to explore further. In a solar cell structure of SnO₂:F/CdS/SnS-CUB:Ag/C-Ag, a conversion efficiency of 1.5% is achieved, opening up a path toward improving tin sulfide solar cells produced by chemical deposition via diffusion of Ag provided through ion-exchange reaction of SnS-CUB in a dilute AgNO₃ solution. An encouraging new result is that heating of SnS-CUB at 450 °C in presence of S-vapor produces phase-pure p-type Sn₂S₃ film with an Eg of 1 – 1.4 eV and a light generated current density for solar cells in excess of 30 mA/cm². Such conversion takes place via an intermediate formation of SnS₂ due the descending values of the enthalpy of formation of these materials: in kJ/mol, – 91 to – 99 (Sn₉-rock salt - cubic or ORT); – 131 (SnS₂); and – 230 (Sn₂S₃). With energy level diagram very close to that of SnS-ORT, and with an advantage of p-Sn₂S₃ to be phase-pure, free from detrimental n-SnS₂, here is an alternative tin chalcogenide for solar cells. A major attraction of Sn₂S₃ is that it may stabilize also an n-type semiconductor, as per theoretical
model. With a low lattice thermal conductivity, it is also poised to be a prospective thermoelectric element.

**EL04.13.18**

**Cl-Doped SnS Single Crystal and Its N-Type Conduction**

Issei Suzuki¹, Sakiko Kawanishi¹, Yuki Iguchi², Koichi Sato², Takahisa Omata¹ and Hiroshi Yanagi¹; ¹Tohoku University, Japan; ²University of Yamanashi, Japan

Tin monosulfide (SnS) is expected as a light-absorber material for next-generation solar cells due to its advantageous properties: the optimal band gap (~1.0 eV), high light absorption coefficient just above the band gap, and non-toxic and earth-abundant constitutional elements. Since Sn vacancies are easy to form in SnS due to their low formation enthalpy and introduce holes, SnS naturally exhibits p-type conduction and inversion of the carrier type to n-type by doping is quite difficult [1,2]. Nevertheless, n-type SnS was reported in very limited case, that is, heavily Pb-doped SnS (Sn₁₋ₓPbxS, x>0.15), which would, however, cancel the advantage of non-toxicity of SnS [3]. SnS-based solar cells fabricated so far accordingly employed hetero-junction structures, for instance, p-SnS/n-CdS or p-SnS/n-Zn(O,S) [4]. These devices involving the hetero-junction exhibited low conversion efficiencies of ~5% at highest because of unfavorable band offset and/or defect states at the hetero-junction interface suffering from interface recombination [5]. In order to improve the conversion efficiency of the SnS-based solar cells, n-type SnS which enables p/n homo-junction is therefore indispensable.

In this study, we grew single crystals of Cl-doped SnS (i.e., SnS₁₋ₓClₓ) using SnCl₂ as a flux, expecting that chlorine substituting sulfur of SnS would generate electrons. The mixture of Sn, S and SnCl₂ powders were sealed in the vacuum silica glass tube and heated at 520 °C for 24 h, and subsequently cooled down to 240 °C over a period of 36 h and then to room temperature over a period of 12 h. The remaining flux (SnCl₂) was washed away with ethanol and acetone.

Single crystals of SnS in the form of shining lamellate with a surface in perpendicular to the a-axis were obtained. Typical surface area and thickness of the crystals were from 10 to 20 mm² and from 28 to 39 μm, respectively. EPMA analysis indicated that Cl was homogeneously distributed in the single crystal with a concentration of 0.14 at% and segregation of Cl was not found.

Hall coefficient of the single crystal was negative, which indicates that the carrier type is successfully inverted to n-type by Cl doping. The Fermi level of the Cl-doped SnS single crystal determined by XPS was 0.1 eV below the conduction band minimum, whereas that of undoped p-type SnS is generally located at 0.2-0.3 eV above the valence band maximum [2,5], which clearly supports that Cl-doped one is n-type. Hall mobility of electrons of Cl-doped SnS single crystal measured in perpendicular to a-axis was 101 cm²V⁻¹s⁻¹, which is at the same order of magnitude as the Hall mobility of holes of undoped SnS single crystal (100-500 cm²V⁻¹s⁻¹ [6]).

**EL04.13.19**

The Influence of Deposition Temperature and Duration on VTD-SnS Absorber Layer

Jae Yu Cho¹, Taehoon Kim², Hee-Sun Yun², Pravin S. Pawar³, YunSeog Lee², Doh-Kwon Lee⁴ and Jaeyeong Heo⁵; ¹Chonnam National University, Korea (the Republic of); ²Seoul National University, Korea (the Republic of); ³Chonnam National University, Korea (the Republic of); ⁴Chonnam National University, Korea (the Republic of)

Orthorhombic tin sulfide (SnS) has recently been emerged as a very promising absorber material for thin-film solar cells (TFSCs). It has an ideal optical band gap (~1.3 eV) and it comprises of relatively earth abundant constituents and non-toxicity. But till date, the highest efficiency obtained from the SnS-based solar cells is 4.36%, which is fairly low compared to its theoretical limit of ~32%. SnS is a non-cubic material unlike CIGS or CdTe, crystallizing in an orthorhombic structure (JCPDS No. 39-0354, a = 4.3291 Å, b = 11.1923 Å, c = 3.9838 Å). It easily leads to the formation of layered features. Therefore, controlling the morphology of the SnS absorber with dense and pinhole-free grains is crucial.

In this study, the influence of vapor transport deposition (VTD) conditions of tin sulfide (SnS), i.e., growth temperature and duration, on the formation of secondary phases, preferred orientation, and solar cell performance, was investigated. In the growth temperature effect experiment, the morphology is grew as plate form with increasing
temperature and the secondary phase was found at low temperature. Also, it was confirmed that the film thickness was increased linearly with duration and when the growth duration increases to 10 min, a dramatic improvement in the device performance is noted. Finally, fabricated SnS TFSCs (thin film solar cells) achieved near 4% efficiency ($V_{oc}$; 0.342 V, $J_{sc}$; 19.8 mA cm$^{-2}$, FF; 58.0%) at 600 °C growth temperature and 10 minutes duration. In addition, working stability under continuous illumination and damp-heat (85/85) conditions was investigated for the best cell in this study.

*Understanding the Band Gap of Germanium Selenide* Christopher Savory$^1$, Philip Murgatroyd$^2$, Tim D. Veal$^2$, Jonathan Alaria$^2$ and David O. Scanlon$^1$; $^1$University College London, United Kingdom; $^2$University of Liverpool, United Kingdom

Germanium selenide, GeSe, is a member of the IV-VI family of chalcogenide semiconductors, including the champion thermoelectric SnSe, and has itself been studied in the context of many electronic applications, including thermoelectrics, photocatalysis, phase-change memory and photovoltaics.$^{1,2}$ Despite an increasing amount of research interest in recent years, some questions still remain over its fundamental properties, particularly its bulk band gap, recorded values of which range from 1.06 eV to over 1.5 eV with uncertain characterisation as indirect or direct.$^{3,4}$ Theoretical values using standard Density Functional Theory (DFT) also demonstrate similar variation, although the monolayer is consistently a direct gap semiconductor.$^5$ Given the fundamental importance of the band gap to a material’s use within optoelectronic applications, clarification is necessary to establish the most optimal application for this material.

In this study, we use multiple levels of theory, from standard and hybrid DFT to quasiparticle self-consistent GW calculations in combination with Fourier-transform Infrared Spectroscopy (FTIR) measurements of single crystal and thin films of GeSe to characterise its band gap and provide further understanding into its suitability as a solar absorber. We also discuss how the balance between in-sheet covalent bonding and van der Waals interactions between layers affects the electronic properties of the material, including the influences that have previously lead to variations in recorded band gap. Finally, we examine its dynamical stability in comparison with Raman spectroscopy to examine the structural behaviour of the system, and how this can further influence the overall behaviour of GeSe. We believe these results will help influence future interest in GeSe as a solar absorber as well as further discussion surrounding the IV-VI family.

*Modern Solar Cells Based on the World’s Oldest Photovoltaic Material—Selenium and Selenium-Tellurium Alloys for Thin-Film Photovoltaic* Ido Hadar, Tze-Bin Song, Weijun Ke, Xiaobing Hu, Zhongzhen Luo, Vinayak Dravid and Mercouri G. Kanatzidis; Northwestern University, United States

The photovoltaic properties of selenium have been discovered over 140 years and were utilized at that time to produce the first solid-state ‘thin-film’ solar cell. This discovery boosted modern research and technologies based on semiconductors, and lead to the implementation of selenium in many functional devices. Upon the rise of competitive semiconductors and mainly silicon, the usage in selenium slowly declined. In recent years, the photovoltaic community gains new interest in this simple elemental semiconductor as a possible absorber for extremely low-cost and highly scalable solar cells. For this application, selenium shows few desirable properties such as high absorption coefficient, intrinsic environmental stability and fabrication at low-temperature (below 200°C).

In this research, we first study the main parameters that are required to optimize the quality and efficiency of selenium-based solar cells, using modern tools and approach. We indicate the importance of careful annealing of the selenium film, very close to its melting temperature to obtain high-quality films. As selenium has an anisotropic structure, composed of 1D chains, we study how the alignment of the crystals in the thin film changes the device.
properties. Finally, we indicate the importance of light illumination (and excitation) of the film during the fabrication process to enhance and improve the crystallization of the film.

Following these results, we study how the selenium bandgap (1.7 eV), can be tuned to the optimal value for photovoltaic absorber (1.2-1.4 eV), by alloying selenium with the isomorphic low bandgap semiconductor tellurium. We found that the addition of tellurium causes a strong non-linear shift of the alloy’s valence band minimum energy, leading to a non-linear decrease of the bandgap. This non-linear shift enables to reach the desired bandgap by alloying a fairly small amount of tellurium (~10%). Photovoltaic devices based on the selenium-tellurium alloy indeed show improved current density and spectral response as a result of the optimized bandgap. The overall efficiency of the selenium-tellurium devices is still lower than the pure selenium devices, due to lower voltage and fill-factor, but we indicate the main causes to the lower properties and suggest some improvements to the device structure which should improve the device efficiency.

**EL04.13.22**

**Electrical Properties of c-Se/Ga_2O_3 Avalanche Photodiodes** Keitada Mineo, Shigeyuki Imura, Kazunori Miyakawa, Masakazu Namba and Misao Kubota; NHK Science & Research Laboratories, Japan

The demand for high resolution and high-speed imaging devices has increased with the emergence of next-generation broadcasting systems such as full-featured 8K Super Hi-Vision with 33 million pixels and 120 Hz frame rate, which are respectively 16 and 4 times greater than those of current 2K Hi-Vision systems. However, with increasing number of pixels and frame rate, the sensitivity of the image sensor decreases. The sensitivity decreases because of a reduction in the amount of light received per pixel and per frame. To address this problem, we have been studying the stack-type complementary metal–oxide semiconductor (CMOS) image sensor overlaid with a poly-crystalline selenium (c-Se)/gallium oxide (Ga_2O_3) photodiode [1][2]. In this image sensor, high sensitivity can be realized by multiplying photogenerated charges using the avalanche phenomenon. c-Se has a high absorption coefficient in the entire visible light range compared to silicon (Si) that is mainly used to make conventional photodiodes. Therefore, incident light can be absorbed in a thinner film and charge multiplication can be induced using relatively low voltages compared to conventional Si photodiodes. Ga_2O_3 has a wide bandgap of 4.5 eV; the large energy barrier between the work function of indium tin oxide as an electrode and the valence band of Ga_2O_3 prevents hole injection from the electrode, thereby increasing the dark current. To further reduce the operating voltage required for avalanche phenomenon in the c-Se/Ga_2O_3 photodiode, we investigated the effects of doping impurities into Ga_2O_3 and c-Se. First, Sn-doped Ga_2O_3 was fabricated via RF sputtering using a mixed target of tin oxide (SnO_2) and Ga_2O_3. By increasing the concentration of Sn that served as a donor, the photocurrent increased at a low voltage because the increase in Ga_2O_3 carrier concentration achieved via Sn doping caused the depletion layer to mainly spread into c-Se. Then, tellurium (Te)-doped c-Se was prepared by annealing amorphous Se (a-Se) formed on a thin Te nucleation layer. By increasing the carrier concentration of c-Se via the diffusion of Te that served as an acceptor, the avalanche phenomenon could be observed at a low voltage because a high electric field was applied to c-Se. By adding impurities to both Ga_2O_3 and c-Se, an avalanche multiplication factor of 10 could be obtained at an operating voltage of 16 V, which is lower than the operating voltage of non-doped photodiodes (21 V). We believe that the c-Se/Ga_2O_3 avalanche photodiode will lead to the development of high-sensitivity image sensors.

**EL04.13.23**

**Amorphous Selenium Direct Conversion X-Ray Detector with 7.8-Micron Spatial Resolution** Chris Scott1, Yunzhe Li1, Celal Con1, Michael Farrier1 and Karim Karim1,2; 1KA Imaging, Canada; 2University of Waterloo, Canada

Imaging using x-ray radiation plays a significant role in advancing industry and fundamental research by utilizing the highly penetrating nature of x-rays to study the internal composition of materials. Image quality is fundamentally limited by the number image forming photons, which is governed by the detector quantum efficiency (QE). Conventional high spatial resolution scintillator-based indirect conversion detectors have poor QE due to thinning of the scintillator to minimize secondary optical scatter. This makes them non-ideal for emerging scientific imaging
tasks such as phase-contrast x-ray imaging (e.g. for visualizing low density composite materials).

We have developed a direct conversion detector by integrating amorphous selenium (a-Se) photoconductor material and a CMOS readout circuit with 7.8 µm pixel pitch. Unlike the optical scatter in scintillators, the spread of absorbed energy from x-ray interactions in the photoconductor does not significantly degrade spatial resolution as the a-Se thickness is increased. The detector was vertically integrated by CMOS post-processing using thermal evaporation. An a-Se layer of 118 µm and top biasing electrode were directly deposited. After packaging, wire-bonding was performed below the glass transition temperature of a-Se to prevent crystallization. Finally, a high-voltage connection was provided from the package to the surface of the electrode. A biasing voltage of 500 V was applied to the electrode, resulting in an internal electric field of 4.2 V/µm.

The detector was characterized at 60 kV with 2 mm Al filtration. Using the slanted-edge technique the pre-sampling MTF of the detector was measured. The line-spread function had a full width at half-maximum of 8.7 µm and in the spatial frequency domain the MTF decreased to 30% at Nyquist frequency, ≈64 cycles/mm, i.e. equivalent to 7.8 µm spatial resolution. The theoretical upper bound on the DQE at zero spatial frequency, DQE(0), is equal to the detector QE of 0.49. The measured DQE(0) was determined to be approximately 0.42, a decrease due to the presence of noise and additional pathways of signal loss.

To the best of our knowledge, this characterization demonstrates the highest spatial resolution direct conversion detector reported for the hard x-ray regime. In addition, our results suggest that a-Se photoconductors offer a high detection efficiency alternative to scintillator technology for high spatial resolution x-ray imaging tasks such as phase contrast x-ray imaging.

EL04.13.24
Two-Stage Melt Processing of Phase Pure Selenium for Printable Triple Mesoscopic Solar Cells Jiawen Wu1,2 and Hongwei Han1,2; 1Huazhong University of Science & Technology, China; 2Wuhan National Laboratory for Optoelectronics, China

Hexagonal selenium with a direct band gap has been developed for optoelectronic applications through the last 130 years. Most advances have been made using vacuum deposition or solution methods. Herein we demonstrate a simple two-stage melt processing (TSMP) method to incorporate selenium in printable triple mesoscopic solar cells under ambient conditions. While a simultaneously triggered polymerization and depolymerization between several types of Se chains happen during the melt processing, we successfully realize phase-pure hexagonal selenium inside the mesopores with high crystallinity. We found that the TSMP method has an obvious effect on the CB energy level, band gap and crystal phase of selenium by ultraviolet electron spectroscopy, ultraviolet-visible absorption spectroscopy and in situ X-ray diffraction. Compared with the single melting process, the power conversion efficiency of the printable mesoscopic device was increased eight times to 2% through TSMP. These findings provide a new strategy for the melting process to obtain a more efficient photovoltaic device.

EL04.13.25
Evolution of Physicochemical Properties as Function of Size and Design Principles of Transition-Metal Dichalcogenide Nanoflakes—Insights from Ab Initio Investigations Naidel A. Caturello1, Rafael Besse1, Augusto C.H. Da Silva1, Diego Guedes-Sobrinho1, Matheus P. Lima2 and Juarez L. F. Da Silva1; 1University of São Paulo, Brazil; 2Federal University of São Carlos, Brazil

Two-dimensional transition metal dichalcogenides (2D TMDs) have been brought into the limelight due to their unique optical, electronic, and mechanical properties, which enables them for a wide range of applications.[1,2] Defined by the chemical formula \( MQ_2 \), where \( M \) is a transition-metal and \( Q = S, Se, Te \), each monolayer of a 2D TMD is composed of a metallic plane sandwiched by two \( Q \) planes, where the coordination around the metal atoms can be trigonal prismatic, octahedral, and distorted octahedral (named 2H, 1T, and 1T' phases, respectively).[3] Despite the great technological and scientific interest drawn by those compounds, the atom-level understanding of how the physicochemical properties of 2D TMDs evolve with system size is still far from satisfactory. Thus, we report \textit{ab initio} density-functional theory investigations of 2D TMDs nanoflakes with diverse sizes and chemical compositions, namely (i) \( (MoSe_2)_n \), with \( n = 15, 63, 108, 130, 154, \) and \( 192,[4] \) (ii) \( (MoQ_2)_n \), \( Q = S, Se, Te \), with \( n = 1 – 16,[5] \) and (iii) \( (WQ_2)_n \), \( Q = S, Se, Te \), with \( n = 1 – 16, 36, 66, \) and \( 105.[6] \) We found that the 1T' phase has the lowest energy for small MoSe\(_2\) nanoflakes, and a size-induced 1T' → 2H phase transition occurs, which is mainly
due to the higher edge formation energy of the 2H phase. Furthermore, for the $n = 1 - 16$ size range for both Mo$Q_2$ and W$Q_2$ nanoflakes we observed a transition in energetic preference from structures elongated in one dimension with almost-equilateral trusses composed metallic lattices (1D), to 1T' nanoflakes. The mechanism of stabilization of the 1T' nanoflakes in relation to the 1D geometries results from a combination of two stabilization effects, namely the edge charge modulation in the edges of the structures, and the distortion of the octahedral geometry throughout the core of 1T' nanoflakes. Both 1D and 1T' maintain the same $Q$-terminated edge configurations, which stabilizes both morphologies in relation to 2H stoichiometric monolayer fragments. Since the edge charge effects are more intense in the order Te $<$ Se $<$ S, the cluster size in which 1D $\rightarrow$ 1T' occurs increases in the order $M_S^2 < M_{Se}^2 < M_{Te}^2$, $M = Mo, W$. Furthermore, for the W$Q_2$ nanoflakes we have established systematically that the most stable nanoflakes are composed of junctions between triangular building blocks. The geometric forms originated from those junctions are stabilized due to maximization of bonds formed within the core of the nanoflakes. Therefore, by extending the sizes of the nanoflakes we could extend our understanding to the interplay of nanoflake size and stability. As a whole, our investigations could establish that the mechanisms of stabilization of the group-6 TMDs nanoflakes can be summarized as follows: (a) conservation of the $Q$-terminated edge configuration; (b) geometry of the nanoflakes as junctions of triangular building blocks; (c) edge charge modulation effects in order to stabilize 1T' nanoflakes opposed to 1D stripes; and (d) octahedral distortions responsible for breaking the degeneracy of electronic levels. Therefore, we could establish the criteria for the proposition of stable $MQ_2$, $M = Mo, W$; $Q = S, Se, Te$ nanoflakes, and our findings can help to explain independently obtained experimental results.[6]

EL04.13.26
High Performance Ag:Se Nanoparticle Based Flexible Near-Infrared Photodetectors Won-Yong Lee, Seunghyun Ha, Hyunjae Lee and Jaewon Jang; Kyungpook National University, Korea (the Republic of)

Novel, low-voltage, high-detectivity, solution processed, flexible near-infrared (NIR) photodetectors for opto-electronic applications were realized and their opto-electronic properties were investigated for the first time. This was achieved by synthesizing Ag:Se nanoparticles (NPs) in aqueous solutions, and depositing highly crystalline Ag:Se thin films at 150 °C with re-distributed Ag:Se NPs in aqueous inks. The high conductivity and low trap concentration of the 150 °C annealed Ag:Se films result from the Ag formed inside the films and the improved film quality, respectively. These factors are both critical for the realization of high-performance flexible photodetectors. The fabricated device exhibited a high detectivity of $7.14 \times 10^9$ Jones (above $1 \times 10^9$) at room temperature, delivering low power consumption. This detectivity is superior to those of reported low bandgap semiconductor systems, although the device had undergone 0.38% compressive and tensile strains. Moreover, the performance of the device is better than that of MoS$_2$-based phototransistors, black arsenic phosphorus field-effect transistors (FETs) or commercial thermistor bolometers at room temperature (D* $\sim 10^8$ Jones) and exposed to mid-infrared (MIR) light.

Design and Synthesis of Novel Semiconductor Nanostructures for Photon Upconversion Tory Welsch, Jill Cleveland, Eric Chen, Christopher Milleville, Kyle Lennon, Jing Zhang, James Bork, Joshua Zide and Matthew Doty; University of Delaware, United States

Photon upconversion is a process by which two or more low-energy photons are absorbed and one higher-energy photon is emitted by a material. Materials that can achieve photon upconversion are desirable for many applications such as optoelectronic devices, drug delivery, and photovoltaics. A key advantage of using semiconductor nanoparticles for photon upconversion is their wide tunability in structure, which consequently affects their absorption and emission properties. We have synthesized colloidal quantum dot (QD) heterostructures for this purpose, in which two QDs with different bandgaps are separated by a wide-bandgap nanorod. While our
CdSe(Te)/CdS/CdSe core/rod/emitter structures demonstrate near-infrared (NIR)-to-visible photon upconversion, their upconversion efficiencies show significant room for improvement. The performance of these structures can be enhanced through a better understanding of their underlying properties and the effect of these properties on upconversion efficiency. While we can further our understanding through theoretical modeling, we must also consider the constraints of available synthesis techniques. Synthesis parameters such as ion precursors, organic ligands, and temperature, among others, can be tuned within well-studied procedures to create structures with the desired composition, structure, and resulting optical behavior. For example, introducing a bandgap gradient along the nanorod through doping has been found to funnel carriers to the emitter, increasing both quantum yield and upconversion efficiency. We have therefore studied an “inverted” emitter/rod/core structure which allows this gradient to form more naturally during synthesis. We have also found that charge carrier separation can be improved by controlling the position of the core along the rod and by optimizing the length of the rod. This has led us to explore spherical core/shell/shell structures with varying shell thicknesses and gradients and to explore other material compositions such as PbS to further tune absorption and emission wavelengths. We present these synthesis methods, the resulting structures, and their impact on upconversion performance as characterized by photoluminescence and power dependence measurements. We describe how further upconversion performance enhancement can be achieved through improved structural control, which will allow for future incorporation into various photonic device applications.

**Mid-IR Ag2Se-Based Colloidal Quantum Dot Photodetectors** Ayaskanta Sahu¹, Dong Kyun Ko², Shihab Hafiz², and Michael Scimeca¹; ¹New York University, United States; ²New Jersey Institute of Technology, United States

Mid-wavelength infrared (IR) photons have high penetration through airborne obscurants such as fog and mists, rendering mid-IR photodetectors ideal for use in long-distance thermal sensing and enhanced night vision applications. Colloidal quantum dot-based mid-IR photodetectors present a promising path toward fabricating sensors and imagers at significantly reduced cost compared to state-of-the-art epitaxial grown quantum-well IR detectors. Herein, we report on recently discovered silver chalcogenide quantum dots that exhibit distinct optical absorption in the mid-IR. These colloidal quantum dots demonstrate a narrow bandgap metastable tetragonal phase, not available in bulk, and contain excess electrons, allowing intraband optical transitions between the first and the second conduction energy levels. In this talk, I will present the synthesis, characterization, and photoconductive photodetector device characteristics of this relatively benign colloidal IR material, in contrast to highly toxic Hg-based competing mid-IR devices.

**EL04.13.29**
**Molecular Modeling of Two-Dimensional Quantum Dot Solids Formation Using the Simple Molecular Reactive Force Field** Isaiah Chen and Paulette Clancy; Johns Hopkins University, United States

Quantum dots composed of lead chalcogenides (PbX, X = S, Se, Te) have shown considerable promise for use in various applications ranging from photovoltaics to optoelectronics, including commercial implementations in displays and cell phones. However, there has been limited use with these nanoparticles in electronic devices due to the lack of coupling between multiple quantum dots. Consequently, there has been a significant amount of research focusing on the combination of self-assembly and directed attachment of colloidal quantum dots at fluid interfaces to form two-dimensional quantum dot superlattices. Currently, the mechanism for the formation of two-dimensional quantum dot superstructures is not fully understood and, not unrelatedly, materials that are produced experimentally contain defects that hinder the performance of the material. Various factors, such as inhomogeneous coupling, variation in quantum dot size and shape, and positional misalignment, create structural disorder that is detrimental to the overall charge transport in the chalcogenide material.

We are using ab initio Density Functional Theory (DFT) and Molecular Dynamics (MD) to study the atomic behavior behind the oriented attachment of multiple colloidal lead sulfide quantum dots. These methods serve as an important tool for elucidating the thermodynamic and kinetic factors that govern the interactions between the organic ligands bound to the surfaces of the quantum dots and the amine-based chemical trigger used to remove them from the surface and the epitaxial bridge formation between multiple colloidal quantum dots. We have studied reactions between the ligands and the chemical trigger in solution using the PBE functional in DFT.

While the DFT calculations provide an accurate picture of the interparticle interactions, we need to turn to a semi-
empirical approach that will allow us to access orders-of-magnitude-larger system sizes. To do so, and to accurately model a system with multiple lead sulfide quantum dots, we use the Simple Molecular Reactive Force Field (SMRFF), which we have developed to model the reactive processes that give rise to PbS bond formation. The SMRFF potential is drawn from a combination of simple potentials (Morse/Tersoff, Lennard-Jones, and Coulombic). The parameters for each individual potential are obtained using a training set with multiple 32-atom geometries. For each geometry, the energy of the system is calculated using DFT and the SMRFF parameters are optimized to match the energy as closely as possible. With this fully parameterized SMRFF potential, we are then able to provide the first reactive force field simulation of epitaxial bridge formation between multiple PbS quantum dots. The ability to watch this process allows us to understand how misalignment and processing conditions, such as thermal annealing, affect the nature of the bridges including defect formation.

**EL04.13.30**

**Electrochromism of Electrophoretic CdSe QD Films**

Yauhen Aniskevich\(^1\,^2\), Mikhail Artemyev\(^2\), Genady Ragoisha\(^2\) and Eugene Streltsov\(^1\); \(^1\)Belarusian State University, Belarus; \(^2\)Research Institute for Physical Chemical Problems of Belarusian State University, Belarus

Quantum dots (QDs) and QD films are actively studied due to their properties tunable by particle size, shape and composition. Electrochemical treatments can affect QD film properties, e.g. by surface modification or electrochemical doping. The electrochemical doping proceeds via electron transfer from an electrode substrate to quantum dot which fills energy level in conduction band. The latter causes changes in QD film absorbance and luminescence.

Here we report on electrochemistry and spectroelectrochemistry of CdSe QD films obtained by electrophoretic deposition on FTO from CdSe QD colloidal solution.

Cyclic voltammetry of CdSe QD films in deaerated 0.1 M TBAPF\(_6\) solution in acetonitrile has revealed particle size effects which were also dependent on electrode potential scan rate. A cathodic current shoulder develops in the negative scan below −1 V followed by monotounous current increase at more negative potentials. Current response after scan reversal depends on the QD particle size. For the smallest particles studied (2.8 nm), no considerable anodic current was observed, contrary to the case of bigger particles (6.3 nm) which caused a distinct anodic peak. The negative scan also produces changes in absorbance spectra of the QD films by filling electron energy levels in conduction band. As the potential is scanned negatively, absorbance of first exciton decreases almost to the background level. The variation of absorbance reveals electrostimulated changes in the whole film not restricted to the interface. The changes in optical properties were observable even with naked eye, while the electrode color was varying in the potential scan. Spectroelectrochemical data have revealed reversible character of the electrostimulated optical effects.

We also consider effects of oxidant in the electrolyte solution on electrochromic response.

Thus, our investigation has revealed the reversible electrochromic behavior of electrophoretically deposited oleate-capped CdSe QD films with the size-dependent electrochemical response of the films.

This work has been supported by Horizon 2020 research and innovation program under MSCA-RISE-2017 grant agreement No. 778357.

**EL04.13.31**

**Copper-Based Chalcogenide Nanostructures—Tunable Structural and Electronic Properties towards Enhanced Photoconductivity**

Richard A. Taylor, Shanna-Kay Spencer and Kimberly Weston; University of the West Indies, Trinidad and Tobago

In recent years, copper-based multinary chalcogenide semiconductors have emerged as promising non-toxic, low-cost and high efficiency alternatives for thin film solar cell applications. However, it is still difficult to prepare them in high quality and controllably tune their structural, electronic and optical properties. As such, our research has been focussed on developing facile and attractive routes to tune structure and optical properties of promising ternary chalcogenide solar absorber materials including un-doped and doped copper indium sulphide (CIS) and the emerging copper antimony sulphide (CAS) nanostructures, as examples. In particular, we have been able to effect time-dependent and dopant-dependent phase transformation of CIS and CAS nanoparticles via hot-injection colloidal chemistry using a unique combination of metal-organic precursors and capping agents over a range of temperatures. Un-doped CIS quantum dots of quasi-spherical morphology with fairly narrow size distribution (5.6 ± 1 nm) exhibit time-dependent phase transformation from wurtzite to chalcopyrite structures. However, wurtzite to
chalcopyrite phase transformation was also induced in silver-doped CIS with increasing Ag⁺ dopants and corresponding tuning of electronic absorption and emission properties across the visible to near-infrared spectral region influenced by In³⁺ and Ag⁺ interstitial and Cu⁺ vacancy defects. Also, as-synthesized (60 – 70 °C) CAS nanoparticles (2 – 20 nm) exhibit tunable morphology of spherical, hexagonal and plate-like structures with tunable indirect band gap between 3.39 and 3.54 eV, atypical for CAS. These findings suggest attractive routes to tuning structure and optical properties and effective means for possibly enhancing photoconductivity in these ternary chalcogenides. With detailed elucidation from powder X-ray diffraction, Raman spectroscopy, transmission electron microscopy, atomic force microscopy, energy-dispersive X-ray spectroscopy, X-ray photoelectron spectroscopy, steady-state and time-dependent electronic spectroscopy we have been able to propose mechanisms of phase transformation and the effect of stoichiometry (including intrinsic and extrinsic dopants) on structural and electronic properties in these materials for tunable photovoltaic effects.

EL04.13.32
Analysis of Self-Assembled Quantum Dot Superlattices for PV Applications Adam J. Moule¹, Xiaolei Chu¹, Hamed Heidari Mezerji¹, Alex Abelson², Caroline Qian², Davis G. Unruh¹, Chase M. Hansen¹, Gergely Zimanyi¹ and Matt Law²; ¹University of California, Davis, United States; ²University of California, Irvine, United States

Epitaxially-fused colloidal quantum dot (QD) superlattices promise to combine the unique photophysics of QDs with the efficient band transport of bulk-semiconductors. PbS and PbSe QD layers have demonstrated multiple exciton generation in response to photo excitation by high energy photons. We would like to extend the multi-exciton generation to thick arrays of QDs, which is possible if the structural order of the film is improved to reduce electronic traps. Here we focus on fabrication of extended superlattice films with multi-layers of QDs and examine how the fabrication method affects the local order. Specifically, we form ordered arrays of QDs at a liquid-liquid interface and then reduce the spacing between QDs using in-situ ligand exchange. The resulting films are characterized using high-resolution scanning transition electron tomography (STET). We are able to resolve the position of each QD in a sample encompassing 1000’s of QDs. In addition of the particle positions, we also resolve the presence (or lack of) of epitaxial connections between neighboring QDs and the thickness of the neck formed between neighboring QDs. This morphological information is used to generate an electronic model. Our model shows that the energetic disorder caused by heterogeneous epitaxial bridging between QDs in a single domains is about one order of magnitude less important than the presence of disorder at grain boundaries between superlattice domains. This presentation will explore the link between structural and electronic order in these complex 3D samples.

GaN Nanowires on Diamond for NV-Center Control Martin Stutzmann, Martin Hetzl, Max Kraut, Theresa Hoffmann and Julia Winnerl; Technische Universität München, Germany

Diamond is an interesting substrate for the growth of GaN nanowires and other nanostructures such as nano-fins for a number of reasons. It is chemically and mechanically very stable, has a high thermal conductivity, a much larger electrochemical window than GaN, is optically transparent up to a photon energy of about 5.3 eV, and can be very effectively doped p-type by controlled substitutional boron incorporation, e. g. during CVD growth. Therefore, heteroepitaxial structures of AlGaN thin films on diamond substrates have been investigated with increasing emphasis since more than a decade, mainly for electronic and optoelectronic applications. In comparison, much less work has been devoted the growth of AlGaN nanowires on diamond, which is the main topic of the work described here.

We are interested in GaN nanowires on single crystalline diamond substrates for electrical and optical addressing and read-out of nitrogen-vacancy (NV) centers as the most sophisticated solid-state qubits available so far. The target of this work is to develop a technology for the integration of surface-near NV-centers in the intrinsic layer of p/i-diamond/n-GaN hetero-diodes with varying concentrations of implanted NV-centers were then fabricated and characterized with respect to their optical and electronic properties. In particular, it was observed that the efficiency of the optical read-out of the NV photoluminescence is increased by an order of magnitude for diamond covered with an optimized periodic GaN nanowire array compared to the bare diamond substrate. Fourier imaging of the NV photoluminescence allows the determination of the crystallographic orientation of single NV centers underneath a GaN nanowire. Furthermore, efficient electroluminescence of NV centers could be achieved by forward current injection. Finally, an outlook will be given to the future implementation of GaN nano-fins and -grids on different substrates including diamond.

Diamond Electronic Devices for Power Electronics Etienne Gheeraert1,2; 1University of Grenoble-Alpes, France; 2University of Tsukuba, Japan

The key to the efficient transmission and conversion of low-carbon electrical energy is the improvement of power electronic devices. Diamond is considered to be the ultimate wide bandgap semiconductor material for applications
in high power electronics due to its exceptional thermal and electronic properties. Two recent developments - the emergence of commercially available electronic grade single crystals and a scientific breakthrough in creating a MOS channel in diamond technology, have now opened new opportunities for the fabrication and commercialisation of diamond power transistors. These will result in substantial improvements in the performance of power electronic systems by offering higher blocking voltages, improved efficiency and reliability, as well as reduced thermal requirements thus opening the door to more efficient green electronic systems.

In the literature, several diamond-based field-effect-transistors (FETs) have already revealed good on state performance and high blocking voltage capability (~2kV) in a wide range of operating temperatures. The possibility of generating an inversion regime in diamond metal-oxide-semiconductor FET (MOSFET), and the new Deep Depletion regime (D2MOSFET) specific to wide bandgap semiconductors pave the way for a new generation of power devices. The critical part of the transistor is the gate oxide, with electrical charge traps located within the oxide or at its interface with the semiconductor. These traps can screen the gate potential and shift the threshold voltage, making the devices unusable.

The current research carried out mainly in Japan and Europe will be presented, with the various device architectures explored, including MOSFET, MESFET, D2MOSFET and rectifiers. Results obtained in the framework of the first European research collaboration on diamond devices, aiming at fabricating the first HVDC diamond based converter will also be presented.

Diamond Growth and Device Technology for Quantum Sensing Mutsuko Hatano; Tokyo Institute of Technology, Japan

Nitrogen-vacancy(NV) centers in diamond have superior physical properties at room temperature for quantum sensing of the magnetic field, electronic field, temperature, and pressure enabling scalable applications from atomic-scale to macroscopic range. We would like to introduce our recent progress on materials and devices.

- Homoepitaxial growth: Higher generation yield of selectively-aligned NV ensemble formed with precise depth control for scalable applications [1,2].
- Heteroepitaxial growth: Diamond film with aligned NV ensemble on Si (111) substrates via the 3C-SiC layer by original antenna-edge type microwave plasma CVD [3].
- Devices: Charge state control of NV centers by pn junctions [4]. As applications, we would like to introduce the bio-cell imaging with the magnetic marker[5], internal device sensing [6], and probe-type prototype system.

This study was supported in part by MEXT Q-LEAP and KAKENHI (17H01262 and 18H01472).

Development of an Ultra-Sensitive Biosensor Based on Mid-Infrared Diamond Waveguide Spectroscopy
Mikael Karlsson¹², Pontus Forsberg¹, Lars Österlund¹², Fredrik Nikolajeff¹², Per Ola Andersson¹², Joakim Bergström¹, Julian Haas³ and Boris Mizaikoff⁴; ¹Uppsala University, Sweden; ²Molecular Fingerprint Sweden AB, Sweden; ³FOI Swedish Defence Research Agency, Sweden; ⁴Ulm University, Germany
In this presentation, our latest work in the development of an ultra-sensitive biosensor based on diamond waveguides will be highlighted. We have during the last years been working on the design and fabrication of mid-infrared (MIR) diamond waveguides. The diamond MIR waveguides together with a broadband tunable quantum cascade laser (QCL), emitting in the so called molecular fingerprint region, are the two key elements in our newly developed label free MIR biosensor. In our approach MIR light is coupled into microfabricated diamond waveguide structures, which are purposefully designed to sustain single or multimode standing waves. The associated evanescent waves that are created at the waveguide surface will extend into the surrounding media and interact with the analyte thus provide the sensing volume. In existing commercial technologies, attenuated total reflection IR (ATR-IR) spectroscopy, IR light from a thermal emitter is coupled through a millimeter sized diamond crystal, with up to 10 internal reflections in the diamond crystal. This is a powerful technology and is today used for i.e. quality control in medical and food industry, protein analysis, forensics, etc. However, the relatively low sensitivity of this technique hinders its use in many applications. Our biosensor achieves unsurpassed sensitivity due to the large number of standing waves nodes created in our waveguides which roughly can be translated to the number of internal reflections per length unit is maximized. Moreover, the use of a bright QCL laser as a light source further increases the sensitivity of our biosensor – therefore an ultra-sensitive sensor is realized. Finally, the diamond waveguide material facilitates further functionalization by means of organic chemistry thus extending the capabilities of traditional silicon or gold based biosensor technologies, and we demonstrate here one possible route to fabricate selective affinity layers for protein fishing on nanocrystalline diamond overlayers.

Several designs of diamond waveguides are discussed, ranging from thin film diamond slab waveguides, rib waveguides, to microfabricated free hanging diamond waveguides. Different dimensions of microfabricated polycrystalline diamond waveguides have successfully been fabricated with thicknesses ranging between 5 to 15 µm. Focused ion beam etching has been applied to study the effect of controlled surface roughness of the in- and out coupling area of the waveguides, and to establish limits of attainable throughput of the waveguides. The complete setup of the biosensor is presented.

To demonstrate the strength of using a bright QCL as a light source, we show how a multi-reflection diamond crystal (450 µm thick) can be used for non-invasive glucose monitoring in human saliva. Furthermore, we present measurements on different types of analytes at low concentrations using our waveguide designs to demonstrate the sensitivity of the sensor.

Currently, our main activity is on analyzing different forms of the protein alpha-synuclein, which is relevant in understanding the mechanism behind Parkinson’s disease. We have previously shown that ATR-IR spectroscopy can be used to analyze the secondary structure of different alpha-synuclein aggregates. Moreover, it is also possible to see the difference in the IR-spectra between the native state and the neurotoxic misfolded state of the protein. However, the ATR element is impractical to functionalize and the sensitivity of the ATR-IR spectroscopy is too low to be used on relevant samples from patients. In contrast, our diamond waveguide biosensor exhibits the desired key properties to analyze the secondary structure of alpha-synuclein at biologically relevant concentrations. Future work includes the functionalization of the diamond waveguide sensor surface to selectively adsorb alpha-synuclein from cerebrospinal fluid, with the ultimate goal to detect Parkinson’s disease at an early stage.

11:00 AM EL05.02.02
Alligator Photonic Crystal Cavities in Bulk Diamond Kevin C. Chen1, Sara Mouradian2, Eric Bersin1 and Dirk R. Englund3; 1Massachusetts Institute of Technology, United States; 2University of California, Berkeley, United States

Central to quantum information processing is the entanglement generation rate, which can be Purcell enhanced by coupling a quantum emitter to a cavity. One-dimensional hole-y photonic crystal cavities in diamond have already demonstrated >10,000 quality factors and small mode volumes [1], two necessary characteristics for achieving high cooperativity. However, color centers such as the nitrogen vacancy center typically exhibit severe spectral diffusion near surfaces, resulting in reduced coupling rate under the presence of holes. Inspired by Hood et. al.’s atomic platform [2], we propose using the alligator photonic crystal cavity that removes the airgaps and thus pushes the emitters farther away from surface charge states. Here, we report the simulation results and the characterization of alligator cavities in bulk diamond. Realization of this nanophotonic structure allows for a more noise-resilient cavity QED system essential for constructing a scalable quantum network.

The ability of pigeons to sense the magnetic field of the Earth has long been established through behavioral studies, however, the underlying biophysical mechanisms are yet to be determined. Magnetoreceptors in the beak\(^1\), retina\(^2\) and inner ear hairs\(^3\) have been proposed. Markers for neuronal activation have previously been used to link the vestibular brain-stem region to magnetic stimulation\(^4\). This activation is contingent on the lagena being intact, providing strong evidence that magnetoreceptors are present in inner ear hairs and support the ferrimagnetic particle receptor hypothesis for magnetoreception. These results warrant further investigation into iron containing cells within this part of the pigeon anatomy. The discovery of quasi-spherical structures in the cuticular plate of the inner ear hair of pigeons was subsequently made, with these structures being termed ‘cuticulosomes’\(^3\). These objects are of potential relevance to the problem of magnetoreception due to their position in the pigeon anatomy and because they contain ferritin granules. Cuticulosomes have been imaged using TEM and characterized using elemental analysis. Statistics surrounding the occurrence of these spherical structures having been developed through Prussian Blue staining experiments, however, we have limited information on their magnetic properties\(^3\).

Quantum magnetic microscopy techniques\(^5\)–\(^7\) provide an opportunity to remedy that situation. The nitrogen-vacancy centre in diamond has a sensitivity to magnetic fields which allows for the mapping of both fluctuating magnetic moments and of static magnetic fields from samples affixed to the surface of the diamond\(^8\). Here we apply diamond-based quantum magnetic microscopy to probe the fluctuating magnetic fields emanating from individual cuticulosomes. The magnetic images are correlated back to the anatomical location providing critical in-situ magnetic information. The stray magnetic field from the cuticulosomes was also mapped using our quantum imaging microscopes under the application of a bias magnetic field. The magnitude of the stray magnetic field increases with the size of the bias field applied with the dependency of the stray fields on the externally applied field providing additional insight into the magnetic properties of cuticulosomes.

The quantum imaging technique applied here provides new physical insights into the magnetic properties, i.e. magnetic susceptibility, of individual cuticulosomes. The information gleaned will aid in the effort to understand the functionality of cuticulosomes, and crucially, if they have any bearing on the ability of pigeons to sense magnetic fields.

11:30 AM *EL05.02.04
Lightweight and Compact Laser Processing Heads Based on Diamond Lenses Martin Traub\(^1\), Carlo Holly\(^2\), Mario Hesker\(^2\), Angelo Di Meo\(^3\), Dennis Arntz\(^4\), Jan Bremer\(^1\), Dieter Hoffmann\(^1\), Christoph E. Nebel\(^1\) and Reinhart Poprawe\(^5\); \(^1\)Fraunhofer Institute for Laser Technology ILT, Germany; \(^2\)TRUMPF Photonics, Inc., United States; \(^3\)RWTH Aachen University, Germany; \(^4\)EdgeWave GmbH, Germany; \(^5\)Fraunhofer Institute for Applied Solid State Physics IAF, Germany
For laser materials processing like cutting and welding, multi-kw continues wave fiber and disc lasers are used. State-of-the-art high power laser optics used for these applications are mainly based on fused silica as an optical material. High purity synthetic fused silica offers high transmission, but due to the limited thermal conductivity, significant radial thermal gradients occur inside the optical components caused by the residual absorption of the substrate’s and coating’s material. As the lenses have to be cooled at the outer non-irradiated section of the aperture, these gradients cannot be avoided by design. The inhomogeneous temperature distribution of the lenses causes three effects: firstly, the shape of the lens changes due to thermal expansion. Secondly, the index of refraction varies, and thirdly, mechanical tension is caused by inhomogeneous heating of the lens, and thereby stress birefringence can be observed. Therefore, first and higher order optical properties of optical systems for high-power lasers depend on the temperature, leading to focal shift and thermally induced aberrations commonly referred to as thermal lensing. In addition, high thermal loads of the optical coatings and the bulk material limit the minimum diameter of the optical setup.

Due to its outstanding optical, thermal and mechanical properties, monocrystalline synthetic diamond is a very promising material to overcome these limitations: the extremely high thermal conductivity which is approximately three orders of magnitude higher compared to fused silica results in a nearly uniform temperature profile and provide efficient cooling of the optical coatings on the diamond-air interfaces. In addition, the diamond’s high Young’s modulus and index of refraction allow for thinner lenses as the radius of curvature is nearly three times larger for a diamond lens compared to a fused silica lens of the same power, and the coating design also benefits from the high index of refraction.

In a cooperation of the three Fraunhofer Institutes ILT, IAF and IPT the complete process chain for setting up small and lightweight laser processing heads has been developed. This process chain includes optimized CVD based growth of synthetic diamond, grinding, centering as well as characterization of diamond lenses, optical design of all-diamond optical systems for materials processing, high performance optical thin film coatings for diamond lenses, and mechanical design as well as testing of laser processing heads. To characterize the diamond lenses, we have measured surface deviation, surface roughness, local birefringence and the intensity profile of a laser beam focused by diamond lenses designed and manufactured by the Fraunhofer consortium. The coating consists of a single layer of a low-absorption material.

We have realized two compact material processing heads based on diamond lenses. The first demonstrator is designed for thin metal sheet cutting. One of the main goals of the optical and mechanical design process was to minimize the laser processing head’s weight and size. Therefore, no conventional fiber mount and collimating optics was foreseen. Instead the optical fiber is directly connected to the laser processing head. The lens mount is made of copper and cooled by water. To adjust the nozzle’s outlet to the laser’s focal plane, the nozzle can be axially moved by a threaded cylinder. The realized laser processing head weights approx. 200 g. For the cutting experiments, a 1 kW single mode fiber laser was used, and the sheet metal was attached to a motorized x-y-table. The second demonstrator is used for laser material deposition and is based on a similar optical and mechanical design, but generates a larger laser spot. This demonstrator was also successfully tested in first material processing experiments.

SESSION EL05.03: Diamond Growth I
Session Chair: Matthias Muehle
Monday Afternoon, December 2, 2019
Hynes, Level 1, Room 107

1:30 PM *EL05.03.01

An inductively coupled toroidal plasma is used as an energy source alternative to microwave plasma for chemical vapor deposition (CVD) of diamond material. With up to 12 kW output power, the patented Plasmability platform leverages a powerful, scalable, and efficient 400 kHz RF power supply.

The Plasmability system has been designed specifically for the needs of diamond deposition: high flux atomic hydrogen (power density ~800 W/cm³) distributed uniformly as a line source. As currently manifested, the plasma
shape is ideal for the growth of single crystal diamonds in arrays up to 15mm wide by 35mm long. Plasma-to-sample distance is dynamically controlled during the entire growth process over a range of several millimeters, keeping the growing surfaces at all times at an optimum distance relative to the plasma.

Recent average growth rates of homoepitaxial single crystal diamond exceed 160 um/hr with optical grade clarity. Raman spectroscopy, XRD rocking curve, and birefringence of the material verify the growth of high-quality diamond. Leveraging the high growth rates available, Plasmability is pursuing large area single crystals (beyond 1 inch).

This work is carried out in part under support from Army Research Laboratory SBIR Contract W911QX-18-C-0017.

2:00 PM EL05.03.02
MPACVD Growth of 4-inch Diameter Diamond Films at 2.45GHz with High Uniformity (<5%) Alexandre Fiori1, Mariko Suzuki1 and Philippe Bergonzo2,3; 1Seki Diamond Systems, Cornes Technologies Ltd., Japan; 2Seki Diamond Systems, Cornes Technologies USA, United States; 3University College London, United Kingdom

Progresses in CVD allowed high quality diamond films to be deposited on large area for emerging applications. 4-inch diameter diamond films can be produced by large and low energy-efficiency hot-filament CVD and 915MHz plasma-assisted CVD systems. At the opposite, small chamber and energy-efficient 2.45GHz plasma-assisted CVD systems appear less attractive for large area deposition due to the shorter wavelength of the microwave source. De facto, three resonance modes of the 2.45GHz microwave cavity must be necessarily superposed in order to obtain a plasma large enough to cover a 4-inch area1. Recent encouraging simulations indicated that superposed resonance modes2 of a 2.45GHz microwave cavity could be stable in a clamshell-type MPACVD system. Simulations aside, stable microwave resonance modes must be experimentally identified in presence of plasma and feed gas mixture to perform CVD process. Indeed, the presence of plasma and gas mixture with non-uniform dielectric constants distribution in the microwave cavity modified the resonance modes from simulation results.

In this study, a 2.45GHz MPACVD has been employed to grow 4-inch diamond films on Silicon wafers. Effects of plasma conditions and substrate temperature on the deposition rate and thickness uniformity of diamond films have been studied. It suggested that substrate temperature distribution and diamond film quality are affected by gas convection and IR light emissions from the plasma. Furthermore, film thickness uniformity has been improved by a continuous plasma boundary layer on the diamond film. Preliminary results showed variations in diamond film thickness <1% and <5% for 3-inch and 4-inch areas respectively, with growth rates in the order of 0.8 µm/h using high quality process conditions (low methane, no nitrogen). Values above 3 µm/h are conceivable at high methane content or beyond with nitrogen addition.

Towards Large-Area mm-Thick Diamond Single Crystals with Optimized Optical Properties Ovidiu Brinza1, Alexandre Tallaire2,1, Riadh Issaoui1, Vianney Mille1, Fabien Benedic1 and Jocelyn Achard1; 1LSPM-CNRS, Laboratoire des Sciences des Procédés et des Matériaux, Université Paris 13, France; 2IRCP-CNRS, Institut de Recherche de Chimie Paris, Chimie ParisTech, Université Paris Sciences et Lettres, France

Thanks to its intrinsic outstanding optical and semi-conducting properties, diamond is one of the most promising candidates for a large number of high added-value applications[1]. Among them power electronics devices as well as quantum sensors based on nitrogen-vacancy or silicon-vacancy color centers offer great perspectives. However, the development of such applications is still hampered by the low availability of large and thick diamond single crystals with very well controlled of point and extended defect densities.

In the last twenty years, the microwave Plasma Assisted Chemical Vapour Deposition (PACVD) technology has witnessed important progresses allowing the control of crystal quality, purity and doping[2]. Nevertheless, synthesis of high quality single crystalline diamond layer still remains limited in size due to the very low availability of substrates with dimensions higher than typically 5x5 mm² at a reasonable cost [3]. Moreover, the ability of the process for growing diamond layers thicker than a few mm without any growth interruption is not yet clearly
demonstrated.

In this presentation we will focus on this particular topic where growth strategies for diamond single crystals fabrication by MWPACVD will be presented. The control of crystal morphology as a function of growth conditions will be discussed as well as the feasibility of fabrication of 4 mm thick large area (8X8 mm²) diamond substrates without growth interruption. Attention will be also paid to the control of doping level in order to provide diamond material suitable for power and quantum sensing related applications.

Grotjohn¹,²; ¹Michigan State University, United States; ²Fraunhofer USA Center for Coatings and Diamond Technologies, United States; ³Kyma Technologies Inc., United States

The electrical, mechanical, and thermal properties of diamond make it a promising material for new generation electronic devices. To accelerate the continuing progress of this technology, researchers require access to high quality, large-area substrates. One approach to producing large area substrates is to use Microwave Plasma-Assisted Chemical Vapor Deposition to grow a continuous layer of single crystal diamond across an array of individual diamond plates in a process known as the mosaic technique. In this technique multiple individual diamond substrates are cut and polished to be lattice matched and then a continuous diamond layer is grown across all the individual substrates forming a larger single crystal piece. Our effort has been to minimize the misorientation of the neighboring substrate tiles, reducing stress in the overgrown layer, and demonstrating low misorientation (≤ 0.25°) across the mosaic crystal for the three orthogonal crystal directions. In this report, we especially focus on the capacity of the diamond lattice to accommodate and relieve the stress due to the remaining misorientation along selected crystal directions as the crystal growths thicker. High resolution x-ray diffraction is used to map the orientation of the grown layer across the surface. Subsequent growths allow us to chart the evolution of the misorientation as the layer thickness is increased. Results show how the overall reduction rate in relative misalignments are dependent on the initial interface configuration and top surface off-cut orientations. Mosaic samples composed of up to 4 tiles have been grown up to 11mm x 11mm using this technique.

Diamond for High Power RF Electronic Devices Kevin G. Crawford, James D. Weil, Pankaj B. Shah, Mahesh R. Neupane, Dmitry A. Ruzmetov, A G. Birdwell and Tony Ivanov; U.S. Army Research Laboratory, United States

Interest in the diamond material system for electronic applications has rapidly increased in recent years, becoming a
With its ultrawide band-gap of 5.47 eV, extremely high thermal conductivity of > 20 Wcm⁻¹K⁻¹ and intrinsically high breakdown field of 10 MV/cm, diamond is a promising candidate in achieving next generation high-power electronic devices [1-4]. Progress in this area has been typically hindered by the lack of matured doping techniques and on-going development of novel fabrication strategies to overcome the challenges in working with diamond [5]. The U.S. Army Research Laboratory is investing in the development of surface transfer doped diamond field effect transistors for RF power applications [6-8]. Surface transfer doping offers an alternative to substitutional doping that alleviates the challenges of introducing impurity dopants into diamond’s tightly packed carbon lattice. Historically, spontaneous accumulation of volatile atmospheric adsorbents on the hydrogen terminated diamond surface when exposed to air has provided the necessary surface acceptor states for transfer doping [1, 9]. However, this method of transfer doping when exposed to ambient air is highly sensitive to environmental conditions such as temperature, humidity and molecular composition [9]. More recent results demonstrate enhanced surface transfer doping utilising high electron affinity transition metal oxides, such as MoO₃. By further encapsulating these materials with thick dielectric, we observe excellent long-term and thermal stability. This approach of encapsulated metal oxide has been incorporated into our diamond MESFET designs, improving output current density and stability of devices in both atmosphere and with elevated temperatures. Through a novel approach to gate lithography, gate-source spacing has been reduced to < 100 nm for a 400 nm gate length. Comparing a range of gate-source and gate-drain spacings showed improved peak output current and transconductance, while also significantly improving device breakdown. These results show great scope for improvement of diamond power devices through adoption of tailored design features, such as asymmetric gates, and incorporation of robust, encapsulated, transition metal oxides for superior doping.

Low Noise Diamond Delta-Channel FET Simulation Study Liping Hua¹, Wesley Spain¹, Matthias Muehle², John D. Albrecht¹, Timothy Grotjohn¹,² and Tom Zimmermann¹; ¹Michigan State University, United States; ²Fraunhofer USA, Inc, United States

The technological efforts to access geothermal energy or natural resources, such as fossil fuels, are steadily increasing and motivate the industry to drill much deeper wells. In order to drill wells efficiently, data monitoring from the downhole drilling process such as, pressure, temperature, inclination, and azimuth are all important to the drilling equipment’s condition. However, during the downhole drilling process, temperature variations, pressure amplitude fluctuations, and mechanical rig vibrations have the potential to cause high noise levels in the sensor circuits. That can significantly decrease the signal-to-noise ratio of the sensor circuits, which can ultimately result in a loss of the monitoring signal. To acquire data from a high noise environment, high-temperature stable low-noise sensor circuits are required. The base unit of those circuits is a durable low-noise field effect transistor (FET). Current commercially available Si-based sensor circuits can operate at a maximum temperature of 300 °C for wells just as deep as 12,000 ft. A great challenge of downhole drilling beyond 12,000 ft is the steadily increasing...
We have studied diamond solution gate FETs (diamond SGFETs) which can operate in solutions [2]. Diamond methods [1].

SGFETs are directly immersed in solutions and the drain current (a common source potential line was connecting the gate electrode with SGFET. In this work, we removed the common potential line to realize an electric wireless communication and investigated propagation distance in the seawater environment.

In this communication system, the gate electrode was applied with an input voltage from a gate electrode. We proposed the new electric seawater communication method utilizing the gate electrode as a transmitter and SGFET as a receiver [3]. However, the previous work was not considered entirely wireless because a common source potential line was connecting the gate electrode with SGFET. In this work, we removed the common potential line to realize an electric wireless communication and investigated propagation distance in the seawater environment.

In this communication system, the gate electrode was applied with an input voltage $V_G$ from 100kHz to 10MHz. SGFET was applied with an output voltage $V_{DD}$. A load resistance $R_D$ was connected to the drain electrode of SGFET. Then, the electric signals ($v_G$) were transmitted from the gate electrode to SGFET in NaCl 35g/L solutions which had the same concentration as seawater. Distance between the gate electrode and SGFET was gradually increased from 0.1m to 5m using a cylindrical tube (diameter=2cm). In each distance, the switching characteristics, $v_{DS}$ of SGFET, were measured.

The switching characteristics show that SGFET responds to $v_G$ at least 10MHz in each distance. The $v_{DS}$ of SGFET is observed with differential pulses responding to the $v_G$ potential change. We assume that differential pulses mainly occur due to series CR (high-pass filter) circuit with the electric double layer capacitance $C_{EDL}$ of a SGFET channel and the load resistance $R_D$. As a result, propagation distances of electric signals are at least 5m. In contrast, $I_{peak}$ of differential pulses decreases as the distance increases from 0.1m to 5m. This is because the solution resistance $R_{Sol}$ increases as the electric signals are transmitted in a longer path. $R_{Sol}$ is defined as $R_{Sol}=\rho l/A$ where $\rho$ is resistivity of solutions, $l$ is distance and $A$ is cross sectional area. In this case, $\rho=0.2\Omega m$, $A=\pi r^2$, then, the value of $R_{Sol}$ is calculated as $(0.2/\pi)\times 10^4\Omega$. However, $R_{Sol}$ might become much smaller in a large cross-sectional area such as seawater in open space. In conclusion, this method can be applied to wireless communication in seawater with the propagation distances of at least 5m.

In order to match the temperature requirements, the silicon-based circuits need to be replaced. Materials with wider bandgaps than silicon provide that distinctive advantage of high-temperature operation stability. The wider bandgaps offer higher operating temperatures before the thermally activated intrinsic carrier current causes latch-up in the sensor circuits. Diamond is chosen for its ultra-wide bandgap with 5.45 eV compared to silicon with a bandgap of just 1.1 eV. However, all doping impurities in diamond possess a high thermal activation energy. To engineer a diamond circuit able to operate over a wide temperature range between 0 °C and 600 °C, a diamond delta-channel FET concept is proposed. This concept is based on a sandwich structure that consists of a highly boron doped film in between of two intrinsic diamond layers. A full activation of the boron acceptors can be achieved by high doping concentrations of $10^{20}$ cm$^{-3}$. The total sheet charge concentration of the FET profile should not exceed $4\times10^{13}$ cm$^{-2}$ profile due to breakdown limitations, requiring a maximum thickness of the delta channel of only 4 nm. Because of an out-diffusion of free charge carriers into the intrinsic diamond material adjacent to the highly doped delta-channel, the charge carriers can reach higher hole mobilities within the delta-channel design. The high charge carrier density combined with the high speed of its charges lead to a high current drive, and correspondingly results in a high transconductance, which perfectly fits to a low-noise sensor circuit design.

In this work, a low noise diamond delta-channel FET is proposed for electronic circuits operating up to of 450 °C. This delta-channel FET structure is designed in TCAD Sentaurus, and simulation results of its performance will be presented. The noise performance versus temperature will also be reported on based on the simulations.

Short Distance Electric Seawater Wireless Communication Utilizing Diamond Solution Gate FET Kaito Tadenuma1, Yutaro Iyama1, Yu Hao Chang1, Yukihiro Shintani1 and Hiroshi Kawarada1,2; 1Waseda University, Japan; 2The Kagami Memorial Research Institute for Materials Science and Technology, Japan

Seawater wireless communication has been required for scuba diver’s communication, seawater drone control, development of seabed resources, etc. The conventional communication methods are acoustic wave, visible light wave and electromagnetic wave. On the other hand, electric seawater communication can take advantage of the high electrical conductivity of seawater. This is more suitable for short distance communication than the conventional methods [1].

We have studied diamond solution gate FETs (diamond SGFETs) which can operate in solutions [2]. Diamond SGFETs are directly immersed in solutions and the drain current ($I_{DS}$) is remotely controlled by electric signals ($V_{GS}$) from a gate electrode. We proposed the new electric seawater communication method utilizing the gate electrode as a transmitter and SGFET as a receiver [3]. However, the previous work was not considered entirely wireless because a common source potential line was connecting the gate electrode with SGFET. In this work, we removed the common potential line to realize an electric wireless communication and investigated propagation distance in the seawater environment.

In this communication system, the gate electrode was applied with an input voltage $V_G$ from 100kHz to 10MHz. SGFET was applied with an output voltage $V_{DD}$. A load resistance $R_D$ was connected to the drain electrode of SGFET. Then, the electric signals ($v_G$) were transmitted from the gate electrode to SGFET in NaCl 35g/L solutions which had the same concentration as seawater. Distance between the gate electrode and SGFET was gradually increased from 0.1m to 5m using a cylindrical tube (diameter=2cm). In each distance, the switching characteristics, $v_{DS}$ of SGFET, were measured.

The switching characteristics show that SGFET responds to $v_G$ at least 10MHz in each distance. The $v_{DS}$ of SGFET is observed with differential pulses responding to the $v_G$ potential change. We assume that differential pulses mainly occur due to series CR (high-pass filter) circuit with the electric double layer capacitance $C_{EDL}$ of a SGFET channel and the load resistance $R_D$. As a result, propagation distances of electric signals are at least 5m. In contrast, $I_{peak}$ of differential pulses decreases as the distance increases from 0.1m to 5m. This is because the solution resistance $R_{Sol}$ increases as the electric signals are transmitted in a longer path. $R_{Sol}$ is defined as $R_{Sol}=\rho l/A$ where $\rho$ is resistivity of solutions, $l$ is distance and $A$ is cross sectional area. In this case, $\rho=0.2\Omega m$, $A=\pi r^2$, then, the value of $R_{Sol}$ is calculated as $(0.2/\pi)\times 10^4\Omega$. However, $R_{Sol}$ might become much smaller in a large cross-sectional area such as seawater in open space. In conclusion, this method can be applied to wireless communication in seawater with the propagation distances of at least 5m.
The H-terminated surface of diamond when exposed to NO2, O3 or just laboratory air forms a 2D hole conductive layer in the diamond surface with a surface resistance 1.5 k ohm sq⁻¹. Field effect transistors, FETs, made in this conductive layer have exhibited impressive currents, 1.3 A mm⁻¹ [1], and high operational frequencies, fT = 70 GHz [2]. However, this surface layer is not stable and FET performance degrades over time on the scale of hours to days [3]. Overcoating the diamond surface with Al2O3 generates a higher surface resistance, 5 k ohm but the diamond’s surface resistance is stable in time. However, FETs using Al2O3 degrade when electrically stressed [4]. This presentation describes using an atomic layer deposition technique, ALD, to deposit an oxide alloy of Al2O3 and SiO2 with resistances between 1.8 to 3.5 k ohm sq⁻¹, which is stable at room temperature in laboratory air for > ½ yr and to 600 °C in N2. FETs using this alloy exhibit no degradation when electrically stressed for >120 hr in laboratory air.

This 2D hole conductive layer is generated by a non-diamond absorbed or deposited layer that removes electrons for diamond’s valance band, generating mobile positive charges, holes, in the diamond. Compounds that have such electron gettering properties are called Lewis Acids. Oxide alloys of Al2O3 and SiO2 are industrially used as Lewis acid catalysis in the petroleum industry. Neither Al2O3 nor SiO2 alone exhibit significant acid properties. However, the surface of the oxide alloy contains a very deep electron acceptor with a Hammett acidity, H₀,max, of -11.99 [5] at a surface density of 1.6x10¹⁴ cm⁻² [6]. From the H₀,max value the acceptor trap is estimated to be 0.7 eV below the valence band of H-terminated diamond.

We found that ALD deposited Al2O3/SiO2 did not decrease the surface resistance over that of just Al2O3. However, two procedures were found to give lower resistances. One was to precoat the ALD system with SiO2 and then deposit ALD Al2O3 on the H-terminated diamond to the desired thickness. The other approach was to co-deposit SiO2 and Al2O3 using H₂O, Al(CH₃)₃, and (OC(CH₃)₃)SiOH, which resulted in a diamond surface resistance equivalent to that obtained with Al2O3 alone. However, by rapid thermal annealing to 600°C for 1 minute the lower resistance was obtained. Typical surface mobilities with both ALD procedures were from 50 to 70 cm² V⁻¹ s⁻¹ with carrier densities of 3x10¹³ to 6x10¹³ cm⁻². We speculate that carrier densities >10¹⁴ and lower surface resistances are possible with appropriate control of this alloy at the diamond surface.

DISTRIBUTION STATEMENT A: Approved for public release: distribution unlimited. This material is based upon work supported by the Under Secretary of Defense for Research and Engineering under Air Force Contract No. FA8702-15-D-0001. Any opinions, findings, conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the Under Secretary of Defense for Research and Engineering.
Two-dimensional hole gas (2DHG) diamond FETs have demonstrated excellent radio-frequency (RF) performances such as cutoff frequency ($f_T$) = 70 GHz [1], maximum oscillating frequency ($f_{\text{max}}$) = 120 GHz [2] and output power density ($P_{\text{out}}$) > 2.1 W/mm at 1 GHz [3, 4]. These achievements are results of miniaturizing gate length and access region using self-aligned-gate (SAG) process. However, diamond FETs fabricated by SAG process is low breakdown voltage (about ~20 V). So, the carrier velocity ($v$) calculated from $f_T = v/2 \pi L_G$ is low (< 0.6×10^7 cm/s) and RF voltage swing at large-signal operation is small. To solve these issues, diamond FETs need to be fabricated a high-voltage resistant structure. Recently, we have fabricated high voltage diamond FETs exceeding 1500V [5] with 200 nm atomic-layer-deposition (ALD)-Al$_2$O$_3$ film. The channel mobility of 2DHG diamond FETs are as low as around 100 cm$^2$/Vs, Above 0.4 MV/cm (40 V/μm), however, the hole velocity reaches the saturation velocity of 1.4×10^7 cm/s and the low mobility does not so much affect FET performance in the high electric field. In this study, ALD-Al$_2$O$_3$ 2DHG diamond MOSFETs with 100 [6] and 200 nm Al$_2$O$_3$ were fabricated on a II-a polycrystalline diamond substrate which has high crystallinity, (110) preferential orientation and grain size of approximately 300 μm. The dimension of devices at 200 nm thick Al$_2$O$_3$ diamond MOSFETs are as follows. The source-gate length ($L_{SG}$) and the gate length ($L_G$) were fixed 0.5 μm and 1 μm, respectively, while the $L_{GD}$ ranged from 1.5 to 4.5 μm.

As a result, the carrier velocity exceeded 1.0×10^7 cm/s at 100 nm thick Al$_2$O$_3$ diamond MOSFET and reached to 1.4×10^7 cm/s at 200 nm thick Al$_2$O$_3$ diamond MOSFET. The latter devices maximum drain current density was −740 mA/mm at $V_{GS} = −28$ V and $V_{DS} = −40$ V, the lowest on-resistance of 25 Ω mm and the transconductance of 13 mS/mm at $V_{DS} = −40$ V with 9 V $V_{GS}$ 16 V were obtained. Extrinsic $f_T$ was 22 GHz at $V_{GS} = 16$ V and $V_{DS} = −40$ V for $L_{GD} = 1.5$ μm. Hence, using $f_T = v/2 \pi L_G$, the carrier velocity achieved 1.4×10^7 cm/s by $f_T$ of 22 GHz at $L_G$ of 1 μm. It is the first diamond MOSFET operation at the saturation velocity and is comparable to GaN based HEMTs. RF large-signal performance was evaluated using load pull system at 1 GHz in class-A operation. At 100 nm thick Al$_2$O$_3$ diamond MOSFETs, the maximum $P_{\text{out}}$ of 3.8 W/mm was obtained at high $V_{DS} = 50$ V. It is the highest in diamond [6]. At 200 nm thick Al$_2$O$_3$ diamond MOSFET, the $P_{\text{out}}$ of 2.5 W/mm and maximum power gain of 8.0 dB were obtained at $V_{GS} = 16$ V and $V_{DS} = −70$ V for $L_{GD} = 4.5$ μm. The large-signal RF performance was evaluated at $V_{DS} = −70$ V for the first time in diamond.

potential approximation, they discussed about the importance of the different scattering modes to the mobility values. In this work, we will extend the previous work to the general of diamond/oxide interface (H- and O-terminated) and introduce a full description of the valence bands and hole scattering mechanisms (light holes, heavy holes, spin-orbit and sub-bands due to quantum confinement). The maximum expected mobility achievable in a diamond 2D hole gas will be discussed and compared to recent experimental results.

Recent Progress in Inversion Channel Diamond MOSFET Norio Tokuda1,2, Tsubasa Matsumoto1, Takao Inokuma1, Satoshi Yamasaki2,1, Hiromitsu Kato2, Toshiharu Makino2 and Christoph E. Nebel3,1; 1Kanazawa Univ, Japan; 2National Institute of Advanced Industrial Science and Technology, Japan; 3Fraunhofer Institute for Applied Solid State Physics, Germany

We demonstrated the first operation for an inversion channel MOSFET using diamond semiconductor [1]. Here, we precisely controlled the MOS interface using an atomic layer deposition of Al2O3 film on OH-terminated diamond (111) surface and pn-junctions using selective growth of heavily B doped on n-type diamond layer for the formation of source/drain. The field-effect mobility $\mu_{FE}$ of the p-channel diamond MOSFET was $8 \text{ cm}^2/\text{Vs}$ at the highest, which is much lower than the hole mobility of $6,300 \text{ cm}^2/\text{Vs}$ at RT [2]. Recently, we investigated the interface state density $D_{it}$ dependence of $\mu_{FE}$ in inversion channel diamond MOSFETs [3]. In this study, we will report the key techniques for the demonstration of the inversion channel diamond MOSFET and its recent progress.

A Contact Resistance Comparison with Different Thickness of PEALD Al2O3 Passivated H-Diamond MOSFET with Al2O3 Dielectric Layers Yichen Yao, Harshad Surdi, Manpuneet Benipal, Franz A. Koeck and Robert J. Nemanich; Arizona State University, United States

A prior study from our group has achieved an ohmic contact with thin PEALD Al2O3 on top of a hydrogenated diamond surface establishing a sheet resistance ~16 kOhms/square. In this study, we extend the application of the PEALD interfacial layer as a protective passivation layer to avoid degradation of the hydrogen terminated conducting surface during during device fabrication process. from XPS characterization, the valence band offset confirms that the electrons from the valence band of diamond can be transferred to states of this very thin Al2O3
interfacial layer. As a first step to fabricating MOSFET devices, different PEALD Al2O3 thicknesses are used to establish the source and drain contact. We used pure Au as the contact metal, and Al / Au for the gate contact. A circular FET design was used to reduce the gate leakage current and a 4 nm thermal ALD Al2O3 layer was used for the gate dielectric. A threshold voltage of 0.8 V is shown in the device with a highest drain current of ~40 mA/mm. The gate length of these devices is 4 or 6 microns with an asymmetrical distance of LGS of 4 microns and LGD of 16 microns. The results show a decreasing trend of the contact resistance of the PEALD Al2O3 interfacial layer with reduction of the thickness of this tunneling layer. Our device results have indicated that the interfacial Al2O3 layer, may reduce the contact resistance for a H-diamond MOSFET.

This research is supported by the NSF through grant DMR-1710551 and a grant from MIT-Lincoln Laboratory.

9:15 AM EL05.05.03
(111) Vertical-Type 2DHG Diamond MOSFETs with Hexagonal Trench Structures Jun Nishimura¹, Masayuki Iwataki¹, Nobutaka Oi¹, Aoi Morishita¹, Atsushi Hiraiwa¹ and Hiroshi Kawarada¹;² ¹Waseda University, Japan; ²The Kagami Memorial Research Institute for Materials Science and Technology, Waseda University, Japan

In power devices, vertical structure is suitable for low on-resistance and large current operation which are required for power electronics. We have ever reported (001) vertical-type diamond MOSFETs [1] using two-dimensional hole gas (2DHG) which is induced irrelevantly of their crystal orientation by C-H termination structure and high temperature atomic layer deposition (ALD)-Al2O3 [2]. In this paper, we fabricated vertical-type 2DHG diamond MOSFETs with hexagonal trench structures using the (111) diamond for the first time. The (111) diamond has advantages for high carrier density owing to their C-H dipole structure and low sheet resistance [3] compared to the (001) diamond. As the results, the maximum current density is 3 times higher than that of the previous works at the same drain voltage (VDS) [1]. And, the minimum specific on-resistance Ron of 9.2 mΩcm² was obtained the device with large hexagonal trench of 12 µm on a side. Fabrication process was as follows. First, the undoped and nitrogen-doped layer were epitaxially grown on the (111) p+ diamond substrate by microwave plasma chemical vapor deposition (MPCVD). The nitrogen-doped layer (~1×10¹⁹ cm⁻³) worked as a current blocking layer. Second, hexagonal trench structures were formed by inductive coupled plasma reactive ion etching. Length on each side of the trench (WT) was 10-20 µm, and depth (DT) was fixed at 3.0 µm. Third, 200 nm regrowth undoped layer was deposited by ALD method. The gate length was fixed to 6 µm, while 3 µm (half) of the gate overlapped with the source electrode. The drain current density (ID) normalized by gate width of 72 µm (6WT) at VDS of -20 V and -50 V are -250 mA/mm and -680 mA/mm, respectively. Those values are almost 3 times higher than those of vertical-type (001) diamond FETs at the same VDS [1]. The main reason is the conduction path of the former (001) vertical FET are composed of {001} surface only, but those of the present (111) vertical FETs are higher (111) surface and {110} or {211} side walls, where the sheet conductance is higher than that of {001}. The drain current on/off ratio is about 9 orders of magnitude at room temperature. For this result, the film thickness and concentration of the nitrogen-doped layer are sufficient. The maximum drain current density and lowest specific on-resistance normalized by device active area are -5400 A/cm² and 9.2 mΩcm² for VDS of -50 V and VGS of -20 V. The specific on-resistance is lowest ever reported for the (111) diamond FETs. These performances will be improved by the device structure miniaturization and drift layer resistance reduction. If the trench size shrinks to as small as 2 µm, the Ron will be below 1 mΩcm².

Diamond:H/Transition-Metal Oxides Transistors—From MOSFET to MESFET Moshe Tordjman¹,², Youngtack Lee¹,³, Alon Vardy¹, Rafi Kalish² and Jesus A. del Alamo¹;¹Massachusetts Institute of Technology, United States; ²Technion—Israel Institute of Technology, Israel; ³Inha University, Korea (the Democratic People's Republic of)

Surface transfer doping of hydrogen-terminated diamond (Diamond:H) leading to a two-dimensional hole gas (2DHG) represents a significant recent advance towards high-performance diamond transistors. Recently, Transition-Metal Oxides (TMO), such as MoO3, WO3, V2O5 and ReO3,¹⁴ have been shown to yield a far more efficient and stable surface transfer doping process. This is of great significance for future diamond electronics.
In this talk, we present recent progress in Diamond:H FETs by engineering the gate stack from a typical metal-oxides-semiconductor FET (MOSFET) towards a metal-semiconductor FET (MESFET). This is seen to yield a drastic improvement in key features such on/off ratio (8 orders of magnitudes), a very low subthreshold swing (67 mV/dec) and low gate leakage.

A comparative Diamond:H/Transition-Metal Oxide FET study will be also presented and will show how the different Transition-Metal Oxides properties influence FET performance. A proposed oxide approach is suggested and demonstrated that enhances hole drift mobility by a factor of two, while keeping a high value of carrier concentration.

Based on these findings, a path towards improvement of Diamond:H/TMO transistor performance and stability will be outlined.

Normally off Hydrogen Terminated Diamond Field Effect Transistor (C-H MOSFET) Device with Deep Donor Doping Using Nitrogen Termination

Reem M. Alhasani, Mohammed M. Alhasani, Taichi Yabe and Hiroshi Kawarada; Waseda University, Japan

The p-type conduction of hydrogen terminated (C-H) diamond is attractive for developing high preference of high power or high frequency devices such as high-power field effect transistor (FET) [1]. In this work, the interface charge effect with nitrogen doping on C-H diamond FET is investigated. So far, we have reproduced the FETs characteristic of C-H diamond FET by 2-dimensional (2D) acceptor model [2] or 2D negative charge sheet model [1] confirmed 2D hole gas (HG) close to surface. However, these acceptors or negatively charged sites are scattering centers for carrier (holes) transport near the C-H surface. The device exhibits good DC operation and achieved both normally off and normally on characteristics depending on nitrogen concentration [3]. Before that the normally off mode achieved with oxygen termination in diamond full or partially close to C-H diamond FET. Partially SiO2 in C-H diamond also exhibited normally off operation achieved with -3eV threshold voltage and maximum current density IDMAX=-44mA/mm[4].

In this work, the normally off (enhancement mode) C-H diamond Al gate overlapped field effect transistor (FET) with donor investigated. We simulated nitrogen doping (donor model) in concentration of 3e16 cm-2 corresponding to near surface positive charge of 5e11 cm-2. All the device parameters are similar to the former simulation [1] where source and drain contact resistance is very low because of very low Schottky barrier height (SBH) [5]. As gate is negatively biased, an upward bending of valence band is observed. It indicates that there is a hole accumulation layer (2DHG) under valence band maximum at the diamond side. The MOSFET capacitor characteristic shows the fixed fermi level position as a function of capacitance voltage at 1.7eV from the conduction band due to nitrogen as donor. The maximum current density of the Al2O3/C-H diamond device is ~70 mA/mm at the gate voltage of -26V with-voltage step of 4V between +26V~-26V. Also, we observed the gate threshold voltage Vth= -3V with negative gate bias normally off operation. The reason is that no intersection between valence band and fermi level caused by the positive charge cancelling the negative charge at Al2O3/C-H diamond interface. So, the negative charge effect at the interface becomes very weak leading to normally off.

Electrochemiluminescence at Boron Doped Diamond Electrodes—A Powerful Tool for Analytical Applications Emmanuel Scorsone and Matthieu Hamel; CEA, France

Electrochemiluminescence (ECL) is a phenomenon in which photons are emitted during electrochemical reactions. It already proved to be a very promising analytical tool for sensing applications where both high sensitivity and selectivity are needed. Indeed, it merges the advantages of chemiluminescent analysis with the absence of background optical signal, with wide possibilities for reaction control using diverse electrochemical protocols. ECL can be observed in organic solvents where both oxidized and reduced forms of luminescent species are produced, e.g. by sweeping electrode potential between anodic and cathodic. Excitation energy is then obtained from recombination of oxidized and/or reduced species. As an example, superoxide ions may be involved through electrochemical reduction of dissolved oxygen. In aqueous environments, simultaneous oxidation and reduction of luminescent species is difficult to achieve due to electrochemical splitting of water, implying the use of a co-reactant. In this case luminescent species are oxidized at the electrode together with the co-reactant, which gives a strong reducing agent after some chemical transformations. In this context, Boron Doped Diamond electrodes offer numerous advantages that have been little explored for ECL analytical applications. They display high electrochemical stability together with resilience to fouling, and good optical transparency. Furthermore, in aqueous media electro-generated hydroxyl radicals play important roles in ECL, implying that a co-reactant family can be expanded by taking advantage of the strong oxidation ability of electrogenerated hydroxyl radicals at boron doped diamond electrodes. The potential of diamond electrodes for ECL analytical applications will be discussed and illustrated through a comparative study using different electrode materials. An example of application for foodstuff analysis will be presented.

10:45 AM EL05.06.02
Full Diamond Implant for Neural Prosthesis Lionel Rousseau1, Emmanuel Scorsone2, Gaelle Lissorgues1, Blaise Yvert3 and Serge Picaud4; 1ESIEE Paris, ESYCOM, UPEM, France; 2LIST/LCD, France; 3BrainTech Laboratory U1205 Inserm, France; 4Institut de la Vision, UMR 7210, France

Some properties of diamond are very interesting for the development of implantable medical devices. Especially they offer a way to achieve stable implants. This is due to the chemical stability of the material, along with its high density, which prevents any chemical species to penetrate into the bulk of any diamond layer. Furthermore diamond can be doped with boron to achieve outstanding electrode materials for the stimulation of biological tissues. A major issue associated with chronic implant for neuronal interfacing is that structure is not hermetic. This is due to the fact that metal tracks are generally embedded in polymer layer to isolate them from the tissues. But following long term implantation, the polymers are likely to swell and water molecule will migrate inside the polymer thus modifying its dielectric properties. To address this issue, we propose to develop a full diamond implant by combining intrinsic material and BDD electrodes. By assembling the same material both for stimulation electrodes and passivation layer we are aiming to prevent current leakage at the interface.

To validate this new structure we developed strips that combine boron doped and intrinsic diamond materials. These structures are placed on an accelerated aging set up for several days. The BDD electrodes are stimulated by biphasic pulses in Phosphate Bovine Solution (PBS) and the stability of the electrodes in these conditions is monitored by electrochemical impedance recording. Strips with conventional materials have also been fabricated (organic or inorganic materials) to compare their behavior in the same experimental conditions with our diamond based structures. The preliminary trials demonstrate that diamond structures are stable at least over 45 days.

Furthermore, in order to achieve a cortical implant, it is necessary to fabricate soft implantable devices. It is well
known that diamond is the hardest material with a high Young modulus close to 1000 GPa. To demonstrate the feasibility of a soft full diamond implant structure, a novel implant containing metal track in contact with BDD electrodes and encapsulated in thin intrinsic diamond was fabricated. Here intrinsic diamond is locally open above the BDD electrodes to allow interfacing with neurons. The mechanical properties (flexibility, etc.) of such an implant are currently being investigated and in-vitro and in-vivo testing are being prepared.

Enabling Efficient, Economical Grid-Scale Energy Storage through Diamond  
Alex Bates, Mahendra Sunkara, Sam Park and William Paxton; University of Louisville, United States

Redox flow batteries (RFBs) are considered by many to be the most logical approach to addressing grid-scale energy needs. A RFB operates via an exchange of energy through the simultaneous electrochemical reduction and oxidation of redox couples in half-cells. A redox couple consists of an oxidizing species and its corresponding reducing species. The fundamental RFB consists of two electrolytes (containing the redox couples), two electrodes, and an ion-exchange membrane. The electrolytes are stored in external tanks and are cycled through the electrochemical cell via pumps or gravity. As the electrolytes flow, redox species are brought to the electrode surface where they either give or receive an electron from an external circuit. During this process the cell is either charged or discharged and the converted species flow back to the storage tanks.

RFB technology offers several advantages over current state of the art energy storage technologies including: 1) Scalability – capacities ranging from 1kW to 100+MW with minimal design changes; 2) High efficiencies – expected round-trip efficiency of ~85%; and 3) Separation of power and energy – capacity can be increased by simply increasing the volume of stored electrolyte. Implementation of RFBs have been hindered by availability of redox couples. Vanadium is the most predominant redox couple as it possesses multiple oxidation states, allowing it to be used in both sides of the battery (Positive electrode: V^{5+} ↔ V^{4+}; Negative Electrode: V^{2+} ↔ V^{3+}). While other redox couples are such as Fe, Cr, and Br are frequently reported, there are very few that are compatible with the graphite electrodes used in the standard RFB configuration. Recent results have demonstrated boron-doped diamond (BDD) to be an exceptional alternative to the standard graphite electrode by enabling a wide range of redox couples that are more cost effective, environmentally friendly, and sustainable while also offering improved efficiencies and energy densities than current state-of-the-art.

Diamond has proven itself to be a superior material for a variety of applications and its utility in electrochemistry has become increasingly apparent over the past decade. In addition to diamond’s ability to resist fouling and corrosion in extreme environments, it’s most critical advantage for flow batteries is it’s extremely high overpotential for both hydrogen and oxygen evolution (-1V to 2.5V, respectively). This large window enables the use redox couples that would occur in either the hydrogen or oxygen evolution reaction regime with common electrodes such as graphite or platinum. Despite these advantages, it has not been until now that BDD has been considered for use in RFB technology and has led to the identification of several additional relevant redox couples that were previously out of reach. This research represents a monumental advancement of redox flow battery technology and could be the solution to grid-scale energy challenges.

11:15 AM EL05.06.04
Boron-Doped Diamond Superconducting Quantum Interference Devices Operating above Liquid Helium Temperature  
Aoi Morishita¹, Taisuke Kageura¹,², Ikuto Tsuyuzaki¹, Shotaro Amano¹, Minoru Tachiki², Shuichi Ooi², Shunichi Arisawa², Yoshihiko Takano⁰ and Hiroshi Kawarada¹,⁴, ¹Waseda University, Japan; ²National Institute for Materials Science, Japan; ³Kagami Memorial Laboratory for Materials Science and Technology, Japan

Superconducting quantum interference devices (SQUIDs) are widely used as high-sensitive magnetometers in several fields. However, there is still a problem with material robustness in advanced SQUID applications such as scanning SQUID microscope. Superconducting boron-doped diamond is one of the materials that can solve the above problems due to its excellent robustness and characteristics. Recently, we have demonstrated a first single crystalline diamond SQUID [1], whose Josephson junctions (JJs) were formed by step-edge structure. However, it was operated at 2.6 K because the structure included (001) sector superconducting transition temperature $T_c$ of 4.0 K [2]. Operating temperature of SQUID is significant for constructing a complex SQUID system with a simple cooling system. Thus, in this work, we have demonstrated diamond SQUIDs operating above liquid helium temperature 4.2 K using only (111) growth layer with $T_c=10$ K [3].

JJJs were fabricated by epitaxial growth on shallow trench as below: The boron-doped diamond layer was epitaxially grown across the 30 nm deep trench, which was formed via focused ion beam method. The weak link was formed in
the boundary of discontinuous (111) sector on the trench. The effective loop area ($A_{\text{eff}}$) was 68\times68 \mu m^2 and strip width was 36 \mu m. It showed two-step superconducting transition at 10.5 K and 8.0 K. The $I$-$V$ characteristics from 1.6 K to 10 K showed clear DC Josephson effect. There was no hysteresis above 4.0 K. The critical current $I_c$ was 0.42 mA and the $J_{\text{c}}R_{\text{n}}$ product was 0.21 mV at 4.2 K, where $R_{\text{n}}$ is the normal resistance. In the magnetic field dependence of voltage, SQUID oscillation was observed up to 10 K. The oscillation interval ($B_{\text{ext}}$) was 0.52 \mu T. This value agreed with calculated $B_{\text{ext}}$ obtained by $\Phi_0/A_{\text{eff}}$ where $\Phi_0$ is flux quantum. We also fabricated another sized SQUID, which had smaller $A_{\text{eff}}$ (=21\times56.5 \mu m^2) and narrower strip width (=15 \mu m) than the former. It operated up to 8.0 K. For this sample, $B_{\text{ext}}$ was 1.70 \mu T, which agreed with calculated $B_{\text{ext}}$. Therefore, the operations of SQUIDs were demonstrated up to 10 K for former larger sample, and 8.0 K for latter smaller sample. These operating temperatures are dramatically higher than those of SQUIDs of both step-edge structure [1] and nanocrystalline diamond [4]. For the larger sample, $V_{\text{p-p}}$ was 2.0 \mu V and magnetic field sensitivity $V_{\text{p-p}}/B_{\text{ext}}$ was 3.8 \mu V/\mu T at 8.0 K. For the smaller sample, $V_{\text{p-p}}$ and $V_{\text{p-p}}/B_{\text{ext}}$ were 4.0 \mu V and 2.4 \mu V/\mu T, respectively at 8.0 K. These values are higher than that of diamond SQUID with step-edge structure, 1.6 \mu V/\mu T.

In conclusion, we have demonstrated two different sized diamond SQUIDs composed of only (111) boron-doped growth layer operating above liquid helium temperature.

11:30 AM EL05.06.05
Development of Single Crystal CVD Diamond Based Microdosimeters for Particle Therapy Izabella A. Zahradnik1, Michal T. Pomorski1, Philippe Barberet2, Zeljko Pastuovic3, Jeremy Davis4, Ludovic De Marzi5, Wataru Kada6, Guillaume Boissonnat1, Alexandre Dabat-Blondeau1, Samuel Salvador2, Laurent Leretier7, Yolanda Prezado8, James Vohradsky4, Dominique Tromson1, Samuel Saada1 and Anatoly Rosenfeld4; 1CEA Saclay, France; 2CNRS, UMR5797, CENBG, France; 3ANSTO, Australia; 4CMRP, University of Wollongong, Australia; 5Institut Curie, Centre de Protonthérapie d'Orsay, France; 6Gunma University, Faculty of Science and Technology, Japan; 7LPC Caen, France; 8CNRS/NARA, France

Particle therapy is an innovative mode of radiotherapy (RT) for cancer treatment. The determination of the relative biological effectiveness (RBE) of the clinical particle beams deployed in such RT is of great importance for both the estimation of the therapeutics effects in tumour and the right input parameters for the treatment planning system with the aim of sparing the healthy tissue around the tumour. The physical microdosimetric parameters, such as lineal energy, are used as input parameters for the MK (microdosimetric kinetic) model to calculate the RBE of a given ion beam (protons and $^{12}$C ions). However, there is a lack of practical experimental tools to characterize this quantity, which is a challenging task. In this context, diamond detectors have shown dosimetric advantages, such as outstanding spatial resolution, good sensitivity to high beam intensities, small energy dependence, radiation hardness and tissue equivalence. For more than ten years, CEA-LIST has been developing diamond-based dosimeters for RT applications. Currently, based on scCVD diamond membranes, new prototypes of microdosimeters for particle therapy are being developed at the CEA Diamond Sensors Laboratory (LCD).

Materials and Methods: Two novel diamond-based dosimeter prototypes have been developed based on a super-thin self-standing scCVD diamond membranes obtained by deep Ar/O$_2$ plasma etching process. The processing of the first prototype, DIAµDOS p+ consists additionally of a p+-i junction which was created by a CVD growth of thin boron-doped scCVD layer on top of an intrinsic 4 \mu m thick diamond membrane. Multiple microdosimetric sensitive volumes ($\mu$SVs) were formed on the membrane surface using projection photolithography, followed by local plasma etching of the p+ diamond layer. The characteristic behaviour of the micro p+-i junction was determined by a 1.8 V built-in potential which resulted in full depletion of the device at 0V-bias$^2$. In the processing of the second prototype, DIAµDOS-guard-ring, only single crystal CVD diamond membrane was involved. A thin layer of Al for electrical contacts has been deposited on both sides of the membrane. On the front side, using laser photolithography, $\mu$SVs in different sizes have been shaped. These $\mu$SVs are interconnected by thin bridges and surrounded by an isolating guard ring in a distance of 2 - 10 \mu m from the active region. Applying different bias to the back electrode of the device and collecting the signal at the $\mu$SV’s electrode, a full CCE for different particles can be achieved. Results: The characterization of the diamond microdosimeters has been made possible by particles microbeams at IBIC facilities in Australia, France and Croatia. The active $\mu$SVs of the microdosimeter were irradiated using a raster scanning method and the charge transport properties of the device determined with sub-micron precision by measuring the charge collection efficiency, radiation hardness, $\mu$SVs 3D spatial definition and
the pulse-height spectra. By combining all measurements a large range of experimental measured lineal energy was explored. Using MC radiation transport and TCAD simulations, the obtained measurements with the diamond microdosimeter were compared with theoretically predicted results. The radiation response, as well as the design of the sensors, were optimized. The final prototype of the diamond-based device was integrated with universal sponsors carrier and a suitable multi-channel electronics. The performance of the diamond device was evaluated using clinical particle beams at Ion Therapy Centers in France and Japan. Finally, the response of the diamond microdosimeter in conjunction with MKM was used for RBE determination and demonstrates the great potential of diamond microdosimeter and its ability to measure microdosimetric quantities in clinical ion beams. \(^1\)M. Pomorski et al., Appl. Phys. Lett. 103, 112106, 2013, \(^2\)I. A. Zahradnik et al., Phys. Status Solidi A, 1800383, 2018.

**11:45 AM EL05.06.06**

**Performance of 4.5-μm PIN Diamond Diodes as Thermal Neutron Detectors** Jesse Brown\(^1\), Jason Holmes\(^1\), Franz A. Koeck\(^1\), Holly Johnson\(^1\), Manpuneet Benipal\(^1\), Kevin Herminghuysen\(^2\), Praneeth Kandlakunta\(^2\), Andrew Kauffman\(^2\), Susan White\(^2\), Anna Zaniewski\(^1\), Ricardo Alarcon\(^1\), Raymond Cao\(^2\), Stephen Goodnick\(^1\) and Robert J. Nemanich\(^1\); \(^1\)Arizona State University, United States; \(^2\)Ohio State University, United States

The properties of diamond that contribute to its value in radiation detection include large bandgap, high electron and hole mobilities, high breakdown field, and high displacement damage threshold. These properties combine to enable radiation hard, low background, and efficient particle detectors. Research at Arizona State University has developed and demonstrated diamond p-i-n particle detectors based on epitaxial growth of n-type, phosphorus doped diamond, p-type, boron doped diamond, and high purity undoped (intrinsic) diamond. The detector i-layer thickness has been adjusted to match the penetration depth of designated alpha particles, which minimizes background due to gamma radiation and high energy particles. Moreover, the detectors operate in pulse mode with a bias of only a few volts. The unique properties of the p-i-n diode led to the development of a new method to mitigate the effects due to the accumulation of trapped charge in the diamond. Recognizing these advantages led us to propose the development of an efficient thermal neutron detector through the integration of a boron nitride neutron absorption layer and an optimized diamond p-i-n detector. Like diamond, boron nitride is a hard, high temperature material that is expected to survive in extreme environments. A number of BN/diamond pin neutron detectors have been fabricated at Arizona State University and tested at the Ohio State University Nuclear Reactor Laboratory. The tests include pulse counting measurements at a thermal neutron beamline with a flux of \(4\times10^6\) n/cm\(^2\)/s, and irradiation of the detectors in the core of the reactor for a fluence of \(10^{15}\) n/cm\(^2\). The thermal beam results show performance as expected with no significant background above threshold and with a reasonable expectation of pulse counting capability at fluxes up to \(10^{10}\) n/cm\(^2\)/s. The irradiation results indicate the onset of a new capability in advanced sensor instrumentation based on diamond diodes.

**The Tin Vacancy Center in Diamond—An Interesting New Qubit Candidate?** Christoph Becher; Saarland University, Germany

Quantum bits based on solid-state spins are promising and potentially scalable systems for the implementation of quantum technologies ranging from quantum information processing to quantum-enhanced sensing and metrology. Ideally, they combine individually addressable spins with very long coherence times, optical emission spectra with narrow homogeneous and inhomogeneous broadenings and bright single-photon emission. In this respect, impurity-vacancy color centers in diamond based on group-IV elements (SiV, GeV, SnV, PbV) have emerged as interesting systems promising to combine all desired favorable properties.

Both the SiV and the GeV center feature superior spectral properties, i.e. at liquid helium temperatures (4K), they exhibit a narrow zero phonon line (ZPL) with a four-line fine structure and close to lifetime-limited linewidths [1,2].
Furthermore, both allow for fast all-optical addressing and control of their spin states [3,4]. However, at temperatures around 4K both color centers exhibit spin coherence times ($T_2^*$) of only a few tens of nanoseconds due to phonon-induced decoherence processes [3,4] and the SiV reaches millisecond spin coherence times only at millikelvin temperatures and in pure samples [3,5]. A potential resort are vacancy defects with a heavier group-IV impurity atom, such as SnV and PbV centers, featuring a larger ground state splitting and thus less susceptibility to phonon-induced decoherence.

Here, we report on spectroscopy of SnV centers [6,7,8] where we find two charge states, i.e. SnV(-) and SnV(0), which both show promising optical properties. The SnV(-) features a ground and excited state splitting considerably larger (850 GHz and 3000 GHz, respectively) as compared to the SiV center, potentially enabling long spin coherence times even at liquid He temperatures. This defect is a bright single photon emitter, showing a narrow inhomogeneous distribution of zero phonon lines in a high-temperature annealed sample [6] and truly lifetime-limited transition linewidths down to 20 MHz. Furthermore, we determine the charge transition from the negative to the neutral charge state as a function of the excitation wavelength and find it to coincide well with theoretical predictions [9]. For the SnV(0) center we find emission lines that again agree well with theoretical calculations [10]. The neutral charge state is particularly interesting due to its potentially long electron spin coherence times.

Development of Scalable Technology for NV-Magnetometry and Photonics on Single Crystalline Diamond
Christian Giese¹, Patricia Quellmalz¹, Helge Gehring², Wolfram Pernice² and Christoph E. Nebel¹; ¹Fraunhofer IAF, Germany; ²University Muenster, Germany

The unique properties of the negatively charged nitrogen vacancy color center (NV⁻) in single crystalline diamond have been explored for developing new types of devices for photonics and scanning probe magnetometers with high sensitivity and spatial resolution over more than a decade. This growing field is in need of thin, free-standing ultra-clean diamond devices with complex geometries. The fabrication of such structures in large numbers will be the topic of this presentation.

Free-standing diamond devices as photonic crystals or NV-scanning-probe heads are typically manufactured from diamond membranes of below 30µm thickness. The latter are expensive and available only in small numbers which makes a scaling of the production very challenging. In addition to this, the homogeneity in thickness below micron level is crucial for many applications and remains practically unachievable via polishing on large surfaces.

An alternative method based on so-called faraday-cage-angled-etch (FCAE) pioneered at the group of prof. Loncar at Harvard university is based on the capability to create free-standing diamond devices via dry chemical underetching. We have employed FCAE to create mechanical and optical components and will report on the characteristics of the devices investigated via SEM as well as optical and mechanical metrology.

Rapid, High-Resolution Magnetic Microscopy of Single Magnetic Microbeads
Julia M. McCoey, Robert W. de Gille, Babak Nasr, Jean-Philippe Tetienne, Liam T. Hall, David A. Simpson and Lloyd Hollenberg; University of
Melbourne, Australia

Magnetic microparticles are used in a variety of research applications including cell sorting\(^1\), targeted drug delivery\(^2\) and optical force traction microscopy\(^3\). The magnetic properties of such particles can be customized for specific applications with the uniformity of individual magnetic microparticles having a significant bearing on their function. Prior to the study discussed here, most magnetic characterization techniques have quantified the magnetic properties from large bead ensembles\(^4\). As such, there is a significant demand for magnetic imaging techniques to evaluate and visualize the magnetic fields from single beads. New insights into the magnetic uniformity, anisotropy, and alignment of magnetic domains can be found through measurements of the magnetic properties of single beads. Here, magnetic microscopy based on the nitrogen-vacancy centre in diamond is applied to image and characterize individual magnetic beads with varying magnetic and structural properties: ferromagnetic and superparamagnetic/paramagnetic, shell (coated with magnetic material), and solid (magnetic material dispersed in matrix). The magnetic microscopy described here probes both the fluctuating moments of the beads studied as well as their static magnetic moments. The single-bead magnetic images identify irregularities in the magnetic profiles from individual bead populations. Magnetic simulations account for the varying magnetic profiles and allow to infer the magnetization of individual beads\(^5\). Additionally, this work shows that the imaging technique can be adapted to achieve illumination-free tracking of magnetic beads, opening the possibility of tracking cell movements and mechanics in photosensitive contexts.

**Quantum Sensing of Atomically Thin Magnets** Patrick Maletinsky; Basel University, Switzerland

The recent discovery of long-range magnetic order in atomically thin “van der Waals” (vdW) crystals has attracted significant attention due to their fundamental and technological interest, including predictions of exotic magnetic phases and unique opportunities to control magnetism at the atomic scale. I will present recent experiments, where we employ a single-spin-based quantum sensing technology for quantitative, nanoscale probing of atomically thin vdW magnets. Specifically, I will describe experiments, where we employ a diamond-based, scanning probe quantum sensor to address magnetism in the prototypical vdW magnet CrI\(_3\), down to the level of atomic monolayers. Our approach enabled nanoscale imaging of magnetic domains, quantitative determination of CrI\(_3\)’s layer-dependent magnetization, and revealed a delicate interplay between magnetic and crystalline order in CrI\(_3\). Next to addressing fundamental open questions in the nanomagnetism of atomically thin CrI\(_3\), our results yield attractive perspectives for future probing of dynamical properties of two-dimensional spin systems using single spin quantum sensors. Amongst other things, these could yield experimental evidence for the still elusive quantum spin liquid, which is believed to occur in monolayers of certain vdW compounds.

**Imaging the Domain Pattern of In-Plane Layered Antiferromagnets using Diamond Magnetometry** Martin S. Wornle, Pol Welter and Christian Degen; ETH Zurich, Switzerland

Antiferromagnetic materials are promising candidates for new memory devices with fast electrical writing and readout capabilities. Imaging the magnetic state of antiferromagnets on the sub-micrometer scale, however, is challenging because these materials do not exhibit a macroscopic magnetization.
In this talk, we will discuss the application of scanning diamond magnetometry for investigating the microscopic domain structure of in-plane layered antiferromagnets, like tetragonal CuMnAs. After introducing the basics of the technique, we will discuss models and concepts for analyzing the magnetic stray field emanating from the antiferromagnetic domains. We will further show that current pulses lead to changes in the domain pattern and analyze these changes as a function of the current amplitude and direction.

4:00 PM EL05.07.06/MQ01.03.06
Metrology Driven Development of Point Defect Synthesis and Localization Nazar Delegan¹, Samuel J. Whiteley²,¹, Edward Bielejec¹, David D. Awschalom²,¹ and Joseph F. Heremans¹,²; ¹Argonne National Laboratory, United States; ²The University of Chicago, United States

The negative nitrogen-vacancy (NV⁻) defect in diamond has quantum spin properties observable from cryogenic temperatures to ~1000 K. Parallel to this, SiC based divacancy (VV) complexes photoluminesce in the telecom infrared range, extending their technological applicability. Both of these spin-based quantum sensors are known to be responsive to changes in local strain, electric, magnetic, and thermal fields. Building on this foundation, we discuss recent advances of defect 3D localization in the context of improving and controlling their spatial resolution and crystalline environment. This progress is fueled by nanoimplantation and nanoscale strain-sensitive X-ray imaging techniques. The insights provided serve to better understand the defect’s lattice surroundings, guide future synthesis efforts, improve the creation efficiency, and advance the goal maintaining coherence times of the spin states.

4:15 PM EL05.07.07/MQ01.03.07
First Principles Discovery and Understanding of Color Centers in Diamond for Quantum Information Science Isaac Harris¹,², Christopher J. Ciccarino², Johannes Flick², Dirk R. Englund¹ and Prineha Narang²; ¹Massachusetts Institute of Technology, United States; ²Harvard University, United States

Defect centers in diamond are promising candidates for applications such as quantum sensing, networking and computation. Previous work has experimentally identified several defects such as the NV⁻ and group IV related defects. However none of these color centers have shown the ideal combination of optical transitions, coherence times, and ease of fabrication and integration, motivating an ab initio search of new color centers in diamond. Towards this goal, we present first principles calculations of a new class of emitters, the group III-vacancies, which are theoretically shown to have a promising ground state structure for quantum applications, a noise insensitive optical transition, and are thermodynamically favored in intrinsic diamond. The ground state fine structure, as well as the excited electronic structure will be discussed in this talk. Further, we will show the electron-phonon coupling parameter calculations to determine the Jahn-Teller distortion, as well as the phonon sideband of the optical emission. Finally, we will discuss how the ab initio results compare with experimental quantities such as the ground state spin structure and optical emission properties.

4:30 PM *EL05.07.08/MQ01.03.08
Understanding and Mitigating Quantum Decoherence of Nitrogen-Vacancy Center Spins for High-Spatial Resolution Quantum Sensing Ania Bleszynski Jayich¹ and Dolev Bluvstein²; ¹University of California, Santa Barbara, United States; ²Harvard University, United States

The nitrogen vacancy (NV) center defect in diamond is emerging as a powerful quantum-enabled technology, in particular in the realm of sensing and imaging with ultra-high spatial resolution. The performance of these solid-state quantum sensors is highly dependent on their quantum coherence and charge-state stability, which are sensitive to their local environment. Surfaces are an important part of the defect's environment, in particular when targeting high spatial resolution sensing, which necessitates close proximity between the sensor and target. To identify and mitigate the deleterious environmental effects, I discuss several materials-based and quantum-control approaches. Specifically, I discuss the formation of highly-coherent NV centers via a gentle, bottom-up method of nitrogen delta-doping during chemical vapor deposition growth of diamond thin films followed by low energy (~ 150 keV) electron irradiation. I present measurements of the density and coherence properties of the NV centers formed in this way as a function of growth and irradiation parameters [1]. In the second part of the talk, I discuss the spin and charge state properties of shallow NV centers, and introduce techniques to mitigate decoherence due to paramagnetic surface spins [2] as well as charge state instabilities near surfaces [3]. These approaches to improved sensors will ultimately enable truly nanoscale spatial resolution imaging of magnetic, electric, and thermal fields in a
variety of condensed matter and biological systems.

Structural Characterization of Phosphorus- and Nitrogen- Co-Doped Nano-Crystalline Diamond Grown by MW PE CVD
Fernando Lloret1,2, Sanakaran Kamatchi Jothiramalingam1,2, Marina Gutierrez3, Paulius Pobedinskask1,2 and Ken Haenen1,2; 1Hasselt University, Belgium; 2IMEC vzw, Belgium; 3Univ de Cadiz, Spain

Diamond is a very interesting material for many applications due to its excellent properties. The advantage of nanocrystalline diamond (NCD) facing single crystal diamond is the possibility to cover large areas. However, the granular nature of NCD leads to properties based on the interplay between grains and grain boundaries.[1] Grain boundaries are then fundamental in NCD layers. In this direction, the addition of nitrogen during the growth process has been reported to affect to the grain size. Appropriate N2 contents can increase the sp² bonding structure in NCD films, promote the smoothness of diamond surface, and efficiently raise the conductivity of electrons, thus making the films possessing n-type conducting property.[2] However, these properties are associated to a modification of the microstructure of the diamond films which, in turn, altered the electrical properties of the films. An alternative for n-type doping is the use of phosphorus atoms. Substitutional phosphorus incorporation in NCD films with a concentration of about 10¹⁹ cm⁻³ has been already reported.[3]

In this work, NCD layers co-doped with nitrogen and phosphorous are studied. With the aim to obtain the advantages of both dopants, i.e. good conductivity and smoothness surface, a 200 nm thickness N-P co-doped NCD layer has been grown by microwave plasma enhanced chemical vapor deposition (MW PE CVD) over 100-oriented Si substrates. The phosphorous content as well as the methane concentration were kept constant while N2 was varied from 0.2% to 2% for each sample. Optical emission spectroscopy was carried during the depositions revealing the main species in the plasma for the different gas mixtures. Scanning electron microscopy (SEM) observations show an increase of the surface roughness for samples growth at low N2 ratio. This is confirmed by transmission electron microscopy (TEM). TEM micrographs show a drastic change in the film morphology with the N2 increasing. Grain size is reduced with the increasing of the N2 during growth. Scanning mode TEM (STEM) - electron energy loss spectroscopy (EELS) shows the increase of the sp²-sp³ ratio with the N2 addition. Phosphorus incorporation in the layers is also revealed.

EL05.08.02
High Power, High-Frequency Diamond RF Schottky Barrier Diodes Cristian J. Herrera-Rodriguez1, Xenofon Konstantinou1, Aaron Hardy2, Timothy A. Grotjohn1,2, John D. Albrecht1,2, John Papapolymerou1 and Michael Becker2; 1Michigan State University, United States; 2Fraunhofer USA CCD, United States

CVD diamond is one of the most promising semiconductor materials for RF applications due to its exceptional mechanical, electronic, and thermal properties, such as wide bandgap, high breakdown electric field, high mobility, and high thermal conductivity. Therefore, CVD diamond constitutes a material ideal for high-power, high-frequency, and fast switching applications. The Schottky potential barrier at a metal-semiconductor interface is good for fast switching and it has a low voltage drop in the forward biased regime of a Schottky Barrier Diode (SBD). SBDs are fast because the dynamic response of the switching operation is dominated by the extraction and injection of the majority carrier into the depletion region of the Schottky/diamond junction, with no minority carrier recombination being involved. This study fabricated and tested diamond SBDs for high frequency, high power applications.

Schottky Barrier Diodes were fabricated on layered lightly/highly boron doped (p-/p+ respectively) epilayers on High-Pressure, High-Temperature (HPHT) diamond substrates. High-quality diamond epitaxial layers were grown at MSU by Microwave Plasma-Assisted Chemical Vapor Deposition (MPACVD) using 2.45 GHz microwave resonant cavity systems. The large-signal SBD impedances were obtained using Active Load/Source-Pull (L/S-P) by injecting 20 dBm at 10 GHz to the diode with -4 V applied, giving a value of $\text{out} = 40.2 - j169.3 \Omega$ and $\text{in} = 57.74 - j293.8 \Omega$. After conjugately matching the diode input and output, an output power of $\sim 32 \text{dBm} = 1.58 \text{W}$ was attained for an injected power of $\sim 34 \text{dBm}$, giving an RF power density of W/mm**2 and a loss of approximately 2 dB. The SBD s-parameters were measured. In order to extract the loss due to impedance mismatch during the s-parameters measurement, impedance matching at 10 GHz was performed using the Advanced Design System (ADS) software using stub input/output matching networks. A loss of $\sim 1.75 \text{dB}$ was obtained in the post-matching simulations. It should be underscored that the small-signal SBD impedances extracted from the s-parameters vary from the large-signal impedances obtained via Active L/S-P. This is expected since the SBD dynamic resistance changes with RF power.

EL05.08.03
Generation and Removal of sp² Carbon on Diamond and Nanodiamond Surfaces Kerry Whittlesea1, Simon Astley1, Joseph Durk1, Simon Cooil1, Benjamen Reed1, Tom Wang2, Rachel Cross1 and Andrew Evans1; 1Aberystwyth University, United Kingdom; 2Element Six, United Kingdom

The ability to modify and functionalise the surface of nanodiamonds make them suitable and useful for a vast variety of applications from drug delivery to nanocomposites1,2, however, the detonation synthesis of nanodiamonds produces shells of graphitic carbon around the bulk diamond-like core3. The graphitic shell is desired in applications such as drug delivery and biological composites as it enhances surface reactivity4. However, in the majority of applications, this shell is considered an impurity as it prohibits the properties of the nanodiamond surface, which can be terminated and treated in ways which are beneficial.

Whilst sp² carbon surface layers can be generated at high temperatures in ultra-high vacuum, the surface layers of sp³ carbon on diamond and nanodiamond are removed by annealing in either air or oxygen atmospheres5 at ambient pressures. Previous studies have reported that the temperature at which sp³ carbon at the bulk diamond surface is converted to sp² carbon can be significantly reduced in the presence of a metal catalyst6. The conversion at the bulk diamond-metal interface can be controlled to form single or multi-layer graphene as diamond can provide the source of carbon and is an ideal lattice-match substrate for the growth of graphene7.

A similar process of heating in the presence of a metal catalyst was applied to nanodiamonds where a reduction in the conversion temperature between sp³ carbon to disordered sp² carbon was observed. Using surface sensitive photoelectron-based techniques, the removal and generation of sp³ carbon on diamond and nanodiamond surfaces has been studied for a selection of substrate materials and surface preparation.

Nonlinear Optical Response from Diamonds—The Effect of NV Centers
Mari Motojima1, Yuta Kainuma2, Toshu An2, Hidemi Shigekawa2 and Muneaki Hase1; 1University of Tsukuba, Japan; 2Japan Advanced Institute of Science and Technology, Japan

The optical and magneto properties of the negatively charged nitrogen-vacancy (NV) center in diamond has been extensively investigated because of its application to quantum sensing, such as magnetic and electric fields and to quantum information technologies. In most cases, near-infrared luminescence upon the excitation by green laser can be controlled by the irradiation by microwave, which tunes the optical transition path between the excited and ground states. To extend the optical property of diamond over the current generation of linear optical regime, one requires ultrashort laser pulses, which enables one to induce nonlinear optical effect, such as the nonlinear refraction and nonlinear absorption. Almeida et al. recently reported on nonlinear optical spectra in high-purity diamond using femtosecond laser pulses with photon energy from 0.83 to 4.77 eV and measured coefficients for the nonlinear refraction and nonlinear absorption [1]. Because of the absence of defect-related bands below the band-gap (Eg = 5.5 eV), the two nonlinear optical effects were enhanced for E = Eg/2. Although there are several investigations on nonlinear optical effects in diamond and nano-diamonds [2,3], the effects of the NV center on the nonlinear optical phenomena have not yet been examined. This issue is, however, important to further study new functionality of diamond photonics to advance nonlinear quantum sensing. Here we explore the NV center induced nonlinear optical effects in pure diamond, specifically optical Kerr effect and two-photon absorption in transparent region using 800 nm light, at which NV related bands will be sensitive. It is found that both the nonlinear optical effects enhanced by the introduction of NV centers.

EL05.08.05
The Effect of Methane Concentration on the Properties of Lightly Boron-Doped Single Crystal Diamond Layers
Rozita Rouzbahani1,2, Fernando Lloret1,2, Danny E. Vanpoucke1,2, Sanakaran Kamatchi Jothiramalingam1,2, Daniel Araujo3 and Ken Haenen1,2; 1Institute for Materials Research (IMO), Hasselt University, Belgium; 2IMOMEC, IMEC vzw, Belgium; 3Dpto. Ciencia de los Materiales, Universidad de Cadiz, Spain

The fabrication of high power diamond electronic devices requires an improvement of the crystalline quality of the doped layers. This is one of the limiting factors of the structural and electrical properties of chemical vapor deposited (CVD) layers. Although recent advances in CVD synthesis have enabled the growth of free-standing, single crystal, intrinsic, and boron doped diamond, defects—such as dislocations—remains an important point of attention. Several research groups1,2 have reported on the significant influence of the [B]/[C] ratio in the plasma feedgas on the electrical properties of B-doped single crystal diamond (SCD) films. In this study, the impact of the methane concentration on the crystalline quality and electrical properties of lightly B-doped SCD layers is investigated. The samples were grown in a homemade CVD reactor on 3X3 mm2 Ib (100)-oriented high pressure high temperature (HPHT) substrates. Growth was performed in a conventional [CH4]/[H2] plasma (1%, 2%, and 3%) with residual trimethylboron as the boron source, used for all of the samples. The p layers were characterized by Hall effect in a wide temperature range, Fourier transformed infrared (FTIR) spectroscopy, X-ray absorption spectroscopy (XAS), X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM), optical microscopy, and transmission...
electron microscopy (TEM). The TEM study of the sample grown at 1% methane concentration showed a high-quality $p$-SCD film without any observed dislocations in a thickness of 1 μm. In the XAS measurements of the sample grown at 3% methane, small absorption peaks occurred around 282 eV to 285 eV in the C K-edge region which are assigned as acceptor levels in semiconducting B-doped diamonds. These peaks were not observed in the samples grown at lower methane concentrations (1% and 2%). XPS measurements indicated that the intensity of the B 1s peak is increased by increasing the methane concentration which showed a higher B-doping level. In FTIR spectroscopy, the 2800 cm$^{-1}$ peak has been used by research groups to estimate the vacant acceptor concentrations in the range of $10^{16}$ to $10^{18}$ cm$^{-3}$. The boron concentrations estimated by FTIR were compared to the result of the Hall effect which confirmed the same [CH$_4$/H$_2$] dependence as observed by X-ray spectroscopy, with a sample grown at 3% methane showing a higher boron incorporation than those grown at 1% and 2% methane concentrations in the plasma feedgas. These results were corroborated by first principle density functional theory (DFT) calculations. The formation of more growth centres, due to higher methane concentrations, are found not to significantly change the adsorption energy of the boron impurity at nearby sites. Instead, these growth centres are shown to dramatically increase the formation of missing H defects, which are premium boron incorporation sites, thus indirectly increasing the boron concentration.

Mesoscale Crystallographic Structure Analysis and Boundary Condition Influence on Lateral Grown Single Crystal Diamond by Microwave Plasma Assisted Chemical Vapor Deposition Shengyuan Bai, Ramon D. Diaz and Elias Garratt; Michigan State University, United States

For decades, diamond has shown superior properties that make it desirable for novel electronic materials. However, fabricating large size high quality single crystal diamond wafers faces multiple challenges. Lateral outgrowth of CVD diamond with designated pocket holders makes it highly possible for large size diamond wafers to be realized. A mixed analysis of crystallographic structure of laterally grown CVD diamond and influence of pocket holder boundary condition is key to understanding how to eventually fabricate large size high quality single crystal diamond wafers by microwave plasma assisted chemical vapor deposition (MPACVD).

In this work, single crystal diamonds were grown laterally on High Pressure High Temperature (HPHT) substrates with designated pocket holders by Microwave Plasma Assisted Chemical Vapor Deposition (MPACVD) and characterized by a micro X-ray diffraction (μ-XRD) mapping technique with a 300 μm beam size to show the evolution of diamond crystal structure information during growth and provide feedback on growth strategies. By understanding how crystal structure evolves during growth we can understand the mechanisms linking processing conditions the structure and properties of grown material.

A series of CVD diamond is grown on standard HPHT (3.5mm x 3.5 mm) with various thicknesses (600 μm – 1400 μm) using designated sample holders. High-resolution x-ray rocking curve (HRXRC) and full width at half max (FWHM) μ-mapping of the (400) diamond peaks illustrate the evolution of crystallographic changing after each processing. Relatively low values for misorientation (typically within 0.05°+/−0.003°) and FWHM (typically around 0.025°+/−0.003°) for CVD diamond are compared after a series of growth. Evolution mapping of growth and regrowth suggest an upper limit in FWHM exists for a single CVD growth, which is promising for CVD diamond to have a high quality single crystal sample. Thus, a large size single crystal CVD diamond with uniform crystal orientation (low bending in the crystal structure) and low mosaicity (small FWHM) can be achieved.

Moreover, preliminary results demonstrate single crystal CVD diamond prefers to grow laterally in an exponentially decay way towards the pocket boundary, and smooth single crystal diamond (SCD) edges are formed after growth. The growth trajectory of the diamond profile satisfies an exponential decay relationship as it gets closer to the pocket boundary, which suggests a moderate plasma density region makes the main factor for a diamond sample to grow as a single crystal. Based on the growth rate according to specific diamond crystal orientation, lateral
outgrowth using series of designated pocket holders shows the effective diamond area can be enlarged from the 3.5mm x 3.5mm standard HPHT to around 5mm x 5mm CVD diamond in a single run. Regrowth on CVD plate using iteration method with wider iteration holders is promising for SCD samples to keep growing even larger.

Hydrogen-Terminated Diamond Field-Effect Transistor with Double Dielectric Layers of HfSiO4/Al2O3
Yanfeng Wang, Xiaohui Chang, Wei Wang and Hong-Xing Wang; Institute of Wide Band Gap Semiconductors, School of Electronics and Information Engineering, Xi’an Jiaotong University, China

Diamond film collects all the outstanding properties of mechanics, electronics, heat, and optics etc. together making it have potential applications in the fields of wide range optical transparent window material, super-hard coating tolls, especially, in the field of high power electron devices which can work with high frequency and in high temperature environment. Recently, researchers have extensively investigated hydrogen-terminated diamond (H-diamond) field effect transistors (FETs). H-diamond surface can form a p-type conduction layer with a sheet hole density and hole mobility of 10^{13} cm^{-2} and 50-150 cm^{2}V^{-1}s^{-1}, respectively. However, this conduction layer is thermally and chemically unstable and vulnerable to the ambient environment such as oxidation of diamond surface or higher annealing even in vacuum. All these would cause the missing of p-type conduction layer and the degradation of FET performance. This problem could be solved by fabricating dielectric layers on diamond surface to maintain the p-type conduction channel, which also acts as a insulators. Various dielectric layers have been used such as SiO2, Al2O3, HfO2, Ta2O5, and ZrO2 on H-diamond surface. However, there are few reports on using dielectric of HfSiO4, which has excellent thermal stability, adequate band gaps (from 15 to 25 depending on hafnium content).

In this work, investigation of H-diamond FETs with ALD-Al2O3/ SD-HfSiO4 dielectric layers have been carried out. Firstly, gold electrodes were patterned on H-diamond by electron beam evaporation technique. Secondly, UV-ozone was used to insulate p-type conduction channels between source and drain electrodes. The length of channels were 20μm. Then, 4nm ALD-Al2O3/ 30nm SD-HfSiO4 dielectric layers were fabricated on p-type conduction channels by ALD and SD technique. Finally, electrical properties of this diamond FETs were investigated. The detail will be presented in the conference.

SESSION EL05.09: Diamond Processes/Technology

Fabrication and Characterization of Modified Boron-Doped Diamond Electrodes for Peroxynitrite Detection and Quantification
Eman Darwish1,2, Mai Rashwan1,3, Jinyi Wang1, Sayed Moalla2, Zeinab Answer3, Haitham Kalil4 and Heidi Martin1; 1Case Western Reserve Univ, United States; 2Port Said University, Egypt; 3Suez Canal University, Egypt; 4Cleveland State University, United States

Endogenous and exogenous, reactive oxygen species (ROS) have a significant, damaging effect on cell metabolism, including in neural systems. Peroxynitrite (PON) has emerged as a secondary ROS that is linked with oxidation and/or nitration of biomolecules, and is the product of the diffusion-limited reaction of superoxide and nitric oxide radicals. Its short lifespan and fast reactivity increase the challenge of measuring its concentration under physiologic conditions. Several methods exist for peroxynitrite detection in aqueous environments, yet the problem of real-time quantification remains. In this paper, the electrochemical behavior of peroxynitrite has been studied using boron-doped diamond (BDD) microelectrodes. For more than a decade, diamond-based sensors have been successfully applied to electrochemical detection of various analytes in biological and environmental systems, due to its wide potential window, and stable, low background current. In addition, the diamond has more predictable surface to fine-tune for optimized detection of peroxynitrite. In this research study, the direct, real-time electrochemical oxidation of peroxynitrite on BDD electrodes was investigated. A wide range of physicochemical characterizations was conducted to demonstrate the catalytic
oxidation of PON on surface-modified diamond microelectrodes. Initial attempts were made to determine whether PON is generated during simulated, neural stimulation pulses, in a nitric oxide containing environment. Developing BDD microsensors that can monitor the electrochemical signature of peroxynitrite will be an important step forward towards improving the safety of electrical stimulation of cells as well as general monitoring of PON levels as an indicator of tissue deterioration and age-associated diseases.

Thermal Optimization of Metal/Nanocrystalline Diamond Junctions via Diffusion Barriers Henry Aller1, Zhitao Guo1, Karl Hobart2, Tatyana I. Feygelson2, Alan J. McGeoughy1, Andrew Gellman1 and Jonathan A. Malen1; 1Carnegie Mellon University, United States; 2U.S. Naval Research Laboratory, United States

Overheating cripples the efficiency of electrical devices. Diamond heat sinks can facilitate heat dissipation and directly lower operating temperatures. The advent of nanocrystalline diamond (NCD) deposition techniques provide the ability to work with diamond on nanometer length scales, which cannot be done with traditional machining. Thermal optimization of metal/NCD junctions, used to adhere NCD to the device, is required to maximize the efficiency of the heat sink.

We examine thermal transport across Au/contact/NCD junctions, for the contacts Cr, Ni, and Ti. For each contact, the thermal boundary conductance (TBC) is measured using frequency domain thermoreflectance for contact thicknesses between 0 and 10 nm. Cr and Ti are predicted to chemically react with NCD to form enthalpically favorable carbides. Grown carbides add thermal resistance, lowering the TBC of the Au/contact/NCD junction. During deposition of the contact, NCD grain boundaries may act as low-resistance highways for carbon diffusion, promoting carbide growth. Thus, fine-grained materials like NCD may be at risk of forming low TBC junctions with metals, hindering the ability of future NCD heat sinks. To mitigate reactions, we deposited 0 to 10 nm thick Ni diffusion barriers between Cr or Ti and the NCD. The measured TBC of the Au/(Ti or Cr)/Ni/NCD junctions is used to quantify the improvement from reaction mitigation.

Synthesis and Characterisation of Tin Monoxide—A Potential Ultra-Low Work Function Multilayer for Terminating Diamond Surfaces Sami Ullah, Mattia Cattelan, Gary Wan and Neil Fox; University of Bristol, United Kingdom

Diamond electrodes terminated with surface layers can impart significant changes to the electronic properties of a diamond interface and we have previously reported on studies of the tunability of surface work function by substituting hydrogen with oxygen under controlled conditions 1. Engineering a functionalised diamond surface that is stable and reproducible is of technological importance to future diamond electronic devices such as Schottky junctions and electron-emitting electrodes for field emission, thermionic energy converters, secondary electron multipliers.

Tin monoxide has been considered as potential material for battery anodes, coating, gas sensing, catalysis, etc. The application area of SnO extends over photovoltaics, displays, information storage, etc. as it has a large optical bandgap of 4.12 eV, high transparency (~90%) non-toxic and abundant 2. SnO has been found to form a layered structure in a crystallographic direction of [001] with a monolayer thickness of 0.48 nm. Sn 5s form a lone pair of electrons which point towards the interlayer spacing and result in dipole-dipole interaction leading to a Van der Waals gap of 2.52 A between the layers. Various groups have demonstrated the growth of SnO mono and multiple layers by various methods but many of these result in an upper SnO2 layer that forms as soon as the sample is taken into the oxygen environment as SnO is metastable and hence rapidly converts into SnO2.

We have produced mono and multiple layer SnO on conductive, p-type single-crystal diamond under ultra-high vacuum (UHV) conditions by e-beam evaporation and characterised in-situ by Spot Profile Analysis Low-Energy electron diffraction (SPA-LEED)and Energy Filtered Photo Emission Electron Microscopy (EF-PEEM) and X-ray Photoemission Spectroscopy (XPS). We quantify the change in work function between mono and few-layer SnO and its effect upon the barrier height of a p-type diamond Schottky junction.

High Pressure and High Temperature Treatment for Ion Implanted Diamonds Rei Fukuta, Yohei Murakami, Fumitaro Ishikawa, Masafumi Matsushita, Toru Shinmei, Hiroaki Ohfuji and Tetsuo Irifune; Ehime University, Japan

High pressure and high temperature (HPHT) technique is a process enabling diamond synthesis and the control of diamond properties. The HPHT-processed diamonds show characteristic properties which cannot be achievable by the other technique. E. g., there is a report for optical emissions from Sn-vacancy (Sn-V) center in HPHT-treated diamond reported by Iwasaki et al.[PRL 119, 253601, 2017.], which shows the prospect for its application to a light source of quantum emitters. Nanoscale structural design trying to obtain new functions of existing materials is a key issue for the realization of future devices and applications. To explore the functions of diamond, HPHT technique would have potential to activate its unknown properties as in the case of impurity activations of the above reports. We consequently investigate the effect of HPHT treatment on P and Sn implanted diamond on its surface.

For the investigations, we employed commercially available single crystalline diamond (001) substrate synthesized by chemical vapor deposition. We introduced P and Sn by ion implantation at $1 \times 10^{20}\text{cm}^{-3}$ uniformly from the surface to the depth 300 nm and 50 nm, respectively. Subsequently, we applied HPHT treatment at 15 GPa and 2300°C for 20 min. The treatment is expected to induce recrystallization and heal the damage of the diamond surface. The sample surface after HPHT treatment showed square holes aligned to specific crystal orientation, suggesting crystallographic rearrangement of constituent elements. Secondary ion mass spectrometry showed the profiles of P and Sn after HPHT with the density similar to the ion implantation. We also observed atmospheric impurities, H, O, and N in the diamond. The amount of those elements varies by the conditions of ion implantation and HPHT treatment. Hence, the proper ion implantation and HPHT treatment can preserve the implanted elements in the host matrix and suppress the contaminations of atmospheric elements. The Sn-doped sample showed sharp photoluminescence emission at 1.999eV and 2.003eV at low temperatures after HPHT as reported by Iwasaki. These results show great potential of HPHT as a material engineering tool for diamond.

9:15 AM EL05.09.05
Lateral Boron Doped Diamond Nanowires—Fabrication and Function Alex C. Pakpour-Tabrizi; University College London, United Kingdom

Electronically active low dimensional structures have been made in a variety of material systems. Nanowires in particular are of interest in fields as varied as quantum computing, sensing and power electronics to name but a few. By utilising a mix of additive and subtractive processing a novel lateral diamond nanowire is fabricated and characterised. The substrate and foundation for this nanowire is a highly boron doped diamond epilayer, grown on high purity insulating single crystal diamond. The dopants are confined spatially in a 1-2nm region, this delta function like distribution can be shown to have similar electronic properties to a bulk doped. The $\delta$-doped epi-layer is then patterned and etched to leave wires with dimensions on the order 10-20nm and arbitrary controllable lengths. In this talk we will discuss the transport mechanisms and phenomena observed, as well as showing a novel field effect transistor utilising a number of these wires to achieve high current handling and demonstrate the scalability of this unique technology.

Single crystals of diamond have high mechanical strength and are very resilient to high-intensity X-ray radiation. Diamonds are thus irreplaceable in applications across X-ray optics and high-pressure physics, serving as windows, monochromators, and anvils in high pressure cells. The physics underlying diamond’s unusual properties stems from its strong $sp^3$ covalent bonds and simple symmetry. As diamonds eventually damage under ultra-high intensity X-ray radiation, the tetrahedrally bound $sp^3$ carbon atoms are known to graphitize to trigonal bipyramidal $sp^2$ hybridized carbon atoms. This change in local symmetry mechanically destabilizes the material by adding low-energy pathways along which the crystal may deform. Studies of the mechanism by which high-energy X-rays graphitize diamond and the resulting changes to the mechanical properties have been limited. Few characterization techniques can measure the lattice defects and microstructure of a crystal deep beneath its surface—especially as the material responds to external stimuli.

We use ultrafast dark-field X-ray microscopy to directly image changes to the phase, strain and lattice tilt with ultra-high sensitivity as diamond responds to the high intensity X-ray radiation at an X-ray free electron laser. With these results, we demonstrate how minor changes to the microstructure of diamond from the incident radiation cascade into large-scale deformations. This work demonstrates how this novel high-sensitivity technique can give us a new view of the link between radiation and mechanical damage in diamond, informing applications across X-ray science, high-pressure science and astrophysics.

This work was performed in part under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

9:45 AM EL05.09.07
Experimental and Modelled I-V Characteristics of Boron-Doped Diamond at High Electric Fields Including Self-Heating Effect Andrew Taylor1, Nicolas Lambert1,2, Pavel Hubík1, Jiri Bulir1, Joris More-Chevalier1, Hasan Karaca1, Clément Fleury1,2, Jan Voves2, Zbyněk Soban2, Dionyz Pogany3 and Vincent Mortet1,5; 1Institute of Physics of the Czech Academy of Sciences, Czechia; 2Czech Technical University, Czechia; 3Technische Universität Wien, Germany; 4Silicon Austria Labs, Austria; 5Czech Technical University in Prague, Czechia

Diamond is a wide band gap semiconductor with high thermal conductivity, carrier mobility and breakdown field, which make it particularly suitable for the fabrication of high power electronic devices. However, the development of diamond devices is limited by the high ionization energy of its dopants, which leads to only a small fraction of them being ionized at room temperature. When stressed by a high electric field, a current multiplication has been observed in boron-doped diamond (BDD) attributed to Impurity Impact Ionization (III) and the ionization of the neutral acceptors1. In this work, we analyse the current multiplication in BDD including the combined effects of Self-Heating (S-H) and III. Epitaxial BDD layers with different acceptor concentrations in $3.1 \times 10^{18} - 6.1 \times 10^{19}$ cm$^{-3}$ range have been grown in an AX5010 microwave plasma enhanced chemical vapour deposition system. Quasi-static current-voltage (IV) characteristics were measured using a Transmission-Line Pulse setup2 with 100 ns pulse duration on concentric titanium/gold ring-disk electrodes structures patterned by standard lithography and wet etching methods. S-H was analysed using Transient Interferometric Mapping (TIM)3 of the thermal energy distribution between electrodes in ns time scale. The experimental IV characteristics were modelled by taking into account S-H effect and III using finite element method. The simulated IV characteristic, in particular the negative differential resistance (NDR) region appearing due to S-H effect, is in good agreement with the experimental data. This work was financially supported by the project 17-05259 S of Czech Science Foundation and the SGS Student Grant “Electric Discharges II: experimental research, modeling and applications” ID: SGS19/167/OHK3/3T/13.

Engineering and Transport Properties of Diamond Bipolar Devices Aboulaye Traore1,2, Toshiharu Makino1,2, Hitoshi Umezawa2, Hiromitsu Kato3, Masahiko Ogura2, Yukako Kato2, Daitsuke Takeuchi2 and Satoshi Yamasaki2; 1University of Tsukuba, Japan; 2National Institute of Advanced Industrial Science and Technology, Japan

Semiconducting diamond is touted for its outstanding intrinsic and thermal properties that promise tremendous devices performances advantages for power control and conversion applications. Over the last few decades, basic works in diamond growth and doping have allowed the extension of known devices technologies to diamond as well as the development of new devices concepts. However, to achieve high performance diamond devices that can outperform the existing and emerging technologies, much remains to be understood in many areas such as the diamond devices physics, the effects of defects (intrinsic and extrinsic) on diamond devices transport properties, the diamond surface passivation, and the diamond devices design (edges termination issues).

This presentation will be focused on the electrical transport in diamond bipolar devices such as diamond p-i-n diode. Bipolar diamond devices are very promising and attractive devices because of the conductivity modulation phenomenon that allows to counterbalance the effects of high ionization energies of dopants in diamond (0.58 eV and 0.38 eV for Phosphorus donor and Boron acceptor respectively).

In our work, diamond p-i-n diodes have been used to study carrier recombination mechanisms, charge carrier dynamics, and impact ionization in diamond. Our pioneering works on the electrical characterization of the diamond p-i-n diode in dynamic and the optimization of diamond p-i-n devices design to suppress the electric field crowding at devices edges for an accurate measurements of impact ionization coefficients by electron beam induced current method (EBIC), will be introduced and discussed.

11:00 AM EL05.10.02
Tunable Barrier for High Temperature Diamond PIN Diodes Mohamadali Malakoutian1, Harshad Surdi2, Franz A. Koeck2, Manpuneet Benipal3, Srabanti Chowdhury1, Stephen Goodnick2 and Robert J. Nemanich2; 1University of California, Davis, United States; 2Arizona State University, United States; 3Advent Diamond, United States

The wide bandgap, high carrier mobilities, high breakdown field and highest thermal conductivity identify diamond as the ideal power semiconductor material. A particular advantage of diamond over all other semiconductors is operation in high temperature, high radiation and extreme environments. Diamond PIN diodes or PIN-Schottky diodes will be crucial components in power conversion and control systems that can operate in extreme environments. In this study the transport characteristics of high purity diamond PIN and PIN-Schottky diodes are measured and simulated for temperatures ranging from room temperature to 500°C. While the forward current density increases due to dopant activation and thermionic emission, the reverse current increases by many orders of magnitude consistent with thermionic emission theory. The diode forward/reverse rectification ratio consequently decreases by many orders of magnitude. Attempts to engineer the barrier using different metals (with different work functions) show very limited success. This study presents an alternative approach where the diode barrier is engineered by increasing the phosphorus doping in the n-type layer. Experimental results and simulations establish that the barrier can be varied from about 1 eV to greater than 3 eV which restores the high temperature (500°C) rectification ratio to nearly 10^4. The simulations also consider the forward current properties and they establish how the specific diode characteristics can be tuned for operation at elevated temperature up to and exceeding 500°C. This tunable approach appears may provide an advantage for diamond diodes (over other power semiconductors) for high temperature operation.

Observation of Metallicity in n-Type Doped Diamond Thin Films Dhruba Das and Mamidanna Ramachandra Rao; IIT Madras, India
Electronic properties of doped-diamond are of great technological interest due to the possibility of diamond-based electronic devices for high power electronics and for the fabrication of QUBITs. With a bandgap of 5.5 eV at room temperature (RT), diamond is an electrical insulator however when it comes to substitutional incorporation of impurities in its lattice via doping, it becomes extremely selective unlike Si and Ge and its conductivity has been seen to change drastically with doping. Doping of diamond lattice by boron to make it p-type has been the most successful so far by incorporating boron atoms in the gaseous phase during the growth process and this has shown enhanced electrical conduction making it metallic and even superconducting [1,2] signaling an insulator-to-metal transition (IMT) at low temperatures provided the dopant concentration is above a critical value ~10^{21} cm^{-3}. Nitrogen and phosphorus are the famous candidates for the n-type doping in diamond which contributes an extra electron in the system. Nitrogen doping has not yet brought much success in terms of electrical conductivity during the past one decade as it fails to form a shallow donor level with its donor level at Ec − 1.7 eV because of dramatic localization of the donor electron on a neighboring carbon atom with a subsequent formation of a lone-pair on the nitrogen atom. Phosphorus, on the other hand, being a large impurity does not relax in an analogous fashion unlike nitrogen, and thus leads to a substantially shallower donor level at Ec − 0.6 eV, which is still rather deep for room-temperature ionization.

Over the last two decades, much work has been done on making diamond n-type with increased conductivity but so far, the highest achieved conductivity is 143 (Ω-cm)^{-1} [3,4] in nitrogen doped (20% N2) ultrananocrystalline diamond (UNCD). For the first time, we report the formation of n-type diamond by nitrogen doping in ultrananocrystalline diamond deposited on silicon substrate with resistivities similar to copper (ρ_{copper} ~ 1.68 x 10^8 Ω-m at 20 °C) with metallicity being observed throughout the temperature regime for few doping concentrations. Developing nitrogen doped UNCD thin films was carried out by depositing an ultrananocrystalline diamond thin film on Si in hot filament chemical vapor deposition reactor followed by ion implantation by N⁺ ions with different energy and fluences and subsequent annealing to make the vacancies and dopants mobile so that substitutional doping can be ensured inside the lattice. These implanted films were characterized by Raman spectroscopy for their UNCD nature before and after annealing post-implantation.

Boron Doping Quantification in Single Crystal Diamond by Solid Solution Strengthening Fernando Lloret₁², David Eon³, Etienne Bustarret¹ and Daniel Araujo⁴, ¹Hasselt University, Belgium; ²imec vzw, Belgium; ³Univ. Grenoble Alpes, CNRS, France; ⁴ Universidad de Cadiz, Spain

The metallic behavior of highly boron doped diamond (BDD) is an asset for the development of the future diamond-based electronic technology. However, boron concentration quantification still remains expensive and, in some cases, difficult. Secondary ion mass spectroscopy (SIMS) is the most accurate technique but requires special care when steep profiles are involved [3]. It is also a very expensive tool. Alternatively, boron doping can also be quite precisely evaluated by cathodoluminescence (CL). This technique collects the photons generated by the interaction of the incident electrons with the electrons of the sample. The consecutive radiative recombination signal depends on the electronic properties of the sample. In particular, at low temperature, excitons bound to boron impurities have specific spectral signatures that make it possible to determine the boron levels. However, one of the main restrictions to the use of this technique is the presence of dislocations. The strain generated around the dislocation bend the valence and conduction bands trapping all the carriers. Their mobility is then strongly reduced and electrons and holes recombine mostly through non-radiative channels, while a relatively weak broad band (A-band) may result from the remaining radiative carrier recombination at the dislocation. In regions where the density of defects is high enough to close all radiative channels, the evaluation of the doping levels by CL is no more possible. In this case, the quantification of boron becomes a challenge. We propose here to use the interaction between boron atoms and dislocations specific to these regions in order to estimate the doping level by transmission electron microscopy. Substitutional boron incorporation within BDD can be seen as allowing elements into the crystalline lattice forming a solid solution. The non-uniformity generated by boron atoms makes plastic deformation more difficult by impeding dislocation motion, thus creating an increase in the yield stress of the material also called strengthening.
Upon lateral growth, dislocations are pushed forward, along a specific course \(^2\). Their trajectory varies when they pass through a doped layer because of the solid solution strengthening. An increase in the dislocation length is observed, necessary to accommodate locally the additional tension generated by the boron impurities in the doped layer. In this work, boron doped/undoped superlattices have been laterally overgrown over patterned substrates. Two 001-oriented HPHT substrates were etched away by inductively coupled plasma reactive ion etching (ICP-RIE) leaving a pattern array of 5 µm diameter and 1µm height disks. Over these substrates, p\(^+\)/p bilayers were grown with different [B]/[C] ratios for each sample. The presence of dislocations was ensured by the roughness substrate surface after etching. The dislocation length was measured by high resolution TEM for both samples. Boron content was then estimated by the above proposed method, and compared to that reported in the literature for similar growth conditions.

**Ab Initio Study of Boron, Boron-Hydrogen and Vacancy Complexes in Diamond and Their Effect on the Electronic Structure of Diamond**

Nandan Tandon\(^1\), John D. Albrecht\(^1,2\) and Timothy A. Grotjohn\(^1,2\); \(^1\)Michigan State University, United States; \(^2\)Fraunhofer USA Center for Coatings and Diamond Technologies, United States

Diamond has been identified as an attractive material for high power devices because of its physical and electronic properties. In comparison to other wide-bandgap semiconductors diamond exhibits high carrier mobilities and thermal conductivity. The electronic properties of diamond are defined by the dopants that are present during growth or introduced in diamond to achieve p- and n-type conductivity by ion implantation of boron or phosphorous respectively. This process of introducing dopants also creates defects such as vacancies and interstitials along with the presence of dopant atoms. Among the implanted dopants, the number of activated dopants is found to be only a few percent. Thus, it is interesting to study the geometry of dopants and other factors which result in such low levels of active dopants.

In this work we have used first principles density functional theory based calculations within the supercell approximation to identify the structure and electronic properties of complexes formed from carbon vacancy, boron, boron-hydrogen and interstitials in diamond. Total energy calculations were performed to identify ground state structures for various defects and formation energies were used to predict the probability of presence of that defect. Ionization energies for different defects are evaluated using the marker method. Formation energy of substitutional boron is found to be lower in presence of hydrogen. As seen by others, we also find that a single vacancy relaxes into a tetragonal distorted structure of the nearest carbon atoms from the original tetrahedral structure. This structure is lower by 0.22 eV compared to the original tetrahedral structure. Activation energy of vacancy diffusion is found to be 2.8 eV using the nudged elastic band method. Spin-polarized calculation of single vacancy shows that there is small magnetic moment on all 4 carbon atoms surrounding the vacancy and the total energy of such a calculation is lower than a paramagnetic calculation. Other results which include spin-polarized calculations on diamond will also be shown.
Nitrogen vacancy (NV) center in diamond is expected as a magnetic sensor with high sensitivity at room temperature and single NV center succeeded in detecting $^1$H spins out of the substrate [1]. For improvement of magnetic sensitivity, both shallow and aligned NV ensemble is required since the magnetic sensitivity is inversely proportional to the root of number of NV centers contributing to the measurement [2, 3]. Delta-doping of N was tried by diamond growth on N-terminated (001) diamond and estimated 2D concentration of NV centers was $1 \times 10^{11}$ cm$^{-2}$ [4]. This method can control the depth of NV ensemble precisely unlike ion implantation or N-doped layer which are popular methods to fabricate NV ensemble. However, NV centers in (001) delta doped layer would be not aligned because possibility of each four sites adjacent to N becoming a vacancy are equivalent. In the case of (111) delta doping layer, NV centers will be aligned because a top site is more preferable to become a vacancy than other three equivalent sites. Recently, we established the method to fabricate N-terminated diamond with high coverage causing no damage on the surface [5, 6]. We partially succeeded to make aligned two-dimensional NV ensemble from N-terminated (111) diamond with half mono layer coverage embedded by high purity (111) diamond film. N-terminated (111) surface was fabricated by nitrogen radical exposure method [5, 6]. After that, thin layer (thickness is about 10 nm) of high purity (111) diamond film was epitaxially grown on the N-terminated surface using microwave plasma enhanced chemical vapor deposition method. We confirmed that N density in the high purity diamond film was below $1 \times 10^{16}$ cm$^{-3}$ by secondary ion mass spectroscopy (SIMS). We also confirmed the formation of NV ensemble with 2D concentration of about $1 \times 10^{11}$ cm$^{-2}$ using the confocal PL-intensity mapping. Optically detected magnetic resonance (ODMR) with static magnetic field applied along the [111] axis was used to determine whether the NV ensemble was highly aligned or not [7]. The ODMR spectrum of the NV ensemble had only two dips, which might be derived from the NV center whose orientations were aligned along the [111] axis. In conclusion, NV ensemble was fabricated by diamond growth on N-terminated (111) diamond and was aligned along the [111] axis.

Optical Emission Properties of Ion-Implanted Nanodiamonds and Their Applications Sini Nanadath Shibu1, Dzianis Saladukha1, Tomasz J. Ochalski2, Haitao Ye2 and Chengming Li3; 1Cork Institute of Technology, Ireland; 2University of Leicester, United Kingdom; 3University of Science and Technology Beijing, China

The recent development of novel super-resolution imaging techniques coincides with the efforts to synthesize optically bright and stable biomarkers. It is known that the electrical resistivity of nanodiamonds is quite high with a bandgap of 5.5 eV and at room temperature they are dielectrics. Fluorescent nanodiamonds (FNDs) can be produced using a variety of methods with a wide range of sizes ranging from several nanometers to tens of micrometer, which defines their penetration and adhesion properties. Nano-diamonds (NDs) synthesized by microwave plasma chemical vapor deposition (MPCVD) techniques are an interesting class of diamond materials that can be used for a plethora of applications.

There has been low usage of FNDs as a biomarker due to their weak quantum efficiency compared to all other biomarkers, nanoparticle, and fluorescent dyes. Thus, the main challenge is to enhance the emission intensity from the FNDs. The NDs are subjected to nitrogen ion-implantation at an implantation energy 20keV with various implantation fluences. Implantation depth concentration and crystalline distortion level profiles have been calculated using Low Energy Approximation. The NV defects fabricated through implantation are optically active color centers which will enhance the photoluminescence properties by energy transitions between the defect states and carbon states. Here we report the comparison between the unimplanted and nitrogen ion-implanted diamond nanoparticles on the basis of photoluminescence and Raman spectroscopies. In addition, we will be investigating the concentration

Final Program 1/13/2020 311
of nitrogen atoms and crystal disorder influence on the optical emission dynamics of diamond nanoparticles. The present study will provide guidance for the future synthesis of fluorescent nano-diamond markers for biosensing and bioimaging applications in multidisciplinary fields. For example, we can use the differently doped nanodiamond fluorophores mixed with milk powders as biomarkers to identify the various milk constituents.

Growth Mechanism of SiV Centre Rich Diamond Multiply Twinned Particles and Their Applicapility in µ-Light-Emitting Diodes
Jürgen Weippert1, Taro Yoshikawa1, Christoph Schreyvogel1, Lutz Kirste1, Michael Kunzer1, Andreas Graff2, Volker Cimalla1 and Vadim Lebedev1; 1Fraunhofer Institute for Applied Solid State Physics (IAF), Germany; 2Fraunhofer Institute for Microstructure of Materials and Systems (IMWS), Germany

The inclusion of Silicon Vacancy (SiV) centers into synthetic diamond has already proven to be a valuable tool for the production of optoelectronic devices such as p-i-n diodes, photonic crystals or single-photon emitters[1]. In our recently published work we have shown the preparation of synthetic diamond multiply twinned particles (MTPs) in icosahehedron shape[2]. Here we present the expansion of this work regarding MTPs having the shape of both completed dodecahedrons and icosahehedrons which were grown by plasma-assisted CVD on Si(111) surfaces. This process ensures the reliable inclusion of SiV centers thus eliminating the necessity of any post-CVD implantation methods. Also, the resulting lms provide a sufficient conductivity for further applications.

The growth mechanism was found to consist of several differentiable steps: first, octahedral, single crystalline particles grow up to edge lengths around ca. 300 nm. At this stage, the formation of penetration twin structures sets on, resulting in the controlled growth of particles with dodecahedral and later icosahedral symmetries. The SiV centers form predominantly by redeposition of sputtered Si atoms at the initial growth stages and by bulk diffusion along grain boundaries for thicker films.

Their characteristic photoluminescence emission at 738 nm was found to have a FWHM in the range 3-4 nm. Closed MTP layers were used to fabricate diodes and µ-LEDs based on vertical diamond/Ti Schottky contacts by sputtering 500 μm thick Ti electrodes atop the grown films. Already with this simple approach a long-time photostability with constant spectral features could be achieved.

Effects of Annealing on Defect Concentrations and Structures in Irradiated Single-Crystal Diamond
Erik Vyhmeister-Cancel1 and Elias Garratt1,2; 1Michigan State University, United States; 2Fraunhofer Center for Coatings and Diamond Technologies, United States

Single-Crystal diamond is a promising material of interest for next-generation radiation sensors in extreme conditions, such as the LHC or FRIB. A major property of interest is the resistance of diamond to radiation damage.

Radiation damage in diamond is confined almost exclusively to the creation of point-like defects. Due to its radiation hardness, the lattice is not amorphized as in Silicon, with interstitial-vacancy pairs being the primary damage caused. At temperatures above 100C, carbon interstitials become mobile and can recombine with lattice vacancies, healing the lattice. At temperatures >400C, vacancies mobilize, further

Defect structures are studied by the use of Raman and Photoluminescence (PL) spectroscopy, expanding on previous work that used X-Ray diffraction (XRD). XRD imaging comparing irradiated to non-irradiated regions of diamond show no clear connection between diffraction profile and radiation damage. Radiation damage at doses of 10^15 neq/cm² does not appear to cause amorphization, but instead a distribution of point defects. Point defects in diamond are optically active, accessible with PL, and Raman can measure structural irregularities that create additional vibrational modes.

This study presents spatially resolved imaging of point defects, correlating residual damage directly to the intensity of incident radiation. The effects of different annealing procedures on the types of defects (GR1, NV0) present in the
diamond are investigated. Additionally, concentrations and the spatial correlations between different types of defects are studied.

Radiation damage causes decreases in detector efficacy and charge collection efficiency. Removing these point defects by annealing increases the overall lifespan of the detector, reducing operational costs. This research evaluates and determines the optimal annealing procedure for single-crystal diamond damaged by GeV heavy ions, and possible applications to other radiation damage.

A Spectroscopic Surface Study of Amine-Terminated Nanodiamonds Kerry Whittlesea, Simon Astley, Anita Brady-Boyde, Joseph Durk, Zheshen Li, Tom Wang, Rachel Cross and Andrew Evans; 1Aberystwyth University, United Kingdom; 2Centre for Storage Ring Facilities (ISA), Denmark; 3Element Six, United Kingdom

Nanodiamonds are a promising nanomaterial being considered for an increasing number of applications as they possess many of the exceptional bulk diamond properties, such as hardness and non-toxicity, at sub-micron length scale, making them more bio-compatible1. The termination, functionalisation or modification of the nanodiamond surface is an important factor when considering its potential applications; for example, functionalising the nanodiamond to attach specific bio-molecules2. This is due to its high surface to bulk ratio and surface reactivity. There is further interest in nanodiamonds as fluorescent biomarkers due to the well-explored defect in diamond known as the nitrogen-vacancy (NV-) centre. Incorporation of the NV- centre, which is sensitive to external magnetic fields and can be detected optically3, is very successful in bulk diamond and in larger nanodiamonds4, but is still challenging for smaller nanodiamonds.

There is an interest in amine-terminated nanodiamonds as it would allow a variety of functional molecules, such as DNA, antibodies, and polymer building blocks, to be more easily and straightforwardly bonded to the nanodiamond2. Understanding the surface chemistry and properties is important in order to optimise the attachment of different molecules to the nanodiamonds and deliverance into the body.

In this study, the surface of amine-terminated nanodiamonds has been measured and characterised using a variety of spectroscopic techniques. Surface-sensitive photoelectron spectroscopy techniques (XPS, UPS, and NEXAFS) under ultra-high vacuum and in near ambient pressures (NAP-XPS) have been used to anneal and measure the surface of the nanodiamonds. Fourier Transform Infrared Spectroscopy (FTIR), a non-destructive widely used technique used to identify organic materials, was used to provide more detail on the chemical structure of the nanodiamond. The FTIR spectra were recorded at the AU-IR beamline at ASTRID2, Denmark, where the synchrotron radiation based FTIR provides enhanced spatial resolution as a result of increased brightness.

This paper presents a detailed spectroscopic study of amine-terminated nanodiamonds with the aim of better understanding the surface for potential biophysics applications.

Near Ambient Modification of Nanodiamond Substrates for Applications in Drug Delivery Simon Astley¹, Di Hu¹, Kerry Whittlesea¹, Tom Wang², Rachel Cross¹ and Andrew Evans¹; ¹Aberystwyth University, United Kingdom; ²Element Six, United Kingdom

Fluorouracil (5FU) is a highly asymmetrical, polar molecule commonly used in a range of cancer drug treatments including bowel, breast and skin cancer. Previous studies show that 5FU suffers a catalytic degradation on silver substrates, but is inert on graphene [1,2]. Nanodiamonds are enabling the exploitation of diamond’s unique properties at ever decreasing length scales in applications such as quantum optics, biosensors and drug delivery [3,4]. With their high surface: bulk atomic ratio, the surface termination of nanodiamonds is a crucial design parameter in all of these applications; for example in controlling their attachment to specific bio-molecules or aggregation in specific biological sites based on their zeta potentials [5]. The Nitrogen-Vacancy (NV-) centre, which can be commonly found in nanodiamonds, allows for in-situ biosensing.

To investigate changes in the surface termination of nanodiamonds exposed to gases and liquids at high temperature, in-situ photoelectron spectroscopy has been applied under ultra-high vacuum and at near-ambient pressures using laboratory and synchrotron radiation excitation. This has been done to monitor changes in chemical composition and electronic properties of the nanodiamonds and to observe, in real time, the evolution of oxygen species to discover the optimal treatment controls for obtaining specific bonding types for attaching individual drug molecules.

Using these modified surfaces, 5FU has been attached to various diamond and nanodiamond surfaces. The adsorption was found to be strongly dependent on the surface termination, where the ratio of 5FU to the diamond surface can be controlled, and this effect can be seen for all sizes of nanodiamonds.

Fabrication of Nanodiamond and Q-Carbon by Ultrafast Quenching of Carbon Structures for Electron Field Emission Devices Ariful Haque and Jagdish Narayan; North Carolina State University, United States

In this study, we report on the direct conversion of sp² rich carbon nanotube (CNT) and amorphous carbon structures into nanostructured diamond and Q-carbon by nanosecond pulsed laser annealing for electron field emission (FE) applications. Upon irradiating the CNTs with nanosecond pulsed laser at a suitable energy density, the tips and bends of the CNTs are melted in a highly undercooled state (due to the geometry constraint of the temperature distribution and 1D heat flow) to form the ideal platform for efficient FE devices. The highly undercooled state of carbon is a metastable phase and the nucleation of nanodiamonds occurs from this state. The whole process (rapid melting, solidification, and growth) takes place in less than 200-250 ns. The characteristic Raman peak at 1332 cm⁻¹ downshifts to 1324 cm⁻¹ for diamond nanostructures due to the phonon confinement effect. The high-resolution electron-energy-loss spectroscopy of the laser irradiated CNTs shows a characteristic peak at 292 eV for σ⁺ for sp³ bonding of diamond. The diamond crystal structure and the local crystalline perfection and orientation at the laser...
irradiated regions are confirmed by electron-back-scatter-diffraction in high-resolution scanning electron microscopy. The laser irradiated CNT structures with nanodiamond seeds were used to grow large diamond crystals in hot-wire chemical vapor deposition. Furthermore, nanosecond pulsed laser annealing technique was used to convert the amorphous carbon film (grown by pulsed laser deposition) into large area quenched carbon (Q-carbon) film for field emission applications. The Q-carbon field emitter shows excellent field emission properties, such as a low turn-on electric field of ~2.40 V/μm, the high emission current density of ~32 A/cm² and a critical field of ~2.45 V/μm for transition from a linear region to the saturation region in the F-N plot. Moreover, the Q-carbon field emitters illustrate enhanced field emission properties and good field emission stability throughout the temperature range from room temperature to 500K. Overall, this work shows that the pulsed laser annealing technique can be used efficiently for the controlled fabrication of nanodiamond and Q-carbon based high-performance field emitters on different substrates for versatile applications.

4:15 PM EL05.12.04
Nanodiamonds as Raman Probe to Assure Blood Quality Sofia Navarro-Espinoza, Karla Santacruz-Gómez, Mónica Acosta-Elias, Erika Silva-Campa, Jose A. Sarabia-Sainz, Alexel J. Burgara-Estrella, Aracely Angulo-Molina, Beatriz Castaneda, Diego Soto-Puebla and Martin R. Pedroza-Montero; Universidad de Sonora, Mexico

Storage of blood, even in blood bank conditions, generates the deoxygenation of red blood cells (RBC) and morphological changes that alter the erythrocyte membrane, changing its normal shape and functional reliability. These disturbing phenomena impair the capacity of RBC to transport oxygen and diminish the quality of blood. In this work, we investigate how the RBC changes evolve in time (from 0 to 18 days) with a combined scanning laser technique based on AFM-Raman to evaluate roughness, osmotic fragility, and oxygenation characteristics. To enhance the Raman signal and distinguish the oxygen markers, we added nanodiamonds (ND). The ND showed an additional feature; they helped to reoxygenate the blood and interrupted the generation of reactive oxygen species (ROS). The analysis of the deoxygenation process revealed that morphological alterations do not generate biochemical changes in the hemoglobin Raman fingerprint, even though RBC became more fragile and prone to breakage. This effect is noteworthy because after a transfusion RBC have to pass through tiny capillary vessels, where good elastic properties of RBC are needed. The results also indicate that blood has to be used within the first five days after collection to reduce storage lesions and assure quality.

4:30 PM EL05.12.05
Thermometry of Intracellular Structures with Nanodiamonds Martín R. Pedroza-Montero¹, Francisco A. Pedroza-Montero¹, Karla Santacruz-Gómez¹, Mónica Acosta-Elias¹, Erika Silva-Campa¹, Jose A. Sarabia-Sainz¹, Alexel J. Burgara-Estrella¹, Aracely Angulo-Molina¹, Beatriz Castaneda¹, Sofia Navarro-Espinoza¹ and Diego Soto-Puebla¹; ¹Universidad de Sonora, Mexico; ²universidad de Sonora, Mexico

Nanodiamonds (ND) have a significant impact on medicine and biology because of their biocompatibility properties and unaltered performance in physiologic environments. Furthermore, their low toxicity allows working very close to cells, even at the intracellular level. The metabolic processes related to the life of the cell generates or consumes thermal energy. The disturbance of those vital processes by pathologies and stressing factors induce changes in the cell temperature, while reparation or programmed death are triggered. The measurement of temperature improve the knowledge of biologic events, and it is a useful resource for monitoring treatment or therapy; it also provides information of particular interest in the study of the pathology of cancer. A nanothermometer based on ND is an excellent option because it possesses magnetic, electric, and optical properties that exhibit a dependence on temperature in the biologic range centered around 37.5°C. In this work, we present experimental insights and data from the emission spectra of fluorescent nanodiamonds (FNDs), and we followed its behavior as the temperature changes through a phenomenological model. For a more realistic approach, we used FNDs with different N-V centers concentrations in solution. We fit the fluorescence curves to remove background and other spurious luminescent processes associated mostly with impurities or contamination. We also performed calculations based on changes of intensity, semi-width, and position shifts related to the Zero-Phonon Lines of N-V centers to obtain thermometric scales with low errors and precision around 0.01°C. Also, we incubated FND HeLa cells and evaluated the time stability of the fluorescent signal at RT. The results allow establishing FND as thermal probes for reading temperature both in situ and in real time, based in their luminescence signal with the use of simple instrumentation.

4:45 PM EL05.12.06
Nanodiamonds for Improving Lubrication of Titanium Surfaces in Simulated Body Fluid Asghar Shirani¹.
Hip implants are often made from titanium or titanium-based alloys. However, wear during the operation inside the human body is a key source of implant failure and adverse health effects. We propose new insight on the lubrication of titanium components. Addition of small amounts (less than 0.2 wt.%) of nanodiamonds (NDs) to simulated body fluid promotes a substantial improvement in friction (3 times reduction) and wear (up to 2 orders of magnitude wear reduction) behavior of the titanium surfaces. Interestingly, the amount of NDs needed for improvement of friction and wear characteristics is critically dependent on the applied loads. With higher contact loads, larger concentrations of NDs are needed for better friction and wear reduction. Analysis of the wear track formed during sliding indicates the formation of a carbon-rich tribolayer which improves tribological properties of the contacting surfaces. Our results suggest that the carbon layer is formed from the nanodiamonds embedding in the top layer of titanium.

8:30 AM *EL05.13.01
Simulation of Diamond Surface Chemistry—Reactivity and Properties Karin Larsson; Uppsala University, Sweden

The diamond material possesses very attractive properties, such as superior electronic properties (including high carrier mobility), large electrochemical potential window, and a controllable surface termination. Boron-doped diamond surfaces, with attached Pt nanoparticles as the catalytic surface, are nowadays working as a new class of electrode materials. The boron-doped diamond electrode is a semiconducting material with very promising properties like i) a wider potential window in aqueous solution, ii) low background current, and iii) corrosion stability in aggressive environments. The phenomena of diamond surface termination have experimentally been observed to significantly influence the broad-band infrared reflectivity and conductivity. H-terminated diamond surfaces have been found to be hydrophobic, and to show unique p-type surface electronic conductivity. On the other hand, oxygen-terminated diamond surfaces generally show hydrophilic properties, but no electronic conductivity.

The surface reactivity of diamond is expected to affect both chemical processes at the surface and properties related to the surface electronic structure. Examples of factors with the capability to influence the surface reactivity are i) type of plane, ii) surface termination, and iii) doping. Theoretical modeling based predominantly on Density Functional Theory (DFT) has during the last decade proven to become highly valuable in the explanation and prediction of experimental results. The simulation and theoretical analysis of especially surface reactivities has been shown to aid important information.

At this presentation, the combined effect of surface termination and doping on the electronic properties of diamond surfaces, will be especially highlighted. In addition, the effect by a water adlayer will also be considered. All results are based on high-level calculations using DFT calculations.

9:00 AM EL05.13.02
Diamond Surface Band Bending Estimation by ARXPS Gonzalo Alba¹, Rodrigo Alcántara¹, Pilar Villar¹, Jesús Cañas², Juliette Letellier², Gauthier Chicot², David Eon², Daniel Araujo³ and Julien Pernot²; ¹University of Cádiz, Spain; ²Université Grenoble Alpes, Institut Néel, France

Diamond surface XPS contributions is still having a big controversy in the literature and most of the measurements are based on surface normal photoelectron emission. In this sense, angle-resolved XPS experiments allow to obtain different sensitivity depth by varying the electron take-off angle, what is useful to clarify surface contributions, although it is rarely found in diamond.
Recently, a downward band bending in the very near surface has been reported by using this technique. However, the common interpretation of a band bending in X-ray photoelectron spectroscopy, based on peak energy shifts referenced to a known fixed energy level, can be wrong in some cases. Besides XPS peak shifts could exist due to band bending, the correct estimation in the case of a large band bending with a short width near the surface must be done considering the band bending region as a new XPS peak. The shape of this peak depends on the band bending characteristics and XPS experimental parameters.

In this work, an approximation to the shape of a surface band bending is described theoretically and applied to the deconvolution of ARXPS spectra of H-terminated and O-terminated diamond surfaces. A downward and an upward surface band bending are found, respectively.

Ab Initio Study—Ni Catalytic Effect on Diamond (111) Surface Jeongwoo Yang¹, Jong Hwan Park¹, Jin Woo Park², Byung Deok Yu² and Nong Moon Hwang¹; ¹Seoul National Univ, Korea (the Republic of); ²University of Seoul, Korea (the Republic of)

Although catalytic metals play an essential role in the production of industrial high temperature and high pressure (HTHP) diamonds, their role has not been clearly understood. This study provides a microscopic interpretation on the role of the Ni catalytic metal through density functional theory (DFT) calculations. In addition to the metal solvent-catalytic effect, it has been found that Ni removes the strong π-bond (Pandey chain) on the diamond (111) surface, which is an obstacle to diamond growth. When Ni atoms were attached to the diamond (111) surface, the diamond bulk-like surface was more stable than the Pandey chain surface structure, indicating that de-reconstruction could occur by Ni. The results of projected density of state (PDOS), charge distribution, and Bader charge analysis show directly that the surface C-C π-bond is weakened by the charge redistribution caused by covalent bonding of Ni and C. Also, the nudged elastic band (NEB) calculation shows that the Ni surfactant-mediated growth is kinetically possible. Therefore, applying these results to other elements will provide a better understanding of the role of catalytic metals in diamond growth.

9:30 AM EL05.13.04
Fluorination of Diamond Materials for the Control of Surface Properties Anke Krueger; Universität Würzburg, Germany

For many applications the surface chemistry of diamond is a key factor for the control of properties such as the wetting behavior, the electron affinity of the surface[1] or the control of charge states of lattice defects[2]. By attaching either electron withdrawing or donating surface groups the charge state e.g. of shallow NV centers can controlled.

Additionally, surface termination also plays a role in the density of states and the band structure of the diamond material. Therefore, the homogeneous and stable surface functionalization with electrically active atoms or groups is a key step in the fabrication of diamond based devices for e.g. photocatalytic or quantum applications. Here we report on the fluorine termination of diamond surfaces using different wet-chemical fluorination methods. These treatments lead to highly functionalized materials with different surface species. Characterization using e.g. solid-state NMR techniques, XPS and IR methods have been used to characterize the fluorinated materials qualitatively and quantitatively.

This research has received funding from the European Union’s Horizon 2020 Program (Grant Agreement no. 665085, DIACAT, www.diacat.eu) and Deutsche Forschungsgemeinschaft under grant KR3316/6-2.

Real-Time Oxidation and Reduction of Diamond Surfaces at Near Ambient Pressure Simon Astley, Di Hu, Johnathan Ash, Joseph Durk, Kerry Whittlesea, Simon Cooil, Rachel Cross and Andrew Evans; Aberystwyth University, United Kingdom

The effects of the diamond surface can influence its use in electronic, optical and quantum applications and it is particularly important for nanodiamonds, due to their large surface to bulk ratio. The usual preparation methods for single crystal diamond involve mechanical polishing and etching with the aim of producing flat, defect-free O-terminated or H-terminated surfaces. Nanodiamonds are prepared using similar etching procedures. The surface structure and the terminating species influence properties such as wettability, electron emission and adsorption and the control of surface properties requires precise control of the preparation methods. Here we compare the oxidation and reduction of single crystal diamond and nanodiamonds using acid etching, in-vacuo plasma exposure and annealing in near ambient pressure oxygen and hydrogen. The surface sensitive methods of ultraviolet and x-ray photoelectron spectroscopy (PES) using laboratory and synchrotron sources were used to monitor changes in the physical, chemical and electronic structure during surface oxidation and reduction. Near-Edge X-ray Absorption Spectroscopy (NEXAFS) was applied to determine the unoccupied density of states and the orientation of surface bonding and this synchrotron method is particularly sensitive to non-diamond carbon species at the surface. In-vacuo annealing removes and modifies the surface oxygen as revealed by real-time monitoring of the O1s and C1s core level spectra from room temperature to 1000 C. The PES results are compared with DFT calculations that suggest that ether (C-O-C) groups are the preferred bonding arrangement with alcohol (C-OH) groups preferentially desorbed during the annealing process. Changes in composition were further correlated with changes in electrical conductivity and work function. DFT was also applied to model the desorption of oxygen species at specific temperatures and showed a deformation in the surface/sub-surface structure in situations where only some types of oxygen groups are present. Oxidation and reduction of diamond and nanodiamond surfaces at higher gas pressures were studied using near ambient pressure PES to reveal surfaces of comparable and, in some cases, superior quality to those produced by in-vacuo annealing and plasma exposure. At 1 mbar of O2gas, non-diamond carbon species were removed and an additional oxygen species was observed that was not present on the vacuum-prepared samples, but was predicted by the DFT calculations.

Diamond Nanophotonics with Group IV Defects Igor Aharonovich; University of Technology-Sydney, Australia

Diamond color centers are attractive candidates for integrated quantum photonics circuitry. Over last decade, much focus has been put to study the NV center in diamond. However, its broad emission and low proportion of zero phonon line photons, makes it challenging to scale up and efficient collection of coherent photons. In this talk I will describe our recent efforts into studying a new class of defects, associated with group IV elements such as Si and Ge. These defects exhibit narrow band emission and form a symmetric complex with two vacancies, therefore less susceptible to strain. In my talk I will focus on two aspects: First, I will describe the progress of fabricating nanoscale diamond membranes, that we utilize for electrical excitation and for device fabrication. An example of a rink resonator and a microdisk cavity is shown in figure 1. Second, I will describe emerging experiments involving anti stokes excitation of single quantum emitters, that provide a new avenue for optical sensing with unprecedented sensitivity. I will summarize with an outlook into new potentially interesting color centers.

11:00 AM EL05.14.02
Identifying the Structure of the SnV⁻ Defect in Diamond—Experimental Evidence of the Split-Vacancy Configuration

Ulrich Wahl¹,², Joao Guilherme Correia², Renan Villareal¹, Emilie Bourgeois³,⁴, Milos Nesladek³,⁴, Andre R. Vantomme¹ and Lino M.C. Pereira¹; ¹KU Leuven, Belgium; ²Instituto Superior Técnico, Portugal; ³imec, Belgium; ⁴Institute for Materials Research, Belgium

Point defects in diamond are being intensively investigated, both for their applications in processing and communication of quantum information, as well as for metrology. So far, the negatively charged nitrogen-vacancy center (NV⁻) has been the most studied defect [1]. Thanks to its efficient optical spin polarization and spin-state dependent fluorescence, it is being exploited, for example, in the context of high-sensitivity magnetometers [2]. More recently, owing to their superior optical properties, the group-IV-vacancy centers (SiV⁻ [3, 4], GeV⁻ [5] and SnV⁻ [6]) have emerged as the leading type of point defects for quantum computing and networking applications. Whereas it is generally accepted that the N atom in the NV⁻ center occupies a substitutional C site, the group-IV atoms in group-IV-vacancy centers are expected to occupy bond-centered sites, in a split-vacancy configuration. In this configuration, rather than being accompanied by a neighboring vacancy, the group-IV atom is located at the center of two neighboring lattice positions, while the vacancy is “split” over the two lattice sites. However, experimentally, these structural configurations had so far been only indirectly determined.

In this contribution, we present a detailed, direct characterization of the structure of the SnV⁻ defect. To this end, we relied on the electron emission channeling technique to determine the lattice site of implanted radioactive ¹²¹Sn ions in diamond with very high precision (experiments performed at the ISOLDE facility at CERN, Geneva). The anisotropic patterns of the charged β⁻ particles emitted during the decay of the radioactive isotopes are characteristic of the lattice site of the emitting Sn atoms. From fitting the experimental data to theoretically calculated patterns [7] using a two-dimensional fit procedure [8], the Sn lattice location can be accurately determined. Using a combination of electron emission channeling from ¹²¹Sn and photoluminescence measurements, we have unambiguously identified the SnV⁻ defect in the split-vacancy configuration, with the Sn atom located exactly at the bond-center position (with a precision better than 0.04 Å). While in the as-implanted state the PL spectrum from the sample was dominated by radiation damage-induced features, following annealing at 915°C for 1 hour the signature of the SnV⁻ center (in the form of a strong 621 nm line) was clearly visible. Establishing a detailed understanding of the SnV⁻ structure is particularly important, since the superior properties of the group-IV-vacancy centers are to a large extent a consequence of the inversion symmetry of the split-vacancy configuration.

lab-grown diamonds. Microwave assisted plasma vapour deposition reactors have been widely used to elaborate carbon-based materials in particular diamond. The performance of the process is strongly influenced by the interaction between microwave and the plasma which in fact depends on the precursor gas composition, pressure and operating conditions. Growing diamond for jewellery implies growing rough diamond of 4 to 6 mm in thickness and managing the colour of the diamond after they are cut. Many attempts with different gas composition have been achieved around the world leading to different colours of diamonds as well as different growth rates. We propose here an overview of the different processes used to grow these thick diamonds. Also we propose to show how the local conditions at the plasma / surface interface may strongly change as a function of the conditions in the case of the most simple gas composition, i.e. a mixture of hydrogen and methane. A self-consistent model has been constructed incorporating the stiff methane-hydrogen chemistry. We will discuss some of the results obtained using this self-consistent model and their comparison with the experiments.

SESSION EL05.16: Diamond for Electronic Devices  
Session Chair: Gauthier Chicot  
Thursday Afternoon, December 5, 2019  
Hynes, Level 1, Room 107

1:30 PM EL05.16.01  
Temperature Reduction of AlGaN/GaN MIS HEMTs Using Overgrown Polycrystalline Diamond Films  
Junya Yaita1,2, Kotani Junji1,2, Atsushi Yamada1,2, Shiro Ozaki1,2, Yoichi Kamada1,2, Toshihiro Ohki1,2, Yuichi Minoura1,2, Yusuke Kumazaki1,2, Naoya Okamoto1,2, Kozo Makiyama1,2 and Norikazu Nakamura1,2; 1Fujitsu Limited, Japan; 2Fujitsu Laboratories Ltd., Japan

GaN-based high electron mobility transistors (GaN HEMTs) have been expected for high output power density applications such as radars and long distance wireless communication. Although the GaN has superior electric characteristics, a low thermal conductivity of GaN limits the output power density. In order to improve thermal dissipation, the GaN HEMTs on high-thermal-conductivity diamond has been reported. In addition to the backside of GaN HEMTs, diamond on GaN is expected to improve thermal dissipation. However, there were few reports on the deposition of diamond layer on GaN HEMT and the heat-spreading effect by diamond deposition has not been investigated in detail. In this study, we carried out growth of diamond on GaN HEMTs and investigated the heat-spreading effect by Raman thermography.

Polycrystalline diamond films were directly grown by hot-filament chemical vapor deposition (HF-CVD) on AlGaN/GaN MIS HEMTs. The HEMT devices with SiNx insulator showed low gate leakage current of <10^-2 A/mm even though the diamond growth was carried out under high temperature. In addition, the HEMTs with overgrown polycrystalline diamond films showed higher transconductance of 154 mS/mm than that of non-diamond grown HEMTs of 134 mS/mm. In order to evaluate effect of surface diamond heat-spreader, we performed Raman thermography and clearly observed the temperature reduction of around 10 degrees even under relatively low power operation of ~5 W/mm. This temperature reduction inhibits the degradation of electron mobility caused by increased optical phonon scattering, resulting in increase in transconductance as we experimentally observed. Therefore, direct growth of diamond by HF-CVD on AlGaN/GaN MIS HEMTs enables to temperature reduction and improve its performance.

Seeding and Growth of Diamond on GaN and AlN  
Paul W. May, Edmund Smith, Afaq Piracha and Robson Mackenzie; Bristol University, United Kingdom

With improvements to epitaxial growth and device fabrication, GaN device performance is now limited by near-junction heat removal1. A possible solution to this problem is to deposit a layer of diamond onto the GaN to act as a heat spreader2. Diamond has excellent thermal conductivity, making it well-suited for use as a heat spreader. However, its use in GaN devices is hindered by the significant differences in thermal expansion and lattice constants.
between diamond and GaN\textsuperscript{3,4,5}.

Work has been centred on developing a low temperature diamond CVD process to overcome the significant lattice mismatch and thermal expansion differences between the diamond and GaN layers, which has previously resulted in delamination. A novel seeding process involving 2-step seeding with micro- and nano-diamond particles has also been developed to increase thermal conductivity across the diamond-GaN interface. The deposited layers have been non-destructively examined utilising X-Ray Tomography (XRT), allowing an assessment of the quality of the interface in the middle of the wafer without inducing any stresses and potential delamination onto the substrate. With the optimisation of growth procedures, diamond layers 50 µm thick can now be reliably grown directly onto GaN substrates with no barrier layer, however the interface remains too mechanically weak for most device applications.

To improve adhesion, diamond films were also grown on GaN substrates with barrier layers of either 200 nm of AlN or 20 nm of Al metal. The Al layer is thin enough that we believe it completely converts to aluminium carbide during the CVD process. We shall present results from these growth studies and evaluate the thermal and mechanical performance of these barrier layers, as well as report on progress towards developing a large-area CVD reactor suitable for 6”-diameter GaN wafers.

The Impact of Plasma Temperature on the Stress and Quality Factor of Over-Grown Polycrystalline Diamond on GaN
Mohamadali Malakoutian\textsuperscript{1}, Matthew A. Laurent\textsuperscript{1} and Srabanti Chowdhury\textsuperscript{2}; \textsuperscript{1}University of California, Davis, United States; \textsuperscript{2}Stanford University, United States

Gallium Nitride (GaN) as a wide bandgap material, is an attractive choice for high-power and high-frequency semiconductor devices. However, self-heating effect limits GaN-based high electron mobility transistor (HEMT) capabilities due the lack of effective heat spreading through the device [1]. Polycrystalline (PC) diamond, owing to its high thermal conductivity (10-2000 W/m.K), can be used as a capping layer for spreading the heat [2]. For effective cooling, diamond must be grown as close as possible to the source of heat, which is the channel in a HEMT. In this abstract we describe our approach of growing PC diamond on GaN layer to allow maximum heat transfer from the GaN channel to the diamond layer. Achieving a high-quality diamond-GaN interface is necessary to accomplish effective heat transfer. As hydrogen plasma is one of the main species in diamond growth using microwave plasma chemical vapor deposition system, it damages the GaN and changes the properties of the 2-dimensional electron gas (2DEG). A 20 nm Si\textsubscript{3}N\textsubscript{4} has been used as a protection layer on top of the N-polar GaN on sapphire wafer, which also reduces delamination of the diamond by making a SiC interlayer. As the coefficient of thermal expansion (CTE) for diamond (~1.1 µm/m.K) and GaN/sapphire (~4.1/5.3 µm/m.K) are different, the possibility of diamond delamination due to large residual stress is high. In another aspect, to reach the thermal properties of bulk diamond, it is vital to increase the quality of the grown layer. In this work, we have used Raman spectroscopy and scanning electron microscopy (SEM) to investigate the effect of growth plasma temperature (600-850 C, with 50 C steps) on both the stress and quality factor of PC diamond.

The grain size of the diamond layer increases from 113 nm at 600 C to 419 nm at 850 C and the thickness changes from 130 to 696 nm when the temperature changes from 600 to 850 C. We have observed a higher growth rate in vertical axis than lateral axis, which is due to the high nanoparticle seeding density (>10\textsuperscript{12} cm\textsuperscript{-2}) and growth using hydrogen plasma. The quality factor can be determined by \textit{sp}\textsuperscript{3}/\textit{sp}\textsuperscript{2} carbon bonding ratio of their Raman peaks. Diamond quality factor shows a parabolic behavior and increases with temperature (90.10% at 600 C to 98.57% at 850 C), as the thickness and grain size of the film increase.

The residual stress (thermal and intrinsic) of the diamond film plays a critical role in the delamination of diamond from the substrate. Thermal stress is caused by the difference in the CTE between diamond and substrate during the cooling cycle and intrinsic stress is due to the incorporation of impurities and defect formation. The residual stress in the diamond film can be calculated using the shift in the \textit{sp}\textsuperscript{3} diamond Raman peak from 1332 cm\textsuperscript{-1} [3]. The diamond
Layer stress shows a compressive nature and increases with temperature by a parabolic behavior (-4.2 GPa at 600 °C to -6.3 GPa at 850 °C). Increase in the thickness and grain size is the main reason for larger compressive stress. In this study, up to 850 °C we observed no delamination of the diamond film from the substrate. However, the absolute value of the stress is high, which can be explained by the large compressive stress in sapphire during the cooling process.

Increasing thickness and grain size of diamond results in a higher quality factor (close to bulk diamond), while increases the compressive stress and the possibility of delamination. So, in order to prevent delamination and have a high-quality diamond on GaN/sapphire, it is needed to decrease the compressive stress by relaxing PC diamond layer. The relaxation of diamond layer can be done by adding a thin ultra-nano-crystalline-diamond (UNCD) layer during the growth.

**Design of Efficient Schottky Diodes for Medium-Voltage AC/DC Power Converters**

Xiaoxue Wang¹, Wesley Spain¹, Matthias Muehle², John D. Albrecht¹,², Timothy Grotjohn¹,² and Tom Zimmermann¹; ¹Michigan State University, United States; ²Fraunhofer USA, Inc., Center for Coatings and Diamond Technologies, United States

With the development of long-distance transmission, offshore transmission and renewable energy technology, AC and DC systems have become the popular trend for future power systems. The AC/DC converter is the key part to make it happen. In modern power systems, converter modules like half-bridge structures and full-bridge structures of paralleled insulated-gate bipolar transistor (IGBT) and Schottky barrier diodes are common in the industry. However, the current of a single Schottky barrier diode at the same voltage level lacks greatly behind the IGBT performance. Thus, multiple Schottky barrier diodes may need to be paralleled with IGBTs in order to match the current performance of the IGBTs operating at the same voltage level. Furthermore, due to inherent small variances in the manufacturing process of the Schottky barrier diodes, devices will slightly differ from each other and current asymmetries and an imbalanced voltage distribution potentially occurs in the power modules, leading to higher harmonic waves and severe power losses. Therefore, there are urgent needs of improved Schottky barrier diodes for efficient AC/DC converters in the market.

Diamond is considered as an ultimate semiconductor for high power applications due to its high charge carrier mobility and saturation velocity and excellent thermal conductivity. The extremely high breakdown field up to $10^7$ V/cm is very promising for medium and high voltage rectifiers and converters. To address the highly visible diode performance shortcomings, we designed and investigated a high-power vertical diamond Schottky barrier diode. The newly designed high-power diodes possess a current drive higher than 50 A at a forward bias of 10 kV in the temperature range between room temperature (300 K), optimal diode operation temperature (450 K) and the temperature at full carrier activation of the boron acceptors (800 K). However, the diode performance will be affected by several parasitic elements originated by the choice of the used materials and the device design, which can lead to an electrical field concentrating edge effect. In order to decrease the electric field within the high-power diode and to improve its performance, this work investigates edge effect termination strategies by introducing passivation layer structures, n⁺-guard rings, and floating n⁺-islands. Several high-power diode designs were in-silico tested at different temperatures (300 K, 450 K and 800 K). According to the TCAD simulations, the on-resistance of the power-diode at 450 K is the lowest and a high current density of ~2500 A/cm² can be achieved at 10 kV for the basic diamond Schottky diode design. This performance is also investigated versus variations in the expected electric field breakdown strength of diamond. The implementation of passivation layer structures, guard rings, and floating islands is studied for performance improvements. The here developed design shall be technologically realized and implemented in a highly efficient AC/DC power converter, later on.

**Experimental and Theoretical Study of Impact of Methane Concentration on Boron-Doped Single Crystal Diamond Films for Schottky Barrier Diodes**

Rozita Rouzbahani¹,², Fernando Lloret¹,², Danny E. Vanpoucke¹,²,
Paulius Pobedinskas\textsuperscript{1,2}, Shannon S. Nicley\textsuperscript{1,2,3}, Daniel Araujo\textsuperscript{4} and Ken Haenen\textsuperscript{1,2}; \textsuperscript{1}Institute for Materials Research (IMO), Hasselt University, Belgium; \textsuperscript{2}IMOMEC, imec vzw, Belgium; \textsuperscript{3}Department of Materials, University of Oxford, United Kingdom; \textsuperscript{4}Dpto. Ciencia de los Materiales, Universidad de Cadiz, Spain

Despite recent advances in the synthesis of chemical vapor deposition (CVD) single crystal diamond (SCD), the device performance of applications based on diamond still remains far below the theoretical capacities.\textsuperscript{1} This is mostly associated with the presence of dislocations which leads to an increase of the leakage current and a reduction of the boron concentration in the heavily B-doped layer.\textsuperscript{2} Therefore, the optimization of the growth conditions of B-doped layers has a crucial role in the improvement of diamond based electronic applications such as Schottky barrier diodes. We have grown a series of B-doped SCD films which were characterized to identify the optimal conditions. The B-doped SCD films were grown by microwave plasma enhanced CVD in a home-built reactor on 3 X 3 mm\textsuperscript{2} Ib (100)-oriented high pressure high temperature (HPHT) substrates. Two sets of samples, B-doped and un-doped, were grown with different amount of methane concentration (0.5%-3%) in the plasma. For heavily B-doped SCD depositions, trimethylboron (TMB) was used as the boron source with a constant 997 ppm \text{[B]/[C]} ratio. For un-doped samples, the residual TMB in the chamber was used. The grown layers were characterized by Hall effect in a wide temperature range, Fourier transformed infrared (FTIR) spectroscopy, Raman spectroscopy, X-ray absorption spectroscopy (XAS), X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM), optical microscopy, and transmission electron microscopy (TEM). By means of TEM, the high quality of the $p^{++}$ and $p$ layers was shown, except for the sample grown with 0.5% methane concentration, on which defect features similar to etch-pits were observed and confirmed by AFM. This sample also showed a very low boron incorporation into the $p^{++}$ layer due to the plasma gas chemistry which seems to create etch-pits, as seen in the morphology. FTIR\textsuperscript{3}, Raman spectroscopy\textsuperscript{4}, and Hall effect measurements indicate a higher B-doping level when the methane concentration is increased in both heavily and lightly B-doped SCD films. The electrical conductivity and mobility of the $p^{++}$ samples grown at 1%, 2%, and 3% methane concentration had almost no temperature dependence due to the metallic-like conduction properties in these heavily B-doped films. A careful investigation of the XPS spectra of lightly B-doped SCD layers at various methane concentrations indicated that the intensity of B 1s peak became stronger by increasing the methane concentration. The C K-edge XAS spectra of these layers were recorded in surface sensitive total electron yield (TEY) mode under different incident angle, which demonstrated that the diamond lattice structure can be distorted by increasing the methane concentration resulting in a higher B-doping level. The increase of the B-doping level with increasing methane was corroborated by first principle density functional theory (DFT) calculations. These showed that the presence of CH\textsubscript{2} sites has no significant impact on the binding energy of an adsorbed B atom. However, the presence of CH\textsubscript{2} sites increase the chance of H-defect site formation, providing additional B binding sites. The effect of using various methane concentrations in heavily B-doped SCD layers were further studied in their influence on the performance of Schottky barrier diodes.

**Design Strategies for Anchoring Sulfur in Metal-Sulfur Batteries** Aninda J. Bhattacharyya; Indian Institute of Science, India

Over the last decade, there has been a paradigm shift towards usage of earth abundant and cost effective materials in rechargeable batteries. A prominent example in this context, is sulfur. Sulfur delivers a high theoretical capacity of 1672 mAh g⁻¹, nearly one order higher compared to the best known intercalation cathodes (IOCs) used in Li/Na-ion batteries. The high theoretical capacity originates from the possibility of higher than one exchangeable Li-ion per S-atom (theoretically two exchangeable Li-ions per S-atom) as compared to only one Li-ion/formula unit of IOC. Additionally, S is cheap, highly abundant and non-toxic in nature. Despite these advantages, the chemical reactions determining the mechanism and quantum of electrical energy storage in a liquid electrolyte based Li-S battery pose several challenges. The main challenge is due to the various intermediate polysulfides formed during the reversible conversion of elemental S₈ to metal-sulfide. Bulk of the work related to metal-S rechargeable battery revolves around materials design strategies of a suitable carbon/(non-carbon)-host matrix targeted towards the entrapment of S and prevention of leaching out of polysulfides into the electrolyte. However, this limits the extent of S-loading and depending on the host may simultaneously increase the un-utilizable mass of S in the electrode. The presentation will discuss some of our important recent results in the context of M-S (M: Li, Na, Mg) highlighting the critical role of materials design and in operando monitoring studies for the development of highly stable metal-S bateries. The talk will discuss at length various ways for efficient anchoring of sulfur and the polysulfides at the S-cathode for various rechargeable metal-S batteries. Strategies will include (a) design of novel S-scaffolds based on molecular systems such as covalent organic frameworks (COFs), conducting carbon-based scaffolds, (b) additives and (c) interlayers based on non-carbonaceous nanoparticles. Our studies reveal several interesting fundamental insights related to the mechanism of storage which eventually have strong bearing on the metal-sulfur battery performance.

**Formation of Magnesium Dendrites in Magnesium-Based Batteries and Design of Metallic Magnesium Anodes** Rachel D. Davidson; Texas A&M University, United States

We have recently demonstrated the first definitive examples of dendrite formation in magnesium batteries and will additionally detail our progress towards design of metallic anodes which mitigate such growths. The utilization of metallic anodes holds promise for unlocking high gravimetric and volumetric energy densities for rechargeable batteries, however, lithium metal has a high propensity for dendrite formation, the plating of lithium as anisotropic fractal structures that can bridge across liquid and solid electrolytes to the cathode, thereby short circuiting the cell. Such catastrophic failure represents a major roadblock to this seemingly simple approach to achieving improved storage capacities. Magnesium-based batteries are considered a possible alternative, given the high earth-abundance of magnesium and the potential for higher volumetric energy density offered by its divalent charge. A promising advantage of switching to Mg-based batteries derives from the many reports which claim that Mg is inherently non-dendrite forming. Initial reports noted that Mg could be plated as relatively smooth deposits under charging conditions that resulted in dendritic growth for lithium. Since these reports, there has been substantial progress in development of cathodes and electrolytes, however, there has been little to no further vetting of the notion of
metallic magnesium anodes. Through combining video microscopy studies of symmetric Mg-Mg cells with detailed 3D tomographic characterization of thin film morphologies and mesoscale modeling we demonstrate some of the first definitive examples of dendritic growth on magnesium anodes and elucidate mechanisms of formation. We have additionally designed metallic magnesium nanowire and nanotube arrays which have the potential for yielding low-volume expansion, lower current density anode materials. Our work opens the door for development of anode designs that mitigate dendrite growth, which will be crucial for further progression of Mg-based battery technology.

8:45 AM EN01.01.03
A Scalable Dry-Powder Manufacturing Technology of Lithium-Ion Batteries from Commercial Product to Further Designs Yangtao Liu¹, Jin Liu¹, Brandon Ludwig², Yan Wang¹ and Heng Pan²; ¹Worcester Polytechnic Institute, United States; ²Missouri University of Science and Technology, United States

An advanced power-based spraying technology was developed by us to fabricate electrodes for the lithium-ion batteries to replace the conventional slurry cast method. The additive manufacturing technology is a low cost, highly efficient way to avoid toxic NMP solvent from electrode fabrication. The removal of solvents shortened the production time from days to seconds, analyzed to reduce 20% of production cost, and enabled a more precise control of electrode microstructure during manufacturing. With the continuous processing system, the technology has a good potential to be scaled up and commercialized. Beyond the current commercial materials, we can also demonstrate this technology with a wide range of compatibility on producing electrodes, including different types of cathodes (LCO, LMO, NCM), anodes (MCMB), advanced architecture designs (Ultra-low binder recipe (<1%), high-energy thick electrodes (>280um), hierarchical micro-structured). In addition, the flexible arrangement strategy of spraying guns promoted the development of hierarchical designs to be practically available to the lithium-ion market.

9:00 AM EN01.01.04
Learning Only Buys You So Much—Practical Limits on Battery Price Reduction I-Yun Hsieh, Menghsuan Sam Pan, Yet-Ming Chiang and William H. Green; Massachusetts Institute of Technology, United States

Wide deployment of electric vehicles (EVs) would greatly facilitate global de-carbonization, but achieving the emission targets depends on future battery prices. Conventional learning curves for manufacturing costs, used in many battery projections, unrealistically predict battery prices will fall below $100/kWh by 2030, pushing EVs to be economically competitive with internal combustion engine vehicles (ICEVs) in the absence of incentives. However, in reality, essential materials costs set practical lower bounds on battery prices. Our 2-stage learning curve model projects the active material costs and NMC-based Lithium-ion battery pack price with mineral and material costs as the respective price floors. The learning rates are found to be 3.5% for chemical synthesis and 16.5±4.5% for battery production. The improved model predicts nickel-manganese-cobalt (NMC) battery prices will fall only to about $124/kWh by 2030 – much cheaper than today, but still too expensive to truly compete with ICEVs, due primarily to the high prices of cobalt, nickel, and lithium. Our results suggest that stabilizing raw materials prices and/or stimulating R&D activities on alternative battery chemistries will be important to achieve environmentally sustainable EV-based ground transportation at an attractive price.

9:15 AM EN01.01.05
Investigation of Megahertz Frequency Modulation Effects on Charge and Discharge Behavior of Lithium-Ion Batteries Bohua Wen, Ping-Chun Tsai and Yet-Ming Chiang; Massachusetts Institute of Technology, United States

Over the past several years, reports have emerged of ultrafast charging algorithms for lithium ion batteries [1,2] that in at least one instance [3] is attributed to megahertz frequency modulation of charging/discharging currents. Such algorithms are claimed to dramatically improve active material utilization as well as cycle life, but no mechanisms have been proposed in published work, nor, to our knowledge, have mechanistic studies have been conducted. In this work, we use a recently developed technique [4] in which single electrode particles having capacities of a few nAh can be interrogated with electrodynamic measurements (EIS, GITT, polarization-depolarization) while varying the state-of-charge. This capability allows clean separation of interfacial vs bulk transport limitations at the individual particle level, without complicating factors from typical composite electrode microstructures. To this capability, we have added AC pulse charging and discharging at ultra-low currents (down to picoA) with high-frequency waveforms (up to ~ MHz).
With this capability, we aim to answer a number of questions such as: Are these effects real? Are they significant?
And, what are possible mechanisms by which ion transport kinetics in a lithium ion battery are responsive to megahertz frequency excitation?

This work was supported as part of the NorthEast Center for Chemical Energy Storage (NECCES), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award # DESC0012583.

Enhancing the Viability of Grid Scale Sodium Systems (Na-ion and RT Na-S) through Fundamental In Situ Optical and UV-vis Investigation Rachel Carter1, Danniel Reed2, Ryan H. DeBlock3, Megan Sassin1, Corey T. Love1 and Partha Mukherjee4; 1U.S. Naval Research Laboratory, United States; 2Purdue University, United States; 3University of California, Los Angeles, United States

Replacing lithium ions with sodium ones in energy-storage systems is highly attractive due to the ~1300× enhancement in material abundance. However, the 25% larger volume of sodium ions prevents a drop-in substitution. For example, the typical graphite-based anode used in Li-ion systems are not amenable to reversible Na-ion intercalation and cathodes designed for Li-S cannot accommodate the larger volume expansion. Herein, we employ a specially designed in-situ electrochemical cell developed at the Naval Research Laboratory1 to probe the optical characteristics of electrodes under charge-discharge operation, yielding key information on electrochemical mechanisms.

For Sodium-ion anodes, disordered “hard carbon” anodes show more promise than graphitic carbons for Na-ion cells, but their charge-storage mechanisms are more complex, involving surface association, bulk cation-insertion reactions, and micropore-based deposition. Using the in-situ cell, we examine the sodiation of carbon nanofoam papers (CNFPs), which were recently reported for their high-capacity and high-rate charge-storage properties in nonaqueous Na-ion electrolytes.2 Imaging the CNFP during galvanostatic “discharge” (reduction in half-cell configuration vs. Na metal) reveals distinct color changes from grey to black to bronze to blue, caused by carrier concentration variation with increasing Na-ion association/insertion at the carbon electrode. We correlate these optical changes with variations in the complex discharge profile of the CNFP, which arises from multiple defect- and porosity-enable Na+-storage mechanisms that are supported by this electrode. This fundamental understanding will enable optimization of defect concentration and porosity of this anode material for the realization of this system. Alternatively, the RT Na-S system that boasts higher energy than Li-ion, in addition to high material abundance, is stalled by material challenges at the metal anode and conversion cathode. The soluble nature of discharge products and their interaction with the metal limit energy and cyclability.3 However, using the in-situ cell, careful mapping of discharge mechanisms is achieved in conjunction with anode observation. The discharge products (Na2Sn, 8<n<1) and relative quantities are determined, due to their distinct colors, with UV-vis spectroscopy. Since these behaviors prove strongly dependent on electrolyte solvent, the study is valuable to selection of optimal composition for anode stability and cathode performance.

9:45 AM EN01.01.07
Ultrahigh Speed Charging of LiCoO2 Cathode Thin Film with Dielectric Materials Shintaro Yasui1, Sou Yasuhara1, Takashi Teranishi2, Yumi Yoshikawa2 and Mitsuru Itoh1; 1Tokyo Institute of Technology, Japan; 2Okayama University, Japan
Li ion battery is one of suitable energy storage in our life, such as mobile electronic devices and electric vehicles. For delightful and convenient existence, high speed charging and long battery life are very important. Actually, charging time of smart phone is too long, which is about 5 hours to fully charge when the battery is empty. In this case, 0.2C is used for charging current, otherwise battery capacity is reduced “like broken” under higher C-rate (higher speed charging). This is because SEI layer, which is decomposed materials of electrolyte, LiF, organic solvent etc., is deposited on active cathode and anode materials. In this paper, we have achieved to obtain the ultrahigh speed charging and very tough cycling properties in LiCoO2 cathode thin film battery decorated with dielectric BaTiO3.[1] The important point is the blocking of creating SEI on cathode surface. In details, we have investigated interface reaction between cathode and electrolyte using epitaxial thin film battery. We have tried to insert artificial SEI of high dielectric constant materials, BaTiO3, on the cathode LiCoO2 epitaxial thin film. The high rate performance and cyclability are enhanced by existence of triple phase interface, cathode LiCoO2 – electrolyte LiPF6 (EC:DEC)– dot BaTiO3. The key point of this effect is that high dielectric constant material is better. We will discuss an effect of decolated dot materials. [1] S. Yasuhara, S. Yasui et al., Nano Lett. 19 (2019)1688.

Understanding the Factors Impacting Battery Failure Propagation and Its Mitigation Joshua Lamb and Loraine Torres-Castro; Sandia National Laboratories, United States

Developing battery systems resilient to thermal runaway propagation is of great concern when designing resilience into large battery systems. This is particularly difficult when working with pouch format cells as the format exists primarily to drive increased energy density within systems, which itself makes failure propagation more likely to occur. Our work here focuses on module to module propagation and potential tools that might be used to mitigate this failure. We have constructed 3S3P configuration batteries with various mitigation strategies used to prevent module to module propagation. This has included conductive, insulating and advanced materials and is coupled with analysis of the heat transfer across these barriers to better understand the underlying mechanisms that can better improve propagation resistance in systems constructed with pouch format cells. We have used both mechanical and thermal initiation techniques to explore the different behaviors that might occur when the character of the initial failure changes as well. This includes the failure propagation from a single cell failure initiation as well as the failure of an entire 1S3P module within the pack. Finally, we look at the differing roles that both changes to energy density of the pack as well as changes to the heat transfer between cells might play in mitigating thermal runaway propagation.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Safety Assessment of Solid-State Lithium Batteries Alvaro Masias1,2, Mihir Upadhye2 and Jeff Sakamoto2; 1Ford Motor Company, United States; 2University of Michigan, United States

Continuous improvements in lithium-based battery technology has facilitated the recent growth of personal electronics and the increasing introduction of electrified vehicles. Lithium-ion technology has evolved steadily since its introduction in 1991 with ever increasing specific energy. However, it is likely that more advancements in battery performance characteristics are necessary to enable the widespread adoption of electrified vehicles.

One of the leading candidates for next generation battery technology is the solid state (SS) battery, where a liquid electrolyte and polyolefin thin film separator are replaced by an ionically conducting solid. While SS battery technology replaces the flammable electrolyte of lithium-based technology with a non-flammable ceramic, glass or polymer, the addition of highly reactive lithium metal and potentially brittle separator materials may introduce different safety challenges. In this context, a safety assessment of lithium metal SS batteries is performed against existing international battery safety test standards and regulations, with an emphasis placed on water exposure and vibration.
Catholyte Formulation of Flow Li/O₂ Batteries

Francesca Soavi¹, Irene Ruggeri¹, Federico Poli¹, Catia Arbizzani¹, Stefania Rapino¹, Francesca De Giorgio¹,² and Alessandro Brillonità,² ¹University of Bologna, Italy; ²Battery srl, Italy

Lithium/O₂ (air) batteries are promising exceptionally high specific energy, that can be theoretically 2-3 times higher than today Li-ion batteries.

Low cycling efficiency, low cycle life and slow discharge kinetics are still considered the main issues to be addressed for the development of high performance Li/O₂ batteries. The discharge product, lithium peroxide (Li₂O₂) which is formed on the cathode surface is an insulator that affects battery capacity and causes high overpotential during recharge and, thus, low recharge efficiency.

This process can be controlled by tailoring the electrolyte environment. Glyme-based solvent-in-salt (SIS) electrolytes have been recently proposed for Li-O₂ batteries. In SIS glyme-Li⁺ complexes are formed. They improve the electrochemical stability of the electrolyte and stabilize superoxide ion with a positive effect on cathode passivation.

An additional strategy for improving Li/O₂ battery performance is the use of a flowable catholyte ink. It is an organic dispersion of carbon particles which also acts as oxygen carrier, therefore improving Li/O₂ battery rate response. In this catholyte, ORR takes place on the solid phase of the carbon particles. Consequently, cathode surface passivation is limited, the battery cell death is delayed and the Li/O₂ battery energy increased. Such approach enabled areal capacity of 180 mAh cm⁻², energy of 500 mWh cm⁻² and current of 4 mA cm⁻². Here, we discuss about three strategies to improve semi-solid Li/O₂ battery cycling performance. Specifically, we report on i) a scanning electrochemical microscopy (SECM) investigation carried out to investigate the Li₂O₂ formation mechanism in salt-in-solvent and SIS electrolytes based on TEGDME and LiTFSI and in ionic liquids, ii) a semi-empirical modeling study that enables to predict the best cell design that improves the power gain of the flow Li/O₂ battery and iii) the study of the carbon composition of the semisolid catholyte that permits to achieve the exceptional high specific energy of 1 kWh kg⁻¹.

Determining the Mechanisms by Which Dissolved Transition Metals Cause SEI Failure in Advanced Li-Ion Batteries

Oliver Harris¹, Kevin Leung², Yue Qi³ and Maureen Tang¹; ¹Drexel University, United States; ²Sandia National Laboratories, United States; ³Michigan State University, United States

One of the most serious lifetime problems for established Li-ion and emerging “Beyond-Li” batteries is electrolyte...
degradation from unwanted side reactions. For many high-voltage and high-energy cathode materials, transition metal dissolution is known to accelerate capacity fade leading to unacceptably short battery lifetimes. Metals like Mn, Ni, and Co deposit at the anode and disrupt the formation and performance of the solid-electrolyte interphase (SEI), a vital battery interface responsible for protecting the electrolyte from the highly reductive anode. This results in continual Li loss and uncontrolled SEI growth. Understanding the role of each metal in undermining the passivation of the SEI is necessary to mitigate this degradation and enable commercialization of high-voltage Li-ion cathodes.

In this work, we interrogate the effects of transition metals on the SEI via in-situ electrochemical characterization. We apply generator-collector measurements and other electroanalytical techniques in order to probe mechanisms of transition metal incorporation into the SEI and their effect on through-film electron transport. By using convection to control electrode cross-talk, we observe the presence of metal contaminants from an upstream cathode at the downstream anode. Electrochemically interrogating the SEI with functionalized ferrocene mediators and interpreting voltammetry with continuum-scale models shows that incorporation of dissolved transition metals increases both the density and the activity of active sites within the SEI [2]. In a separate set of experiments, we compare Mn, Ni, and Co contaminants to explain the particularly detrimental effects of Mn [3-4]. We develop microkinetic models for an electron-tunneling mechanism and an electrocatalytic cycling pathway. Density functional theory is used to predict material parameters such as bandgap doping and redox potentials. Comparison of theory and experiment suggests that kinetic parameters dominate over thermodynamic redox potentials and point to the importance of the metal’s local coordination environment within the SEI.

11:45 AM EN01.01.12
Lithium Titanate Hydrates with Superior Power Rate and Ultralong Cycle Life for Lithium-Ion Batteries
Shitong Wang¹, Zilong Tang², Jun Lu³ and Ju Li¹; ¹Massachusetts Institute of Technology, United States; ²Tsinghua University, China; ³Argonne National Laboratory, United States

Ti-based materials (e.g. Li₄Ti₅O₁₂ and TiO₂) have received considerable attention owing to their outstanding high-rate capacity and cycling stability, as well as their improved safety standards over graphite. Here we show there exist a series of lithium titanate hydrates with similar performance compared to most outstanding Ti-based electrodes (including the materials after modification) reported at present. That is, water promotes structural diversity (e.g. 2D layered) and nanostructuring of compounds, but does not necessarily degrade electrochemical cycling stability or performance in aprotic electrolytes. As new members in the Li-H-Ti-O material system, lithium titanate hydrates not only greatly expand the research scope of the Li-Ti-O and H-Ti-O material system, but also propose a new method for electrode materials modification. More significantly, they provide greater inspiration and guidance to other hydrated transition-metal compound systems in energy storage applications.

References:
Due to the large demand of electric vehicles and grid energy storage systems, many ongoing researches are focusing on the improvement of energy density, capacity, cycling stability and rate performance of Li-ion batteries. Lithium, Manganese-rich layered oxide cathode (LMR-NMC) is one of the promising cathode materials for the near future owing capacities of over 250 mAh g⁻¹ and energy density of over 1000 Wh kg⁻¹ between voltage range 2.0 – 4.8 V. Though, two main challenges still remain before these materials can be fully applied commercially; capacity fading and voltage fading. Here, we focus on the structure, properties and electrochemical performance of co-dope LMR-NMC, Na₆Li₁ₓMnₓNi₀.₅₄Co₀.₃₃O₂₋₀.₃Fₓ, synthesized via hydroxide co-precipitation followed by solid-state reaction. Initially, LMR-NMC with single dopant ratio was examined and best performance of each dopant was then selected in order to maximize the capability of co-dope material. Comparison among pristine, Na dope, F dope and co-dope samples were intensively analyzed. Regarding to the electrochemical studies, CD has the best performance in term of capacity (97%) and voltage retention (91%) after 100 cycles at 0.2 C with initial discharge capacity of 260 mAh g⁻¹ at 0.1 C. Based on this discovery, higher voltage and capacity retention LMR-NMC material are obtained allowing us to heighten the possibility of using LMR-NMC commercially in next-generation batteries.

Atomic-Scale Mechanisms of Enhanced Electrochemical Properties of Mo-Doped Co-Free Layered Cathodes for Lithium-Ion Batteries Linze Li¹, Jianguo Yu², Devendrasinh Darbar³, Ethan C. Selt⁴, Jagjit Nanda⁵ and Chongmin N. Wang⁶; ¹Pacific Northwest National Laboratory, United States; ²Idaho National Laboratory, United States; ³Oak Ridge National Laboratory, United States

Cobalt-free layered oxides with high specific capacity and low cost have emerged as promising candidates that can be used as next-generation cathodes for lithium ion batteries. Practical implementation of these materials, however, have been hindered by their low rate capability, structural instability, and fast capacity decay. Recent studies show the introduction of a small amount of cation dopants can strongly improve the electrochemical performance of layered cathodes. But the underlying mechanisms remain illusive due to the lack of information at atomic scale. Here, with a combination of atomic-resolution STEM imaging and first principle calculations, we reveal the microscopic origin of enhanced electrochemical properties of LiNi₀.₅Mn₀.₅O₂ doped with ~1 at % Mo. Our observations provide direct atomic-scale evidence that the small amount of Mo dopants distributed uniformly in the host lattice can significantly hinder the Li/Ni cation mixing. And such structural changes can strongly suppress the detrimental phase transformations not only at the surfaces but also at the grain boundaries within the bulk of the cathode materials, leading to an enhanced capacity and cycling properties. These results provide useful insights into the fundamental understanding of doping effects on the structural stabilities of layered cathodes.

2:00 PM EN01.02.03
The Origin of Al Dopant Enhanced Cycling Stability in NCA Cathodes Lianfeng Zou¹, Jianyu Li², Zhenyu Liu³, Guofeng Wang³, Manthiram Arumugam² and Chongmin N. Wang¹; ¹Pacific Northwest National Laboratory, United States; ²The University of Texas at Austin, United States; ³University of Pittsburgh, United States

For the majority of cathodes in Li ion batteries, cationic doping offers an effective means to enhance electrochemical performance, in which the alien dopants are generally considered to operate via modifying bulk properties. In contact to the liquid electrolyte, the electrode surfaces often act as primary sites that suffer from structural and compositional degradation, however, the doping effects on the modification of electrode electrolyte interface (EEI) properties remain vague. By combining atomic level imaging, spectroscopic analysis and DFT simulation, we demonstrate that the dopant extends its effective domain from bulk to surface via dynamic evolution, which significantly improve the cathode/anode-electrolyte interface stability. Using Ni-rich cathode as a model system, we show that, during the materials synthesis stage, the trace amount of Al dopants migrate and accumulate beyond the surfaces and lead to the epitaxial growth of scattered Al₂O₃ nano-islands; upon cycling, the Al provides an additional physical barrier for slowing down the electrochemical degradation. The buffer zone developed by dopant evolution mitigates the electrode-electrolyte interactions and alleviates the performance decay during the battery operation.

Improving Electrochemical Performance of Lithium-Sulfur Batteries Using Flexible Fibrous Cathode Additives Avinash Raulo and Bhanu Nandan; Indian Institute of Technology Delhi, India

Lithium-Sulfur batteries (LSB) are considered as high-potential candidate for next generation electrical energy
storage technology due to the low cost and naturally abundant sulfur-based cathode, that endows the battery with a high theoretical energy density of 2600 Wh kg⁻¹ and specific capacity of 1675 mAh g⁻¹. However, rapid capacity fading due to the formation of soluble lithium polysulfide (LiPS) intermediates, electrically insulating property of sulfur and LiPS pose great challenges for the realization of long lasting LSBs for commercial applications. Present study dealt with the fabrication of poly(3,4-ethylenedioxythiophene):polystyrene sulfonate-sulfur@polyacrylonitrile electrospun nanofibers, which can be potentially used as flexible additives in the cathode of lithium-sulfur batteries. The unique architecture of thus fabricated nanofibers not only trap the intermediate LiPS and suppress their dissolution into liquid electrolyte but also provide rapid charge transfer pathway to improve the reaction kinetics. As a result, LSB with nanofiber incorporated cathode shows better cycle life and improved rate performance compared to the bare sulfur cathode owing to the adsorption effect of the nanofibers.

Anion Redox Materials—A Comprehensive Study Combining Computation and Experiments Shirley Meng; University of California, San Diego, United States

Intercalation compounds based on transition metal cation redox has been studied over a few decades, while their potential based on oxygen anion redox has been under heated debate recently. The richness of anionic redox chemistry in the solid state inspires the materials community to explore new systems for next generation electric energy storage. At the same time, advanced computational and experimental tools to quantify the anionic redox activities are under development to study the underlying science that triggers a reversible and stable anionic redox activity. Possible approaches are outlined to further improve electrochemical performance of anion redox, realizing its full potential. In this talk, we will showcase the new computational methodology that enables the stabilization of oxidized lattice oxygen ions and follow up by demonstrating experimental evidence that is the true signal of oxidized lattice oxygen ions.

Largely Improved Battery Performance Using Micro-Sized Silicon Skeleton Caged by Polypyrrole as Anode Junjie Niu; University of Wisconsin-Milwaukee, United States

The emerging demands in large energy storage for portable electronic devices and transportations are attracting more interest in developing next-generation lithium-ion batteries (LIBs) with a series of new electrode materials, thus to achieve a 3-5 times higher capacity to meet a strategic perspective energy-density of 500 Wh/kg or higher. Silicon, with a theoretical capacity up to 4000 mAh/g, is considered as one of the promising anodes to achieve this goal. The industry R&D in Si-led anodes is widespread, and the release of commercial products for portable electronics seems imminent, although simultaneous achievement of high capacity and sufficient calendar life for automotive applications remains to be demonstrated due to a 360% volume expansion of silicon (Liu, Nano Lett 2011). The significant volume expansion makes the silicon not suitable for large amount loadings in actual batteries (Szczech, Energy Environ Sci 2011). The current ratio of silicon in graphite anode is typically less than 10%, which largely limits the overall energy density. Certain amounts of strategies have been tried to overcome this challenge by constructing various nano-structured configurations. Due to the light-weight, simple synthesis and low cost, recently scientists start to pay attention in applying polymeric materials in LIBs (Chao, Adv Mater 2014).

In this presentation, I will introduce a largely improved battery performance using micro-sized silicon skeleton caged by polypyrrole polymer as anode, which was synthesized via a facile wet-chemical strategy (Lv et al. 2019, under review). The industry available, micro-sized AlSi alloy was used as precursor, which ensures a scalable production with low cost. The hollow skeleton configuration provides sufficient spaces to accommodate the drastic volume expansion/shrinkage upon charging/discharging while the minimum amount of conductive polymer serves as a protective layer and fast channel for Li⁺/e⁻ transport. The battery with the micro-silicon cage as anode displays an excellent capacity retention upon long cycling at high charge/discharge rates and high material loadings. A specific capacity as high as 1660 mAh/g (~5X times graphite) with a high Coulombic efficiency of ~99.8% and 99.4% were achieved after 500 cycles with 3 mg/cm² loading and 400 cycles with 4.4 mg/cm², respectively. At higher 1.0 C, the capacity close to 1150 mAh/g was remained after 500 cycles with such high loading. The areal capacity of as high as 6.4 mAh/cm² with 4.4 mg/cm² loading was obtained, which suffices a high battery energy density in powering large devices such as electric vehicles (EVs).
Tailoring Electrode-Electrolyte Interfaces in Lithium-Ion Batteries Using Molecularly Engineered Functional Polymers Laisuo Su, Jamie Weaver, Mitchell Groenenboom and B. Reeja Jayan; 1Carnegie Mellon University, United States; 2National Institute of Standards and Technology, United States

The performance and stability of lithium ion batteries (LIBs) depend on charge transfer processes and reactions at electrode-electrolyte interfaces (EEI), making interfaces design a key issue. Here we engineer this interface using conformal, functional polymer nanolayers via a novel vapor-based deposition technique. We demonstrate that poly(3,4-ethylenedioxythiophene) (PEDOT) nanolayer doubles the capacities of LiCoO2 at high rates and extends its 4.5 V cycling life by 160%. The improved rate performance is enabled by high diffusion coefficient of Li⁺ in PEDOT measured from neutron depth profiling. Such behavior is further understood by density functional theory (DFT) calculation. The extended cycling stability comes from strong interactions between PEDOT and Co atoms, as suggested from X-ray photoelectron spectroscopy and DFT calculation. Additionally, in-situ synchrotron X-ray diffraction reveals that PEDOT uniformizes current distribution and improves LiCoO2 structural stability during cycling tests. This work adds understanding and provides guidelines for designing the EEI for advanced LIBs.

The North American Solution to Climate Change and the Role of Battery Storage Christine Hallquist; Cross Border Power, United States

Christine Hallquist, was CEO of a Vermont utility that was recognized for its leadership in transitioning to a 96% carbon-free electric supply by 2018. Christine spent 10 years as a member of a strategic advisory team to the National Rural Electric Association, which provided electricity to 56% of America’s land mass. The advisory group oversaw research projects with the Department of Energy, the National Laboratories, and industry. Christine was vice-chair of the advisory group and scheduled to move to chair when she left to become the democratic candidate for governor of Vermont in 2018. Her role in addressing climate change began in 2005 when the Vermont governor asked her to join an advisory group that traveled to Quebec to hear the report of the Intergovernmental Panel on Climate Change. She has now formed a Canadian Company, Cross Border Power, whose mission is to solve climate change and produce grid-scale storage as part of that mission.

In order to understand the challenge ahead it is important to understand our current energy mix. According to the US Energy Information Administration, 81% of energy consumed in the US comes from fossil fuels. The per-capita daily use of electricity in 2018 was 11.6 kWh with 63% of the electricity generated from fossil fuels. In order to solve climate change, North America will need to transition its energy supply to 100% carbon-free sources of electricity 100% of the time. If we assume no improvement in efficiencies, this means the per capita use of electricity would rise to 61 kWh. That said, we can expect significant improvements in efficiency through transitioning to cold climate and geothermal heat pumps as well as electric transportation. We will increase the amount of electricity generated while transitioning. This will result in significant demand for additional wind and solar on the electric grid.

The electric grid was designed for rotating generators. The collective rotation of the interconnected generators provided system-wide inertia, which resulted in electrical stability. Eliminating those rotating generators and replacing them with wind and solar generation will require a tremendous amount of battery storage to inject the lost inertia and balance the supply with the load. While battery technology has been improving, from a cost and performance standpoint we have a long way to go.

The electric grid in Northern Vermont is already facing electrical stability problems from a large deployment of wind and solar. This area has become an ideal test case for studying impact and solutions. Presently, with all generation operating at peak output, the system is over capacity by at least 1/3, which means the wind projects are required to shut down due to grid stability issues, thus wasting the generation. These same stability issues are
showing up all around the world, including California, Texas, Spain and Germany.

Christine’s presentation will address what is needed to solve the problems on the northern Vermont electric grid as well as what it will take to accomplish the North American Solution to Climate change. She will discuss the economics, physics and engineering challenges as well as the enabling policy changes that will can help accelerate the implementation. Included in her presentation will be the role of battery storage, the present state of storage and what developments are needed in order to fully decarbonize our energy portfolio.

4:30 PM EN01.02.09
A Novel Route for the Large-Scale and Low-Cost Fabrication of Silicon-Graphite Composites for Lithium-Ion Batteries Joseph Schwan¹, Giorgio Nava¹, Matthew G. Boebinger², Matthew T. McDowell² and Lorenzo Mangolini¹; ¹University of California, Riverside, United States; ²Georgia Institute of Technology, United States

Over the last decade the research community engaged in significant efforts to develop silicon-based anodes and boost the energy density of lithium-ion batteries. This goal is considered instrumental for the development of more efficient electric vehicles and stationary storage systems. While, from a material engineering standpoint, silicon-carbon nanocomposites have been demonstrated as one of the most promising strategies to produce electrodes with long-cycle life, overcoming the problem of silicon swelling upon lithiation, synthesis methods suitable for the low-cost industrial-scale manufacturing of these delicate and carefully engineered structures have still to be demonstrated. In this contribution, we present two innovative production systems purposely designed to be simple, cost-effective and suitable for future large-volume material production.

The first innovation is a method to produce silicon nanoparticles -NPs- with (i) high-purity (oxygen content <3%) and (ii) tailored nanoscale size. The system comprises a non-thermal radiofrequency plasma reactor serially connected to a tubular furnace. The plasma discharge quickly converts a silicon containing gas into silicon NPs and ensures a high precursor utilization (over 90%). The aerosol is then seeded into the furnace where the NPs are sintered into larger structures at high-temperature. The final particle size can be precisely adjusted between 5 nm and 60 nm (size distribution within 10% of the average value) by simply changing the temperature of this second thermal stage (800-1000°C).

The second innovation is chemical vapor deposition -CVD- method that allows growing highly graphitized and conformal layers of carbon directly onto the surface of silicon NPs. The NPs are introduced into a hot-wall furnace with an alumina combustion boat and are wrapped with a conformal coating of amorphous carbon resulting from the dissociation of acetylene -C₂H₂- at 650 °C. After removing C₂H₂, the furnace is ramped up to 1000°C in Argon -Ar- yielding a controlled graphitization of the carbon-shell with no detectable presence of silicon carbide.

The combination of the two aforementioned approaches achieves the production of a battery grade silicon-carbon nanomaterials with tunable properties (i.e. size, graphitic carbon content and carbon shell thickness). The as-produced composites demonstrate outstanding electrochemical performance as “drop-in” additives in graphite-dominant anodes. The addition of small amount of the Si-based active material (10% in wt) enables the fabrication of electrodes with a gravimetric capacity of around 600 mAh g⁻¹, first cycle CE of 90% and capacity retention of 81% over 100 cycles. The optimized composite material is used to fabricate a prototype 60 mm x 40 mm high-energy density pouch cell and its performance are compared to the one of a state-of-the-art commercial graphite-based battery.

4:45 PM EN01.02.10
Stable Cycling with High Energy and Power Densities of Silicon-Graphene Anode Electrode for Li-Ion Battery Doyoung Kim¹,², Yongguang Luo², Hee Min Hwang¹,², Simgeon Oh¹,² and Hyoyoung Lee¹,²,²; ¹Center for Integrated Nanostructure Physics, Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

As the era of electric vehicles arrives, it is necessary to develop li ion battery with high energy and power densities. Energy and power density, which are directly related to the performance of an electric vehicles and required by all electric devices. The commercial graphite anode li ion battery has limited gravimetric capacity of ~370 mAh g⁻¹, low charge rate and low retention stability due to the sluggish intercalation reactions during charging. Silicon are emerging as next-generation anode materials to solve these problems. Silicon has a high theoretical capacity (~4,200 mAh g⁻¹), which is ten times higher than commercial graphite anode materials. However it has a significant problem of stability due to the high expansion ratio (~ 400 %) and solid electrolyte interface that accompany the
charging reaction. Silicon is classified as an alloy material that participates in direct bonding with li ions. Because of this, more than a certain amount of li ions are involved in the bonding with silicon, which causes expansion and pulverization at the same time. This is a typical retention stability degradation problem for silicon-based anode electrodes.

To avoid a degradation of a silicon anode for a lithium ion battery, we report new 2D multi-layered rGO/Si electrode prepared by a direct growth of Si into porous rGO film on current collector. The direct Si deposition method on the porous rGO film can intercalate Si layer into the rGO film by replacing oxygen related groups of GO with Si nanoparticles through \textit{in-situ} thermal reduction of GO film. The thickness of rGO/Si thin-layered film can be controlled from a sub-nanometer to micrometer thickness Si electrode. Its rGO layers tightly hold Si layers and also were acted as a pre-volume against an expansion of Si layer with Li charging, leading to give a highly stable li ion battery. The 2D thin-layered film provided a short pathway for Li ion transport insertion and desertion process due to a nanometer thickness of Si and graphene. In addition, the 2D film gave a high conductivity even without binder and/or conductive agents, providing a high initial capacity of 2,978 mAh g$^{-1}$ at 0.5C and a high reversible capacity at 0.5C (~ 1,791 mAh g$^{-1}$ at 500 cycles).

**Optimization of Synthesis and Characterization of Ni-Rich LiNi$_{2-y}$Mn$_{0.5-y}$Co$_{0.5-y}$O$_2$ via Co-Precipitation Method in a Continuous Stir Tank Reactor**  
Anshika Goel, Natasha Chernova, Hui Zhou, M. Stanley Whittingham and Fredrick Omenya; Binghamton University, United States

In the past few years the lithium-ion batteries (LIBs) industry has expanded from consumer electronics to automotive industry. Lithium nickel manganese cobalt layered or NMC are state of the art cathode materials that have replaced the original lithium cobalt oxide cathode due to their promising high energy density. In NMC, Ni provides high capacity to the cathode material, while Co and Mn provide structure stability and safety over cycling. To further increase the energy density, current research is focused on nickel-rich oxides. The structure, morphology, and electrochemical performance of these oxides are highly dependent on the method of synthesis. Even slightest variations in the synthesis conditions can result in widely divergent characteristics when used as cathode material. The presentation will discuss various reaction condition optimization for synthesis of NMCs like pH control, concentration of chelating and precipitating reagents and how does it affect the morphology and other properties of the material like tap density, electrochemistry and magnetic properties. In this work we have used Powdered X-ray Diffraction (PXRD), UV-Vis Spectroscopy, magnetic properties, Scanning Electron Microscopy (SEM) and tapped density to discuss various changes in physical and chemical properties of material with respect to reaction condition.

**TEM Failure Analysis of Electrochemically Delithiated LiNi$_{0.5}$Mn$_{1.5}$O$_4$ Spinel**  
Xiang-Yun Song; Lawrence Berkeley National Lab, United States

LiNi$_{0.5}$Mn$_{1.5}$O$_4$ cathode material which has a higher working voltage (4.8 v) and larger specific capacity (148 mAh/g) has been studied by high resolution transmission electron microscopy (TEM). The purpose of this work was focused on the battery failure mechanism through TEM observations and analysis of microstructural properties of LiNi$_{0.5}$Mn$_{1.5}$O$_4$ spinel material, meanwhile the samples before and after electrochemical cycling was compared. XRD and SEM/EDS were further used to evaluate the battery failure mechanism.
Comparing with fresh LiNi_{0.5}Mn_{1.5}O_{4} particles before cycling, many LiNi_{0.5}Mn_{1.5}O_{4} particles after cycling, which also called original single crystal grains, display a tendency of nano-polycrystalline. This kind of polycrystalline properties can be mainly represented by three major microstructural features in cycled LiNi_{0.5}Mn_{1.5}O_{4} spinel material. First, many electron diffraction patterns that show FFT (Fast Fourier Transform) patterns got from TEM image area do not exhibit a regular single crystal diffraction pattern, but more complex patterns. 2nd, lattice defects appeared in LiNi_{0.5}Mn_{1.5}O_{4} particles, which are proved by lattice images and FFT patterns. And last major difference after cycling is that some smaller nano particles precipitated on the particle surface.

In order to compare and analyze LiNi_{0.5}Mn_{1.5}O_{4} spinel material more efficiency, a detailed lattice structural model of spinel corresponding to the TEM lattice image and its FFT pattern is presented.

**EN01.03.03**

*Unveiling Lithium Storage in Oxygen-Vacancy-Controlled MoO_{3-x} without Any Binders or Conductive Materials*

Sooeun Shin, Jaesang Yoon, Hochul Nam, Eunsoo Kim, Won-Sub Yoon and Hyungjung Shin; Sungkyunkwan University (SKKU), Korea (the Republic of)

High capacity and cycling stability are two important key points in developing lithium-ion batteries. One of potential candidates as an anode material is MoO_{3} is due to facile Li^{+} hosting in layered structure and thus resulting high theoretical capacity. Here, we present oxygen-vacancy-controlled MoO_{3-x}, where oxygen vacancies act as shallow donors and result improved electrical conductivity of the active materials. Without the use of additional binders and conductive materials, we were able to examine the Li-storage mechanism directly on MoO_{3-x}. We clearly demonstrate Li-storage capacity based on reversible formation/disruption of SEI films as an extra with the conjunction of Li ion intercalation as well as electrochemical reactions in the layered structures and surprisingly not resulting from the previously known conversion reactions in MoO_{3-x}. By conjugating the surface of MoO_{3-x} with Cu_{2}O via annealing process, we investigate the role of Cu_{2}O. According to our experimental results obtained by electrochemical analysis, *ex-situ* transmission electron microscopy and *ex-situ* X-ray absorption spectroscopy Cu_{2}O act as an effective catalyst for the formation of SEI films and reversible reaction of MoO_{3-x} with Li^{+} ions. As a result, Cu_{2}O@MoO_{3-x} exhibits a charge capacity of 1,100 mAh/g from the second cycle and maintains high reversible capacity, while MoO_{3-x} exhibits a charge capacity of 900 mAh/g and fades to 590 mAh/g for 100 cycles at 1 A/g. Cu_{2}O@MoO_{3-x} shows capacity of ~ 390 mAh/g at 10 A/g up to 1,000 charge/discharge cycles.

*Mitigation of Microscale Reaction Heterogeneity by Crystallinity Tuning for Ni-Rich Cathode in a Li-Ion Cell*

Hyungyeon Cha and Jaephil Cho; UNIST, Korea (the Republic of)

To date, nickel-rich cathode materials have been greatly developed by modification of surface and bulk morphology, structural design, and concentration gradients. However, the intrinsic problems originated from the morphological characteristics have not been completely prevented. The anisotropic expansion of each primary particles give rise to the morphological collapse upon the long-term cycling, resulting in a reaction inhomogeneity of the secondary particles.

Interestingly, we have investigated such reaction inhomogeneity induce the serious state-of-charge (SOC) heterogeneity in the thick electrode. We carried out 3-electrode full-cell test with an additional lithium metal electrode to track the LiNi_{0.6}Co_{0.2}Mn_{0.2}O_{2} (NCM) cathode and graphite anode potential. These results show the cathode and anode potential steadily rise during the cycling at the high temperature of 45 °C. Noticeably, the cut-off potential was upraised from the 4.38 V to 4.47 V after 200 cycles, indicating that the additional lithium ions could be extracted from the cathode structure. We confirmed the potential was different according to the position in the thick electrode and the high potential distribution was concentrated on the surface particles from the Raman spectroscopy analysis using the cross-sectioned electrode. The Raman spectroscopy is a powerful and novel analysis tool for observing the degradation of metal oxide cathode materials in a microscale. The overutilization of the cathode particle in the surface accompanies severe morphological collapse with nickel dissolution, threatening the integrity of the graphite particles. In this regard, we suggest tuning the crystallinity of the NCM particles from the polycrystallinity to single grain. We intensively investigated the degradation mechanism of the single grain LiNi_{0.8}Co_{0.1}Mn_{0.1}O_{2} and conventional NCM under the high temperature.
Understanding the Multivalent Charge-Storage Mechanism of Na$_3$V$_2$(PO$_4$)$_3$ for Aqueous Zinc-Ion Batteries

Jesse S. Ko$^1$, Partha P. Paul$^1$, Natalie Seitzman$^2$, Ryan H. DeBlock$^3$, Bruce S. Dunn$^3$ and Johanna N. Weker$^1$;

$^1$SLAC National Accelerator Laboratory, United States; $^2$Colorado School of Mines, United States; $^3$University of California, Los Angeles, United States

Research on “beyond lithium-ion” technology remains to be an ongoing challenge in identifying materials capable of reversibly storing multivalent ions, such as Mg$^{2+}$, Ca$^{2+}$, and Zn$^{2+}$. For prospective Zn$^{2+}$-based positive electrode materials, questions regarding the accommodation of Zn$^{2+}$ remains largely unanswered. In the present study, we explore the charge-storage mechanism of a V-based Na$^+$ superionic conductor (NASICON) framework, Na$_3$V$_2$(PO$_4$)$_3$ (NVP), by X-ray synchrotron characterization to unravel potential-dependent structure-property relationships. We ascribe the reversible electrochemical behavior of NVP cycled in a Zn$^{2+}$-based electrolyte to a two-stage intercalation process involving both Na$^+$ and Zn$^{2+}$. The initial charging profile at C/20 indicates Na$^+$ extraction from Na$_3$V$_2$(PO$_4$)$_3$ to NaV$_2$(PO$_4$)$_3$, observed by a single plateau in the galvanostatic charge/discharge profile, while subsequent discharge results in two plateaus corresponding to Na$^+$, then Zn$^{2+}$ insertion. Operando X-ray diffraction of the zinc-ion cells were collected to examine the changes associated with the first charge/discharge cycle, which showed reversible behavior based on shifts in X-ray reflections. To examine distinct changes linked with Na$^+$ and Zn$^{2+}$ two-stage intercalation process, electrodes were prepared ex situ for Rietveld refinement to understand variations in the crystal structure parameters. Furthermore, changes in V oxidation state, V-O coordination, and the presence of Zn$^{2+}$ was studied by X-ray absorption spectroscopy. The results of this work present a thorough investigation of the multivalent charge-storage mechanism for a well-established NASICON framework, and may provide further insight into other related structures.

Honeycomb Layered Cathode Frameworks for Rechargeable Potassium-Ion Battery

Titus Masese$^1$, Kazuki Yoshii$^1$, Minami Kato$^1$, Satoshi Uchida$^1$, Zhen-Dong Huang$^2$, Keigo Kubota$^3$ and Hiroshi Senoh$^1$; $^1$National Institute of Advanced Industrial Science and Technology (AIST), Japan; $^2$Nanjing University of Posts & Telecommunications, China; $^3$AIST-Kyoto University Chemical Energy Materials Open Innovation Laboratory (ChEM-OIL), Japan

Potassium-ion battery (PIB) has recently attracted great attention, as a low-cost alternative to lithium-ion technology. PIB can be a high-voltage contender considering the significantly negative potential of the K$^+/K$ redox couple, which is close to or even lower than Li depending on the solvent [1]. Nonetheless, the large ionic radius of potassium coupled with significant strain accompanying potassium extraction / insertion, the number of potassium-based compounds (particularly, cathode materials) has greatly been undercut. In this work, we will highlight the electrochemical performance of honeycomb-based layered frameworks as potential cathode frameworks for rechargeable potassium-ion batteries [2].

Carbon Nitride Phosphorus as an Effective Lithium Polysulfide Adsorbent for Lithium–Sulfur Batteries

Vandung Do$^{1,2}$ and Won Il Cho$^2$; $^1$Korea University of Science and Technology, Korea (the Republic of); $^2$Korea Institute of Science and Technology, Korea (the Republic of)

Lithium–sulfur (Li–S) batteries are attracting substantial attention because of their high-energy densities and potential applications in portable electronics. However, an intrinsic property of Li–S systems, that is, the solubility of lithium polysulfide (LiPS), hinders the commercialization of Li–S batteries. Herein, a new material, that is, carbon nitride phosphorus (CNP), is designed and synthesized as a superior LiPS adsorbent to overcome the issues of Li–S batteries. Both the experimental results and the density functional theory (DFT) calculations confirm that CNP possesses the highest binding energy with LiPS at a P concentration of ~22% (CNP22). The DFT calculations explain the simultaneous existence of Li–N bonding and P–S coordination in the sulfur cathode when CNP22 interacts with LiPS. By introducing CNP22 into the Li–S systems, a sufficient charging capacity at a low cutoff
voltage of 2.45 V, is effectively implemented, to minimize the side reactions, and therefore, to prolong the cycling life of Li–S systems. After 700 cycles, a Li–S cell with CNP22 gives a high discharge capacity of 850 mAh g\(^{-1}\) and cycling stability with a decay rate of 0.041\% cycle\(^{-1}\). A 4-stack pouch cell with a high-S-load of 6.1 mg cm\(^{-2}\), which shows a capacity of 699 mAh g\(^{-1}\) and CA of 93\% after 74 cycles at 0.2 C. This is primarily ascribed to strong interactions between LiPS and CNP22, as well as a high S reutilization during cycling. The incorporation of CNP22 can achieve high performance in Li–S batteries without concerns regarding the LiPS shuttling phenomenon. The advantages of the Li–S cells with CNP22 are obvious, and therefore, CNP22 is a suitable material for constructing reliable Li–S batteries.

**Ultrastable and Fast Battery with an Organic Cathode and Liquid Potassium-Sodium Anode**

Roman Kapaev\(^1,2\), Keith J. Stevenson\(^1\) and Pavel Troshin\(^1,2\); 1Skolkovo Institute of Science and Technology, Russian Federation; 2Institute of Problems of Chemical Physics, Russian Federation

Alkali metal-ion batteries using metal anodes (Li, Na, K) are attractive because of their high specific capacities and low voltages. However, these anodes suffer from the dendrite growth issue, which causes short-circuiting of the cells and might lead to their ignition and even explosion. Recently, it has been proposed to use dendrite-free anodes based on potassium-sodium alloys (PSAs), which are liquids at temperatures down to −12.6 °C. However, there are no reports where asymmetric cells with PSA-based anodes show stable operation for >1000 charge-discharge cycles. This is likely due to the relative instability of the cathodes that have been utilized in these cells.

Here we developed a cell with the PSA-based anode and an organic polymer cathode, which is a derivative of hexaazatripenylene. The selected cathode material ensures excellent stability over >10000 cycles at 10 A g\(^{-1}\) (>70 C rate, specific capacity 135 mA h g\(^{-1}\)) with 88\% capacity retention after 10000 cycles. In addition, the organic cathode demonstrates exceptionally fast redox kinetics, showing the discharge capacity of 60 mA h g\(^{-1}\) at 50 A g\(^{-1}\) (>800 C rate), which is ~30\% of the capacity reached at a relatively low current density of 0.2 A g\(^{-1}\).

**EN01.03.10**

**Advanced Cathodes for Intermediate-Temperature Na Batteries**

Xiaowen Zhan, Xiaochuan Lu, Jeff Bonnett, Nathan Canfield, Hee-Jung Chang, Jonathan Sepulveda, Vincent Sprenkle and Guosheng Li; Pacific Northwest National Laboratory, United States

The challenges associated with integrating renewable resources, such as the intermittent solar and wind power, have placed substantial demands on the development of energy storage systems. Sodium-based battery technologies that are economical (because Na is abundant) and have long cycle life are gaining importance especially for stationary energy storage applications. Intermediate-temperature Na batteries have demonstrated several advantages over their conventional high-temperature counterparts, including superior battery safety, lower operating temperature and manufacturing cost, potentially longer cycle life, and easier assembly. However, there is still a lack of cost-effective cathode materials with high energy density and rate capability suitable for large-scale applications. In this work, we will introduce some of our recent findings on advanced conversion-type cathodes for intermediate-temperature Na batteries with the emphasis on new cathode reaction mechanisms.

**EN01.03.11**

**X-Ray Imaging Analysis in All-Solid-State Secondary Battery Using Silver Ion**

Koji Kandori\(^1\), Hisao Yamashige\(^2\), Noritoshi Furuta\(^3\), Takamasa Nonaka\(^4\) and Yuki Orihashi\(^1\); 1Ritsumeikan University, Japan; 2Toyota Motor Corporation, Japan; 3SOKEN, Inc., Japan; 4Toyota Central R&D Labs., Inc., Japan

All-solid-state rechargeable batteries are expected to be used widely as post lithium-ion batteries. Recently, the ionic conductivity of the solid electrolyte has been dramatically improved to the similar order as organic electrolytes. However, to improve the performance of all-solid-state rechargeable batteries at the cell level, it is important to not only enhance the ionic conductivity of the solid electrolyte but also to understand the diffusion behavior of carrier ions in composite electrodes. Ion diffusion in composite electrodes is complicated during charging and discharging in all-solid-state rechargeable batteries. In the case of a liquid electrolyte using an organic solvent, the transport number is lower than 1.0[1], and it is known that ion concentration distribution is caused in the electrolyte[2, 3]. On the other hand, in principle, no ion concentration distribution occurs in the solid electrolyte since in the solid electrolyte, the transport number of carrier ions is approximately one. Therefore, it is considered that ion diffusion phenomena in solid electrolytes are different from liquid systems. Although ion diffusion in composite electrodes of
bulk-type all-solid-state batteries proceeds through active materials and solid electrolytes, its diffusion path is very complicated, and its analysis is a challenge. Therefore, few observation examples of the dynamic behavior of carrier ions during the operation of the batteries have been reported. Another factor is that lithium ion, which is a general carrier ion, is a light element and it is difficult to detect the ions directly. In this research, as a model case of the all-solid-state rechargeable battery, the diffusion behavior in the composite electrode was directly observed by high energy synchrotron X-ray using the all solid secondary battery cell which uses silver ion as a carrier. Silver ion conductors have the advantage that solid electrolytes exhibiting high conductivity at room temperature have already been reported[4]. Also, silver ions are sensitive to X-ray. By using X-ray transmission imaging method with synchrotron X-ray with high transmittance, spatial resolution, and temporal resolution, the silver ion concentration distribution in the electrode during charging and discharging in the model battery was directly observed[5]. From the obtained results, the apparent diffusion coefficient in the composite electrode was calculated.

A silver-ion conductor, Ag₆I₄WO₄, was prepared as a solid electrolyte for all-solid-state silver battery. To observe the ion concentration distribution in the bulk-type all-solid-state rechargeable battery, an Ag | Ag₆I₄WO₄ | TiTe₂ cell was fabricated. Synchrotron X-ray radiography measurements were performed in SPring-8 (Hyogo, Japan). X-rays were irradiated during discharge with a constant potential at 72 mV, and transmission intensity was measured with a two-dimensional detector to obtain an image.

The apparent diffusion coefficient in the composite electrode was estimated from this imaging measurements. This result suggests that ion diffusion in the composite electrode governs the performance. Thus, it has been suggested that ion diffusion in the composite electrode is important at a scale of hundreds of microns of the actual electrode thickness.

Advanced Lithium/Oxygen Flow Batteries—Challenges and Opportunities
Francesca De Giorgio¹, Alessandro Brilloni²,¹, Federico Poli²,¹ and Francesca Soavi²,¹; ¹Startup BETTERY, Italy; ²University of Bologna, Italy

Advanced, next-generation lithium batteries play a key role in the market penetration of electrochemical energy storage systems that will boost the progress of sustainable alternative sources of energy and transport. The emerging flow lithium batteries (FLBs) are attracting great interest thanks to the combination in a unique solution of the high specific energy of lithium batteries and the design flexibility of redox flow batteries that, in turn, allow to decouple energy and power.

Different kinds of FLBs have been proposed, such as batteries featuring semi-solid anolytes and/or catholytes with Li-ion intercalation powders, such as LiFePO₄ or Li₄Ti₅O₁₂, dispersed in organic electrolyte, and Li/S, Na-ion and Li/O₂ flow batteries. However, advancements in materials, cell design and concepts are still mandatory to achieve the leap forward in next battery generation.

BETTERY is an Italian Innovative Startup that aims to bring into market a radically new battery concept, i.e. NEw Semi-Solid flow lithium OXygen battery (NESSOX) that combines the high energy density of Li/O₂ batteries with the flexible and scalable architecture of redox flow batteries. NESSOX, featuring a lithium metal anode and a semi-solid, flowable catholyte, displays the highest practical specific energy and energy density ever reported, up to 500 mWh cm⁻², allowing to extend the drive range of electric vehicles to consumer acceptable values. The flowable nature also permits a breakthrough in the battery field thanks to the fast recharge by “catholyte refueling”. The main technology challenges faced by BETTERY to bring NESSOX into market are here presented and discussed.

Fabrication of Iron(II) Oxide Embedded Hole-Rich Carbon Shells for Efficient Electrocatalysis in Rechargeable Zn-Air Battery
Dong Eun Kim, Seung Youn Lee, Muhyeon Kim and Chang Keun Kim; Chung-Ang University, Korea (the Republic of)

Hole-rich carbon shells containing Iron(II) oxide (Fe$_2$O$_3$@NHC) were fabricated and exploited as electrocatalysts for rechargeable Zn-air battery. Fe$_2$O$_3$ particles were firstly synthesized by a hydrothermal reaction of Iron(III) nitrate, followed by wrapping glucose on the particles. The resulting glucose-coated Fe$_2$O$_3$ particles were annealed with urea to incorporate nitrogen on the carbon sp$^2$ structure, and then etched by hydrogen peroxide to form hole-rich structure. The formation of Fe$_2$O$_3$@NHC was confirmed by some analysis including HR-TEM, XPS, Raman and BET. The Fe$_2$O$_3$@NHC exhibited high specific surface area and high electrochemical surface area (ECSA) due to its hole-rich structure and incorporated N species. The electrocatalytic activity of the Fe$_2$O$_3$@NHC was confirmed by rotating ring disk electrode (RRDE). The Fe$_2$O$_3$@NHC exhibited outstanding oxygen reduction and evolution reaction activities in alkaline condition, which were comparable to noble-metal based catalysts. When the Fe$_2$O$_3$@NHC was used as a catalyst for the cathode of Zn-air battery, the battery showed outstanding energy density and good charge-discharge cycle stability. Therefore, the excellent catalytic activity and stability of Fe$_2$O$_3$@NPCs make them promising catalysts for rechargeable Zn-air battery.

EN01.03.14
Capacity Degradation Due to LiNi$_{0.5}$Co$_{0.2}$Mn$_{0.3}$O$_2$ Phase Transition at Cathode Composite Using Li$_6$PS$_5$Cl Solid Electrolyte in All-Solid-State Batteries
Hyeon-Ji Shin$^{1,2}$, Jiwon Jeong$^{1,3}$, Kyung Yoon Chung$^{1,2}$ and Hun-Gi Jung$^{1,2}$; $^1$Korea Institute of Science and Technology, Korea (the Republic of); $^2$Korea University of Science and Technology, Korea (the Republic of); $^3$Korea University, Korea (the Republic of)

Commercialized lithium ion batteries (LIB) have applied on electric vehicle running over 300 miles, but there is still a hazard of flammability due to liquid based electrolyte. Therefore, many researchers have been trying to ensure safety issues of flammable accident from liquid electrolyte. Solid electrolyte (SE), especially sulfide based SE, is expected that ionic conductivity in all-solid-state batteries (ASSBs) could catch up with liquid electrolyte level in LIB. Among the various sulfide-based SE, Li$_6$PS$_5$Cl (LPSCl) have been considered as promising SE because of its low cost, relatively stable with conventional cathode, and high ionic conductivity (1.3x10$^{−3}$ S cm$^{−1}$) at room temperature[1].

Average capacity have 140 mAh g$^{−1}$ using LiNi$_{0.5}$Co$_{0.2}$Mn$_{0.3}$O$_2$ (NCM523) active material as cathode and LPSCl as SE. However, the electrochemical performance of pellet-type cell consisting of NCM523 composite cathode/LPSCl/Indium foil shows that the capacity is rapidly decreased after 20 cycles, and the capacity retention falls down below 50% within 50 cycles. Janek’s group reported a side reaction of carbon-containing cathode composite which accelerates the oxidation of sulfide-based SE on cathode surface[2].

In this study, interestingly, we figured out that declined lifetime of cell is originated from not only side reaction in which an electrolyte is decomposed at interface between NCM523 active material and LPSCl but also cathode deterioration due to NCM523 phase transition. In particular, TEM analysis revealed that the Ni/Li cation mixing resulting in phase transition from layered R(−)3m phase to the spinel phase Fd(−)3m, and this result could be supported by confirming the change of Ni oxidation states analyzed by XANES. From above analysis, the similar mechanism as LIB has been observed to cause cathode deterioration, and we will discuss further more in detail which system is occurred the deterioration more quickly and what the reason is.

A Thermal Management Approach for Safety Operation of Electric Vehicles or Hybrid Electric Vehicles
Application Jeemut Bahan Sangiri, Chandan Chakraborty and Sudipto Ghosh; Indian Institute of Technology Kharagpur, India

Li-ion batteries (LIBs) are one of the promising energy storage devices with diverse applications in portable devices, Electric Vehicles (EVs), Hybrid Electric Vehicles (HEVs) due to their impressive energy density and cycle life. However, the issues like abnormal temperature inside the LIBs leads to thermal runaway, material degradation, capacity fading and hence the performance deteriorates. In this work we have incorporated finite element method (FEM) based technique to couple thermal and electrochemical model in the battery electrode for safety and reliability. The FEM model explains about the quantification of heat generation inside the battery pack by integrating convection forced air cooling with the battery pack to maintain the temperature of the battery pack within the safety limits. Consequently, this model is tested with a real-time system for the superior battery health and performance.

EN01.03.16
Mn0.9Co0.1O2 Spinel Coatings for the Stabilization of Nickel-Rich NMC Cathodes for Li-Ion Batteries
Luqman Azhari and Yan Wang; Worcester Polytechnic Institute, United States

NMC811 (Ni0.8Mn0.1Co0.1O2) is a cathode material of significant commercial interest for next generation lithium ion batteries due to its higher capacity and lower cost compared to current LiCoO2 cathodes (200mAh/g vs 140mAh/g). However, in the highly charged state (V > 4.3V vs Li/Li+), side reactions between high valence nickel and electrolyte jeopardize prolonged usage and stability. In this work, we address these issues by utilizing an industrially viable coprecipitation process to apply a chemically stable Mn0.9Co0.1O2 spinel coating to protect the NMC material. After forming the metal hydroxide precursor, dilute solutions of manganese and cobalt sulfate are added in order to encourage coating formation while preventing supersaturation and the subsequent precipitation of separate crystals. The thin Mn0.9Co0.1O2 spinel coating formed post-sintering is observed to improve capacity retention during electrochemical cycling at an upper voltage cutoff of 4.5V and at elevated temperatures of 55°C. In addition, electrochemical performance at high charge/discharge rates surpasses that of MnO2-coated NMC811. The results suggest a method for an industrially viable process to synthesize and stabilize Ni-rich cathodes for improved lithium-ion batteries.

EN01.03.18
Tungsten Oxide Coated Graphite Anode Material for Enhancement of High Rate Capability Lithium-Ion Battery
Dong Jae Chung1, Dae Sik Kim2, Hyun Jong Kim1, Hyun Dong Yoo1 and Hansu Kim1; 1Hanyang University, Korea (the Republic of); 2Korea Electronics Technology Institute, Korea (the Republic of)

As demands for electric vehicles (EV) and mobile electronics are increased, energy storage device becomes important. Lithium ion Battery (LIB), currently one of the most promising solution to EV, has critical issue in terms of fast charging problem. Graphite material, currently used as anode materials for LIB, has prominent limitation in term of high rate capability. To overcome this limitation, many materials have been researched for alternative of commercialized graphite material. Herein, we prepared tungsten oxide coated graphite by facile sol-gel reaction. the prepared tungsten oxide coated graphite showed enhanced the high rate capability of LIB. Without any reversible capacity fading, the tungsten oxide coated graphite anode electrode showed an outstanding rate capability of 90.28 % of the capacity retention at a rate of 5C (1800 mA g\(^{-1}\)) compare to that tested at a rate of 0.2C (72 mA g\(^{-1}\)). In further characterization, microstructure and electrochemical performance of the tungsten oxide coated graphite will be discussed in more detail.

EN01.03.19
A Novel Approach to Synthesize Micrometer-Sized Porous Silicon with Internally and Externally Interweaved CNT as a High Performance Anode for Lithium-Ion Batteries
Donglin He, Tianying Wang, Ping Li and Xuanhui Qu; University of Science and Technology Beijing, China

Silica fume is an industrial by-product or solid waste of the manufacture of silicon metal and ferrosilicon alloys,
which is collected from the smoke dust of electric arc furnaces. When the smelting temperature reaches 1700 °C or more in the electric furnace, bits of silicon reacts with oxygen in the air to form silicon monoxide, which can be further oxidized to silica. After cooling, silica fume is obtained by collecting the fine spherical particles via a dust collector. Recently, silica fume has been widely used as the admixtures to product concrete and cement. However, exploring high value-added utilization from silica fume is still expected for silicon smelters.

In this work, we synthesized a novel structural microspheres consisting of cross-linked CNT, porous Si/SiOx nanoparticles, CNT, and carbon coating (CNT/SFDP-Si/SiOx@C microspheres) by combining an inverse water-in-oil microemulsion approach with magnesiothermic reduction, in which silica fume, an inexpensive industrial by-product, is used as the porous Si precursor. The CNT/SFDP-Si/SiOx@C microspheres features a unique secondary structure, providing multiple significant advantages for solving the problems associated with Si. (I) the nanosized primary particle size prevents fracture; (II) the internal luxuriant voids offer enough space for the expansion of Si; (III) the internally and externally wired CNT construct a long distance electrically conductive networks and a electrical fast track to reinforce electron transport and acts as a structure protector to keep stability of the secondary microspheres without been destroyed; (IV) carbon exhaustively coats the outerface of the microspheres and inner nanosized Si particles, reducing SEI formation and retains the internal void space for silicon expansion; and (V) the space-efficient packing inside the secondary particles the micron-sized secondary microspheres possess low surface area and high tap density.

Thus, the CNT/SFDP-Si/SiOx@C microspheres displays stable capacities of 576.2 mAh g−1 at 2 C over 1000 cycles. The excellent electrochemical performance of CNT/SFDP-Si/SiOx@C microspheres manifests its supremacy as widespread anode material for both LIBs.

EN01.03.22
Cobalt-Free Quaternary Amorphous Alloy Cathodes for Lithium-Ion Battery Tiange Yuan and Oleksandr Voznyy; University of Toronto, Canada

Currently, lithium cobalt oxide cathodes have been extensively used in personal electronic devices due to their light weight and high energy density. However, the high cost of cobalt due to its decreasing available resource limits its application in electric vehicles manufactures. We synthesized quaternary cobalt-free amorphous alloys through a high-throughput robotic synthesis system with machine learning. The amorphous materials promise high structural flexibility for tuning and a less-energy-intensive production. The sol-gel synthesis enabled us to obtain multicomponent homogeneous amorphous alloys. The properties of materials were easily tuned by adjusting procurers’ ratio, temperature, reaction time. The combination of high-throughput synthesis with machine learning helped us to avoid the guess-and-check method and fastened the research. Theoretical modelings revealed the working mechanism of amorphous materials. We obtained quaternary amorphous cathode with unprecedented performance while avoiding undesirable toxic or expensive components.

Deeply Rechargeable Zinc Anodes in Alkaline Electrolyte Nian Liu; Georgia Institute of Technology, United States

Zinc metal anode possesses 3 times the volumetric capacity of Li metal anode, is compatible with non-flammable aqueous electrolyte, and remains on the same side of separator when discharged to ZnO in alkaline electrolyte. Indeed, primary zinc-air batteries have long been used for electronic devices requiring extremely high energy density (e.g. hearing aid). However, rechargeable zinc-air batteries have not been successful, preventing their entrance into larger markets such as electric vehicles, data center UPS, and indoor machinery. In this presentation, I will show my lab’s recent efforts towards making deeply (100% depth of discharge) rechargeable zinc-based
batteries, via nanostructured material design. This presentation is based on the following six recent publications from my lab:
2. Graphene oxide-modified zinc anode for rechargeable aqueous batteries. *Chemical Engineering Science* 2019, 194, 142-147. (Cover article)

Lithium Metal Plating Stability against Solid Electrolytes—Understanding and Experimental Validation Paul S. Albertus; University of Maryland, United States

Enabling the stable cycling of Li metal at rates and other metrics of practical significance is a key route to substantially increase the energy content of Li-based batteries beyond present Li-ion technology. Therefore, a careful analysis of lithium plating stability across a range of conditions and materials platforms is essential to understand and quantify the processes that lead to lithium growth through a separator and subsequent cell shorting. This talk will provide an overview of the current state of understanding of lithium plating stability, with a focus on both modeling and experimental methodologies. Emphasis will be placed on solid electrolyte systems, along with current gaps in knowledge and experimental validation of plating stability hypotheses. A number of practical issues and perspectives gained from the time the author served as a Program Director at ARPA-E working in the area of lithium metal batteries will also be included.

9:15 AM EN01.04.03
In Situ Characterization of Heterogeneity in Parasitic Li Plating During Extreme Fast Charging in Lithium-Ion Batteries Partha P. Paul1, Vivek Thampy1, Chuntian Cao1, Hans-Georg Steinrueck1, Andrew Jansen2, Venkat Srinivasan2, Ira Bloom1, Tanvir Tanim3, Michael F. Toney1 and Johanna N. Weker1; 1Stanford Synchrotron Radiation Lightsource, United States; 2Argonne National Laboratory, United States; 3Idaho National Laboratory, United States

With the increasing demand for electric vehicles, there is an urgent need for Li-ion batteries (LIBs) with extreme fast charging (XFC) capabilities. A major challenge in such batteries is retention of battery capacity over cycling under XFC conditions when recharging times are comparable to traditional refueling times. Current literature states parasitic Li plating on the anode is the major factor contributing to decreasing battery capacity and therefore shortened battery life [1]. However, the techniques used for understanding Li plating under in situ conditions has primarily involved characterization of Li by averaging over entire specially built cells [2].

While this approach provides a good starting point, the plating process is expected to be heterogeneous across the cell. Therefore, we use X-ray diffraction to:
1. Study the spatial heterogeneity in Li plating across a full pouch cell at various length scales.
2. Correlate the total amount of plated Li to the capacity loss of the cell during cycling.

The non-destructive nature of X-ray based techniques enables characterization of the Li plating across multiple length scales on the same cell. Towards this, single layer pouch cells (4cm x 6cm) with a porous graphite anode, NMC (LiNi0.5Mn1.5Co2O4) cathode and an EC:MC electrolyte were charged at different rates within the XFC regime and characterized using high energy x-rays.

At the mm-scale, powder diffraction was used to study the spatial heterogeneities and correlations between various species at the cell level. The analysis showed that the intensity of plated Li was directly correlated to the intensity of Li-graphite staged phases (LiC), even after discharging. These Li-rich regions in the cell also corresponded directly to depleted anode
(reduced graphite intensities), irrespective of the charging rate and regime. Additionally, the regions showing high Li intensity were analyzed for the orientation spread of plated Li. At the end of 450 cycles, the plated Li shows a random polycrystal orientation, without any direct evidence of a preferential texture, as suggested by some earlier studies [3]. Finally, the persistence of Li plating with increased number of XFC cycles as well as the effect of the cycling rate were examined in detail at the cell level. At the microscale, microdiffraction was used to study regions with significant Li plating, as found from the mm-scale scans. Such microscale analysis yields the size of plated Li crystallites as well as the local orientation/texture of plated Li, as a function of the charging rate and capacity fade.

The understanding gained from this study provides foundational knowledge of the conditions that promote and those that minimize parasitic Li plating. Based on this knowledge, parameters such as the XFC charging rate, charging protocol, electrolyte composition and anode architecture can be optimized, such that parasitic plating is minimized. This optimization will in turn help to guide the rational design of the next generation of XFC capable LIBs with a consistent performance.

9:30 AM EN01.04.04
Quantifying Inactive Lithium in Lithium Metal Batteries Chengcheng Fang1, Jinxing Li1, Minghao Zhang1, Yihui Zhang1, Fan Yang2, Min-Han Lee1, Mei Cai3, Jing Gu2, Kang Xu4 and Shirley Meng1; 1University of California, San Diego, United States; 2San Diego State University, United States; 3General Motors Research and Development Center, United States; 4U.S. Army Research Laboratory, United States

Inactive lithium (Li) formation is the immediate cause of capacity loss and catastrophic failure of Li metal batteries (LMBs). Differentiating and quantifying the Li⁺ in solid electrolyte interphase (SEI) components and the unreacted metallic Li, which together comprise the inactive Li, is the key to understanding the mechanisms leading to capacity decay. However, this has not yet been successful due to the lack of effective diagnosis tools that can accurately differentiate Li⁺ in SEI and the unreacted metallic Li. Here, by establishing a new analytical method, Titration Gas Chromatography (TGC), we accurately quantify the contribution from unreacted metallic Li to the total amount of inactive Li. We identify the unreacted metallic Li, rather than the (electro)chemically formed Li⁺ in SEI, as the dominating cause for the inactive Li and capacity loss in LMBs, clearing the long-term misconception in the field that the low CE is caused by the continuous repairing of SEI fracture. Using cryogenic electron microscopies to further reveal the micro- and nanostructure of inactive Li, we identified two ways for deposited metallic Li to lose electronic connections with the bulk electrode, thus becoming electrochemically inactive. Coupling the quantification of the global content of inactive Li to observations of its local atomic structure, we reveal the formation mechanism of inactive Li in different types of electrolytes, and determine the true underlying cause of low CE in Li metal deposition and stripping. We ultimately propose strategies for highly efficient Li deposition and stripping to enable Li metal anode for next generation high energy batteries.

Visualization of Ion Transport in Liquid and Polymer Electrolyte for Lithium Metal Batteries Yuan Yang and Qian Cheng; Columbia University, United States

Visualization of ion transport in electrolyte provides fundamental understandings of electrolyte dynamics and electrolyte-electrode interaction, shedding light on material designs to enhance device performance, such as batteries and fuel cells. However, this task is extremely challenging for existing techniques, since it is difficult to capture the low ionic concentration (<1 M) and the fast dynamics (1-10 s) of the electrolyte. Here we show that an emerging Stimulated Raman Scattering (SRS) microscopy offers the required spatial (sub-micrometer optical resolution), temporal (faster than 1 s per frame) and chemical (around mM) sensitivities to address this challenge.

The SRS microscopy has been used to study ion depletion and lithium dendrite growth in both liquid and polymer electrolyte, and distinct behaviors are observed. In liquid electrolyte, we observe a three-stage lithium deposition
process, each corresponding to no-depletion, partial-depletion and full-depletion regime of Li⁺, respectively. A positive feedback mechanism between the inhomogeneous growth of lithium and the local ionic concentration or flux. In polymer electrolyte, we clearly see phase separation due to ion depletion and observe the accompanying transport of plasticizer inside, which was not observed in the past. These new understanding also leads to new strategies to suppress lithium dendrites. This study shows that SRS microscopy is a powerful technique for imaging ion transport and will open various applications in materials and energy fields.

Challenge of High Energy Batteries for Electric Vehicles Application Mei Cai, Shuru Chen and Fang Dai; General Motors, United States

Highly emerged electric vehicle (EV) market evokes the demands on advanced batteries with high energy density. Li-metal batteries, including Li-NMC and Li-S, have been recognized as promising candidates beyond conventional Li-ion for next generation EV application. However, besides the energy density, automotive industry has other critical requirements on specific parameters. In this talk we will first present the requirements for future electrical vehicle application and the impact of high energy density Li-metal batteries on automotive industry. Some recent development on Li-NMC and Li-S batteries will be reviewed. The concerns and challenges of using Li metal as anode in batteries will be discussed. Moreover, we will also compare the difference of Li-NMC and Li-S in the EV applications and their specific challenges. Lastly, we will introduce some strategies on how to solve these challenges from both materials and cell levels, and also show some of our recent progress on Li-metal batteries.

11:00 AM EN01.04.07
Enhancing Electrode/Electrolyte Interfacial Stability in Solid State Lithium Batteries by Surface Coating Yuan Yang, Qian Cheng and Aijun Li; Columbia University, United States

Interfacial stability is critical to the performance of solid-state batteries. Various promising solid electrolytes are unstable with either cathode or anode, such as sulfide electrolyte / LATP / LAGP with lithium metal, and polyethylene oxide (PEO) electrolyte with 4 V layered oxides. Such incompatibility limits the performance and commercialization of solid state batteries. In this talk I will present recent studies on improving interfacial stability of LATP/Li and 4 V cathode/PEO interface. At the LATP/lithium interface, a nanoscale boron nitride coating blocks electron transfer and can significantly enhance the stability between LATP and lithium. Long cycle life of 500 cycles is achieved in LiFePO4/LATP/BN(PEO)/Li cells. On the other side, we also enhance the stability between 4 V cathode and PEO electrolyte by surface modification. Long cycle life of 400 cycles is achieved, much better than previous reports.

Conduction Mechanism and Electrochemical Stability of Closo-Borate Electrolytes for All-Solid-State Batteries Léo Duchêne, Ryo Asakura, Ruben-Simon Kühnel, Arndt Remhof and Corsin Battaglia; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The conduction mechanism and electrochemical stability of closo-borates, a particularly promising class of solid-state electrolytes for all-solid-state batteries [1,2], is investigated. We find from electrochemical impedance spectroscopy that the temperature dependent conductivity is characterized by three distinct regimes of conductivity. In the lowest temperature regime, conductivity remains low before a glass-like transition identified by X-ray diffraction and calorimetry causes a faster increase of cation conductivity through site disordering. Correlated ion diffusion evidenced by nuclear magnetic resonance originates from the coupling of the cation and anion motion due to short-range ion-ion interactions combined with background energy fluctuations, which we can associate through quasi-elastic neutron scattering experiment to fast librations of the anions. In the third regime, the thermal energy
increases above the background energy fluctuations resulting in non-correlated ion diffusion. I will further discuss recent progress in the fabrication of all-solid-state batteries based on closo-borate electrolytes and strategies to increase the electrochemical stability to enable a 4 V all-solid-state battery class bringing closo-borate-based all-solid-state batteries to a technology readiness level comparable to that of sulfide-based all-solid-state batteries.

**Bridging Length Scales via Advanced Analysis Techniques for All-Solid-State Energy Storage Systems**

Nikhilendra Singh\(^1\), Timothy S. Arthur\(^2\), James Horwath\(^2\), Eric A. Stach\(^2\), Marm Dixit\(^3\) and Kelsey B. Hatzell\(^3\);\(^*\)
\(^{1}\)Toyota Research Institute of North America, United States; \(^{2}\)University of Pennsylvania, United States; \(^{3}\)Vanderbilt University, United States

Advances in hybrid and electric technologies combined with a demand for green initiatives have motivated recent diversification in energy storage research for automotive electrification. To meet customer expectations for hybrid and electric vehicles, furthering the capability of existing battery systems remains critical. As such, new battery systems with higher energy density, power density and cycle life than the state-of-art Lithium (Li)-ion battery are needed. Post Li-ion battery systems, especially those focused on the utilization of Li metal have recently come to the forefront of research. The ability to directly utilize Li metal anodes in rechargeable batteries presents itself as an ideal, albeit challenging, situation. Li metal anodes could provide a maximum possible theoretical specific capacity (3860 mAh/g) in comparison to commercially used anodes (e.g. graphite – 380 mAh/g). Hence, significant efforts in recent literature have targeted the development of robust systems, capable of use with Li metal. One such system is Li-sulfur which has attracted attention due to its high theoretical capacity (1673 mAh/g) and potential low cost. However, this system is hindered by polysulfide dissolution and electrolyte decomposition at the Li metal anode. Among the various strategies which have been employed to overcome such hurdles, the use of solid-state electrolytes (inclusive of polymers, gels and conducting ceramics) stands out, as the implementation of solid-state electrolytes can also serve as a mechanical barrier towards Li dendrite formation. However, these electrolytes exhibit relatively lower ionic conductivities and display poor interfacial stability towards Li metal anodes. While advances in solid-state electrolyte materials continue to improve their ionic conductivities, little is known about the interfacial interactions between sulfide-based solid-state electrolytes and Li metal which can greatly affect their electrochemical performance. Hence, studies into understanding the relationship properties between Li metal and these solid-state electrolytes is essential towards realizing a sulfide-based all-solid-state Li battery.

Here, we present the electrochemical properties of various sulfide-based solid-state electrolytes in contact with Li metal. Further, we present tandem analytical ex-situ and in-situ studies via transmission electron microcopy and X-ray tomography to reveal the interfacial interactions between Li metal and solid-state electrolytes, the deposition and dissolution properties of Li metal from these electrolytes, and the effects of the deposition and dissolution properties on the bulk electrolyte structure. The presented studies allow for comparisons of Li deposition and dissolution properties below and above the critical current densities for each solid-state electrolyte material and stand to help clarify both interfacial and morphological evolution mechanisms during Li cycling from them.

**Nanostructured Ionic Liquids in Lithium Metal Batteries**

Lan Zhang\(^1\), Haiyan Bian\(^1\) and Suojiang Zhang\(^1\);\(^*\)
\(^{1}\)Institute of Process Engineering, CAS, China; \(^{2}\)University of Chinese Academy of Science, China

With wide liquid range, negligible vapor pressure, strong designability, high thermal and electrochemical stability, ionic liquids (ILs) are almost the ideal candidate for safe electrolyte in lithium ion or lithium metal batteries. While for one thing, most ILs are highly viscos, which may possibly reduce the electrolyte conductivity; and for the other, ILs are composed of large cations and ions, complicated interaction with lithium salt usually lead to reduced Li ion transference number (t\(_{\text{i,li}}\)). As a result, in spite of all the fascinating characteristics, most IL electrolytes still show limited conductivity and t\(_{\text{i,li}}\), which hinder them far from application.\(^{1-3}\)

Combining the concept of ionic liquid and nanostructured materials, nanostructured ionic liquids (NIL) is a new type of matter that possess the properties of both IL and nano materials. By tethering IL structure onto nano particles
such as SiO$_2$, Al$_2$O$_3$, we prepared several NILs and use them in lithium sulfur flow battery\cite{4},

electrospun nano fiberous separator\cite{5}, as well as electrolyte additive, we found that the NILs could increase the $t_{Li^+}$ by anchoring the cation, and its strong interaction with anion could further regulate the transport of anions, on which enhanced electrochemical performance could be obtained.

Design of Single-Ion Polymeric Nanoparticles for Solid-State Lithium Metal Battery Applications **Luca Porcarelli**\textsuperscript{1,2}, Haijin Zhu\textsuperscript{1}, Roberto H. Aguirresarobe\textsuperscript{2}, Nicolas Goujon\textsuperscript{2,1}, Jose R. Leiza\textsuperscript{2}, Maria Forsyth\textsuperscript{1,2} and David Mecerreyes\textsuperscript{2}; \textsuperscript{1}Deakin University, Australia; \textsuperscript{2}University of the Basque Country, Spain

While inorganic nanoparticles have received great attention for solid-state lithium metal battery applications, rather less interest has been paid to all-polymeric nanoparticles despite the availability of easily up–scalable polymerization techniques for the synthesis of nanoparticles with functionalized surfaces. In this work, we report composite electrolytes based on all-polymeric methacrylic sulfonamide nanoparticles designed to provide transference numbers close to unity. Mixing the particles with conventional electrolytes, such as poly(ethylene oxide) or propylene carbonate, we obtained mechanically robust nanocomposite electrolytes with storage moduli values as high as 10\textsuperscript{6} Pa and ionic conductivity values up to 10\textsuperscript{-4} S cm\textsuperscript{-1}. The comparison of lithium dynamics and mechanical properties suggest decoupling of these two antagonistic properties in our nanocomposite electrolytes. Pulsed–field gradient NMR showed that the mobility of lithium–ions exceeded by several orders of magnitude the mobility of the sulfonamide anions tethered to the particle surface. Finally, the electrochemical performance of symmetrical lithium cells are presented, showing promising results. Our findings suggest that all-polymer nanoparticles could represent a paradigm shift for solid-state lithium metal battery applications.

2:00 PM EN01.05.02
Polymer in Quasi-Ionic Liquid Electrolytes for High-Voltage Lithium Metal Batteries **Haiping Wu**\textsuperscript{1}, Linchao Zhang\textsuperscript{1,2}, Xia Cao\textsuperscript{1}, Quyan Li\textsuperscript{1}, Michael S. Ding\textsuperscript{3}, Kang Xu\textsuperscript{1}, Jiguang Zhang\textsuperscript{1} and Wu Xu\textsuperscript{1}; \textsuperscript{1}Pacific Northwest National Laboratory, United States; \textsuperscript{2}Institute of Solid State Physics, China; \textsuperscript{3}U.S. Army Research Laboratory, United States

All-solid-state lithium (Li) metal batteries (LMBs) are considered good candidates for the next generation power sources because of their excellent safety compared to the liquid electrolyte-based batteries. However, the poor interfaces between the inorganic solid electrolyte and the two electrodes (cathode and anode) make the practical applications of all-solid-state inorganic batteries very challenging. Polymer electrolytes are more promising in processability due to their flexible characteristics. Polyethylene oxide (PEO) is the most widely studied polymer in Li metal polymer batteries (LMPBs). Nevertheless, the performance of conventional LMPBs remain limited by the poor room-temperature ionic conductivity of the PEO-based electrolytes. Conversely, the low oxidative resistivity of ethylene oxide (EO) segments (< 4 V vs. Li/Li\textsuperscript{+}) of PEO restricts the utilization of 4 V class cathode materials in LMPBs, resulting in a low energy density of the batteries. Therefore, developing high voltage all-solid-state LMPBs is of high significance. In this work, polymer-in-salt electrolytes (PISEs) were developed by mixing PEO and lithium bis(fluorosulfonyl)imide (LiFSI) at high Li\textsuperscript{+}/[EO] ratios. The optimal PISE exhibited a high oxidation voltage (4.38 V vs. Li/Li\textsuperscript{+} on Al) and moderate conductivity (0.07 and 0.27 mS cm\textsuperscript{-1} at 60 and 80 °C, respectively).
The all-solid-state Li|PISE|LiNi_{1/3}Mn_{1/3}Co_{1/3}O_2 cells were evaluated with a high cut-off voltage up to 4.4 V. Additional details will be reported during the 2019 Fall Materials Research Society (MRS) Meeting & Exhibit and ensuing presentation.

Dispersion Quantification of an Ion-Conducting Polymer in Electrodes for Solid-State Batteries Adriana A. Rojas, Tatiana Loureiro, Lucienne Buannic, Brian Chiou, David Laughman and Wesley Hoffert; A123 Systems, United States

With an increase in demand for high energy dense storage devices for electric vehicles or intermittent energy sources, comes an increase for the need for efficient processing of materials that lead to safe and optimal-performing batteries. Safety can be enhanced with the incorporation of solid-state materials whereby an ion-conducting polymer matrix is established through the mixing and coating process of an electrode. These ion-conducting pathways are heavily dependent on the starting material sizes, the composition of the electrode, as well as the type of mixing profiles that are implemented. The efficacy of these ion-conducting pathways are quantified systematically from SEM images using existing computer packages in order to understand the best set of conditions that can lead to high-performing electrodes for safe solid-state lithium ion batteries.

2:30 PM *EN01.05.04
Single-Ion Conducting Polymer Electrolytes for Safer High-Energy Lithium Batteries Dominik Steinle¹², Huu-Dat Nguyen³, Zhen Chen¹², Alexander Mayer⁴, Elie Paillard⁵, Stefano Passerini¹², Cristina Iojoiu³ and Dominic Bresser¹²; ¹Helmholtz Institute Ulm (HIU), Germany; ²Karlsruhe Institute of Technology, Germany; ³University Grenoble Alpes / CNRS, France; ⁴Forschungszentrum Juelsch, Germany

Polymer electrolytes are considered to play a decisive role for the realization of safer rechargeable batteries and may, additionally, allow for the employment of lithium metal anodes, thus, paving the way for significantly higher energy densities.¹² Beside mechanical strength, especially three characteristics appear to be of paramount importance: (i) Single-ion conduction to prevent the reversed cell polarization, negatively affecting the long-term cycling stability, (ii) suitable ionic conductivities at ambient temperature, and (iii) a homogeneous lithium deposition upon charge to avoid the dendritic metal deposition.¹² While (i) has successfully been addressed already in literature, commonly by covalently tethering the anionic function to the macromolecular backbone,¹³ (ii) appears to be intrinsically limited by its dependency on the segmental relaxation of the polymer.¹⁴ Remarkably, the key to overcome the conductivity limitation and simultaneously address also (iii) may rely on introducing structure into polymer electrolytes.⁵⁶
Starting from a brief review, covering early and very recent work, selected strategies for this general approach will be highlighted. A particular focus will be set on fundamental insights into the charge transport mechanism and how this translates into enhanced electrochemical properties as well as selected results for high-energy lithium batteries comprising Ni-rich Li[Ni_{1-x-y}Mn_xCo_y]O_2 cathodes – a cathode material that had commonly been considered incompatible with any polymer electrolyte due to its challenging interface chemistry.

High Capacity LiS-Batteries—New Materials, Concepts and Mechanisms Aleksander Matic, Marco Agostini, Shizhao Xiong, Matthew Sadd and Carmen Cavallo; Chalmers Univ of Technology, Sweden

To reach a step change in energy density of rechargeable batteries new chemistries need to be considered as the current state-of-the-art, the Li-ion battery, is approaching its theoretical limit. Among potential chemistries for next generation batteries the LiS-battery has for some time been highlighted as one of the most promising. The interest stems from the high specific capacity of the reaction between Li and S and a theoretical energy density of a LiS-cell up to five times higher than current Li-ion technology. In addition, sustainability is more and more at focus in battery technology and being based on abundant materials LiS-technology has also the potential radically improve this aspect.

Despite the very promising characteristics LiS-technology has so far not been realized in large scale applications due to problems involving low utilization of active material, low practical energy density, slow kinetics resulting in poor rate capability, and capacity fading. Most of the problems are directly related to the conversion reaction between Li and S where polysulfide intermediates (Li2Sx), which are soluble in many of the common battery electrolytes used, are produced. Whereas the solubility of polysulfides can be a problem in terms of loss of active material and side reactions if they migrate out of the cathode, it is also a prerequisite in order to have high active material utilization and fast kinetics. Thus, the key is to manage polysulfide dissolution, rather than preventing it, to prevent side reactions on the anode (most commonly Li-metal) and to maximize the fraction of active material in the cell, i.e. minimizing the amount of electrolyte as well as inactive components such as binders and conducting agents. New materials concepts are needed both for the electrode and the electrolyte in order to achieve this. Recently there has been considerable progress with the development of nanostructured and functionalized carbon structures on the cathode side as well as functional separators and new electrolytes.

In this contribution we present new materials concepts based on the use of self-supporting carbon structures and the use of catholytes, where a part of, or all, active material is dissolved in the electrolyte [1-3]. Carbon nanofiber membranes and self-standing graphene-based aerogels can be used directly as electrodes, without further processing or the addition of conducting agent, binders or metal current collector, thus maximizing the amount of active material in the cell [2-3]. The performance of these materials will directly depend on their nanostructure (surface areas, pore size and pore distribution) and on presence of functional groups being able to interact with the dissolved polysulfides. With a catholyte, on the other hand, we can both increase the amount of active material in the cell as well as help forming a stable interphase on the Li-anode [4]. We show that by these routes high practical energy density, high sulfur utilization, and stable cycling can be obtained in cells with high sulfur loading and very low amount of electrolyte. We also present result from operando experiments (Raman spectroscopy and x-ray imaging) where we directly follow the processes taking place during discharge and charge, as well as from complementary ex-situ techniques, in order to understand the reaction mechanism in these systems.

Dendrite Suppression for Metal Anodes Using Liquid Crystalline Electrolytes Zeeshan Ahmad, Zijian Hong and Venkatasubramanian Viswanathan; Carnegie Mellon University, United States

There is an increasing need for high energy density batteries for achieving complete electrification of transportation. Batteries based on metal anodes like lithium can achieve energy densities much higher than the current state of the
art. However, these batteries have been plagued by an unstable and uncontrollable growth of dendrites during electrodeposition leading to short circuit and loss of Coulombic efficiency. Here, we present a new approach using liquid crystalline electrolytes to suppress the growth of dendrites during electrodeposition in metal anode-based batteries. Liquid crystalline electrolytes provide fast ionic transport together with high cation transference number, wide temperature window, non-flammability and low-cost bulk manufacturing [1, 2]. However, the dendrite suppressing nature of liquid electrolytes due to their orientational order has not been explored. A nematic liquid crystalline electrolyte with a perturbed director field due to interface with lithium metal is associated with bulk distortion and anchoring free energy. This changes the free energy of lithium ions in the electrolyte leading to a change in the equilibrium overpotential and thereby the kinetics of metal electrodeposition when used in a metal anode-based battery. We employ a phase-field model to simulate the electrodeposition of lithium in the presence of a standard and liquid crystalline electrolyte. On comparison of metal surface growth metrics with a standard electrolyte, we find considerable suppression of dendrite growth using a liquid crystalline electrolyte. Finally, we propose some design guidelines for the properties of the liquid crystalline molecules/polymers in order to achieve dendrite suppression for practical applications in batteries.

Electrolytes for Lithium-Sulfur Batteries Rebecca Glaser1, Feixiang Wu1, Billy Johnson1, Jud Ready1, Mohan Sanghadasa2 and Gleb Yushin1; 1Georgia Institute of Technology, United States; 2U.S. Army Combat Capabilities Development Command, United States

As the world faces a growing need to electrify and reduce carbon emissions, batteries offer much needed energy storage for electric cars, mobile devices, and the grid. For transportation and mobile devices, lightweight batteries are key, while non-toxicity is important for low environmental impact. The lithium-sulfur (Li-S) battery combines low weight, non-toxicity, low cost, and high capacity. With one of the highest theoretical capacities (1166 mAh/g) of any conversion-type cathode, the pursuit of low cost, long-lasting Li-S batteries is a global research focus. However, it is difficult to achieve the promised high theoretical capacity because of polysulfide dissolution in to the electrolyte and reaction at the Li anode surface, depleting the active material in the cathode. Current electrolytes are not effective enough at managing the polysulfide dissolution and have the negative side effects of high viscosity and high cost. In this study, we evaluate several new electrolytes with advantageous physical properties. We compare conventional sulfur cathodes to high-loading cathodes to look at the impact of wetting on performance. The impact of salt combinations and ratios on conductivity, viscosity, electrochemical performance, and SEI composition will be discussed in this talk.

4:30 PM EN01.05.08
Surface Chemistry and Electrocatalysis in Metal Phosphide-Stabilized Li-S Batteries Yiren Zhong1, Yuxiang Yang1, Lichang Yin2, Peng He1 and Hailiang Wang1; 1Yale University, United States; 2Institute of Metal Research, Chinese Academy of Sciences, China

Abstract: Lithium-sulfur batteries promise high energy density, but their poor cycling stability has been limiting their practical applications. The unstable performance is tightly associated with the insulating nature of sulfur and the dissolution and diffusion of the lithium polysulfide (LPS) intermediates with the subsequent parasitic reactions and low S utilization. These problems will be further aggravated in the cells with a high loading cathode at a lean-electrolyte condition, which, however, is critical for realizing the projected high energy of Li-S batteries in practice. Herein, to solve these issues, we introduce a new class of LPS trapping materials, conductive metal phosphides to the Li-S batteries. Using cobalt phosphide (CoP) as an example, we first explore the surface chemistry and demonstrate that the surface oxidation layer, naturally generated under ambient environment, plays a key role in absorbing the LPS species and promoting their conversion kinetics, thus the performance of lithium sulfur batteries is stabilized. The CoP containing electrode with ultrahigh sulfur loading of 7 mg cm−2 could deliver a striking areal capacity of ~5.6 mAh cm−2 that is stable over 200 cycles. In another effort, we further verify that this distinct electrocatalytic and LPS binding effect could be applied to the lean electrolyte condition. The sulfur electrodes containing molybdenum phosphate (MoP) show the great decrease in the overpotentials for the charging and...
discharging reactions, giving rise to improvements in capacity, rate performance, and cycling stability.\textsuperscript{2} As a result, high-performance sulfur electrodes, that are steadily cyclable at a high areal capacity of 5.0 mAh cm\textsuperscript{-2} with a challenging electrolyte/sulfur (E/S) ratio of 4mL E mg\textsuperscript{-1}S, are successfully realized.

\textbf{Dual-Functioning Superoxide Carrier for Stable and Efficient Lithium-Oxygen Batteries} Youngjoon Bae, Hyeokjun Park, Youngmin Ko and Kisuk Kang; Seoul National University, Korea (the Republic of)

Low round-trip efficiency and poor cycle stability remain as major challenges of lithium oxygen (Li-O\textsubscript{2}) batteries. These issues are primarily triggered by or correlated with the radical species that are produced during the operation of Li-O\textsubscript{2} cell, which significantly deteriorate the electrolytes and air-electrodes. Regulating the reactivity of radical species in an electrochemical cell would thus open up opportunities to mitigate such side reactions. Here, we introduce a dual functional superoxide carrier that is capable of quenching the reactive radical species produced in Li-O\textsubscript{2} cell into stable intermediate complexes both in discharge and charge processes. It leads to a significant suppression of side reactions with a remarkably improved oxygen efficiency. In addition, it is found that the superoxide carrier is also capable of scavenging the superoxides from the surface of discharge products upon charging, thus substantially lowering the charging overpotential. The combined radical mediation and the scavenging of superoxides enables the cycle stability of a practical Li-O\textsubscript{2} cell employing the superoxide carrier over 200 cycles with 1,000 mAh/g specific capacity. Our findings indicate the importance of controlling the reactivity of radical species and suggest a new pathway to the stable and efficient Li-O\textsubscript{2} batteries.

\textbf{SESSION EN01.06: Sodium-Ion Battery}
\textbf{8:45 AM EN01.06.02}
\textbf{Storage for DAYS—Materials and Technologies for Long-Duration Energy Storage} Scott Litzelman\textsuperscript{1}, Max Tuttman\textsuperscript{1}, Vivien Lecoustre\textsuperscript{2}, Sean Vail\textsuperscript{2} and Gokul Vishwanathan\textsuperscript{2}; \textsuperscript{1}Advanced Research Projects Agency-Energy, United States; \textsuperscript{2}Booz Allen Hamilton, United States

Several grid energy services such as frequency regulation, demand charge management, and distribution upgrade deferral can be satisfied using energy storage systems with durations typically between 30 minutes and four hours. To enable deep penetration of renewable generators while maintaining grid reliability, however, long-duration energy storage (LDES) systems will be needed. To be cost-competitive, LDES systems require a unique optimization of various attributes—different than conventional lithium-ion battery systems--such as capital cost for energy, capital cost for power, and round-trip efficiency.

This presentation will introduce novel LDES technologies that are being funded by the Department of Energy, Advanced Research Projects Agency-Energy (ARPA-E) Duration Addition to electricitY Storage (DAYS) program that can cost-effectively provide 10 to 100 hours of power to the electric grid. The DAYS projects span a range of concepts, including electrochemical systems with low-cost active materials, pumped thermal storage via inexpensive storage media such as sand and concrete, thermophotovoltaics, and geo-mechanical storage. Key technical challenges and opportunities will be discussed. Although broad adoption of LDES for commercial applications will require policy changes, this presentation will also highlight potential early applications that can enable commercial scaling of these technologies.

\textbf{9:00 AM EN01.06.03}
Energy storage devices allow us to use energy in a flexible, high efficient and eco-benign way, which has profoundly shaped our everyday life. The most successful energy storage device is lithium-ion battery (LIB), which has dominated the portable electronic devices and are now penetrating deep into vehicle markets[1]. However, the limited reserves of lithium[2] and cobalt in the earth crust cannot fulfill the huge demand gap of electrochemical energy storage, and the fast expansion of LIB industry has already led to accelerated cost rising[3]. Therefore, worldwide research programs strategically encourage the development of energy storage devices beyond LIB, among of which, sodium ion battery (SIB) is a very attractive one.

Electrochemically charging induced phase transition is a common and thermodynamically-driven phenomenon for variety of cathode materials, which couples with chemical and mechanical effects leading to performance degradation. Phase transition is particularly complex for layered sodium transition metal oxides and its related detrimental effects remain elusive. Doping electrochemically inactive elements is proven to be an effective approach to suppress the phase transition and Na-vacancy ordering to achieve improved electrochemical performance. Herein, we take P2-type Na2/3Ni1/3Mn2/3O2 (P2-NNM) as an example to scrutiny the detrimental consequences upon high voltage cycling. We find that repeated P2-O2 phase transition breaks down cathode primary grains by generating high density of intragranular cracks, which is qualitatively proved to be the main cause of performance decay. Intriguingly, the nucleation and growth of intragranular crack is through loss of atoms rather than cleavage, resembling the stress corrosion cracking mechanism which preferentially nucleates at P2/O2 phase boundary. Moreover, we find the P2-structured cathode is not sensitive to surface degradation, which explains the superior performance of P2-NNM cathode when cycling at low voltage.[4] we also investigate Mg-doped P2-structured Na0.67Ni0.33-xMn0.67MgxO2, and find doping electrochemically inactive elements is an effective method to suppress grain cracking, leading to improved cyclability[5].

For modern society, energy storage and distribution are critical, with sodium ion batteries (SIB) potentially filling a critical role as a low-cost technology from earth abundant resources well-positioned to augment - or where suitable replace - lithium ion batteries (LIBs).[1] Thus, SIBs have gained prominence due to strong interest from both research and industry.

Here we explore current state-of-the-art Na-ion batteries in terms of both electrodes. Hard carbon-based materials are currently preferred for their low cost and operating voltage (and hence high energy density). Meanwhile, the most promising cathodes include sodium manganese-rich layered oxides (with the formula NaM1-yMyO2; y ≤ 0.33, M is one or more transition metals, e.g. Ni, Ti, Fe, etc.), due to their potentially attractive physical, electrochemical, and commercial properties.[2] However, these suffer from Jahn–Teller distortion, which may cause loss of capacity and multiple step plateaux. Nevertheless, doping and substitution have been employed to stabilize the structure and/or increase the average Mn oxidation state – resulting in many new materials with improved performances.[3–5] Critically, it has been shown that even small quantities can affect a significant improvement without sacrificing the advantages of these systems.

Given that many of these first-generation technologies are approaching commercialisation, as highlighted in our prototyping and commercialisation section, it is important to consider which future areas of research will best unlock the potential of SIBs.

Improving the power density and rate capability of Na-ion systems has led to interest in nascent Na-ion hybrid capacitors (a coupled supercapacitor- and faradic-type electrode). We will discuss the topic, including remaining challenges (e.g. initial pre-metalation, safety and cost) and the promising development of low-cost hard carbon and
high-performance intermetallic electrodes.[6,7]

High energy density, by contrast, is being targeted through advances in Na-air and Na-Sulfur (NaS) systems. Recent work has highlighted the great versatility offered by graphene-based aerogels as air-cathodes, thanks to their low density, high electronic conductivity, and adjustable porosity.[8] From this work, we will examine the specific role of this porosity on both cell capacity and efficiency - which has led to the development of a high-performance cathode, and represents a foundation for future Na-O2 cathode design.

The challenges and advances in ambient-temperature sodium-sulfur (Na-S) batteries will also be presented. This system is a safe alternative to commercialized high-temperature Na-S batteries (working at 300-350 °C), offering high theoretical energy density and low cost. Different optimization approaches, such as applying fluorine-containing electrolyte solvents with redox mediator additives or gel polymer electrolytes, will be highlighted.[9,10]

Meanwhile, safety and cyclability (key factors for any energy storage system) are being addressed by the ongoing development of all solid-state systems, and advances in this area will be discussed briefly.

Through this presentation, we hope to highlight the benefits of sodium-based energy storage systems, provide context for the current state-of-art, and provide insights into the future pathways for development.

First Principle Study of the Role of Lattice Dynamics on Ionic Conductivity of Solid-State Sodium Superionic Conductors Hamidreza Seyf, Vilas G. Pol and Partha Mukherjee; Purdue University, United States

All-solid-state batteries have the potential to be safe and more energy dense than traditional rechargeable batteries. This emergent energy-storage technology, however, is still critically limited by the (electro)chemical issues at the solid electrolyte/electrode interface and low ionic conductivity of the solid electrolyte. To accelerate the discovery of new superionic conductors is essential to establish meaningful relations between ionic transport and simple materials descriptors. Recent experimental studies on lithium fast-ion conductor suggested that there exists a correlation between lattice dynamics and ionic transport. It has been shown that in lithium-based fast ion conductor, the lattice softness correlates with low activation energies. Although, such findings highlight new strategies in controlling lattice dynamics to discover new lithium-ion conductors with enhanced conductivity, the universality of such lattice dynamics-based descriptors to understand and potentially control the ionic mobility of other ion conductors such as sodium is not clear. In this work, using an extensive ab initio molecular dynamics simulation based on density functional theory, we examine the applicability of the existing descriptors to a number of NASICON-like (sodium superionic conductors) and demonstrate the links between lattice dynamics and ionic transport in these structures. Finally, the correlation between lattice softness and pre-exponential factor of Na diffusivity, activation energy, and hopping attempt frequency will be obtained.

Pillared Structure Design of MXene with Controlled Interlayer Spacing for High Performance Lithium/Sodium-Ion Storage Jianmin Luo1, Wenkui Zhang2, Xinyong Tao2 and Weyyang Li3; 1Dartmouth College, United States; 2Zhejiang University of Technology, China

Two-dimensional transition metal carbide materials (termed MXenes) have attracted great research interest for
electrochemical energy storage applications. Herein, with inspiration from the unique structure of pillared interlayered clays, our group demonstrated the fabrication of a series of pillar-structured MXene (Sn⁴⁺/S atoms pillared MXene) via a facile liquid-phase alkali metal ion/cationic surfactant pre-pillaring and Sn⁴⁺/S atoms pillaring methods. The interlayer spacing of Ti₃C₂MXene can be precisely controlled to be between 1 and 2.71 nm according to the size of the intercalated pre-pillaring agent (alkali metal ion, cationic surfactants). Because of the pillar effect, the obtained Sn⁴⁺ pillared MXene delivers a remarkable stable capacity of 765 mAh g⁻¹ at 0.1 A g⁻¹ for lithium-ion storage, and the obtained S atoms pillared MXene delivers an improved Na-ion capacity of 550 mAh g⁻¹ at 0.1 A g⁻¹ (=120 mAh g⁻¹ at 15 A g⁻¹, the best MXene-based Na⁺-storage rate performance reported so far), and excellent cycling stability over 5000 cycles at 10 A g⁻¹. We believe this pillared structure design of MXene will provide insight in synthesizing MXene-based nanostructures for high-performance energy storage devices.

Anionic and Cationic Substitution to Control the Properties of Vanadium Fluorophosphates for Na-Ion Batteries Laurence Croguennec¹,²,³, Jacob Olchowka¹,²,³, Hoang Bao Long Nguyen¹,³,⁴, Thibault Broux¹,²,³, Paula Sanz Camacho¹, Carlos E. Alarcon Suesca¹,²,³, Dany Carlier-Larregaray¹,²,³ and Christian Masquelier⁴,²,³; ¹CNRS, University Bordeaux, France; ²RS2E, Réseau Français sur le Stockage Electrochimique de l’Energie, France; ³ALISTORE-ERI European Research Institute, France; ⁴Université de Picardie Jules Verne, France

Optimized carbon-coated Na₃V₂(PO₄)₂F₃ showed exceptional rate and electrochemical cycling capabilities, more than 4000 times at 1 C rate, as demonstrated by performance of the first hard carbon//Na₃V₂(PO₄)₂F₃ 18650 prototypes of 75 Wh kg⁻¹ prepared by our partner CEA.¹ These attractive results, among others, participate to a renewed interest in the field of Na-ion batteries considering vanadium fluorophosphates at the positive electrode. The optimization of their electrochemical performance requires the control of the carbon coating,¹ and the careful tuning of the oxygen and thus vanadyl-type defects’ concentration through a deep understanding and control of the reaction synthesis. Indeed, the competition between the ionic V³⁺=F bond and the covalent V⁴⁺=O bond has a major effect on the structure of the pristine materials, and then on the phase diagram and redox mechanisms involved upon their cycling in batteries.²,³ The influence of the anionic and cationic substitution will be illustrated for series of phases Na₃V₂ₓMₓ(PO₄)₂F₃₋ₓOₓ (M= transition metal) combining mainly Synchrotron X-ray diffraction and spectroscopic studies.²,³

Directional Flow-Aided Sonochemistry Yields Graphene with Tunable Defects to Provide Fundamental Insight on Sodium Metal Plating Behavior David Mitlin; University of Texas at Austin, United States

We report a directional flow-aided sonochemistry (FAS) exfoliation technique that allows for unparalleled control of graphene structural order and chemical uniformity. Depending on the orientation of the shockwave relative to the flow aligned graphite flakes, the resultant bilayer and trilayer graphene is nearly defect free (at-edge sonication graphene "AES-G") or is highly defective (in-plane sonication graphene "IPS-G"). AES-G has a Raman G/D band intensity ratio of 14.3 and an XPS derived O content of 1.3 at.%, while IPS-G has I_G/D of 1.6 and 6.2 at.% O. AES-G and IPS-G are then employed to understand the role of carbon support structure and chemistry in Na metal plating/striping for sodium metal battery (SMB) anodes. The presence graphene defects and oxygen groups is highly deleterious: In a standard carbonate solution (1M NaClO₄, 1:1 EC:DEC, 5vol.%FEC), AES-G gives stable
cycling at 2 mA/cm² with 100% CE (within instrument accuracy), and an area capacity of 1 mAh/cm². Meanwhile IPS-G performs on-par with the baseline Cu support in terms of poor CE, severe mossy metal dendrites, and periodic electrical shorts. We argue that SEI stability is the key for stable cycling, with defects IPS-G being catalytic towards SEI formation. For IPS-G, the SEI layer also shows F-rich "hot spots" due to accelerated decomposition of FEC additive in localized regions.

Highly Performing P/C Composite Anodes for Na-Ion Batteries Eliana Quartarone¹, Emanuele Vigo¹, Tobias Eisemann², Cristina Tealdi¹ and Stefano Passerini²; ¹Univ of Pavia, Italy; ²KIT, Germany

In the last years, black phosphorous has emerged as one of the most studied materials proposed as anode for rechargeable energy storage devices due to the high gravimetric and volumetric energy density, low cost and high availability. The 2D nature of this system makes it particularly intriguing and is the most studied and investigated form among the P allotropes. Two major drawbacks of the use of phosphorus as anode are under investigation. The first is the huge volumetric change due to the reaction P à R₃P (with R = Li, Na, K) that is of the order of 300-500% moving from Li to K. This colossal volume variation is consequence, of the poor cyclability of these electrodes. To overcome this problem, the strategy to develop P/C composites, has been recently explored. The other one is the optimal preparation of BP and relative composite. Black phosphorus is typically prepared by high-energy ball milling starting from the commercially available red phosphorous. However, several combinations of parameters (mainly speed rotation, filling factor, and duration) must be considered to have reproducible syntheses.

Here, we present some recent results on the optimization approach of Black Phosphorus as anode for advanced batteries. Particular attention is devoted to address the role of Carbon on the electrode electrochemical performance.

11:45 AM EN01.06.10
Sodium Induced Structural Changes of Carbon Coated TiO₂ Anatase Nanoparticles—High-Performance Materials for Na-Ion Batteries Giorgia Greco¹, Katherine A. Mazzio¹, Xinwei Dou² and Stefano Passerini²; ¹Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; ²Karlsruhe Institute of Technology, Germany

The most promising candidate to replace lithium-ion batteries (LIB) are the Sodium ones (NIB). This is not only due to sodium abundance but also because of the main principles and cell structure, are very similar to LIB ones. Due to these benefits, SIBs are expected for use in applications related to large-scale energy storage systems and other applications not requiring top-performance.¹,²

The relevant issue that affect the large scale application of those battery systems is the anode material. Graphite and silicon, largely used in LIB, doesn’t show great performances in NIB.³,⁴ Hard carbon looks very promising because of capacity, the abundance and cost⁵, but suffer of instability in particular at long term.

In this work we propose a carbon-coated TiO₂ that looks very promising in term of capability, abundance, low-cost, and most importantly, shows high stability during cycling.⁶

In this work we show a comprehensive structural characterization study that combine XRD and XANES and EXAFS techniques in order to have a complete electronical and structural overview of the modifications induced by sodiation and desodiation. This work also demonstrates for the first time a coherent explanation of the structural changes observed, where an electrochemical induced short-range ordering is revealed upon cycling.

SESSION EN01.07: Zn Ion Battery

(More) Uniformly Reacting Electrodes Simplify Cell Engineering—The Case for Architectural Design Debra R. Rolison¹, Brandon J. Hopkins¹, Jesse S. Ko¹, Megan Sassin¹, Christopher Chervin¹, Joseph Parker¹, Jeffrey W. Long¹, Samuel W. Kimmel²⁻¹ and Christopher P. Rhodes²; ¹U.S. Naval Research Laboratory, United States; ²Texas State University, United States

Electrochemists understand that one electrode reacting in a more uniform manner allows more uniform reactivity at the countering electrode — unless that opposing electrode suffers from poor electrode kinetics or poor conductivity. This reactivity/conductivity mismatch under stress, such as deep depths of discharge or hundreds-to-thousands of charge–discharge cycles, is all too common between the positive and negative electrodes in batteries. Bringing an architectural perspective to the multifunctionality of energy-storing electrodes ensures wiring the critical per second reactions (electron transport, ion transport, and molecular transport) throughout the volume of the re-designed electrode, which concomitantly distributes the reacting surfaces in 3D, parcels out the imposed global current density to those surfaces rather than to a cross-sectional area, thereby lowering the local current density [1]. This concept will be explored with three case studies. The first two are enabled by zinc sponge anodes, which retain a metallic core that persists in 3D for direct wiring to the current collector even to >90% utilization of the metal [2,3]. When Zn sponges are cycled in alkaline electrolytes versus highly conductive silver oxide cathodes, high cycle life is obtained, even without relying on the cell engineering of additives and separator design typically required to thwart silver colloids spalling off during cycling [3]. When Zn sponges are cycled at high rate and to deep DOD in alkaline electrolytes versus harvested nickel hydroxide cathodes with the far lower conductivity and slower heterogeneous redox rates characteristic of NiOOH, 100% theoretical coulombic efficiency fades after 50+ cycles that can be immediately reversed by replacing the nickel electrode. We are thus currently redesigning the nickel cathode to develop better wiring to match the high performance of the monolithic zinc architecture. In the third case, we demonstrate that in neutral aqueous electrolytes of zinc sulfate and sodium sulfate, the discharge reaction at MnO$_x$ powder-composite cathodes can be transformed to hybrid capacitor+battery performance by using cathodes comprising nanoscale MnO$_x$–painted carbon nanofoam paper [4].

2:00 PM EN01.07.02
Reformulating Zinc-Sponge Battery Electrodes for Large-Format Applications Brandon J. Hopkins, Megan Sassin, Christopher Chervin, Joseph Parker, Jeffrey W. Long and Debra R. Rolison; U.S. Naval Research Laboratory, United States

Rechargeable zinc (Zn) batteries are safe, sustainable, and energy-dense alternatives to Li-ion batteries. Recent advances, such as monolithic Zn-sponge electrodes, have enabled long cycle lives by suppressing the formation of short-circuiting dendrites even after deep levels of discharge and charge. A substantial barrier to their widespread use has been the difficulty of manufacturing large-format electrodes for high-power applications. Here, we describe the development of scalable, multi-scale manufacturing methods to increase the mass production of zinc sponge electrodes, demonstrated through the fabrication and evaluation of electrodes in large-format cells. The potential of these electrodes for large-format zinc batteries is assessed through ex-situ and in-situ electrochemical characterization.
adoption in large-format applications has been their insufficient mechanical integrity when scaled beyond 1 cm². While most approaches to fortify these electrodes involve adding supportive inactive materials, we enhance electrode strength by tuning the zinc architecture via electrode-emulsion and heat-treatment modifications that also increase energy density and obviate lengthy processing steps. This reformulation achieves an electrode tensile strength that maps to large-format electrode sizes while maintaining a rechargeable capacity and retaining high energy density when paired with a nickel electrode. This advance in scalability provides an opportunity for applications that require large electrodes such as batteries for grid-storage, personal electronics, and electric vehicles.

2:15 PM EN01.07.03
The Dynamic Behavior of the Discharge Product in Zinc-Alkaline Batteries
Brendan E. Hawkins, Damon Turney, Ankur Jadhav, Gautam Yadav, Robert Messinger and Sanjoy Banerjee; The City College of New York, United States

Rechargeable zinc-alkaline batteries are attractive candidates for stationary energy storage applications because of their high energy density, low cost, inherent safety, and environmental friendliness. However, widespread commercialization of these batteries has been prevented, in part, by the low cyclability of the zinc metal electrode. One reason for the limited cyclability is the accumulation of discharge product in the electrode resulting in passivation and loss of active material. In historical literature, various types of discharge species have been identified, and the discharge product has been treated as an inert species that simply occupies space and blocks ion transport to the active material. In this work, we demonstrate that the discharge product, zinc oxide, undergoes dynamic chemical changes as a function of electrode potential, which affect properties such as the color, composition, and conductivity of the electrode. The dynamic properties of the zinc discharge product must be considered when developing new architecture and additives for rechargeable zinc electrodes.

In this study, we used a combination of in operando and ex situ techniques to investigate the chemical structure of the discharge product in zinc-alkaline electrodes. Namely, in operando Raman spectroscopy was used to demonstrate that the vibrational modes of the discharge product change as a function of voltage, indicating a change in the composition or structure of the discharge product. Simultaneous optical microscopy revealed an accompanying color change in the discharge product as a function of voltage. Subsequently, quantitative ex situ solid-state ¹H and ⁷Li magic-angle spinning (MAS) NMR spectroscopy were used to observe local environments and dynamics of cations in the crystal structure of the discharge product. Our observations suggest that the zinc oxide discharge product in zinc-alkaline batteries is electrochemically active, and that the properties of the material have a dependence on electrode voltage. This talk will summarize the effects of voltage on the discharge product and demonstrate the importance of considering the dynamic behavior of the discharge product when developing future rechargeable zinc electrodes.

Recent Advances in Rechargeable Zinc Manganese Dioxide Batteries for Grid Applications
Sanjoy Banerjee; City College of New York, United States

Zinc (Zn) anodes and manganese dioxide (MnO₂) cathodes are the electroactive components of alkaline cells which have dominated the market for single discharge disposable batteries for decades. They have high energy density, low cost, and outstanding safety and environmental characteristics. Transforming this non-rechargeable technology into a rechargeable system has the potential to provide very low-cost, safe and environmentally benign solutions for grid-scale energy storage. However, poor charge-discharge reversibility, especially of the MnO₂ cathode at high depths of discharge (DOD), has limited application of this otherwise very attractive technology.

Recent breakthroughs in obtaining excellent rechargeability of high DOD Zn anodes and MnO₂ cathodes achieved at the City University of New York Energy Institute (CUNY-EI) in partnership with Urban Electric Power, Inc. (UEP) will be reviewed. These developments, which received the 2019 ACS/EPA Green Chemistry Challenge Award, are now being commercialized to realize cell costs in the $40/kWh range. In this talk, the challenges in developing and manufacturing products based on such breakthroughs, e.g., into grid-scale rechargeable Zn/MnO₂ batteries for energy storage, will be discussed.

4:00 PM EN01.07.05
High Energy Density Zn-Ni Aqueous Semi-Solid Flow Battery for Grid Scale Energy Storage Thaneer Malai M. Narayanan1, Yun Guang Zhu1, Michal Tulodziecki1, Hernan Sanchez2, Quinn Horn2, Gareth McKinley1 and Yang Shao-Horn1; 1Massachusetts Institute of Technology, United States; 2Exponent, Inc, United States

Grid scale energy storage requires high energy density, low-cost and safe systems. Semi-solid flow battery is attractive to achieve these objectives as its energy density not limited by the active species solubility, and also enables usage of wide range of cheap and safe solid active material and aqueous electrolyte. In this study, we have designed high energy density suspensions for Zn-Ni alkaline semi-solid flow battery. Firstly, stability of the suspension was ensured by suspending the solid particles in polymer and 7 M KOH electrolyte matrix. Then, effect of conductive additive concentration on the electrochemical performance of the suspension was studied in a static cell. By selecting suitable concentration of conductive additive (14 w% of carbon black), we were able to achieve high energy density semi-solid battery (134 Wh/L catholyte, ~3 times of VRFB). Rheological study of these suspensions showed they have yield stress about ~200 Pa. As they don’t require high flow rate and narrow channels as VRFB, we found that the pumping loss in the flow channels for these suspensions is negligible (<1% w.r.t. energy output). Finally, scalability of this Zn-Ni semi-solid flow battery is tested in a 3-D printed flow cell.

4:15 PM *EN01.07.06
Water-in-Salt Electrolyte Li-Ion Batteries Chunsheng Wang; University of Maryland, United States

Water-in-salt electrolytes have considerably expanded the electrochemical window of the electrolytes to 3 to 4 volts, making it possible to couple many high capacity anodes and high-voltage cathodes for Li-ion, Na-ion and Zn batteries. Since the water is strongly bonded to the salts, the low water activity in electrolytes allows the cell to be open to the air and operate in a wide temperature range. The high oxidation stability window also enables a halogen conversion–intercalation chemistry in graphite that produces composite electrodes with a capacity of 243 milliampere-hours per gram (for the total weight of the electrode) at an average potential of 4.2 volts versus Li/Li+.

4:45 PM EN01.07.07
Materials and Performance of Metal Hydride/Air Battery for Stationary Energy Storage System Masatsugu Morimitsu; Doshisha University, Japan

A metal hydride/air battery (HAB) is an aqueous secondary battery consisting of a hydrogen storage alloy electrode, an air electrode, and an alkaline solution, of which the discharge reaction is water generation and the charge one is water decomposition. This unique system brings out the potential of air batteries which are no limitation on discharge capacity of the positive electrode unnecessary to storage the active mass, resulting in higher power density and energy density than the other types of secondary batteries. It is of importance that the discharge product is water, not solid, so that the plugging of the air electrode during discharge by solid products like lithium oxide in lithium/air batteries never occurs. The materials of HAB are further important in viewpoint of safety, because they are all non-flammable and are easily handled in air. Therefore, HAB is one of the promising candidates for next generation energy storage devices, which need that high performance and high safety should be compatible. Our project on the HAB development has been financially supported by Japan Science and Technology Agency (JST) from 2012 under the collaboration of two universities and three companies, in which the air electrode with bi-functional oxygen catalyst, the negative electrode using high capacity density of hydrogen storage alloy, and the cell design and configuration have been developed and modified. This paper presents the materials and performance of HAB including the preparation, characteristics, and activities of novel oxygen catalysts and the cell performance on energy density over 900 Wh/L and cycling behaviors of 500 cycles or more. A future plain for the application of HAB to stationary energy storage systems, which has been just started under Low Carbon Technology Research and Development Program by Ministry of the Environment (MOE), Japan, will be also indicated.
Large-scale energy storage is of significance to the integration of renewable energy into electric grid. Despite the dominance of pumped hydroelectricity in the market of grid energy storage, it is limited by the suitable site selection and footprint impact. Rechargeable batteries show increasing interests in the large-scale energy storage; however, the challenging requirement of low-cost materials with long cycle and calendar life restricts most battery chemistries for use in the grid storage. Recently we introduced a concept of manganese-hydrogen battery with Mn$^{2+}$/MnO$_2$ redox cathode paired with H$^+/H_2$ gas anode, which has a long life of 10,000 cycles and with potential for grid energy storage. We later expand this concept by replacing Mn$^{2+}$/MnO$_2$ redox with a nickel-based cathode, which enables $\sim 10\times$ higher areal capacity loading, reaching $\sim 35$ mAh cm$^{-2}$. We also replace high-cost Pt catalyst on the anode with a low-cost, bifunctional nickel molybdenum cobalt alloy, which could effectively catalyze hydrogen evolution and oxidation reactions in alkaline electrolyte. Such a nickel-hydrogen battery exhibits an energy density of $\sim 140$ Wh kg$^{-1}$ and estimated energy cost of $\sim$83 per kilowatt-hour and excellent rechargeability with negligible capacity decay over 1,500 cycles. The excellent stability and the low cost of the rechargeable hydrogen batteries demonstrate attractive characteristics for large-scale energy storage.

Synthetic cost and long-term stability remain two of the most challenging barriers for the development of aqueous organic redox flow batteries for grid scale energy storage. In this work, we present a new method for synthesizing water-soluble anthraquinones from inexpensive starting materials. Two anthraquinones have been synthesized by the method at the time this abstract is being submitted. Both of them show remarkable chemical stability of both oxidized and reduced forms: no chemical decomposition at high temperature for two weeks. When paired with a Ferro/ferrycyanide posolyte, a full cell of 1 V is achieved, exhibiting a capacity fade rate of around 0.02% per day, which is among the most stable redox-active molecules reported. One of these species has a solubility of 1 M, corresponding to 53.2 Ah/L, at pH 12. This method may be extended to the synthesis of other redox-active aromatics.

The redox-flow battery has gained increased attention as an alternative to Li-ion batteries for grid-scale energy storage. While a number of flow battery chemistries have been developed and are undergoing commercialization, none satisfy the full set of requirements necessary for wide-scale deployment. For instance, the vanadium redox flow battery has impressive performance metrics, but is prone to fluctuating costs which are currently prohibitively high. Redox-active organics have recently emerged as promising alternatives to existing flow battery chemistries. These systems offer a level of tunability not available with transition-metal-based systems. A number of redox-active core structures have been reported and for each core structure selective functionalization can modulate the solubility, ionic charge, redox-potential, and a number of other properties, providing nearly endless possibilities for molecular design. Presented will be our recent work on phenazine-based anolytes, which yield cell voltages of over 1 V when coupled with ferrocyanide and can achieve solubilities up to 1.8 M. The effect of various molecular design approaches on solubility, redox potential, and stability will be discussed.
After years of silence, redox-active organic compounds are re-emerging in the energy storage community bringing with them interesting opportunities such as design flexibility and lightweight. Moreover, thanks to the use of abundant chemical elements, organic chemistry provides great opportunities for discovering innovative electrode materials, which could be prepared (i) from renewable resources (biomass) and (ii) via eco-efficient processes, making the concept of greener and sustainable batteries possible [1]. They can also integrate a wide variety of electrochemical device architectures operating both in aqueous or non-aqueous electrolytes. Interestingly, the past decade has seen significant progress in the design of new organic compounds and today a myriad of promising electroactive organic materials have been investigated [2]. In addition, very promising data are now also reported in redox flow cell configuration [3]. Some of them exhibit attractive electrochemical behaviors such as long-term cycling stability and high-rate capability. In addition, they offer different electrochemical activities including the common reversible cation uptake/release as well as access to anion-inserting process bringing to us another playground in designing organic electrochemical storage systems including the development, in principle, of molecular ion batteries [4]. However, several improvements are needed to further promote organic electrode materials especially in terms of energy density values and only few studies have been reported in the literature regarding the assembly of full organic cells.

This contribution aims at reporting recent electrochemical data obtained with crystallized organic materials [5] and explaining how it is possible to tune the electrochemical activity of redox-active organic moieties depending on the molecular assembly and its electrostatic environment. We hope that such findings can pave the way for designing novel chemistries for rechargeable batteries.

The Development of Diels Alder Poly(Phenylene) Membranes for Electrochemical Applications  
Cy Fujimoto; Sandia National Laboratories, United States

With significant growth in the clean energy sector (wind and solar), the search for an energy storage medium which is safe, durable and economical is at an all-time high and a variety of electrochemical systems are being evaluated; multiple flow batteries chemistries and electrochemical hydrogen production (electrolysis). The efficiencies, lifetimes and costs of these electrochemical systems are tied to the membrane separator; however, commercially available membranes do not meet all the requirements. At Sandia National Laboratories, we have been developing both anion and cation exchange Diels Alder poly(phenylene) membranes as electrochemical separators. Since these materials are hydrocarbons they are excellent low-cost alternatives to perfluorinated materials, and since the polymer backbone consists of only aromatic benzene units it offers high chemical and thermal stability. For example, as most electrochemical systems operate in either an acid or alkaline environment to enhance the electrolyte conductivity and widen the operation voltage window, the membrane separator needs to be inert in these conditions. However, it has been found that hydrocarbon polymers that contain heteroatoms in the polymer backbone are attacked in alkaline environment (polymer degradation), while all aromatic DAPP is stable in alkaline environments, even at high temperatures. This presentation will discuss the development and synthesis of various cation and anion exchange materials employing the DAPP backbone, and its performance in a variety of electrochemical applications.

10:45 AM EN01.08.06
Charge and Mass Transfer Enhanced Electrode for High-Performance Aqueous Flow Batteries  
Hongli Zhu; Northeastern University, United States

The scalability for an efficient process to fabricate electrodes with enhanced charge and mass transfer is still a
challenge for flow batteries. For the first time, this work introduces a scalable and effective surface modification method of graphite felt (GF) electrode based on the controlled electrochemical exfoliation to enhance the mass and charge transfer of the electrode. Exfoliation of the GF was conducted in ammonium sulfate ((NH₄)₂SO₄) aqueous solution by breaking the weak van der Waals forces between the graphitic layers. This reaction occurred through anion intercalation and subsequent gas evolutions, causing expansion of the graphite layers at room temperature for 1 min. Consequently, the exfoliation incorporated sufficient oxygen functional groups that increase the active surface area, resulting in enhanced reaction kinetics at the electrode-electrolyte interface and improved hydrophilicity enabling better electrolyte accessibility. The Brunauer-Emmett-Teller (BET) results verified that the specific surface area of E-GF is 1.19 m² g⁻¹, which is two times larger than that of the pristine graphite felt (0.55 m² g⁻¹). Further, spin-polarized density functional theory was also employed to reveal the role of introduced oxygen functional groups in accelerating the vanadium redox reaction. Benefitting from the sufficient oxygen groups and superior wettability, the as-prepared exfoliated GF (E-GF) shows brilliant electrocatalytic activity with minimized overpotential, higher volumetric capacity, and improved energy efficiency. Finally, the RFB assembled with the E-GF electrode delivered voltage and energy efficiencies of ~ 90 and 86 % at the current density of 100 mA cm⁻², respectively. Remarkably, compared to the traditional GF treatment method, the elimination of the high-temperature, energy consuming, and longtime treatment processes make this approach much more energy and time efficient, scalable, and affordable.

A Special TEM Li-Ion Battery Sample Preparation and Application on Investigation of the SEI Layer Nano Structural Property in Lithium Rechargeable Battery Xiang-Yun Song; Lawrence Berkeley National Lab, United States

Due to complex component and sensitive to the air and water of the lithium rechargeable battery, how to prepare a practical useful TEM (transmission electron microscopy) specimen from Li-ion cell has been critical to the TEM application in new generation batteries. We have developed an efficient way to prepare a TEM specimen from lithium ion cells that prevents electrode material contamination and chemical reaction from water or air and damage from mechanical stress.

By using our special technique for TEM specimen preparation the nano structural properties of SEI (solid-electrolyte-interphase) layer in Li(NiMnCo)O₂/graphite cell have been investigated. The MnF₂ nano-crystalline tetragonal structure in SEI layer was found and identified by HRTEM and EELS (electron energy loss spectrum). Furthermore, the morphology of MnF₂ nano-grains, its nucleation, distribution and SEI layer thickness were studied.

By using our special technique for TEM specimen preparation LiNi₀.₅Mn₁.₅O₄ cathode material has also been studied on the battery failure mechanism, which will be reported in other project.

11:15 AM EN01.08.08
Energy Dense Materials for Redox Flow Battery Applications James A. Suttil, Sharmila Samaroo, Neal McDaniel and Chris LaFrancois; Phillips 66, United States

Redox flow batteries (RFBs) offer a number of advantages over current stationary energy storage technologies, such as the decoupling of power & energy and inherently safer designs. However, the energy density of commercially deployed RFB electrolytes is relatively low when contrasted with competing technologies, for example Li-ion battery installations. A significant amount of research has attempted to increase the energy density of the electrolyte by 1) employing non-aqueous electrolytes to improve voltage separation between redox events, 2) increasing the number of electrons transferred between half-cells by employing electroactive species with multiple redox couples, 3) increasing the concentration of the electrolyte by preparing highly soluble or liquid state redox active molecules, or 4) a combination of the previous three modifications. This talk will highlight Phillips 66 investigation of single component iron-based ionic liquids that may satisfy all roles of an energy dense RFB electrolyte: namely the solvent, supporting electrolyte, and redox active species. This presentation will cover the preparation, characterization, and electrochemical testing of the aforementioned energy dense materials.

11:30 AM *EN01.08.09
Ionic Liquid Electrolytes for New Energy Storage Technologies—Towards High Rate and High Efficiency Cycling Robert Kerr, Kalani Periyapperuma, Thushan Pathirana, Mojtaba Eftekharinia, Maria Forsyth and Patrick

Final Program 1/13/2020 360
Howlett; Deakin University, Australia

The device performance characteristics of electrochemical energy storage (EES) technologies makes them suited to a broad range of applications spanning portable electronics and vehicle propulsion all the way to small-scale grid stabilization and remote power backup. With lithium-ion batteries (LIBs) currently the dominant chemistry in the market across all applications, there are now many opportunities to displace LIBs with new and emerging EES technologies that may be better suited to the particular device requirements or operating environment. The choice of electrolyte is one variable that can significantly alter the performance characteristics and desired operating environment of a given technology. Ionic liquids are an intriguing candidate to displace traditional electrolyte solvents owing to a number of favorable physicochemical and electrochemical properties, including thermal and electrochemical stability.

Recent work from within the group into the incorporation of ionic liquid electrolytes (ILEs) into three distinct battery types, namely lithium metal-based, sodium metal-based, and lithium anode redox flow, will be presented here. Investigations into the fundamental electrolyte properties, cycled electrode surface characterisations and device performance aspects have revealed a number of features which make ILEs a surprisingly attractive commercial prospect. The highlights of these features are the ability of ILEs to support high rate Li deposition (20 mA/cm²) through control of the Li nucleation process, and the ability to cycle Li metal with an average Coulombic efficiency of 99.0% over the first 100 cycles in a Cu|LFP configuration using a physical substrate modification approach. An understanding into these behaviors has been developed by considering the transport mechanisms in these electrolytes and the composition of the electrode surface deposits.

In an effort to bring ILEs into an industrially-relevant focus, device prototyping has been conducted at Deakin University’s Battery Technology Research and Innovation Hub (BatTRI-Hub). Here, we have demonstrated the capability of ILEs to enable high energy density pouch cell cycling in prototype devices capable of achieving a specific energy of 400 Wh/kg. Separator design has been identified as a primary factor which limits the cell cycle life and operational temperature range. Some of the key prototyping results will be presented and the implications for commercial application discussed.

Stabilization of Li Anode for High-Energy-Density Li-Metal Batteries Donghai Wang: The Pennsylvania State University, United States

Li metal and Li-alloy based anode materials are the most promising anodes for next-generation Li batteries. The poor interfacial stability (unstable solid-electrolyte interphase (SEI)) in the battery and microstructural failure of Li metal into mossy or dendritic Li during its plating/stripping have been two primary issues hindering their practical application. In this talk, first, I will present a strategy to reinforce the SEI with desired properties including good tolerance to the Li-based material volume change and efficient surface passivation against electrolyte penetration. The strategy works via introducing multiple functional components bonded to the Li-based material surface into the SEI. The SEI reinforced shows much better stability than the SEI reinforced by electrolyte additive strategy, which is the current state-of-art and commercially used solution to SEI stability issue. Second, I will present an approach of structured host for Li metal to promoting uniform Li plating/stripping at high deposition capacity and current density. This approach uses a polymeric sponge with high zeta potential to promote electrokinetic effects so as to alter Li-ion transport properties and reduce concentration polarization for Li plating/striping. High efficiency cycling of Li metal was achieved and demonstrated in Li metal battery cells at low N/P ratio and high deposition capacity and current densities.

Design Principles for Self-Forming Interfaces Enabling Stable Lithium-Metal Anodes Linsen Li1,2, Yingying Zhu2, Vikram Pande3, Venkatasubramanian Viswanathan2 and Yet-Ming Chiang1; 1Massachusetts Institute of Technology, United States; 2Shanghai Jiao Tong University, China; 3Carnegie Mellon University, United States

The path toward Li-ion batteries with higher energy-densities will likely involve use of thin lithium metal (Li) anode (<50 mm thickness), whose cyclability today remains limited by dendrite formation and low Coulombic efficiency (CE). Previous studies have shown that the solid-electrolyte-interface (SEI) of the Li metal plays a crucial role in Li electrodeposition and stripping behavior. However, design rules for optimal SEIs on Li metal are not well established. Here, using integrated experimental and modeling studies on a series of structurally-similar SEI-modifying model compounds, we reveal the relationship between SEI compositions, Li deposition morphology and CE, and identify two key descriptors (ionicity and compactness) for high-performance SEIs. Using this understanding, we design a highly ionic and compact SEI that shows excellent cycling performance in high specific energy LiCoO2 or NCA-Li full cells (1.3 Ah pouch cells, > 300 Wh/kg) at practical current densities. Our results provide guidance for rational design of the SEI to further improve Li metal anodes.

8:45 AM EN02.01.03
In Situ Magnetic Resonance Spectroscopy and Imaging of Li-Plating onto and Diffusion within Anodes of Li-Ion Batteries Sergey Krachkovskiy1, Kevin J. Sanders1, Andres Ramirez Aguilera2, Bruce Balcom2 and Gillian R. Goward1; 1McMaster University, Canada; 2University of New Brunswick, Canada

Li-ion batteries are nowadays considered as the main source of energy for an electric vehicle (EV) application; however, the significantly longer “refueling” time compared to standard internal combustion engine vehicles is a substantial disadvantage from the perspective of the end-user. It is speculated that increasing the charging rate by a factor of three should significantly reduce the gap between EVs and conventional automobiles, promoting further penetration of EVs on the mass market. However, a significant drawback of very rapid charging is lithium plating on the negative electrode, which arises if the current exceeds the intercalation rate at which lithium diffuses into the negative electrode. In this case, a film of metallic Li will deposit on the surface, which subsequently reacts with electrolyte, leading to an increase of the cell internal resistance, a lower capacity, and potential short-circuiting in extreme cases.

Here we report an application of the parallel-plate RF probe to monitor in situ deposition of Li metal on a graphite anode during charging of a single layer prismatic cell, assembled with electrodes extracted from a commercial
battery. We have demonstrated that part of the plated lithium was able to intercalate into the graphite after the
current was turned off. Moreover, the signal of deposited Li metal consists of two resonances corresponding to (1) a
“Li film” on the surface of the electrode, and (2) to dendrites orthogonal to electrodes’ planes. Our data demonstrate
that the Li metal intercalation into the graphite is primarily happening from the former type of deposited metal,
while the lithium stored in dendrites can partially dissolve into the electrolyte during the consecutive discharge of
the cell. Importantly, we were able to quantify the amount of reversibly and irreversibly deposited lithium. Finally, a
coexistence of three stages of intercalated into graphite Li (2L, 2 and 1) is demonstrated during a fast charge cycle,
suggesting a non-uniform lithiation of the electrode in that case.

Li, Si and LiSiOy Thin Films as Model Systems for Silicon Anodes in Li-Ion Batteries
Yun Xu1, Jaclyn Coyle2, Kevin N. Wood1, Eric Sivonxay3, Glenn Teeter1, Conrad Stold1, Sang-Don Han1, Kristin A. Persson3, Anthony
Burrell1 and Andriy Zakutayev4; 1National Renewable Energy Laboratory, United States; 2University of Colorado
Boulder, United States; 3Lawrence Berkeley National Laboratory, United States

Silicon is one of the most promising materials for high energy density anodes in next generation Li-ion batteries.
However, the long-term performance of Si anodes is currently limited due to large volumetric expansion and
contraction upon lithiation and delithiation, as well as continuous solid electrolyte interface (SEI) formation.
Understanding of this SEI is difficult due to its buried nature, rough sample morphology, as well as convolution of
chemical and electrochemical formation processes. Another important aspect of the SEI formation that needs better
understanding is the presence of native oxide SiOx at the Si surfaces exposed to ambient atmosphere.
Here, we report on our recent studies of lithium silicide (LixSi) and lithium silicate (LixSiOy) thin films, as model
systems to study SEI formation on Si anode with SiOx native oxide in Li-ion batteries. The LixSi and LixSiOy thin
films were deposited by combination of sputtering and thermal evaporation, on both Si and Cu foil substrates. The
resulting samples were studies by a combination of electrochemical (charge-discharge profiles, impedance
spectroscopy, etc), spectroscopic (x-ray photoemission spectroscopy XPS, Fourier-Transform Infrared Spectroscopy
FTIR) techniques, with high accuracy enabled by flat homogeneous character of the thin film model samples.
The results of our studies indicate that the SEI can be formed simply by chemical reduction of electrolyte on lithium
silicide surfaces, without any electrochemical driving force [1]. They also suggest that it may be possible to increase
the lifetime of the next-generation Li-ion batteries using prelithiated Si anodes. On the other hand, it is determined
that LixSiOy is not beneficial in stabilizing the Si anode surface during battery operation, due to large electronic
conductivity, and despite its ductile mechanical properties [2]. These results also suggest future directions for design
of artificial SEI layer coatings on Si anode surfaces.

Lithium-Ion Conductivity of Epitaxial Li4Ti5O12 vs State of Charge
Francesco Pagani and Corsin Battaglia; Empa—Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Using an epitaxial thin-film model system deposited by physical vapor deposition, we study the lithium-ion
conductivity of Li4Ti5O12, a common anode material for Li-ion batteries, in the absence of grain boundaries [1].
Epitaxy, phase purity, and composition across the film thickness are verified employing out-of-plane and in-plane
X-ray diffraction, transmission electron microscopy, time-of-flight mass spectrometry, and elastic recoil detection
analysis. We find that epitaxial Li4Ti5O12 grown on a single-crystal MgO(111) surface behaves like an ideal ionic
conductor that is well described by a parallel RC equivalent circuit, with an ionic conductivity of 2.5 × 10–5 S/cm at
230 °C and an activation energy of 0.79 eV in the measured temperature range of 205 to 350 °C [1]. To study
lithium-ion conductivity as a function of state of charge, epitaxial Li4Ti5O12 was also grown on an epitaxial Pt(111)
surface functioning as current collector [2]. Epitaxial Li4Ti5O12 was subsequently cycled galvanostatically in half-
cell configuration vs lithium metal in 1m LiPF6 in EC:DMC organic electrolyte. We find that epitaxial Li4Ti5O12
shows stable cycling at least up to 50 C. We also study lithium-ion conductivity and lithium-ion diffusion as function of state of charge by impedance spectroscopy and galvanostatic intermittent titration technique and interpret our results in the theoretical framework developed for phase-transformation materials [3].

9:30 AM EN02.01.06
Pristine or Highly Defective? Understanding the Role of Graphene Structure for Stable Lithium-Metal Plating David Mitlin; University of Texas at Austin, United States

Abstract: We are the first to examine the role of graphene host structure/chemistry in plating-stripping in lithium metal anodes employed for lithium metal batteries (LMBs). Structural and chemical defects are bad since highly defective graphene promotes unstable solid electrolyte interphase (SEI) growth. This consumes the FEC additive in the carbonate electrolyte and is correlated with rapid decay in CE and formation of filament-like Li dendrites. A unique flow-aided sonication exfoliation method is employed to synthesize "defect-free" graphene (df-G), allowing for a direct performance comparison with conventional reduced graphene oxide (r-GO). At cycle 1, the r-GO is better electrochemically wetted by Li than df-G, indicating that initially it is more lithiophilic. With cycling, the nucleation overpotential with r-GO becomes higher than with df-G, indicating less facile plating reactions. The df-G yields state-of-the-art electrochemical performance; stable plating at 0.5 - 4 mA/cm², areal capacity up to 2 mAh/cm², cycle 1 CE at 98% and cycle 100 CE at 94%. With df-G the post cycled metal surface is relatively smooth and dendrite-free. Conversely, r-GO templates have CE rapidly degrade from the onset, with extensive dendrites after cycling. Extensive SEI growth and associated FEC depletion with r-GO are further confirmed by electrochemical impedance analysis and surface science methods (XPS). We therefore propose the following design rule for next-generation supports for LMBs: An ideal architecture will promote copious heterogenous nucleation of the plating metal, shielding it from the electrolyte. In addition, it is essential that the host is itself non-catalytic towards SEI formation.

9:45 AM BREAK

SESSION EN02.02: Advances in Cathodes I
Session Chair: David Scanlon
Monday Morning, December 2, 2019

10:15 AM *EN02.02.01
High Capacity Cathodes Invoking Oxygen Redox Chemistry Peter Bruce; University of Oxford, United Kingdom

The lithium-rich transition metal oxides, e.g. Li[Li0.2Ni0.2Mn0.6]O2 can store charge on the oxide as well as the transition metal ions (oxygen redox). However, oxygen redox in these systems is almost always accompanied by substantial structural change and voltage hysteresis, limiting their application. Understanding the relationship between the oxidation of O²⁻ ions and the deleterious changes that are triggered by such oxidation is essential if we are to develop strategies for their mitigation and therefore unlock the high capacity of O-redox materials. Recent work on the relationship will be discussed.

10:45 AM EN02.02.02
Anomalous Segregation in Lithium-Rich Layered Oxide Uncovers New Theoretical Design Rule for Stable
Cathode in Lithium-Ion Battery

Here we report the TEM, X-ray, and first-principle investigation of a promising high-capacity lithium-rich 3d-4d (Mn-Ru) transition-metal layered compound. The incorporation of 4d transition metals here offers an uncharted phase space for mechanistic exploration as compared to the well documented 3d transition metal (TM) oxides. Using state-of-the-art electron and X-ray based techniques, we find surprisingly, after cycling, ruthenium segregates out as metallic nanoclusters on the reconstructed surface. Our calculations show that the unexpected ruthenium metal segregation is due to its thermodynamic insolubility in the oxygen deprived surface. This insolubility can disrupt the reconstructed surface, which explains the formation of a porous structure in this material. The revealed mechanism allows us to provide predictive guidance for the future design of lithium-rich as well as stoichiometric layered cathode materials.

This research used resources of the Center for Functional Nanomaterials, which is a U.S. DOE Office of Science Facility, and the Scientific Data and Computing Center, a component of the Computational Science Initiative, at Brookhaven National Laboratory under Contract No. DE-SC0012704. Mitigating Oxygen-Redox-Related Side Reactions in Disordered Rocksalt Li-Excess Cathode Materials for Li-Ion Batteries

There is an imperative need for resource-friendly and high-energy-density cathode materials for Li-ion batteries to satisfy the rapidly increasing need for electrical energy storage. To replace the Ni and Co, which are limited resources and are associated with safety problems in current Li-ion batteries, high-capacity cathodes made of earth-abundant and safer metals have been intensively sought after by battery scientists [1]. In this regard, disordered-rocksalt lithium transition metal oxides (Li-TM oxides) have received much attention as the cathode materials for abundant and safer metals have been intensively sought after by battery scientists [1]. In this regard, disordered-rocksalt lithium transition metal oxides (Li-TM oxides) have received much attention. To operate the disordered rocksalt cathodes, so-called ‘Li-excess’ (i.e., TM-deficient) composition (x>1.0 in Li$_x$TM$_{1-x}$O$_2$, e.g., Li$_{1.2}$TM$_{0.8}$O$_2$) is required, because otherwise, Li diffusion in the materials is very slow [2]. Meanwhile, the decreased TM-content due to ‘Li-excess’ often results in a limited amount of extractible electrons from TM-redox in the materials, for which a large number of electrons from oxygen (O-redox) are often additionally needed upon cycling [7]. Unfortunately, excessive O-redox activity triggers various O-redox-related side reactions, including (i) oxygen loss followed by metal densification and (ii) bulk crystal structure changes, all of which degrade the cycling performance of the disordered rocksalt cathodes [4,6]. Therefore, strategies to bypass the O-redox-related side reactions while maintaining the integrity of the disordered-rocksalt Li-excess framework should be highly important for the improvement of the disordered-rocksalt cathode materials.

In this talk, based on recent studies of fluorinated disordered-rocksalt compounds such as Li$_{1.15}$Ni$_{0.45}$Ti$_{0.3}$Mo$_{0.1}$O$_{1.85}$F$_{0.15}$, Li$_2$Mn$_{2/3}$Nb$_{1/3}$O$_2$F, and Li$_2$Mn$_{1/2}$Ti$_{1/2}$O$_2$F, I will discuss rational strategies to mitigate the O-redox-related side reactions in the disordered rocksalt cathodes [3,6]. In particular, I will show how the introduction of high valent cations (e.g., Nb$^{5+}$, Ti$^{4+}$, Mo$^{6+}$) and fluorine (F-) anion to the metal- and anion-sites,
respectively, can lead to Mn$^{2+}$/Mn$^{4+}$-redox-based disordered-rocksalt cathodes with ultrahigh capacity and a low cost [3].

11:15 AM EN02.02.04 Automated Computational Search of Anion Redox Li-Ion Battery Composition Space Daniel W. Davies¹, Alexander Squires², Keith Butler¹, David O. Scanlon⁴, Aron Walsh¹ and Benjamin J. Morgan²; ¹Imperial College London, United Kingdom; ²University of Bath, United Kingdom; ³STFC, United Kingdom; ⁴University College London, United Kingdom

The recent discovery of anionic redox chemistry in Li-ion batteries has already had promising implications for improving their capacity via increased electrochemical activity. Higher performance materials are now required to make this technology a reality and new strategies for designing compounds that exhibit this phenomenon are needed. Anionic redox activity requires a balance between the quantities $U$ (d-d coulomb repulsion) and $\Delta$ (charge transfer), which in turn are sensitive to the d-metals present in the crystal structure.[1] We present a computational study in which d-metals are systematically substituted into a range of prototypical cathode crystal structures using materials informatics tools that we have previously applied in the context of solar energy materials.[2,3]

The resulting 250 compounds are subject to an automated density functional theory (DFT) screening workflow, using the open-source python package Atomate. Our workflow facilitates the assessment the thermodynamic stability of the new phases, as well as relating electronic energy levels calculated accurately using hybrid DFT to the key heuristics $U$ and $\Delta$, in order to identify the most promising candidates. Data-driven discovery tools powered by supervised machine learning algorithms, which require large, high quality datasets,[4] are then applied to the calculation results in order to suggest new candidate compounds.

microscopy (cryo-TEM) to observe the morphology and surface chemistry of nanoscale electrochemically deposited lithium at atomistic scale. We have also demonstrated cryogenic focused ion beam (cryo-FIB) to characterize three dimensional and bulk morphology of electrochemically deposited lithium. This work depicts not only the importance of cryo-FIB for preparing sensitive battery materials, but also elucidate the impact of electrolyte and additive selection in the density and morphology of plated lithium, which directly impacts long term cycling performance. We further extend cryo-FIB to process and analyze TEM lamella of lithium metal and lithium metal solid-state batteries. The cryogenic imaging techniques can enable a new paradigm for studying beam sensitive materials and electrochemically activated compounds.

2:00 PM EN02.03.02
Ion Transport In Polyester and Polycarbonate Solid Electrolytes Jonas Mindemark; Uppsala University, Sweden

The traditional host material of choice for Li+-conducting solid polymer electrolytes (SPEs) has long been poly(ethylene oxide) (PEO) and with this material most of what we today know about ion transport in SPEs has been revealed. While PEO is an excellent material for solvating Li+ ions, the chelating ability of the oxyethylene repeating units in this material also result in excessive coordination strength, limiting the ability of the cation to shed its coordination shell and transfer between coordination sites. This ultimately restricts cation transport in this material and manifests as notably low cation transference numbers in PEO-based electrolytes. Hence, substantial interest has recently been raised in alternative host materials that show improvements in, e.g., cation transference number and room temperature ionic conductivity. While materials such as polyesters and polycarbonates eliminate the strong coordination of oxyethylene repeating units, other interesting effects become relevant.

This presentation will account for our recent efforts into understanding ion transport in polyesters, polycarbonates, and copolymers thereof, using a combination of molecular dynamics simulations, NMR spectroscopy, IR spectroscopy, and electrochemical measurements. This has revealed important effects of preferential coordination, competing plasticization and steric hindrance of side chains, and correlation of cation transference number with the ion coordination strength. Of particular interest is also the differences observed when comparing Li+ and Na+ conduction in these materials.

2:15 PM EN02.03.03
High-Voltage All-Solid-State Batteries Based on Ceramic-Sulfide Electrolytes William Fitzhugh and Xin Li; Harvard University, United States

The ceramic-sulfide family of solid-electrolytes are amongst the most promising directions for achieving all-solid-state lithium ion batteries. While the ceramic-sulfides are celebrated for remarkably high ionic conductivity, even exceeding conventional liquid-electrolytes, they remain a narrow electrochemical stability window of approximately 1.7-2.1 volts vs lithium metal based on standard thermodynamic prediction. These electrochemical stability windows further narrow upon forming interfaces with many active materials. This talk will cover new approaches for enabling a largely expanded metastability window for both bulk ceramic-sulfides and interphases with common electrodes. 5V cells based on layered Li-Co-O and spinel Li-Mn-Ni-O will be presented that make use of these metastable widening techniques ceramic-sulfide voltages.

The underlying stabilization methods will be discussed from a detailed theoretical perspective. Ceramic-sulfides are known to undergo significant volume expansion during electrochemical decay. This volume expansion has been shown to be a viable means of substantial voltage widening for lithium ion battery cells [1,2]. The discussed theoretical framework will be used to evaluate experimental evidence of voltage-widening in both of the representative ceramic-sulfides Li10GeP2S12 and Li10SiP2S12.

Discussion on the interphases between ceramic-sulfides and common electrode materials will focus on our recent high-throughput computational work[3], in which over nearly 70,000 materials were evaluated for interfacial
chemical and electrochemical stabilities with Li10SiP2S12. This work cataloged over 2,000 coating materials that were determined to form stable interfaces with Li10SiP2S12 in the cathode voltage range (2-4V). These coating materials, combined with widened bulk electrochemical stability, suggest the path forward for all-solid-state lithium ion batteries based on ceramic-sulfide electrolytes.

2:30 PM *EN02.03.04
Lithionics—On the Design of Lithium Oxide Films for Solid-State Batteries and Novel Neuromorphic Computing Functions Jennifer L. Rupp; Massachusetts Institute of Technology, United States

Next generation of energy storage may largely benefit from fast Li+ ceramic electrolyte conductors to allow for safe and efficient batteries. With recent discoveries in thin film processing solid-state lithium ion conductors, such as Li-garnets and LIPON or LiSICON-based solids, have been recently considered as candidate materials not only for next-generation solid-state batteries but also for gas sensors measuring environmental CO2 and memristors owing to the fast ionic transport in the solid-state electrolyte.

In the first part of this talk, we review and underline the advantages of various Li solid-state conductor materials and reflect on opportunities of thin film processing, being a requirement to define precisely the lithium stoichiometries and related electronic state changes for transition metal ions, miniaturize the device, and reach high energy/information densities for energy storage, computation, and sensing.

In the second part, we focus on thin film processing and controlling Lithium stoichiometries to reach fast conductive phases for Li garnets and Li titanates as solid state battery, and memristive neuromorphic computing units. Insights on structure-phase-transport interaction and implications on performances will be exemplified for energy storage aiming high energy densities, and modulations of synaptic artificial weights through lithium induced metal-to-insulator transitions in lithium titanate memristors.

The Electronic Reasons for Li Dendrite Growth in Solid Electrolytes Yue Qi1, Hong Kang Tian1, Zhe Liu2, Yanzhou Ji1 and Long-Qing Chen2; 1Michigan State University, United States; 2The Pennsylvania State University, United States

The experimental observation of Li dendrite growth inside mechanically hard solid electrolytes (SEs) raised an important question; can hard solid electrolytes mechanically stop Li-dendrite growth? Here we report a multiscale model coupling Density Functional Theory (DFT) calculations with the phase-field method to address the question. In particular, we investigate the roles of internal defects, such as pores and crack surfaces, inside a number of solid electrolytes including cubic Li7La3Zr2O12 (c-LLZO), β-Li3PS4, Li1.17Al0.17Ti1.83 (PO4)3 (LATP), and Li2PO2N. It is shown that LLZO surfaces have a much smaller band gap than the corresponding bulk and thus could trap significant excess electrons, while the other three systems do not exhibit significant differences in the surface and bulk band gaps. A fully coupled phase-field model was then developed to further examine the impact of excess surface electrons on the Li dendrite growth morphology in polycrystalline LLZO. This model successfully explained the experimentally observed dendrite intergranular growth and revealed that the trapped electrons may produce isolated Li-metal nucleation, leading to a sudden increase of Li-dendrite penetration depth. Finally, we compared the basic material properties and found that the Li ranked dendrite resistance in these SEs, based on the surface electronic properties instead of mechanical properties, is consistent with a broad range of experimental observations. Therefore, surface band gaps can be used as new descriptors to screen SEs with high Li dendrite resistance.

4:00 PM EN02.04.02
Advanced Safety Sensor for Lithium-Metal Battery via Bifunctional Auxiliary Electrode Orapa Tamwattana1, Sehwan Moon1, Hyekjun Park1, Gabin Yoon1, Won Mo Seong1, Myeong Hwan Lee1, KyuYoung Park1, Nonglak Meethong2 and Kisuk Kang1; 1Seoul National University, Korea (the Republic of); 2Khon Kaen University, Thailand

The demand for rechargeable batteries with higher energy density than lithium-ion batteries that are commercially available has been ever increasing 1, 2. Elemental lithium metal has thus come into the spotlight again as one of the most promising negative electrode materials owing to its exceptionally high theoretical capacity (3860 mAh g⁻¹) and the lowest negative electrochemical potential (-3.040 V vs. a standard hydrogen electrode) 3, 4. Moreover, its stable utilization is pivotal in the success of the next-generation electrochemical systems. Nevertheless, the commercialization of rechargeable lithium metal electrode has been retarded due to the catastrophic safety issue arising from lithium dendrite formation. Even with a small irregularity in lithium metal deposition during the initial stage of charge, further selective and self-amplifying lithium deposition follows due to the presence of favorable deposition sites 5, 6. The needle-like lithium dendrite can penetrate the polymer separator and possibly contact the opposite electrode, and such contact would result in a huge current flow through the internal circuit, triggering joule heating thermal runaway.

Unfortunately, it has been revealed that dendrite formation cannot be completely inhibited and some reported successes are only valid at low current densities and with low utilization levels of lithium metal. Batteries operating under extreme conditions might still be exposed to the potential risk of dendrite growth and internal short-circuit. Therefore, not only protective techniques for lithium metal but also sensing technologies to detect dendritic growth in advance are needed.

Herein, we introduce a lithium rechargeable battery system with a bifunctional auxiliary electrode that can detect the potential signs of an internal short-circuit and simultaneously prevent cell failure by inhibiting further dendritic growth of lithium metal. Based on this working principle, we provide guidelines for bifunctional auxiliary electrode design and demonstrate that it can act as both a safety sensor and a lithium scavenger. Finally, we show that our in-house designed cell, using a flexible and self-standing auxiliary electrode, can effectively alert the danger of a short circuit in real-time without additional dendrite growth. We expect that this finding will open up unexplored opportunities utilizing various auxiliary electrode chemistry for safe rechargeable lithium metal batteries.

**A New Li Metal Electrode by Ironing Controllable Lithium Into Lithiotropic Carbon Fiber Fabric (LiCFF)**

Junjie Niu; University of Wisconsin--Milwaukee, United States

The Department of Energy (DoE) announced the energy density target of >500 Wh/Kg for next-generation lithium-ion batteries in the incoming 3-5 years, to meet the rapidly growing market in electrical vehicles (EVs) and portable electronic devices. Li metal is considered as the most promising candidate as anode (Xu, *Energy Environ Sci* 2014). However, the dendrite forming, low Coulombic efficiency, and unstable solid electrolyte interphase (SEI) pose big challenges in applying Li metal in batteries (Chandrashekar, *Nat Mater* 2012). Here we present a novel, single-side Li-infused carbon fiber fabric (LiCFF) with a controllable, minimized Li loading, which shows a highly reversible plating/striping with an extremely low overpotential of less than 30 mV (Li foil: >1.0 V over 50 cycles) upon >3000 cycles (6000 and 2000 hours) at 1 and 3 mA/cm² in symmetric cells, respectively (*Xi Chen et al., ACS Appl Mater Interfaces, 2019, in print*). With a high areal capacity up to 10 mAh/cm² and a high current density of 10 mA/cm², the cell still shows a minimum overpotential of 150-175 mV after 250 cycles (500 hours). Full cell batteries using the LiCFF as ‘all-in-one’ anode without additional slurry-making process and nickel-manganese-cobalt oxide (NMC) as cathode exhibit an improved capacity retention when compared with Li foil: 32% at 0.5 C and 119% at 1.0 C capacity improved after 100 cycles. In parallel, the mossy/dendritic Li on the LiCFF was largely suppressed, which was confirmed using in-situ observations of Li plating/striping in a capillary cell. The excellent electronic conductivity of the carbon fabric leads to small contact/transfer resistances of 3.4/3.8 Ω (Li foil: 4.1/44.4 Ω), enabling a drastically lowered energy barrier for Li nucleation/growth. Thus a uniform current distribution results in forming a homogeneous Li layer instead of forming dendrite. The current LiCFF as anode with controllable Li (n/p ratio), improved cycling stability, mitigated dendrite formation, and flexibility displays promising applications in versatile Li-metal batteries such as Li-NMC and Li-S.

**Reversible Oxygen-Redox Chemistry for Large-Capacity Sodium-Ion Battery Cathodes**

Masashi Okubo; The University of Tokyo, Japan

Increasing the energy density of sodium-ion batteries is of paramount importance toward achieving a sustainable society. The present limitation of the energy density is owing to the small capacity of cathode materials, in which the (de)intercalation of sodium ions is charge-compensated by transition-metal redox reactions. Although additional oxygen-redox reactions of oxide cathodes have been recognized as an effective way to overcome this capacity limit, the electronic structure during oxygen-redox reactions are yet to be fully understood. In this work, we employed combined analyses of synchrotron X-ray diffraction, soft X-ray absorption spectroscopy, and DFT calculations to demonstrate how reversible oxygen-redox reactions occurs in transition-metal oxides. As an oxygen-redox compound, we studied Na₂RuO₃ and Na₂Mn₃O₇, which exhibit highly reversible oxygen-redox reactions. Detailed analyses revealed that, while nonbonding oxygen 2p orbital plays a central role to trigger oxygen oxidation, hole generated on oxygen 2p orbital is stabilized by interaction with metal d orbitals. Furthermore, we found a self-ordering phenomenon of stacking faults upon desodiation from an oxygen-redox
layered oxide Na$_2$RuO$_3$, realizing much better reversibility of the electrode reaction. The cooperatively ordered vacancy in lithium-/sodium-rich layered transition-metal oxides is shown to play an essential role, not only in generating the electro-active nonbonding 2p orbital of neighboring oxygen but also in stabilizing the phase transformation for highly reversible oxygen-redox reactions.

Towards Co-Free Ultra-High Ni Positive Electrode Materials for Li-Ion Batteries—Understanding the Role of Dopants Marc M. Cormier¹, Hongyang Li¹, Ning Zhang¹,², Aaron Liu¹, Julie Inglis³, Jing Li⁴ and Jeff Dahn¹; ¹Dalhousie University, Canada; ²Northeastern University, China; ³McMaster University, Canada; ⁴Tesla, United States

Increasing lithium-ion battery energy density and reducing cost without compromising lifetime or safety is an important goal for EV applications. While Co has been a critical constituent of Li-ion battery positive electrode materials such as NCA and NMC, instability of Co pricing and concerns about long-term availability motivate the reduction of Co content in these materials. This work pairs first-principles density functional theory (DFT) computations with experimental measurements to gain fundamental insight into how individual dopants influence the structural and electrochemical properties of LiNi₁₋ₓMₓO₂ (y=0, 0.05; M=Al, Mg, Mn, Co) and makes comparison with NCA materials. Trends in capacity reduction as a function of dopant valence and concentration can be explained using simple oxidation state analysis, which is shown to hold on the atomic scale from DFT computations. Similarly, computations over various Li configurations at high states of charge demonstrate preferred structural arrangements for Al and Mg, which helps understand the effective suppression of phase transitions otherwise observed in LiNiO₂ and LiNi₀.₉₅Co₀.₀₅O₂ using dQ/dV analysis and in-situ XRD. Oxygen binding energy computations as a function of dopant type and Li content paired with TGA and ARC measurements further reveal the mechanism through which small dopant concentrations help reduce the reactivity of ultra-high Ni materials with electrolyte at elevated temperature, potentially leading to safer Li-ion cells.

Advanced In Situ X-Ray Diffraction in Revealing the Structural Changes of High Voltage Cathode under the Effect of Different Electrolytes Mei Cai and Meinan He; General Motors, United States

Fluorinated electrolyte is a promising candidate to replace the regular carbonate-based electrolyte because of its impressive anodic stability, conductivity as well as thermo-stability. Yet, most of the fluorinated electrolyte studies focused on the interfacial reaction and electrochemical performance. Although it is equally critical in understanding the interaction between different electrolyte systems and the bulk cathode structure to improve the energy density of the whole cell, the research regarding this topic is limited. In this work, bulk electrode analysis via in-situ XRD technique was carried out to unveil the high Nickel cathode structural changes by using different electrolytes and the results indicate the use of fluorinated electrolyte can mitigate the electrolyte decomposition. Most importantly, it can also assist the preservation of the crystal structure of high Nickel cathode by inhibiting the loss of active Li ion and transition metal during cycling. All results converge to the conclusion that the use of fluorinated electrolyte can not only stabilize the interface but also conserve the bulk structure. Owing to its impressive anodic stability, conductivity as well as thermo-stability, fluorinated electrolyte is a promising candidate over the conventional regular carbonate-based electrolyte for next generation functional electrolyte. Currently, most of the fluorinated electrolyte studies have been focused merely on the interfacial reaction and electrochemical performance. Although it is equally critical in understanding the interaction between different electrolyte systems and the bulk cathode structure to improve the energy density of the whole cell, the research regarding this topic is still lacking. In this work, bulk electrode analysis via in-situ XRD technique was carried out to unveil the high Nickel cathode structural changes in different electrolyte systems and the results indicated the use of fluorinated electrolyte can mitigate the electrolyte decomposition. More importantly, it can also assist the preservation of the crystal structure of high Nickel cathode by inhibiting the loss of active Li ion and transition metal during cycling. All results converge to the conclusion that the use of fluorinated electrolyte can not only stabilize the interface but also conserve the integrity of the bulk crystal structure.

Understanding and Optimization of Solid Electrolytes and Li-S Solid-State Batteries

Wolfgang Zeier
University of Giessen, Germany

The advent of solid-state batteries has spawned a recent increase in interest in lithium conducting solid electrolytes, especially in the lithium thiophosphates. While current lithium electrolytes provide fast-ionic conduction to fundamentally study solid-state batteries, their ionic conductivities are not sufficient for thick electrode configurations, which will really allow high energy densities to be achieved.\(^1\)

In this presentation, we show how an understanding of the structure-transport properties of the lithium argyrodites Li\(_6\)PS\(_5\)X can help tailor the ionic conductivity. We show that an anion site-disorder between S\(^2-\)and X\(^-\)is beneficial\(^2\)and that an induction of the site disorder in Li\(_6\)PS\(_5\)I leads to a significant improvement of the conductivity.\(^3\)Having achieved the fastest lithium argyrodite so far with \(\gamma = 18\) mS/cm, solid-state batteries with thick electrode configurations (150 – 350 \(\mu\)m) can be built. Due to the optimized solid electrolyte, the solid-state battery can be cycled even at 1C with no capacity fade over 150 cycles. This work shows that optimizing solid electrolytes helps to achieve stable cycling at high rates in solid-state batteries with thick electrodes.

Further, we will show how the stability of thiophosphate electrolytes can be measured and that the operation window affects cell performance. Lastly, we show how volume changes, induced by electrochemical (de-)intercalation, affect the performance in solid state batteries providing an understanding of the underlying mechanocchemical influences in Li-S solid-state batteries.\(^4\)\(^-\)\(^6\)

High Energy Batteries with Si- and Li-Metal Anodes—Nanomaterials and Interfacial Design

Yi Cui
Stanford University, United States

The demand from portable electronics and electric vehicles call for high energy batteries beyond the current lithium ion batteries. Here I will present our recent progress on materials and interfacial design to enable much high energy density batteries, which include 1) High capacity Si anodes with success together commercialization; 2) Li metal anodes: host and interface design to over the lithium metal dendrite formation and interfacial instability; 3) Our pioneering development of cryogenic electron microscopy for understanding the battery materials and solid-electrolyte interphase down to atomic scale resolution.
EN02.07.01
The Multiscale and Multi-Modality In Situ and Ex Situ Microscopy and Spectroscopy Diagnosis on the Fading Mechanism of Rechargeable Batteries Chongmin N. Wang; Pacific Northwest National Laboratory, United States

In situ diagnosis appears to be one of the essential methods for gaining insights as how an electrode material failure, therefore feeding back for designing and creating new materials with enhanced battery performances. In this presentation, I will highlight recent progress on ex-situ, in-situ and operando S/TEM for probing into the structural and chemical evolution of energy storage materials. Both ex-situ and in-situ high resolution imaging enables direct observation of structural evolution, phase transformation and their correlation with mass, charge and electron transport, providing insights as how active materials failure during the cyclic charging and discharging of a battery. In particular, I will broadly cover the frontier of the current understanding of the fading mechanism of layer structured cathode and Li dendrite growth and interaction with separators. Subsequently, I will discuss some recent breakthrough experiments and observations for correlating the structural and chemical evolution with the electrochemical properties of both layered cathode and Li metal. In perspective, my presentation will target to stimulate this field of research to re-check what has been understood and what need to be done to tackle the technical challenges facing the application of the layer structured cathode and Li metal anode.

EN02.07.02
Observation of Electrode Reactions in Fluoride Shuttle Battery by Atomic Force Microscopy Taketoshi Minato1, Hiroaki Konishi1, Asuman Celik Kucuk1, Hiroshi Onishi2, Zempachi Ogumi1 and Takeshi Abe1; 1Kyoto Univ, Japan; 2Kobe University, Japan

The applications of rechargeable battery are growing in various field for the efficient energy systems [1]. To expand the application of the rechargeable battery, the developments of innovative rechargeable batteries which overcome the performances of current batteries are required. Fluoride shuttle batteries (FSBs) which is based on the shuttle of fluoride ions in electrolyte and fluorination/defluorination reactions on electrodes [2, 3] contains higher theoretical energy densities than current rechargeable batteries. We have developed organic electrolyte and electrodes from metal fluorides for FSBs [2, 4-10]. However, the reaction mechanisms on the electrode in FSB are not understood. For the further developments of FSB, the analysis of the reaction at the interface between electrode and electrolyte were performed by using atomic force microscopy (AFM) [1, 11-13]. In the presentation, we will show the investigation on the effects of electrolyte composition on the reaction mechanisms.

This research was supported by the Research and Development Initiative for Scientific Innovation of New Generation Batteries (RISING) and Research and Development Initiative for Scientific Innovation of New Generation Batteries 2 (RISING2) projects of the New Energy and Industrial Technology Development Organization (NEDO), Japan.

Lithium-sulfur (Li-S) batteries are a beyond Li-ion battery technology that provides large theoretical capacity (1672 mAh/g) while also being earth-abundant and low cost. In this study, we investigate the behavior of lithium polysulfides (LiPS; Li2Sx, x = 4, 6, 8) and lithium salt (LiTFSI; Li bis(trifluoromethane)sulfonimide) in model electrolyte solutions using small angle X-ray scattering (SAXS). A concentration series of polysulfides (ranging from 100 to 1500 mM depending on the solution) in solvents relevant to Li-S battery electrolytes (DOL:DME, acetonitrile) with a range of polysulfide solvation were selected after an initial screening of common solvents. Some aggregation of LiPS was observed at high concentrations (> 1000 mM based on the mass of sulfur) in both solvents, but DOL:DME-based solutions exhibited aggregation even at low concentrations. Fitting the data with a unified model yielded two distinct populations in the DOL:DME solutions – one with a radius of gyration (Rg) of about 5 Å and one with a Rg of about 12 Å. In the 1 M LiTFSI in DOL:DME solutions, the SAXS data showed a peak at all polysulfide concentrations, indicating quasi-periodic nanostructuring in the solution that is induced by the presence of the LiTFSI salt. This nanostructuring is also present in the 1 M LiTFSI in acetonitrile solutions, confirming that the effect originates from the LiTFSI salt. We will compare experimental results with those from molecular dynamics calculations. These results add molecular level insight into Li-S electrolytes and a better understanding of electrolyte-salt interactions.

The rapid growth in popularity of battery devices has brought energy storage and conversion to the spotlight of materials research. Bringing together researchers from a variety of disciplines spanning science and engineering, it is now a common goal to build batteries that are safe, long-lasting, and powerful enough to serve today’s most demanding applications. In order to meet these goals, a methodical development approach is needed, including material synthesis, processing, characterization, and design iteration.

In recent years, X-ray analysis has become a popular choice for electrochemical device characterization, including X-ray microscopy (XRM), X-ray fluorescence (XRF), and X-ray absorption spectroscopy (XAS). Owing to the high penetrating power of X-rays and non-destructive nature of X-ray interactions with matter, these techniques provide unique insight into electrochemical devices such as batteries, fuel cells, and catalysts. XRM employs the technique of computed tomography (X-ray CT or XCT), yielding 3D models of a material’s microstructure, while XRF provides elemental identification and XAS reveals chemical states. Combining these three techniques together results in a powerful characterization approach that compliments conventional electrochemical measurements and other analysis methods, while delivering new information about the material under study. However, while the use of XRM, XRF, and XAS for electrochemical device characterization continues to rise, the techniques are traditionally limited to synchrotron facilities only, which has limited the reach of these techniques for widespread use.

In our work, we have developed a suite of laboratory X-ray instrumentation, designed with battery, fuel cell, and catalyst research in mind. Our laboratory nano-XRM is capable of providing spatial resolutions down to 40 nm, creating a high-resolution model of material microstructures for time-evolved (4D) characterization and computational simulation incorporating fine features within the specimen. In tandem with this, our laboratory micro-XRF system provides sub-parts-per-million (sub-ppm) elemental detection sensitivities with < 10 um spatial resolutions, and pairs elemental identification with optical and x-ray radiographic imaging for spatially-resolved spectroscopic analysis. The most recent addition to this set of tools is the laboratory X-ray absorption spectrometer, which provides sub-eV energy resolution in a matter of minutes and yields oxidation state, coordination number, and bond length information non-destructively and without extensive specimen preparation. These three systems carry...
with them performance characteristics that begin to mirror those of synchrotron.

Direct Observation of Solution-Phase Discharge in Lithium Oxygen Batteries by Liquid Phase Transmission Electron Microscopy
Hyeokjun Park1,2,3, Donghoon Lee1,3, Jungwon Park1,3 and Kisuk Kang1,2,3; 1Seoul National University, Korea (the Republic of); 2Research Institute of Advanced Materials, Korea (the Republic of); 3Institute for Basic Science, Korea (the Republic of)

Non-aqueous lithium oxygen(air) battery has been considered as a promising next-generation energy storage system because of its highest theoretical energy density among all the battery chemistries which have been introduced so far. However, there are many hurdles in practical demonstration of the high energy density of lithium oxygen battery.1 One typical and serious problem is that premature passivation of insulating Li2O2 inevitably occurs on the surface of the cathode. Using redox mediators such as 2,5-di-tert-butyl-1,4-benzoquinone (DBBQ), coenzyme Q10 (CoQ10), and Vitamin K2, that change the reaction pathway of producing Li2O2 from surface of electrode to bulk liquid phase is now suggested as a key solution to circumvent such passivation problems.2-4 However, such engineering is somewhat empirical with limited mechanistic understanding since most of previous experimental analyses for studying working principles of lithium oxygen battery are based on ex situ experiments. In this work, we implement a liquid TEM holder to capture real time status of the lithium oxygen battery while discharging with a typical redox mediator of DBBQ, which is one of recent emerging electron microscopy techniques for examinations of liquid samples.5,6 We successfully obtain a real time TEM movie presenting growth of Li2O2 on the solution phase and analyze the growth rate, morphology transformation of Li2O2. Interestingly, growth of Li2O2 in electrolyte solution during discharge involves distinct two-step pathway. Our findings can provide the answer for the unsolved question regarding the redox mediation mechanism, growth kinetics of discharge products, and morphology evolution of Li2O2 in lithium oxygen batteries.

Nonaqueous Liquid Electrolyte Based on Lithium bis(fluorosulfonyl)imide (LiFSI) for Lithium-Ion Batteries with Improved Calendar Life
Liyuan Sun1, Kate Digan1, Connor Tomshack1, Mengqing Xu2 and Derek C. Johnson1; 1A123 Systems, Inc, United States; 2Wanxiang A123 Systems Asia Co., Ltd, China

Lithium hexafluorophosphate (LiPF6) is adopted almost exclusively as the conducting salt of the electrolyte in current commercial lithium-ion (Li-ion) batteries because of the high ionic conductivity, good electrochemical stability and lower cost. However, thermal instability of LiPF6, which could lead to the generation of detrimental byproduct hydrogen fluoride (HF) through LiPF6 hydrolysis, raises challenges for LiPF6 based electrolytes to function well at elevated temperatures (>55°C) and in presence of inevitable moisture or alcohol impurities. Lithium bis(fluorosulfonyl)imide (LiFSI), with higher ionic conductivity and thermal stability, could be a promising alternative to LiPF6 since it bypasses the hydrolysis of PF6− that generates HF. However, a major technical challenge for LiFSI to be employed as a primary conducting salt is aluminum current collector corrosion generally seen from
around 4.2 (vs. Li/Li⁺) which is within the operating voltage of Li-ion batteries with lithium nickel manganese cobalt oxide (NMC) cathode. Lithium iron phosphate (LiFePO₄)/graphite Li-ion batteries have an operating voltage between 2.0 and 3.6 V (vs. Li/Li⁺), and therefore, could utilize LiFSI as the primary conducting salt without running into the aluminum corrosion issue.

The intent of this study was to evaluate a series of LiFSI based electrolytes in the LiFePO₄/graphite chemistry. It was found that the calendar life of LiFePO₄/graphite Li-ion batteries was significantly improved in high temperature storage when LiPF₆ was completely or partially substituted by LiFSI. Batteries using LiFSI based electrolytes also demonstrated improved power performance largely due to the superior ionic conductivity of these electrolytes. It was further confirmed that aluminum corrosion is not occurring within the operating voltage of LiFePO₄/graphite Li-ion batteries with LiFSI based electrolytes. This study reveals a promising path forward to produce LiFePO₄/graphite Li-ion batteries with much improved performance so as to meet OEM’s stringent requirements for next-generation Li-ion batteries.

BIAN Based Anode Binder/Additive for Improved Performance of Li-Ion Secondary Batteries Noriyoshi Matsumi, Sai Gourang Patnaik and Raman Vedarajan; Japan Advanced Institute of Science and Technology, Japan

Bisiminoacenaphthene (BIAN) has been an important ligand structure for a variety of metal complex and widely employed as a ligand for olefin polymerization catalysts. However, in spite of their unique electrochemistry, it has not been widely utilized for energy devices. In the present work, firstly BIAN based novel conjugated polymer was prepared by Sonogashira-coupling polymerization and the obtained polymer (P-BIAN)¹ was employed as anode binder in Li/EC:DEC/C type anodic half cells. Second, novel additive material bearing BIAN structure (BIANODA) was synthesized by condensation of acenaphthequinone with 2 eq. of dianiline compound, which was used as additive to improve the characteristics of MNC cathode material (LiMn₁/₃Ni₁/₃Co₁/₃O₂)². Electrochemistry of these materials along with characteristics of fabricated Li ion battery cells under these design protocol will be presented in detail.

The structures of P-BIAN and BIANODA were supported by NMR, IR spectra etc. Mn of P-BIAN was found to be 40000 when measured by gel permeation chromatography (THF as an eluent, PST standards). The BIAN based polymer, P-BIAN shows lower LUMO level in comparison with ethylene carbonate (EC). This means reductive doping of P-BIAN takes place prior to reductive decomposition of EC at anode surface, which will restrict thick SEI formation at anode. When cyclic voltammetry measurements were carried out for coin cell with P-BIAN, peak due to reductive decomposition of EC was not observed, unlike the case of PVDF. Further, after charge-discharge cycles, coin cell with P-BIAN exhibited much smaller internal resistance when compared with PVDF. This indicates that reductive doping of P-BIAN and restriction of SEI decomposition had synergistically decreased internal resistance of battery cells. As a result, coin cell with P-BIAN showed 1.5 times higher discharging capacity in comparison with coin cell with PVDF.

On the other hand, BIANODA has higher HOMO level than that of EC, which enables oxidative polymerization of BIANODA prior to oxidative decomposition of EC. This will restrict thick SEI formation at MNC cathode surface. Use of Schiff base can trap HF generated during the cycling, and strong binding property of BIAN can stabilize MNC cathode for long term use. Consequently, BIANODA additive had enhanced the discharging performance of MNC/EC:DC/Li cathodic half cells.

Designer Electrolyte Additives for High Energy Density Si Anode Based Li-Ion Battery Gebrekidan Gebresilassie G. Eshetu¹,², Felix Aupperle¹ and Egbert Figgemeier¹,³;¹Electrochemical Energy Conversion and Storage Systems Group, Institute for Power Electronics and Electrical Drives (ISEA), RWTH Aachen University, Germany; ²Department of Chemistry, College of Natural and Computational Sciences, Mekelle University, Ethiopia; ³Helmholtz Institute Münster, IEK-12, Forschungszentrum Jülich GmbH, Aachen/Münster, Germany

Silicon (Si) and its derivatives (Si/C composite, SiOₓ) have garnered enormous attention as anode materials for next-generation high-capacity lithium-ion batteries (LIBs). However, despite the prodigious beneficial features of pure Si, its large-scale commercialization is still hindered due to the existence of numerous inevitable defies such as colossal...
volume change during (de-)alloying, inherent low electric conductivity, low Coulombic efficiency, unstable/dynamic solid electrolyte interphase (SEI), electrode swelling, electrolyte drying etc. Among proposed mitigating strategies, the use of a fraction dose of molecular additives is hailed as the most effective, economic and scalable approach to realize Si and its derivative anode based LIBs. Additives can modify the nature and chemical composition of the SEI layer, which in turn dictates the obtainable capacity, rate capability, Coulombic/energy efficiency, thermal reactivity etc. of the battery system. Thus, we report a systematic and comparative investigation of various electrolyte additives, namely tetraethoxysilane (TEOS), (2-Cyanoethyl)triethoxysilane (TEOSCN), vinylene carbonate (VC), fluoroethylene carbonate (FEC), and a blend of TEOSCN, VC and FEC (i.e. VC/FEC/TEOSCN) using electrochemical analysis, X-ray photoelectron spectroscopy (XPS), Density Functional Theory (DFT) calculation and differential scanning calorimetry (DSC). The ternary mixture (FEC/VC/TEOSCN) results in a thinner SEI layer consisting of high shear modulus SEI-building species (mainly LiF). It also provides much improved thermal stability amid all tested additives, evidencing its potentiality to boost high capacity and safer Si anode-based LIBs. Pouch cells fabricated using Si anode, NMC cathode and LiPF6/EC-DEC electrolyte doped with TEOSCN-based additives demonstrated excellent electrochemical cycling performance for over 400 cycles with nearly 100% Coulombic efficiency. The improvement could be explained due to the fact that –C≡N group can undergo a polymerization reaction by decreasing the bond order from triple (C≡N) to double (C=N) and single (C-N) bonds, thus forming a chemically stable and highly ionically conductive material and also possibly Li3N as precipitates on Si surface. Moreover, strong nucleophiles formed by the reduction of the C≡N could attack FEC and/or LiPF6 stripping of –F to form LiF, as evidenced from XPS analysis.

Thus, nitrile-functionalized silanes are highly promising electrolyte additives to boost the electrochemical performance and safety-induced risks of Si anode-based LIBs, emanating from the formation of a robust SEI layer.

We believe that this study gives a valuable understanding and provides new insights on the use of electrolyte additives for highly-energy density and reversible Si and Si-derivative anodes in Li-ion batteries.

From Atomistic Understanding of Correlation and Transport to Design of Next-Generation Ionic Liquid-Based Electrolytes Nicola Molinar1, Jonathan Mailoa2 and Boris Kozinsky1,2; 1Harvard University, United States; 2Robert Bosch LLC, United States

Electrolytes control battery recharge time and efficiency, anode/cathode stability, and ultimately safety, consequently electrolyte optimization is crucial for the design of modern energy storage device. Electrolytes containing ionic liquids (ILs) are often regarded as attractive candidates to replace the currently-adopted organic solvents thanks to their superior chemical stability, however, poor transport properties are hindering their applicability. Given the ionic nature, these systems possess high degrees of ion-Ion correlation, therefore posing a non-trivial yet crucial and interesting challenge to understanding their transport properties.

Here we present molecular dynamics analysis of transport properties in IL-based electrolytes. First, the strong ionic interactions result in significant correlations and deviations from ideal solution behavior. By adopting rigorous concentrated multicomponent solution theory, we show that when accounting for intra- and inter-species correlation, beyond the commonly used uncorrelated Nernst-Einstein-based approach, an anomalously low and even negative Li transference number emerges. Second, we computationally confirm the recently measured negative Li transference number in Li-containing IL-based electrolytes, and extend this surprising result to a vast range of different chemistries, suggesting a universal behavior of this class of electrolytes. Additionally, we characterize the atomistic nature of the anion-cation clusters, formulate a way to compute the effective lithium charge, and show that lithium-containing clusters carry a negative charge in a remarkably wide range of compositions and concentrations. Third, we leverage our microscopic understanding to suggest and test modifications to increase the cation transference number. Our results have significant implications for the adoption of ionic liquid-based electrolytes as they provide a recipe for optimizing transport properties in next-generation highly correlated electrolytes.
EN02.09.01
An All-Solid Lithium-Ion Battery for Active Implantable Medical Devices with High Safety and Performance Stability Lukas Duwe, Arijit Bose and Mike Molinski; University of Rhode Island, United States

An all-solid lithium-ion battery (ASLIB) consisting of a polyethylene oxide (PEO)-based polymer electrolyte with a lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) salt, lithium titanate (LTO)-based anode and lithium iron phosphate (LFP)-based cathode has been fabricated. The solid polymer electrolyte has an ionic conductivity of ~10^{-4} S/cm at 40 °C. The electrolyte is prepared using a solvent free hot-pressing method. The electrodes consist of the active materials (LTO or LFP), carbon black, small amounts of PEO, LiTFSI, and a PVDF binder. A coin cell is assembled using these electrodes and electrolyte. The cell shows stable electrochemical performance over 20 charge/discharge cycles.

EN02.09.02
Scanning Electrochemical Microscopy of Two-Dimensional Titanium Carbide (Ti3C2Tx) MXene—Effects of Interlayer Spacing, Flake Size and Electrochemical Environment Sanju Gupta and Wyatt Ringo; Western Kentucky University, United States

Two-dimensional (2D) layered materials are increasingly studied in effort to discover new compounds and the fascinating properties engineered by their sheet-like structure. Graphene, atomic layer of carbon, is the most researched among 2D materials, albeit limited to just carbon in its composition. Recently, a new emergent family of 2D transition metal carbides and carbonitrides – so called “MXene” – are synthesized that may have wide-ranging applications, including energy storage, polymer nanocomposite fillers, water purification, transparent optical conductive coatings and electronic devices. Nevertheless, before the best application is identified, the fundamental chemical physics of these materials must be understood and therefore synthesis-structure-property relationships must be established. To our expanding interests in this emerging class of materials, we investigate the structure and properties of layered transition metal carbides (Ti3C2Tx) MXenes phases for renewable energy prepared by collaborator. We employed electron microscopy, optical absorption spectroscopy, Raman spectroscopy and advanced electrochemistry including SECM to determine surface morphology, nanoscale structure, lattice vibrational properties and surface sensitive electrochemical properties and physicochemical processes at solid/liquid interface.

EN02.09.03
Prospect of Thermal Shock Induced Healing of Lithium Dendrite Zijian Hong and Venkatasubramanian Viswanathan; Carnegie Mellon University, United States

Dendritic growth plagues the development of rechargeable lithium metal anodes. Recently, it has been reported that self-heating of the cell provides a mitigation strategy for suppressing dendrites. In order to study this phenomenon, we extend our recently developed nonlinear phase-field model to incorporate an energy balance equation allowing a full thermally coupled electrodeposition model using the open-source software package MOOSE. In this work, we consider the interplay between ionic transport and electrochemical reaction rate as a function of temperature and explore the possibility of using thermal shock induced dendrite suppression. We discover that, depending on the electrochemical reaction barrier and ionic diffusion barrier, self-heating could accelerate (larger reaction barrier) or decelerate (larger diffusion barrier) dendrite formation. Given that the electrolyte constituents can be used to tune both barriers, this study could provide an important avenue to exploit the self-heating effect favorably through electrolyte engineering.

EN02.09.04
Design of Graphene-Based Composites with Bio-Inspired Structures for Energy Storage Shenmin Zhu, Chengling Zhu and Yao Li; Shanghai Jiao Tong Univ, China

With the increasing demand for lithium-ion batteries in electronics and vehicles, great efforts have been drawn on promoting both the energy and power densities. The electrochemical properties of electrode materials directly affect
the performance of lithium-ion batteries, and therefore it is the primary issue to develop and optimize new-type electrode materials. The performance of high-capacity anode materials can be improved by constructing nanostructures and combining with carbon materials of high conductivity. How to develop effective and practical methods for the design and synthesis of anode materials for lithium-ion batteries is challenging.

Bionic design has been playing an important role in the invention of new tools. In recent years, a variety of bionic-designed anode materials with hierarchical structures have been developed, but they all share some defects: on the one hand, in most cases only the biological macro appearances were selected to emulate, while the microstructures of plants and animals were neglected; on the other hand, the bionic-designed composites are all based on amorphous carbon, which cannot satisfy the design requirements of anode materials with high rate performance, and therefore other materials with higher conductivity (e.g. graphene) are to be introduced in high-performance anode materials. Herein, this research focuses on bioinspired designing and constructing nanostructured graphene-based anode materials of high performance. By modifying the shape and chemical properties of graphene and controlling the bionic structures of the composites, a series of metal oxide/graphene composite anode materials with high capacity, high rate performance, are prepared and the mechanism is investigated.

Fine-Tuning Electron Correlation in Ternary Vanadium Oxides Justin L. Andrews and Sarbajit Banerjee; Texas A&M University, United States

The use of correlated materials in applications that aim to harness electronic phase transitions or mitigate charge-localization altogether requires synthetic techniques wherein electron migration barriers can be modulated with some meaningful degree of tunability. Vanadium oxides represent an attractive model system owing to the relative narrowness of V 3d-derived bands. V₂O₅ can further intercalate metals (M⁺⁺) spanning the periodic table that trigger rearrangement of the V₂O₅₅ lattice giving rise to a structurally diverse family of mixed-valence compounds (MₓV₂O₅). The extent of electron correlation can be chemically tuned by careful selection of the intercalated metal ion (M) which introduces new electronic states, by stoichiometric control of the mixed oxidation state of the vanadium oxide framework (x), and by low-temperature topochemical modification of the vanadium oxide framework. The utility of this approach is demonstrated by its application to three materials design challenges. First, modulation of the thermally-driven metal-insulator transition in β'-CuₐV₂O₅ is achieved through precise control of Cu stoichiometry. Diffusion of copper between two distinct crystallographic sites is shown to modulate the thermal energy threshold for the melting of a self-trapped polaronic state on the vanadium-oxygen lattice as observed in the broadening of hybridized Cu 3d/O 2p states near the upper edge of the valence band. Notably, precise control is a critical requisite for designing materials for brain-inspired computing applications. In a second example, the copper atoms are topochemically leached from the β/β'-CuₓV₂O₅ compound to stabilize a metastable ζ-V₂O₅ phase with a unique quasi-1D structure. The broader dispersion of d-bands stemming from the lower symmetry crystal structure mitigates self-trapping of polarons relative to the thermodynamically-stable a-V₂O₅ phase, thereby increasing its Mg-ion storage capacity (from 50 to 92 mAhg⁻¹). Finally, the empty ζ-V₂O₅ phase is topochemically intercalated with Sn²⁺ to form a metastable β-SnₓV₂O₅ phase. As a result, hybridized Sn 5s/V 3d/O 2p states are introduced at energetic positions close near the valence band of photoabsorbing quantum dots. By tuning this overlap in β-SnₓV₂O₅/CdX heterostructures, we have achieved sub-picosecond hole transfer from quantum dot to vanadium oxide and demonstrated highly efficient hydrogen evolution.
EN02.09.06
Development of Thick LiCoO₂ Electrodes for High Energy Density Li Solid-State Thin-Film Batteries—A Raman Study Christophe Secouard, Arnaud Bazin, Séverine Poncet, Sami Oukasi and Hélène Porthault; Univ. Grenoble Alpes, France

The emerging market of autonomous microsystems such as Internet of Things and (implantable) medical devices has drawn attention to the need for new energy storage devices. Key features for such power sources are integration in the component architecture, footprint, and performance. Amongst several technical solutions, thin film solid-state lithium batteries (TFBs) appear to be a promising candidate to fulfill these requirements.

We present here the recent advances in our group regarding the development of excellent performance, highly-integrable TFBs. The fabrication process flow was carried out in a clean room environment using the TINY platform. The LiCoO₂/LiPON based TFBs are deposited on 8” silicon wafers in a pilot-line scale environment and subsequently patterned using specifically developed, microelectronics-compatible, photolithography processes. Using micromanufacturing techniques, the 0.75 mm substrate is thinned down to 50 µm and the dies are then laser-diced. The 5.3 mm² TFBs demonstrated discharge capacity above 600 µAh/cm² under C/5 galvanostatic cycling condition in the 4.2-3.0 V potential range. The average capacity loss over 30 cycles is around 0.1 %/cycle at 1 C current density in the stabilized regime.

Despite these state-of-the-art performances, when comparing the same electrode in liquid cell configuration, we notice capacity losses for the TFB and irreversible losses between first charge and first discharge, whichever the configuration. In the present work we use the TFB as an electrode-oriented system model to investigate on the possible phenomena which could account for these losses. We propose to examine the LiCoO₂ electrode and its interface with the electrolyte in various configurations and state-of-charge by means of 2D, cross-sectional Raman spectroscopy mappings. In the TFB configuration, the LiCoO₂ layer is well and homogeneously crystallized at open-circuit voltage (out of fabrication). The Raman mapping image after the first charge (4.2V) indicates that the Li extraction is uniform throughout the whole cathode thickness and no specific interfacial phenomenon is evidenced. Performing the same measurement after the first charge and first discharge reveals a fairly uncomplete restitiation with poor crystalline quality in the partially restitiated areas, which could account for the first-cycle irreversibility.

Flexible Pseudocapacitor with Higher Lifetime and Power Density, Based on Vanadium Nitride Nanoflower Himadri Raha, Debabrata Pradhan and Prasanta Guha; Indian Institute of Technology Kharagpur, India

With the recent trend of rampant development of modern portable electronic devices, their power requirement is changing rapidly, and so it is indispensable to redefine their energy storage systems from all the aspects of science and technology. The new age energy storage devices should store an ample amount of electronic charge even with fast charge transfer rate. The device should have a long lifetime and safe to use. Battery-capacitor hybrid system somehow solves the primary objective, i.e. energy and power density. However, it can not be a perfect choice because of the probable energy loss at the bridging circuit. Also, safety, flexibility and lifetime issues associated with conventional batteries make the hybrid system inferior compared to its electrochemical counterpart; i.e. supercapacitor, which could be a better choice. EDLCs are the fastest and long lasting supercapacitor, but they have poor energy density as compared to pseudocapacitor.

The redox reaction dominated pseudocapacitors suffer from poor lifetime, charge transfer rate and self-discharge through the high ESR. To improve energy density, and lifetime, we prepare flower like V₂N dominated V₂N@V₂C nanocomposite, to be used as a pseudocapacitative electrode material with extremely low ESR. The CV nature of this material confirms that the charge storing is not dominated by redox reaction and the trends of low ESR (about 6 Ω) and higher coloumbic efficiency also supports the finding. Three electrode measurement shows 31.38 mFcm⁻² specific capacitance at 1 mAcem⁻² current density. The less redox dependency and lower ESR improves its capacitance retention rate and coloumbic efficiency by 98% and 95.86% even after 3 thousand charge-discharge cycles. Although the use of lithium based electrolyte may improve energy density but the use of KOH as the electrolyte, makes the device highly safe as compared to lithium based energy storage device. A flexible supercapacitor prototype was fabricated using PVA-KOH gel electrolyte, and that too is performing well in terms of stability, ESR and coloumbic efficiency.

EN02.09.08
All-Solid-State Dendrite-Free Na Metal Battery Enabled by an Ultrathin Interfacial Layer Edward Matios, Huan Wang and Weiyang Li; Dartmouth College, United States
The commercialization of Na metal anode is largely hindered by several long-lasting challenges, namely metallic Na dendrite growth and unstable SEI formation. Meanwhile, these challenges can be effectively resolved by employing non-flammable solid Na conductor as an electrolyte. Solid electrolytes not only can eliminate severe safety concerns, they can also enhance electrochemical stability and prolong cycling life. However, solid ceramic electrolyte NASICON is subjected to high electrolyte/electrode interfacial resistance, leading to poor interface conductivity that results in non-uniform Na ion flux. The pairing of pristine NASICON with high-capacity metallic Na anode gives rise to large NASICON/Na interfacial resistance and poor interface conductivity that result in non-uniform Na ion flux across the interface. Specifically, Na tends to plate preferentially along the grain boundaries of NASICON where the Na ion flux is locally intensified, leading to detrimental dendrite-like nucleation on Na anode over repeated charge/discharge cycles. Theoretically, a homogeneous and stable interlayer with superior Na anode compatibility and ion conductivity can facilitate uniform Na ion flux across the interface, therefore effectively decrease the interfacial resistance and suppress unregulated dendrite-like Na formation during cycling.

In this work, we proposed the direct coating of an ultrathin graphene layer on NASICON by CVD. The Raman spectrum surface-modified NASICON reveals the three characteristic graphene peaks of D band, G band and a relatively weak and broad 2D band. The thickness of graphene-like layer coating on NASICON was estimated by both XPS depth profiling and TEM to be around 4 nm. This interlayer acts as a uniform and conductive network for Na ion transport. As a result, the surface-modified NASICON significantly decreased the interfacial resistance by more than 10-fold (524 Ω cm² to 46 Ω cm²), improved Na plating/stripping stability (at 1 mA/cm² current density with a 1 mAh/cm² capacity) with much smaller voltage overpotential and enabled uniform Na plating with minimized uncontrolled dendrite formation after 1000 cycles. This Na metal cycling with surface-modified NASICON is, to the best of our knowledge, the best performing all-solid-state Na symmetric cells reported. Moreover, SEM images revealed Na electrodes cycled with surface-modified NASICON remained smooth on the surface, while Na electrodes cycled with pristine NASICON exhibited dendrite morphology.

To evaluate the electrochemical performance of surface-modified NASICON as a solid ceramic electrolyte, solid-state batteries were assembled with Na3V2(PO4)3 (NVP) as cathode and bare metallic Na as anode. At 1C current density, NVP/Na battery delivered a high reversible initial capacity of 108 mAh/g with 85% capacity retention (~92 mAh/g) after 300 cycles at nearly 100% Coulombic efficiency. In contrast, the control experiment of NVP/Na with pristine NASICON showcased inferior performance with rapid capacity decay and very unstable voltage profiles.

Subsequently, this surface-modified NASICON was incorporated into an optimized PEO based solid polymer electrolyte, and the synergetic effects of the modified ceramic and optimized polymer electrolytes lead to great improvement in both interfacial wettability and ionic conductivity, leading to great reduction in Na cycling overpotential, facilitating uniform Na plating, and enabling superior Na-S and Na/NVP batteries. Overall, these works can provide valuable insights for all-solid-state dendrite-free battery development.

EN02.09.09

Tuning the Structural Properties of MnOx in MnOx/reduced Graphene Oxide Composites for High-Performance Electrochemical Capacitors Seogi Byun, Jungjoon Yoo and Hyunuk Kim; Korea Institute of Energy Research, Korea (the Republic of)

To overcome the low electrical conductivity, manganese oxide (MnOx) is coupled with reduced graphene oxide (rGO), and it can be significantly overcome through the hybridization. Moreover, the oxidation state and structural properties of MnOx are precisely adjusted to further enhance the electrochemical performance for practical electrochemical energy storages. In this work, MnOx/rGO hybrid films possess different crystallinity and oxidation states compared with bare Mn oxides and they are produced by a simple strategy with combining a solution based synthesis and post-thermal annealing process. The oxidation state and crystallinity (degree of hydrous states) of MnOx in the composite film is easily controlled by tuning annealing conditions such as temperature and atmosphere.
The resulting MnOx/rGO film not only has a high mechanical flexibility, but also the hybrid film based electrochemical capacitors shows remarkably enhanced electrochemical performances such as high specific capacitances and prolonged cycle-life after 10k cycles. Our work indicates that well-adjusted material properties of MnOx (crystallinity and oxidation states) are highly correlated with its energy storage ability. From the hybridization with rGO, our optimized MnOx/rGO hybrid film is potentially utilized as a promising electrode material for high performance flexible energy storage devices, and our proposed strategy can give a new insight for the fabrication of other transition-metal oxides/rGO based composites for flexible and wearable energy storage applications.

EN02.09.10
Enhanced Performance of Phosphate-Based Polyanionic Cathodes Using Water-in-(Bi)Salt Aqueous Electrolyte for Secondary Batteries—Two Case Studies Lalit Sharma1, Kosuke Nakamoto2, Shigeto Okada2 and Prabeer Barpanda1; 1Indian Institute of Science Bangalore, India; 2Kyushu University, Japan

Use of flammable organic electrolytes in secondary batteries possesses a safety threat and also it add to the cost of the battery in terms of battery fabrication. This force us to revisit the possible application of aqueous electrolytes where not only the toxicity is reduced but rate kinetics are also enhanced as there is a two-fold increase in the ionic conductivity. However, the limited working voltage window range to avoid water splitting makes it difficult to test all electrode materials in aqueous media especially high voltage materials. Hence, it is important to look for efficient and stable electrode materials compatible with aqueous electrolytes. Herein, we present two such case studies using earth-abundant Fe-based compounds. In the first case, performance of Na2FePO4F in aqueous electrolytes is demonstrated. The half-cell delivered a discharge capacity of 85 mAh g⁻¹ at 1 mA cm⁻² current density using a three electrode setup with excellent rate kinetics. A full cell assembled using NaTi2(PO4)3 anode delivered a reversible capacity of 85 mAh g⁻¹ at a voltage of 0.8 V battery (Sharma et al, ChemElectroChem, 2018, 6, 444-449). The second work is based on LiFePO4OH anode for aqueous lithium-ion batteries. In organic electrolytes, it delivered a stable discharge capacity of 140 mAh g⁻¹ at 2.6 V vs. Li⁺/Li. However, the half-cell configuration in aqueous electrolyte delivered a discharge capacity of 153 mAh g⁻¹ with very good rate kinetics. Interestingly, it was found to be working in the anodic range for aqueous batteries (Sharma et al, J. Power Sources, 2019, 429, 17-21). A full cell assembled with LiFePO4 cathode delivered discharge capacity of 120 mAh g⁻¹ at 0.8 V. The structural characterization along with electrochemical studies will be presented for both case cases.

EN02.09.11
Rechargeable Aluminium Organic Batteries Dong-Joo Yoo and Jang Wook Choi; Seoul National University, Korea (the Republic of)

While interest in rechargeable batteries has increased due to widespread usage of all-electric vehicles and drones, the locality and cost competitiveness of lithium and transition metal sources are prompting researchers to find alternative battery chemistry that can replace conventional lithium ion batteries (LIBs). As one of the most abundant elements in the Earth’s crust, aluminium has been of interest because it is a widely used commodity material in global commerce and has one of the highest theoretical capacities (8,056 mAh cm⁻³) on account of its multiple charge storage with trivalent ions. However, despite these advantages, research on aluminium ion batteries (AIBs) has not progressed significantly due to the limited electrolytes different from conventional non-aqueous and aqueous electrolytes. In addition, it is highly challenging to design cathode materials for AIBs, because trivalent aluminium ions (Al³⁺) normally have a very low ionic conductivity in most oxide or sulfide-based materials. Herein, we demonstrate a triangular macrocycle as a potential cathode material for AIBs, in which three redox-active organic units of phenanthrenequinone (PQ) are covalently linked. The PQ unit was firstly revealed to react with AlCl₂⁺ complex ions, and the formation of layered stacks of the triangular macrocycles allowed them to alleviate the strain induced during the insertion and extraction of the complex ions, showing high stability over thousands of cycles. Also, the use of cationic complex ions of AlCl₂⁺ increased the energy density of the whole cell by utilizing less chloride from electrolytes than that of anionic complex ions of AlCl₄⁻. These results constitute significant advances in the design of rechargeable aluminium batteries and provide a good starting point for the development of affordable large-scale energy storage devices.

EN02.09.12
An Investigation of Novel Solid State Electrolytes for Sodium Batteries Based on New Organic Ionic Plastic Crystals Karolina Biernacka; Deakin University, Australia
Sodium based batteries are emerging as a viable beyond Li-ion battery technology for future energy storage. Sodium has certain advantages such as greater abundance than lithium, great intrinsic safety and potentially a relatively high energy density. Currently, much research is focussed on the electrode materials (hard carbon anodes and new cathodes) however the electrolyte component is an important enabler of the technology. Ionic liquids and organic ionic plastic crystals (OIPCs) have been shown to be good electrolyte candidates for Na batteries, enabling Na metal anodes.

Organic ionic plastic crystals (OIPCs) are a unique class of solid state electrolyte material that are increasingly drawing attention due to their negligible volatility and increased safety in contrast to electrolytes based on organic, flammable solvents that are typically used in electrochemical cells. Moreover, many OIPCs are characterized by high thermal and electrochemical stability that makes them a perfect candidate for many electrochemical device applications. Tailoring the materials properties can be achieved by pairing various anions and cations. In order to enable use of OIPCs in sodium batteries a source of Na⁺ (as a second component) needs to be added to the neat plastic crystal. Addition of “dopants” to OIPCs may also result in enhanced mobility of ions in the electrolyte material by increasing the number and size of defects.

In this work we focus on a new OIPC - hexamethylguanidinium bis(fluorosulfonyl)imide (HMG FSI) - and the effect of doping with sodium salt (NaFSI). All electrolytes and neat OIPC were evaluated in terms of thermal properties, ionic conductivities, ion diffusion and electrochemical stabilities. HMG FSI displays excellent properties such high conductivity and a wide electrochemical stability window that makes it a promising material as a starting point for new solid state electrolytes. All compositions of OIPC with NaFSI resulted in solid-state electrolytes, and a phase diagram is proposed.

**EN02.09.13**

**Ionic Liquid-Based Gel Polymer Electrolyte Containing Zwitterion Additive for Lithium-Oxygen Batteries**

Hyun-Sik Woo¹, Hyebeen Son¹, Ji-Yun Min¹, Junki Rhee², Ho-Taek Lee² and Dong-Won Kim¹; ¹Hanyang University, Korea (the Republic of); ²Hyundai Motor Company, Korea (the Republic of)

The organic liquid electrolyte for lithium-oxygen battery has been mainly used because of its high ionic conductivity and wide electrochemical stability window. Despite these great electrochemical properties, the electrolyte depletion under semi-open system operation and electrolyte decomposition by highly reactive oxygen radical have been major obstacles to successful development of lithium-oxygen battery. The use of gel polymer electrolyte can effectively encapsulate organic solvent in the cell, suppress the electrolyte decomposition by superoxide anion radicals and provide stable interfacial characteristics with lithium electrode. These unique characteristics make gel polymer electrolyte a desirable electrolyte system for enhancing the cycling performance of the lithium-oxygen batteries. In this work, poly(methyl methacrylate) (PMMA)-based gel polymer electrolyte with non-volatile ionic liquid was synthesized. A chemical cross-linking reaction has been induced in the presence of divinylbenzene as a cross-linking agent by free radical reaction to obtain the three-dimensional cross-linked polymer network. As the non-volatile electrolyte, 1-ethyl-3-methylimidazolium bis(trifluoromethanesulfonyl)imide was added in order to improve the ionic conductivity of the gel polymer electrolyte. In addition, a zwitterion was synthesized and added as a functional additive to increase both dissociation of lithium salt and transport properties of Li⁺ ions as well as enhance the interfacial stability toward the lithium electrode. Our results demonstrate that the cycling stability of a lithium-oxygen cell assembled with gel polymer electrolyte could be remarkably improved by employing zwitterion additive due to its beneficial effects in the gel polymer electrolyte.

**EN02.09.15**

**Controlled Prelithiation Method of Silicon Monoxide by Lithium Naphthalenide for High-Capacity Lithium-Ion Batteries**

Daisuke Ito; Murata Manufacturing Co., Ltd., Japan

Recently, Lithium-ion batteries are widely utilized for a variety of applications, such as consumer electronics and electrical vehicles. Silicon monoxide (SiOx) is one of the most promising candidates for next generation anodes because of the high capacity and excellent cyclability. One of the remained issues for SiOx is the poor first-cycle Coulombic efficiency, in the range of 50-70%. In order to improve the first-cycle Coulombic efficiency, several prelithiation methods have been reported. Here we propose a facile prelithiation method by using a catalytic reaction between SiOx and lithium metal with naphthalene in ether solutions. The reaction continues until the electrochemical potential of SiOx equals to that of lithium naphthalenide. The catalytic reaction with naphthalene offers the practical implementation of highly scalable prelithiation for active materials in lithium-ion batteries. We demonstrate electrochemical performance of the prelithiated SiOx as well as the mechanism of the prelithiation
Li-metal batteries (LMBs) with composite polymer electrolytes (CPEs) have attracted considerable attention compared with conventional Li-ion batteries. However, the uncontrolled Li deposition and the flammability of CPEs are still pressing issues. Here, a non-flammable CPE is fabricated by composing of a flame-retardant trimethyl phosphate as the solvent, a poly(vinylidene) matrix, Li$_6$La$_3$Zr$_{1.4}$Ta$_{0.6}$O$_{12}$ fillers, and a LiClO$_4$ salt. The CPE exhibits unique characteristics including non-flammability, high ionic conductivity, flexibility, and good thermal stability. More importantly, a fluoroethylene carbonate (FEC) additive is used on the surface of Li metal to facilitate the formation of a LiF-rich solid electrolyte interphase layer. The FEC-coated Li|CPE|LiPFeO$_4$ battery exhibits excellent cycling stability (at room temperature) with a discharge capacity of 152 mAh g$^{-1}$ and nearly 100% Coulombic efficiency over 500 cycles at 0.2 C. The non-flammable CPE has a high rate capability of 109 mAh g$^{-1}$ at 4 C. To potentially improve the energy density of the LMB, the LiPFeO$_4$ cathode is replaced with a high-voltage material LiNi$_{1/3}$Mn$_{1/3}$Co$_{1/3}$O$_2$. The obtained Li|CPE|LiNi$_{1/3}$Mn$_{1/3}$Co$_{1/3}$O$_2$ cell exhibits a discharge capacity of 109 mAh g$^{-1}$ after 100 cycles at 0.2 C. Consequently, the strategy offers guidelines for the future development of safe batteries with high energy density.

Mixed ionic-electronic conductors (MIECs), which simultaneously conduct Li ions and electrons, can play a pivotal role when employed in the electrodes of solid-state batteries to achieve high energy and power densities. Both conductive agent and solid electrolyte can be substituted with MIEC catholyte in order to overcome the limitation of the conventional composite cathode such as lithium depletion on the electrolyte surface and CO$_2$ formation during the sintering. Furthermore, it is simpler to build a continuous conduction network between MIEC catholyte and the active material than conventional composite cathode which needs uniformly distributed network of two separate pathways for electrons (carbon) and Li ions (solid electrolyte).

In this study, we proposed new MIECs having perovskite structure. For the systematic materials design, the percolation for the macroscopic lithium conduction has been analyzed, moreover, oxygen vacancy formation and lithium diffusion barrier energies have been calculated with a density functional theory (DFT) and nudged elastic band (NEB) to estimate the electronic and lithium ion conductivities. In perovskites, high oxygen vacancy concentration can lead to high electronic conductivity owing to a large amount of carriers. Specifically, we have explored Li$_x$La$_y$MO$_{1.6}$ compositions with varying 3d transition metals and Li/La/vacancy configuration. With this strategy, we could achieve high lithium ion ($8.8 \times 10^{-5}$ S/cm) and high electronic ($2.0 \times 10^{-3}$ S/cm) conductivity together in the designed MIEC perovskite.

S. Bak and X.-Q. Yang at Brookhaven National Laboratory was supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Vehicle Technology Office of the U.S. Department of Energy through the Advanced Battery Materials Research (BMR) Program, including Battery500 Consortium under contract DE-SC0012704.

The search for next-generation solid-state superionic conductors has attracted significant attention. Among Na superionic conductors, Na$_{11}$Sn$_2$PS$_{12}$ has been reported to have a room temperature ionic conductivity of 1.4 mS/cm.
In this study, we employ density functional theory to study the stability of Na$_{11}$Sn$_2$PS$_{12}$ and further explore the substitution of Sn with Ge. Our results indicate that Na$_{11}$Ge$_2$PS$_{12}$ is more stable than Na$_{11}$Sn$_2$PS$_{12}$. Furthermore, substituting Sn with Ge increases the band gap, improves the room temperature ionic conductivity by a factor of 2, and lowers the activation energy of Na hopping. Statistical analysis suggests that Na$_{11}$Ge$_2$PS$_{12}$ has a faster diffusion along the $ab$-plane compared to the $c$-axis. The Na diffusion in Na$_{11}$Ge$_2$PS$_{12}$ appears to occur with two different mechanisms depending on temperature: 1) an ion hopping process at lower temperatures ($<800$ K); 2) a fluid-like distribution of Na ions at higher temperatures ($>1000$ K). The computations suggest that Na$_{11}$Ge$_2$PS$_{12}$ is a promising candidate as a solid Na electrolyte due to its high room temperature ionic conductivity and phase stability. In light of these simulation results, we expect to stimulate further experimental studies on Na$_{11}$Ge$_2$PS$_{12}$.

Orthogonal Binder and Solvent Selection for Protective Double-Layered Sulfur Electrodes in Lithium-Sulfur Batteries

Kookhan Kim$^{1,2}$, Jungjin Park$^{1,3,2}$, Chunjoong Kim$^{4}$, Byungwoo Park$^{1}$, Jang Wook Choi$^{1}$ and Yung-Eun Sung$^{1,2}$; $^1$Seoul National University, Korea (the Republic of); $^2$Institute for Basic Science, Korea (the Republic of); $^3$University of California, Berkeley, United States; $^4$Chungnam National University, Korea (the Republic of)

The lithium-sulfur (Li-S) battery has been considered one of the promising post-lithium-ion battery systems due to its high gravimetric energy density and environmentally benignity. However, there remain unresolved issues such as the insulating nature of active material and an irreversible loss of polysulfide anions during cycling. In this study, conceived from multi-layer spin coating process in the film technology, a novel double-layered electrode structure comprised of a bottom sulfur cathode and an upper protecting layer (PrL) was developed by using orthogonal pairs of solvent and binder. While two different pairs of the binder and solvent, PVDF-NMP and PE-chloroform, were attentively selected based on Hansen solubility parameters (HSPs) to avoid intermixing between the sulfur cathode and PrL during the electrode fabrication process. Two distinctive carbon materials, mesoporous carbon sheet (MCS) and carbon paper (CP), were adopted as respective conductive media for each layer. This rationally designed electrode showed superior electrochemical performances in cycle life and rate capability. We believe our strategy is one of the key findings to the practical application of Li-S battery.

Solution Processed NiO Nanoparticles towards High-Energy and High-Power Density Inkjet-Printed Supercapacitors

Pavlos Giannakou, Mateus Masteghin, Robert Slade, Steven J. Hinder and Maxim Shkunov; University of Surrey, United Kingdom

The push towards self-powered electronics through energy harvesting, calls for the development of high-performance supercapacitors that can enable sustained, autonomous operation of electronic devices for applications such as wearable electronics, biomedical implants and internet-of-things. Low cost supercapacitors with high energy density can potentially work as stand-alone and maintenance-free power sources when combined with energy harvesters. Therefore, great efforts have been devoted to extend the energy density of these storage systems by using pseudocapacitive transition-metal oxides, which store energy by fast surface redox reactions, enhancing the storage ability of the system, while keeping the energy/cost ratio low. The limited electronic conductivity of most pseudocapacitive oxides leads to high electrode resistance and, consequently, lower power densities. As a result, pseudocapacitive devices with high energy density and high-rate handling ability remain a major challenge. Considering the pressing need for high-power and high-energy density storage devices through low-cost fabrication strategies, our work focuses on the fabrication and integration of high performance, fully solution processed, co-planar NiO micro-supercapacitors through inkjet printing. In this study, the phenomenon of electrical conductivity enhancement of NiO when the material is processed at the nanoscale, was exploited through a developed nanoparticle-based, inkjet-printable ink that was used to produce highly porous NiO electrodes that demonstrated up to 14 orders of magnitude higher electrical conductivity compared to single crystal NiO. The enhanced conductivity of the electrodes was reflected in the ultra-high charge/discharge rate handling ability of up to 50,000 mV s$^{-1}$ and the low relaxation time constant of just 30 ms of the devices, which is among the lowest achieved for any supercapacitors. A surfactant-based saturated magnesium perchlorate aqueous gel electrolyte with extended operating voltage window was developed to enable the operation of the devices up to 1.5 V. The devices showed remarkable areal and volumetric specific capacitances of up to 155 mF cm$^{-2}$ and 705 F cm$^{-3}$ at 5 mV s$^{-1}$ respectively, surpassing the best micro-supercapacitors known. The superior energy and power density of the devices bridges the gap between lithium-ion batteries and electrolytic capacitors, opening new exciting opportunities in the field of electrochemical energy storage and harvesting.
Effective Electrochemical Charge Storage in the High-Lithium Compound Li₈ZrO₆ Andreas Stein¹, Nam Tran¹, Brian Spindler¹, William Smyrl¹, Donald Truhlar¹ and Shuping Huang²,¹; ¹Univ of Minnesota, United States; ²Fuzhou University, China

Li₈ZrO₆, because of its high lithium content, has been considered as a CO₂ absorber, a blanket material for fusion reactors, and as a solid electrolyte for high temperature applications. In this presentation we examine the synthesis, structure, and electrochemical properties of Li₈ZrO₆/carbon nanocomposites as potential cathode materials for lithium-ion batteries with high specific capacity. These nanocomposites were synthesized by the reaction between zirconyl chloride and lithium benzoate as the source of both lithium and conductive carbon. Li₈ZrO₆ is a pseudolamellar compound with high lithium content and containing zirconium as a relatively abundant, low cost transition metal. Although Li₈ZrO₆ is intrinsically a poor conductor its intimate contact with in-situ produced carbon and its small grain size enabled by mechanical delamination allow for reversible electrochemical delithiation. Quantum mechanical calculations suggest that removal of 2 Li/formula unit is topotactic with only 1–2% volume change, but removal of more Li involves a distortion with possible loss of oxygen, although this may be kinetically prevented. In fact, coin half-cells containing Li₈ZrO₆/C as the cathode and Li-metal as the anode exhibited a capacity of 221 mAh/g (which corresponds to extracting 2 Li per formula unit) over at least 140 cycles. By applying a higher capacity limit, a discharge capacity of 331 mAh/g (which corresponds to extracting 3 Li per formula unit) was maintained over 15–20 cycles. Ex-situ and operando X-ray diffraction (XRD) studies of galvanostatically cycled cells showed that at these levels of charge, delithiation follows a reversible path with only small distortions around Zr atoms. During this process, crystalline grain sizes decrease continuously, shortening diffusion lengths within grains but increasing the number of grain boundaries and electrode/electrolyte interfaces. Given that Zr is already in its highest oxidation state in Li₈ZrO₆, charge storage appears to involve partial oxidation of oxygen atoms and production of small-polaron holes, as supported by XRD, X-ray photoelectron spectroscopy, and pair-distribution function studies and predicted by quantum mechanical calculations. At higher depths of charge, delithiation results in amorphization of the active electrode material. The charge storage mechanism in Li₈ZrO₆ is unusual among lithium-ion battery electrode materials and involves a combination of mechanisms that resemble intercalation and conversion reactions, as well as some capacitive storage at higher charge rates. With further refinement, Li₈ZrO₆/C based materials open up opportunities to develop new cathode materials for lithium-ion batteries that may improve on currently existing capacity barriers.

Quasi-Solid State Sodium-Ion Capacitor Based on Ionogel Separator Chunxian Xing and Haitao Zhang; Chinese Academy of Sciences, China

Development of sodium-ion based energy storage devices is becoming more popular on account that the excessive consumption of lithium resources, which will be expected more in the electrical vehicle and grid scale energy storage fields. However, the design and construction of safer sodium ion based devices are still hindered owing to lack of high performance electrodes materials and high ionic conductive solid state separators.

Here, we will report a new type of quasi-solid sodium ion capacitor with high safety and enhanced high-energy density by using flake-shaped MoS₂ nanohybrids and sodium-ion ionogel electrolyte. The optimized quasi-solid state sodium ion capacitor could deliver a high energy density up to 115 W h kg⁻¹ at 70 °C, and excellent durability up to 8000 cycles. The relationship between microstructure and performances was systemically evaluated. Energy storage mechanisms were also exploited by using electrochemical analysis and molecular simulation methods in order to disclose the temperature effects. Our study suggests that high performance capacitors with enhanced energy density and cyclability can be achieved by carefully programmed nanoarchitectures and optimized ionic liquid gel separators.

Reversible Cationic and Anionic Redox in Antifluorite-type Li₆CoO₄ Cathode Materials Hiroaki Kobayashi¹, Takashi Tsukasaki², Yoshiyuki Ogasawara², Mitsuhiro Hibino², Tetsuichi Kudo², Noritaka Mizuno², Itaru Honma¹ and Kazuya Yamaguchi²; ¹Tohoku University, Japan; ²The University of Tokyo, Japan

With the increase in the usage demands of lithium-ion batteries (LIBs) as power sources, it is imperative to further
improve the LIB performance. In particular, cathode materials in LIBs must exhibit a high energy density, long lifetime, and safety. For enhancement of energy densities in LIBs, use of reactions not involving redox of heavy transition metal ions is effective. Recently, using redox reactions of oxide ions in cathode materials has attracted much attention. In cathode materials referred to so-called Li-rich oxides, such as layered-rock-salt which a part of transition metal is substituted by lithium and cation-disordered-rock-salt which transition metal and lithium are located randomly in the same cation sites, an additional high capacity has been reported via the utilization of charge compensation by oxygen in addition to the transition-metal redox.

Antifluorite-type Li$_5$FeO$_4$, Li$_6$CoO$_4$, and Li$_6$MnO$_4$ have potentials as high-capacity cathode materials due to the rich lithium content which can be intercalated/deintercalated. Cathode performances of these materials were first reported in 1999 (S. Narukawa et al., Solid State Ionics 1999, 122, 59.), and very recently observation of oxygen redox in Li$_5$FeO$_4$ was confirmed (C. Zhan et al., Nat. Energy 2017, 2, 963.). However, the amount of reversible capacity with antifluorite-type materials were attributable to only redox of transition metals (Fe$^{3+}$/Fe$^{4+}$ in Li$_5$FeO$_4$ with 173 mAh g$^{-1}$ or Co$^{2+}$/Co$^{4+}$ in Li$_6$CoO$_4$ with 326 mAh g$^{-1}$).

Here we demonstrate reversible oxygen redox in antifluorite-type materials using mechanochemically treated Li$_6$CoO$_4$. After ball-mill treatment, tetragonal Li$_6$CoO$_4$ changed to cubic antifluorite phase. Since no decomposition of Li$_6$CoO$_4$ into CoO and Li$_2$O was observed, the cubic phase was attributed to cation-disordered Li$_6$CoO$_4$. This material exhibited charging capacity of 489 mAh g$^{-1}$ without O$_2$ gas evolution reaction and reversible capacity of 400 mAh g$^{-1}$, indicating more than 2 electrons were transferred reversibly. Co K-edge and O K-edge XANES spectra revealed that both redox of Co$^{3+}$/Co$^{4+}$ and O$^{2-}$/O$^{2+}$ proceeded during charge/discharge. According to XRD patterns, reversible transformation between cubic antifluorite phase and cubic rock-salt phase was observed. Since pristine Li$_6$CoO$_4$ was tetragonal, reversible reaction between tetragonal antifluorite and cubic rock-salt hardly proceed. The large reversible capacity with mechanochemically treated Li$_6$CoO$_4$ was probably derived from both downsizing effect of particles and transformation from tetragonal phase to cubic phase by cation-disordering.

EN02.09.24
Investigating on Lithium Plating/Stripping (P/S) Behavior for High Performance Li Metal Anode Quan Li$^{1}$, Hong y. Pan$^{1}$, Tian C. Yi$^{2}$, Bao g. Quan$^{1}$, Xue l. Wang$^{3}$, Howard Wang$^{3}$, Xi Qian Yu$^{1}$ and Hong Li$^{1}$; $^{1}$Chinese Academy of Sciences, China; $^{2}$Institute of High Energy Physics, Chinese Academy of Sciences, China; $^{3}$University of Maryland, United States

Lithium metal anodes have been considered as the ultimate choice for anode electrodes for rechargeable batteries because of the high theoretical specific capacity (3860 mAh/g), the lowest electrode potential (3.040 V versus standard hydrogen electrode) and low density (0.534 g/cm$^3$). The safety problem caused by the uncontrollable lithium dendrite and the poor cycling performance has limited the application of lithium second batteries several decades. Here the lithium plating/stripping (P/S) behavior are investigated respectively with non-aqueous electrolyte and solid-state electrolyte by combining interfacial modification and ordered three-dimensional structure methods. Lithium plating/stripping (P/S) behavior is regulated by both the interfacial conductivity and distribution of electric field induced by the structure. It was demonstrated that homogenous surface electronic conductivity and ordered three-dimensional structure could be beneficial to significantly improve lithium plating-stripping behavior and reach a high performance lithium metal anode.

EN02.09.25
Micro/nano-Structure VO$_2$/Carbon Nanofibers Interlayer as a Host of Polysulfides Immobilization and Conversion for High-Performance Lithium–Sulfur Batteries Zhihao Yu, TrungHieu Le, Tianji Gao, Ying Yang, Zheng-Hong Huang and FeiYu Kang; Tsinghua University, China

Lithium-sulfur batteries become one of the most promising batteries due to the high theoretical specific energy density. However, practical applications are currently hindered by a few obstacles, such as poor cycle performance notoriously caused by the shuttle effect of lithium polysulfides. Herein, we design a micro/nano-structure VO$_2$/carbon nanofibers composite via a hierarchical control method. And we utilize this self-supporting membrane as the interlayer in lithium-sulfur batteries. The VO$_2$ microsheets with a porous structure introduce an immobilization process of polysulfides, controlling the deposition of Li$_2$S$_3$ or Li$_2$S on the designed interlayer. An arranged relocation of sulfur species is induced during cycling, resulting in a shortened electron passage and an improved utilization of active material. The exposing VO$_2$ nanoparticles on carbon nanofibers provide a large amount of active sites for polysulfide conversion, which can effectively improve the redox kinetics. With a sulfur loading of 2.4mg cm$^{-2}$ and a sulfur content of 80% at the whole electrode level, the cell with micro/nano-structure
MoS$_2$ is a promising 2D material which could serve as anode for fabricating lithium ion batteries with high energy and power densities.\textsuperscript{1,2} Crystallinity (ordered layer structure) and defects (mainly edge and planar defects) in MoS$_2$ are shown to have significant role in deciding the electrochemical performance.\textsuperscript{3} In an effort to disentangle and understand the role of individual contributions on the electrochemical properties, we have synthesized planar and edge defect-rich MoS$_2$ (MoS$_2$-D) nanosheets and defect-suppressed ordered layers of MoS$_2$ (MoS$_2$-C) nanosheets from a wet chemically synthesized precursor. MoS$_2$-D are obtained upon annealing at 500 °C and MoS$_2$-C nanosheets are obtained upon annealing at 900 °C for 1 h. For MoS$_2$-D anodes, the crystallite size is small (∼3 nm) with an average 5 layers of S-Mo-S stack within a nanosheet. The nanosheets are mostly curled, resulting in large number of dislocations, edge and planar defect regions. MoS$_2$-C nanosheets have larger crystallite size (∼10 nm) with an average of 15 S-Mo-S layers. These crystalline nanosheets are mostly flat with less defects and the defects are mostly from the edge terminations and surface regions. Lithiation and delithiation characteristics, effective charge storage capability, rate capability and cycling stability are analyzed in the intercalation regime (1 to 3 V vs Li/Li$^+$). During initial lithiation, MoS$_2$-D nanosheets exhibit large Li intake ($x$=1.9) and show an initial lithiation capacity of 319 mAh/g ($\sim$Li$_{1.8}$MoS$_2$). The MoS$_2$-C nanosheets in contrast show smaller intake of Li ($x$=1.22) and has a capacity of 204 mAh/g ($\sim$Li$_{1.2}$MoS$_2$). The excess lithium intake is attributed to the interaction of lithium ions with planar and edge defect sites in MoS$_2$ nanosheets. The first reversible capacities are found to be 166 mAh/g ($x$=0.99) and 138 mAh/g ($x$=0.82) for MoS$_2$-D and MoS$_2$-C nanosheets, respectively, suggesting that a large fraction of initial Li intake for MoS$_2$-D nanosheets is electrochemically irreversible. At 10C current rate, the MoS$_2$-D and MoS$_2$-C nanosheets show reversible capacity of 37 mAh/g and 67 mAh/g, respectively. This indicates that the rate capability of well crystalline nanosheets is better. Interestingly, when tested for cycling stability at 10C-rate for 1000 cycles, at the end of 1000 cycles a ∼30% increase in capacity is noted for MoS$_2$-D anodes. Contrastingly, MoS$_2$-C nanosheets show capacity fading, with final capacity ∼80% of initial capacity. The decrease in capacity of MoS$_2$-C is due to the increasingly defiant Li diffusion upon continuous cycling. The gain in capacity in MoS$_2$-D nanosheets is attributed to the excess lithium retained at defects during the first lithiation. These excess lithium at defect sites shuttle around, reducing the diffusion lengths for lithium ions, thus effectively activating the electrode over repeated cycling. These results indicate that crystallinity and defects play complementary role in deciding the electrochemical properties of 2D MoS$_2$ in the intercalation regime. Thus, defect-rich nanosheets, MoS$_2$-D, exhibit large capacity at low current
rates and better cycling stability. Defect-suppressed nanosheets, MoS$_2$-C, on the other hand have better rate capability at high current rates and reasonable cycling stability.

Efficiency and Quality Issues in the Production of Black Phosphorus by Mechanochemical Synthesis *Piercarlo Mustarelli*$^1$, Chiara Ferrara*$^1$, Pietro Galinetto*$^2$, Cristina Tealdi*$^2$, Eliana Quartarone*$^2$ and Stefano Passerini*$^3$; $^1$University of Milano-Bicocca, Italy; $^2$University of Pavia, Italy; $^3$Helmholtz Institute Ulm, Germany

Elemental phosphorous is emerging as one of the most intriguing anode materials for Li, Na, and K rechargeable batteries due to its specific capacity of 2596 mAhg$^{-1}$. (1) At the same time, the performances obtained from different tests are far from the theoretical values (~600-1000 mAhg$^{-1}$). Moreover, no clear indications about the phosphorous form most suitable for electrochemical applications is emerged until now. Elemental phosphorous exists as different allotropes, including white phosphorous, WP, red phosphorous, RP, and black phosphorous, BP. Orthorhombic BP, the most stable polymorph, presents a 2D structure, making it particularly intriguing as anode material. The preparation of ortho-BP is thus a central issue in development of anodes based on elemental P. Among the variety of complex synthesis approaches, high energy ball milling, HEBM, starting from the commercially available RP appears to be the most convenient. Even if HEBM is one of the most diffuse preparation method and several experimental procedures have been proposed, no systematic exploration of the synthesis parameters has been tackled to date.

In this work, starting from the mathematical model of energy transfer during the ball milling process, we investigate the effects on RP $\rightarrow$ BP conversion of three experimental parameters, the rotation speed, the milling time, and the weight ratio between the spheres and the milled material (BtPw ratio). The efficiency of the conversion process was verified by solid-state NMR, Raman spectroscopy, and X-ray diffraction. Whereas the first two parameters have a minor importance, the BtPw ratio plays a primary role in the RP $\rightarrow$ BP conversion. Yields approaching 100% can be obtained also with short milling times (15 min) and adequate rotation speed (e.g., 500 r.p.m.), provided that the BtPw ratio $>40:1$ is used. These results confirm the energy sustainability of the mechanochemical synthesis approach. (2)

$^{17}$O NMR and Electrochemical Characterization of Super-Concentrated Solutions as Electrolytes for Lithium Metal Batteries *Piercarlo Mustarelli*$^1$, Irene Ruggeri*$^2$, Andrea La Monaca*$^2$, Francesca De Giorgio*$^2$, Francesca Soavi*$^2$, Catia Arbizzani*$^2$, Vittorio Berbenni*$^3$ and Chiara Ferrara*$^4$; $^1$University of Milano-Bicocca, Italy; $^2$University of Pavia, Italy; $^3$University of Bologna, Italy; $^4$University of Pavia, Italy

The combination of electrochemical techniques with bulk and advanced spectroscopic ones is a powerful tool to investigate the processes occurring in the novel electrochemical energy storage systems based on lithium metal anode. NMR exploits the magnetic properties of atoms nuclei to find out information on the chemical environment in molecules and solids, as well as on its changes over time. The combination of $^7$Li and $^{17}$O (at natural abundance) nuclear magnetic resonance (NMR) [1] and electrochemical characterization is here proposed as an effective approach to investigate the Li$^+$ solvation structures and properties of electrolytes featuring tetraethylene glycol dimethyl ether and lithium-bis(trifluoromethane sulfonyle) imide. The NMR results, also supported by physicochemical characterizations such as thermal gravimetric analyses, differential scanning calorimetry, specific
conductivity and viscosity, provide information about the association of Li\(^+\) ions with anion and solvent molecules, so allowing a deeper knowledge on the relationships among structure and functional properties of super-concentrated solutions. The increase of the electrolyte concentration is, indeed, a multi-effective strategy to improve the performance of high energy batteries featuring Li metal anode [2, 3].

A Safe Quasi-Solid Electrolyte Based on a Nanoporous Ceramic Membrane for High-Energy, Lithium-Metal Batteries

Eliana Quararone\(^1\), Nicolò Pianta\(^2\), Chiara Ferrara\(^3\), Umberto Anselmi Tamburini\(^1\) and Piercarlo Mustarelli\(^2\);
\(^1\)Univ of Pavia, Italy; \(^2\)University of Milano-Bicocca, Italy

The use of lithium metal as the anode for Lithium Metal Batteries (LMB) requires having solid or quasi-solid electrolytes able to block dendrites formation during cell cycling. Here we reported on a hybrid electrolyte membrane based on nanostructured yttria-stabilized-zirconia, sintered by means of High Pressure-Field Assisted Sintering Technique (HP-FAST) in order to retain proper nano-porosity, and activated with a standard LiPF\(_6\)-EC-DMC solution. By a thorough physico-chemical and functional characterization, we demonstrated that the liquid is effectively nano-confined in the ceramic membrane, and the resulting quasi-solid electrolyte is non-flammable. A remarkable conductivity value of 0.91 mS cm\(^{-1}\) was observed at room temperature, with activation energy of 0.2 eV, and cation transference number, \(t^+ =0.55\), substantially higher than that of the pure liquid electrolyte. The hybrid electrolyte showed electrochemical stability up to 6 V vs. Li\(^+\)/Li, and excellent resistance to dendrite formation for more than 350 cycles in a Li/electrolyte/Li symmetrical cell. A full cell Li/electrolyte/LiMn\(_2\)O\(_4\) showed more than 90 mAh g\(^{-1}\) at 2C for more than 120 cycles. These very promising results indicated that nano-porous ceramic hybrid electrolytes may be conveniently used in LMB.

Kinetic Study of Redox Mediators for the Realization of High-Power Lithium–Oxygen Batteries

Youngmin Ko, Hyeokjun Park and Kisuk Kang; Seoul National University, Korea (the Republic of)

The use of redox mediator (RM) effectively reduces the high polarizations of lithium-oxygen batteries by mediating the electrochemical formation and decomposition of the discharge products. As the electrochemical reactions are mediated by RMs, the power capability of the system would be critically dependent on the intrinsic kinetic properties of RM in mediating the reaction. Herein, we performed comparative kinetic study for several reported oxygen evolution reaction RMs by probing RM-assisted charging process with respect to the rate of chemical decomposition of discharge product and the diffusivity of RM in the controlled lithium-oxygen cells. It is found that the overall kinetics of RMs have a positive correlation with the redox potential of RMs, and, multi-redox RMs can display distinct properties depending on its oxidation states. Among RMs investigated, DMPZ\(^{2+}\) (5,10-dihydro-5,10-dimethylphenazine) exhibit the highest reaction rate of lithium peroxide decomposition, while the mass diffusion rate is the highest for TEMPO\(^+\) (2,2,6,6-tetramethyl-1-piperidiny). Additionally, the choice of electrolyte is shown to greatly affect the rate capability of RM-assisted charge, and thus be carefully considered. This study suggests the importance of understanding the kinetics of RMs and provides guidelines for achieving an optimized RM/electrolyte combination to realize high-power lithium–oxygen batteries.

Perovskite Sr\(_{x}\) (Bi\(_{1-x}\)Na\(_{0.97-x}\)Li\(_{0.03}\))\(_{0.5}\)TiO\(_3\) Ceramics with Polar Nano Regions for High Power Energy Storage

Jiyue Wu and Haixue Yan; Queen Mary, University of London, United Kingdom

Dielectric capacitors are very attractive for high power energy storage. However, the low energy density of these capacitors, which is mainly limited by the dielectric materials, is still the bottleneck for their applications. In this work, lead-free single-phase perovskite Sr\(_{x}\) (Bi\(_{1-x}\)Na\(_{0.97-x}\)Li\(_{0.03}\))\(_{0.5}\)TiO\(_3\) \((x=0.30\) and \(0.38)\) bulk ceramics, prepared using solid-state reaction method, were carefully studied for the dielectric capacitor application. Polar nano regions...
(PNRs) were created in this material using co-substitution at A-site to enable relaxor behavior with low remnant polarization \( (P_{r}) \) and high maximum polarization \( (P_{\text{max}}) \). Moreover, \( P_{\text{max}} \) was further increased due to the electric field induced reversible phase transitions in nano regions. Comprehensive structural and electrical studies were performed to confirm the PNRs and reversible phase transitions. And finally, a high energy density (1.70 J/cm\(^3\)) with an excellent efficiency (87.2\%) was achieved using the contribution of field-induced rotations of PNRs and PNR-related reversible transitions in this material, making it among the best performing lead-free dielectric ceramic bulk material for high energy storage.

EN02.09.33

**Asymmetric Supercapacitors Based on 3D Graphene-Wrapped V_{2}O_{5} Nanospheres and Fe_{3}O_{4}@3D Graphene Electrodes with High Power and Energy Densities**

Nageh K. Allam; American University in Cairo, Egypt

Asymmetric supercapacitor (ASC) devices are emerging as effective high-performance energy storage systems. We report on the synthesis of novel and green electrode materials and their use to construct high-performance ASCs. The assembled ASCs are based on 3D porous graphene-wrapped V2O5 nanospheres as the positive electrode and Fe3O4@graphene as the negative electrode. The optimal ratio of the V2O5 nanospheres intercalated graphene sheets in the composite electrodes were identified. Compared to all positive electrode formulations, the V2O5@3DGr (33\%) hybrid electrode achieved the highest specific capacitance (612.5 F g\(^{-1}\)) at a current density of 1.0 A g\(^{-1}\). Based on the excellent electrochemical behavior of the fabricated electrodes, the assembled asymmetric supercapacitor devices of V2O5@3DGr//Fe3O4@3DGr exhibited a maximum energy density of 54.9 Wh kg\(^{-1}\) with a power density of 898 W kg\(^{-1}\) with an extended voltage of 1.8 V in 1.0M Na2SO4 aqueous electrolyte. Furthermore, the ASC device demonstrated excellent cycling stability with 89.6\% capacitance retention over 10,000 cycles. The outstanding electrochemical performance of the fabricated electrodes can be attributed to the synergic effect between graphene sheets and metal oxides (V2O5, Fe3O4) sandwich network structures. Interestingly, the proposed asymmetric electrode materials provide a promising strategy for integrating low-cost transition metal, green electrolyte, high energy, and power densities of supercapacitor devices and that can bridge the gap with commercial batteries.

EN02.09.34

**Improving the Cycling Performance and Reducing DCIR of NMC Cathode Materials by Dry Surface Doping**

Kitae Kim, Yang Shi, Yingjie Xing, Andrew Millonig, Bryan Kim and Derek C. Johnson; A123 Systems, United States

Lithium nickel manganese cobalt oxide (NMC) has become the most promising cathode material for next generation lithium-ion batteries due to high specific capacity and low cost. However, the fast capacity decay and DCIR growth during cycling still limit its practical application. Bulking doping approach can increase the cycling performance, while the specific capacity is sacrificed due to the electrochemically inactivity of dopants. The surface of cathode materials is exposed to the electrolyte and therefore more vulnerable to the lattice volume change and phase change, which greatly contributes to the capacity degradation. Therefore, restricting the doping to cathode surface may minimize the sacrifice in capacity while stabilizing the structures. In this work a unique dry process has been developed to achieve surface doping. This dry process eliminates the contact between the cathode materials with water or organic solvent and the possible damage of the cathode surface. In addition, this process eliminates the multi-step drying process to remove the solvent and the necessity of waste management. The dry surface doping technique significantly improves the cycling performance and reduces the DCIR increase during cycling. Meanwhile the crack formation and growth in cathode materials during cycling is suppressed. The result suggests great promise of using the cost-efficient process to improve the cycling performance and reducing DCIR of NMC cathode materials.

EN02.09.35

**Wide Temperature Range Ion Transport and Tunable Mechanical Properties of Molecular Ionic Composite Electrolytes**

Joshua Bostwick¹, Curt Zanelotti², Ciprian Iacob³,⁴, Andrew Korovich², Louis Madsen² and Ralph Colby³; ¹The Pennsylvania State University, United States; ²Virginia Tech, United States; ³National Research and Development Institute for Cryogenic and Isotopic Technologies, Romania; ⁴Institute of Chemical Technology and Polymer Chemistry, Karlsruhe Institute of Technology, Germany
Polymer electrolytes show promise as alternatives to energy storage and electrochemical devices but have been limited due to their inverse correlation between ionic conductivity and shear modulus. Recently, we have discovered a new class of electrolyte material, termed a molecular ionic composite (MIC), through the combination of poly(2,2')-disulfonyl-4,4' benzidine terephalamide (PBDT), a rigid-rod (aspect ratio ~ 1000) sulfonated polyelectrolyte, and ionic liquids (ILs). MICs are thermally stable materials with simultaneous high conductivity and high modulus. However, the mechanisms underlying this fortuitous combination of properties remain unknown. In this study, we use rheology, dielectric spectroscopy and NMR diffusometry to measure the temperature dependences over a wide temperature range (-90°C to 200°C) of the linear viscoelastic response, ionic conductivity, dielectric constant, and ion diffusion coefficients in a series of non-crystalline MICs of varying PBDT concentration with the ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate (BMIm BF₄). We show that as the PBDT concentration in the MICs increases, the shear modulus increases into the MPa range while maintaining ionic conductivity within a factor of two of the neat IL. Additionally, by comparing the ionic conductivity with ionic diffusion, we show that increasing PBDT concentration in the MICs leads to more ions contributing to the conductivity.

**EN02.09.36 Creation of Fine Spaces by Electrospinning and Application to Electrode Materials of Energy Devices**

Kyoichi Oshida, Nozomi Kobayashi, Kozo Ohsawa, Yoshihiro Takizawa, Tomoyuki Itaya, Masahiko Murata and Shogo Sato; Nagano College, Japan

This study aims to create controlled fine space by electrospinning, and to develop the electrode materials for high-performance energy devices.

With the popularization of mobile devices, household appliances, hybrid vehicles, electric vehicles, and the like, the use of power storage devices is expanding, and further performance improvements are required. Its performance is dependent on the capacity of the electrode. Particulate graphite has been used for the anode materials of currently widely used lithium-ion rechargeable batteries (LIBs), but the battery characteristics close to the theoretical capacity (372 mAh/g) have been realized previously. Therefore, the study of new anode materials is essential to achieve further high performance of storage devices. There is silicon (Si) with a theoretical capacity of 4200 mAh/g as an anode material to replace graphite, but there are many challenges for practical applications, such as the destruction of Si structures due to the large volume expansion rate (300-400%) upon the intercalation of Li ions. In this study, a novel electrode material was developed by compositing Si with carbon nanofibers derived from polyacrylonitrile (PAN).

The nanofibers have a large surface area because of thin nanofibers in complex entanglement with each other by electrospinning. The bulk density of nonwoven fabrics composed of nanofibers is small, and about more than 90 vol.% of them are occupied by space. We tried to absorb the expansion of Si by the space of nanofibers.

Solutions of solvents N,N-dimethylformamide (DMF) mixed with PAN, and Si particles were used for electrospinning. The ratio of PAN to Si particles is 2:1 by weight. Nanospaces are created by the binding of heteromorphic molecules in which different substances are combined at the molecular size level. The voltage from 20 to 30 kV was applied between the nozzle and the collector for electrospinning. Ultrasonic vibration was also applied to the needle tip, which is the nozzle of electrospinning, to forcibly mix the materials during spinning. The texture and structure of the nanofibers were observed and analyzed by SEM and transmission electron microscopy (TEM) combined with image processing.
In order to stabilize the nanofibers produced by electrospinning, they were heat-treated at 280°C in the air. Carbon nanofibers (CNFs) were made from them by heat-treatment at 700 to 1000°C in the nitrogen atmosphere. The prepared sample and polyimide (PI) and N-methyl-2-pyrrolidone (NMP) were kneaded, coated on a copper foil, and fired to prepare an electrode material.

Nano spaces were created in the CNFs and Si particles were able to be contained in the CNFs. Not only large Si particles but also small Si particles were found to contain CNT. In the second cycle of the charge/discharge experiment of LIB electrode made from the materials, a discharge capacity at 500mAh/g was obtained, which was 1.3 times the theoretical capacity using graphite. Although the decrease in capacity from the second cycle to the fifth cycle was small, the capacity decreased to the same level as the theoretical capacity of graphite near 15 cycles. The capacity at the first cycle charge reached 900 mAh/g, resulting in large irreversible capacity. It is considered that electrode breakage occurs, such as Si particles on the CNF surface exfoliate from the fiber due to the volume change. It may be because the energy was used to form organic film (called a solid electrolyte interface (SEI)) on the electrode surface. In order to put the LIB using the present anode material into practical use, it is necessary to suppress the irreversible capacity at the first cycle.

Mixing and electrospinning PAN with Si particles and the like to fabricate functional porous carbon materials with micropore and mesopore connected multidimensional structure leads to the development of next generation energy devices.

EN02.09.37
The Co-Rich Cathode with Controlled Surface Reactivity for Long-Term Lithium-Based Batteries Moonsu Yoon and Jaephil Cho; Ulsan national institute of science and technology, Korea (the Republic of)

The application of lithium-ion batteries (LIBs) has extended from portable devices to smart grid and energy storage system, resulting in the advancement of energy infrastructure in our society today. Yet further improvement, especially in volumetric density, is still required. Among various types of layered cathode materials (LiNi_{1-x-y}Co_{x}Mn_{y}O_{2}) for LIBs, conventional LiCoO₂ (LCO) still holds the record for practical volumetric energy density (2500 Wh L⁻¹ when charged to 4.30 V vs. Li⁺/Li) due to its high compressed electrode density (4.0-4.2 g/cc). For LCO cathode, charging above 4.3 V is a viable method to increase the energy density of LIBs. However, at the voltage limit exceeding ~4.35 V, it is plagued with a rapid capacity fading issue coupled with structural and surface deformations.

Herein, we have demonstrated surface-stabilized LiCo₀.⁹₅Ni₀.₀₅O₂ (denoted as S-LCNO) with superior cycle stability at high charge voltage of 4.45 V under practical conditions (loading density ~15 mg cm⁻², electrode density ~4.0 g cm⁻³ with both coin-type half-cell and pouch-type full-cell testing). Interestingly, the doped-Ni with oxidation state gradient (from 3+ to 2+) in S-LCNO only modestly changed the bulk chemistry, yet significantly modified the surface properties, such as decreasing surface reactivity to electrolyte decomposition in the close-to-surface region. Using spatially-resolved electron energy loss spectroscopy (EELS), we have found that the doped-Ni in Co-rich cathode, which redox potential (Ni²⁺/³⁺ and Ni³⁺/⁴⁺:e⁻ band) located above Co³⁺/⁴⁺:t²g band with respect to the O²⁻:2p band, is likely to mitigate the hole transfer to the O site at charged state, a crucial factor determining the degree of surface reactivity. Indeed, by measuring the leakage current during a floating test, we further observed that S-LCNO stably sustained a mild surface reactivity upon cycling, compared to commercial LCO. As a result, the interfacial degradations, such as surface structure transformation and side reactions from catastrophic EC dissociation, were effectively suppressed. This study would suggest the potential feasibility of facile doping strategy to enhance the surface stability with a comprehensive understanding of the kinetic origin of capacity decay in Co-rich cathode.

EN02.09.38
Designing Energy Storage Material and Layer Fabrication Procedures for the Thin- and Thick- Film Batteries Suman Pokhrel¹,², Michael Gockeln³ and Lutz Mädler¹,²; ¹University of Bremen, Germany; ²Leibniz Institute for Materials Engineering IWT, Germany; ³Fraunhofer Institute for Manufacturing Technology and Advanced Materials - IFAM, Germany

The advancement of the flexible electronic system is crucial for the development of electronic products including mobile, computers and many other related products. A major requirement to such electronics is the implementation of physically flexible high-performance energy storage system. The rechargeable thin films solid-state Li-ion batteries are key to power-drive such modern devices due to their properties such as high energy/power density
and/or high efficiency and long cycle life. Though these batteries are very attractive and promising both in terms of storage capacity and performance, the large scale production of the particle is quite expensive. A new innovative production, process optimization, and automation engineering of the large-scale battery production are important for economic viability. The current industrial Li-ion battery production route carries three major steps including (1) slurry-based electrode preparation (2) cell assembly (3) formation and aging. The recent electrode manufacturing procedure is a very complex and labor-intensive process warranting a new fabrication procedure to fulfill the market demand.

In the present work, the electrode fabrication was carried out following (1) traditional electrode manufacturing procedure with the phase pure Li$_4$Ti$_5$O$_{12}$ powder produced using high throughput screening of the precursor-solvent combinations$^1$ (2) material transfer from the collecting unit to the electrode substrate via role-to-lamination techniques (3) in-situ double flame direct deposition technique for C coating.$^2$ During the production process, the C aerosol stream from one individual flame was mixed with the stream of LTO active material to deposit either on the substrate or the collecting unit. While the in-situ direct deposition technique avoids the use of any solvent or binder for electrode preparation, the lamination technique allows studying the influence of lamination pressures on the electrochemical performance. All the powders/layers were characterized using advanced physiochemical techniques such as XRD, BET, and TEM imaging. The overall performance from role-to-role lamination technique for layer transfer showed enhanced specific discharge capacities compared to reference electrodes prepared using traditional electrode manufacturing procedure. The discharge capacity of 146.5mAh/g for 450 cycles at 1C with the charge retention of 85%, reveal high rate and efficient charge reversibility. This work clearly shows (1) a paradigm shift from labor-intensive electrode fabrication process to directly aerosol deposition (2) possibility of electrode deposition on a flexible/nonflexible polyimide substrate. To test this hypothesis, Li$_4$Ti$_5$O$_{12}$ electrodes were covered with a solid electrolyte and tested against lithium metal electrodes. The battery performance both at flat and physically bent conditions showed feasibility and uniqueness of the electrode fabrication procedure opening a new research opportunities for manufacturing flexible miniaturized thin film batteries.$^3$

The Effect of Lithium Surface Chemistry and Topography on Solid Electrolyte Interphase Composition and Dendrite Nucleation Melissa Meyerson$^1$, Jonathan Sheavly$^1$, Andrei Dolocan$^1$, Monroe Griffin$^1$, Anish Pandit$^1$, Rodrigo Rodriguez$^1$, Ryan Stephens$^2$, David Vanden Bout$^1$, Adam Heller$^1$ and Charles B. Mullins$^1$; $^1$University of Texas at Austin, United States; $^2$Shell International Exploration and Production Inc., United States

Lithium metal is an ideal replacement for graphite anodes in lithium batteries due to its 10 fold higher capacity; however, it suffers from safety and efficiency problems that have so far prevented it from being commercialized. In particular, the tendency of Li metal to form dendritic structures presents a major safety hazard as dendrites can lead to short circuit, thermal runaway, and battery fires. However, the causes of dendrite nucleation are numerous and complex. In order to disentangle these causes we studied the factors affecting dendrite nucleation using an array of analytical techniques, allowing us to examine the surface chemistry and topography with simultaneous ultra-high spatial resolution and chemical selectivity. From this, we developed a 3D picture of the chemical make-up of the native Li surface, the corresponding topography, and the subsequent solid electrolyte interphase (SEI) with better than 200 nm resolution. We find that, contrary to the general understanding, it is the initial surface chemistry rather than the topography that is the dominant factor leading to dendrite nucleation in this system. Specifically, the untreated native Li surface contains inhomogeneously distributed organic material which promotes the formation of LiF-rich SEI in those regions after exposure to electrolyte. These localized LiF-rich regions become preferential locations for dendrite nucleation, leading to inhomogeneous Li deposition on the surface. This has significant implications for battery research as it elucidates a mechanism for inhomogeneous SEI formation, something that is widely accepted, but not well understood. It also highlights the importance of lithium surface preparation prior to cell assembly, which is implicit in much of the literature, but not directly addressed. By homogenizing the native Li
Surface, we were able to homogenize the SEI and therefore, the Li deposition, leading to smaller dendrites and longer cycle life.

**EN02.09.40**  
Phase Transformations in the WO₃-Based Anode for Lithium-Ion Batteries  
Raman Bekarevich¹, Yurii Pihosh², Kei Nishikawa¹, Yoshinori Tanaka¹, Yoshitaka Matsushita¹, Takanobu Hiroto¹, Takahisa Ohno¹ and Kazutaka Mitsuishi¹; ¹National Institute for Materials Science, Japan; ²The University of Tokyo, Japan

Rechargeable lithium-ion batteries (LIBs) became an important part of human life because of unmatchable combination of their properties. In our days graphite is one of the most widespread anode materials, but, its small reversible capacity of 372 mAh g⁻¹ significantly reduces the energy density of LIBs. [1] Thus, an alternative anode material with higher reversible capacity, safety, and low cost needs to be found. Transition metal oxides with relatively high capacity and cycle stability are potential candidates to replace conventional graphite anodes. Tungsten oxide (WO₃) with a theoretical capacity of 693 mAh g⁻¹ stands out against other transition metal oxides due to combination of low cost and very large volumetric capacity of 5274 mAh cm⁻³. [2,3] However WO₃ struggles from the large volume changes upon lithiation / delithiation leading to disintegration of the electrode and fast capacity fade at high charging rates. [4] To address this issue we used a glancing angle deposition technique [5] to create array of vertically aligned WO₃ nanorods (NRs) directly onto current collector. Such anode configuration enables directional electronic/ionic transportation, leading to high electron collection efficiency. [6] Controlled geometry of NRs also enables us to minimize effect of volumetric expansion on the mechanical stability of electrode. [1] As a result, coin cells with WO₃ nanorodes as anode exhibited stable cycle performance up to 3C rates, without disintegration of the electrode. To clarify the lithiation mechanism upon cycling we studied the phase transformations in the active material during the first two cycles. Ex-situ X-Ray diffraction analysis, scanning and transmission analytical electron microscopy in combination with the first principles calculations suggested that conversion reaction plays a very important role in the formation of solid electrolyte interphase (SEI) and further transformation of initial WO₃ material into lithium tungstate. Formation of lithium tungstate at the very first lithiation may cause a large specific capacity drop after the first cycle, previously reported [7] for WO₃-based anodes. More experimental results will be presented and discussed during the conference.

**EN02.09.41**  
Robust Pitch on Si-Based Anode Materials for Suppressing Undesirable Volume Expansion in Advanced Lithium-Ion Batteries  
Minseong Ko¹², Yoonkook Son¹, Kwonhoo Kim¹ and Seong-Hyeon Choi³; ¹Pukyong National University, Korea (the Republic of); ²LIV ENERGY, Korea (the Republic of); ³Chosun University, Korea (the Republic of); ⁴Ulsan National Institute of Science and Technology, Korea (the Republic of)

The huge volume change of high-capacity active materials has hindered their practical application for Li-ion batteries. Although various kinds of surface coating materials were applied to address this issue so far, the suitable coating sources satisfying both low cost and high mechanical strength have not still confirmed. Here, a cheap carbonaceous material, pitch, as a qualified coating source for Si anodes is thoroughly investigated. Specifically, from in situ lithiation and indentation tests, we discovered that pitch-coated Si nanoparticles could withstand both internal and external force without any mechanical failure. Through various physicochemical analysis, we elucidated the distinctive structural properties after its carbonization can support the outstanding mechanical strength. By applying pitch coating on the Si-nanolayer-embedded graphite (SG), pitch was homogeneously distributed on the SG, and it improved the electrochemical performance. Furthermore, in both half- and full-cell tests, pitch-coated SG exhibited higher capacity retention and cycling Coulombic efficiencies than acetylene- and sucrose-coated SG by
effectively mitigating the volume change and suppressing the continuous formation for solid electrolyte interphase. For more details, pitch-coated silicon nanolayer–embedded graphite (SG) exhibits superior capacity retention (81.9%) compared to that of acetylene-coated SG (66%) over 200 cycles in a full-cell by effectively mitigating volume expansion (< 50%), even under industrial electrode density conditions (1.6 g cc\(^{-1}\)). Thus, this work presents new possibilities for the development of high capacity anodes for industrial implementation.

EN02.09.42
Controllable Electrochemical Formation of Lithium Fluoride Coatings for Fluoride-Containing Lithium-Ion Cathodes

Haining Gao, Mingfu He and Betar M. Gallant; Massachusetts Institute of Technology, United States

Fluorine modification of lithium-ion (Li-ion) battery cathodes exhibits promising advantages compared to today's materials, including improved electrode stability, higher discharge/charge voltages, and higher energy density. However, practical applications of fluorinated cathodes are still limited by their synthesis methods. These rely currently on chemical reactions with F-containing reactants (e.g., NH\(_4\)HF\(_2\) or NH\(_4\)F), or solid-state reactions via high-energy ball milling. These methods require highly toxic or corrosive chemicals or consume a significant amount of energy. Here, we demonstrate a non-toxic, energy-efficient, electrochemical method to achieve lithium fluoride (LiF) coatings on electrode materials by reduction of a fluorinated gas: sulfur hexafluoride (SF\(_6\)). By discharging the Li-SF\(_6\) cell, a uniform LiF coating can be formed on the substrate materials (oxides or carbon). The discharge potential of the cell (~2.3 V) is fully within the stability window of the electrolyte, and thus, guarantees the formation of a "clean" LiF coating without contribution from contaminants, such as electrolyte reduction products. By tuning the discharge conditions, the morphology of the LiF coating can be precisely controlled. Additionally, the LiF coating formed in this approach is conformal, nano-scale and in intimate contact with the substrate, making it suitable for applications in battery materials. To demonstrate the practical feasibility of this method, we first applied LiF coating on various transition metal monoxides (MO, M = Mn, Ni) as model substrates for studying the LiF-splitting reaction and resulting phases formed upon cycling. The LiF-coated MO exhibited high reversible capacities (~200 mAh/g) when used as Li-ion cathodes, which can be attributed to successful LiF splitting and F-incorporation. In addition to the electrochemical performance, the morphology of LiF coating, the structural change of LiF-coated MnO during the activation (first charge) process, and the redox reaction mechanism will be discussed. This work develops an electrochemical "soft" synthesis approach for fluorinated cathodes, which is more practical and controllable than most of the currently investigated methods.

EN02.09.43
Advanced Alloying Anode for Magnesium-Air Battery

Shanghai Wei, Fanglei Tong, Xize Chen and Mark Taylor; University of Auckland, New Zealand

Mg-Air batteries have been receiving much attention in the recent years. Due to their high theoretical energy density and relatively low cost, they can be used as promising electrochemical energy storage and conversion devices. The theoretical voltage of the Mg–air battery is 3.1 V and the specific energy density is 6.8 kWhkg\(^{-1}\). However, Mg-air batteries are facing a number of challenges, including high self-corrosion properties and low discharge performance. In the present research, new magnesium alloys have been designed for improving the discharging performance. Microstructure and phase composition of alloys before discharge and after battery testing have been characterised by OM, XRD, SEM, TEM and STEM techniques. The electrochemical properties of these Mg alloys have been analyzed using a three-electrode electrochemical workstation.

EN02.09.44
Vanadium Pentoxide Thin Films and Quasi-Fractal Cathodes for Lithium-Ion Batteries

Judit Lisoni\(^1,2\), Joseba Orive Gómez de Segura\(^1,2\), José Tapia\(^1,2\), Fernando Guzmán\(^4\), Eduardo Cisternas\(^1,5\), Pedro Álvarez\(^1,6\) and Samuel Hevia\(^1,6\); \(^1\)Chilean Ministry of Economy, Development and Tourism, Chile; \(^2\)Universidad Austral de Chile, Chile; \(^3\)Universidad de Chile, Chile; \(^4\)Universidad Católica del Norte, Chile; \(^5\)Universidad de la Frontera, Chile; \(^6\)Universidad Católica de Chile, Chile

Vanadium pentoxide, V\(_2\)O\(_5\), is an interesting cathode material as the extraction/intercalation of Li is feasible without the need of carbon additives. Its theoretical capacity ranges from 294 to 437 mAh/g for two and three Li-ions, respectively. Its drawbacks are well known. It is accepted that nanostructuring the material enhances the battery performance, but it has not been yet explored how the geometry of the cathode can contribute to this matter. In this work, we investigate the electrochemical performance of V\(_2\)O\(_5\) thin films (2D systems) and those with a quasi-fractal
V2O5 was obtained from the thermal oxidation of vanadium layers. The qualification of the oxidation process was done using P-doped Si(100) substrates. The vanadium films were 25-200 nm thick. The oxidation annealing were carried out in air for 1 h at 350-600 °C; the time condition assures that the metal film is fully oxidized. The thickness conversion factor between the metal and the oxide was ~1.3. The quasi-fractal patterning was fabricated via lift-off of the metal layer using cracked white-egg templates ~300 nm thick, following the methodology of B. Han et al [DOI:10.1038/ncomms6674]. In the quasi-fractal systems, the effective area covering the substrate ranged from 10% to 60%. The oxidation procedure is then transferred to stainless steel substrates that are the cathode collector in Swagelok LiB cells. This oxide procedure formation avoids chemical impurities typically found upon wet chemical synthesis, rendering the obtained V2O5 as a simple model system to understand the influence of the cathode microstructure on the battery performance.

The oxidation temperature plays an important role in the crystallinity and morphology of the V2O5 and thus the electrochemical performance. At 500 and 600 °C, we produce single phase V2O5, with an orthorhombic crystalline structure. The 2D oxide films are polycrystalline while the quasi-fractal layers are strongly (010) textured. This is in turn reflected in the topography of the grains, formed by terraces with plateaus: the oxide films consist of rounded grains of a few hundreds of nm’s in diameter while the quasi fractal pattern is formed by elongated rhomboid shapes with lengths as large as 3.5 µm. The cyclability of the films was evaluated in the potential window of 2.0-4.0 V where V2O5 could intercalate 2 mol of Li. We found that the optimum capacity is observed for 50 nm vanadium films oxidized at 500 °C, producing excellent rate capability of 180 mAh/g at 2C and 120 mAh/g at 20C. The quasi-fractal patterns are currently being evaluated.

Our Density Functional Theory modelling of the Li insertion into bulk V2O5 allowed to reproduce the unit cell parameters and obtaining the voltage profile for Li-intercalation, which shows a good agreement with potential difference measured experimentally.

**Rational Design and Sustainable Synthesis of Nanofibrous 3D Architecture for High-Energy, Fast and Safe Lithium Storage**

Shijie Wang1, Rutao Wang1,2, Ye Bian1, Dongdong Jin1, Yabin Zhang1 and Li Zhang1; 1The Chinese University of Hong Kong, China; 2Shandong University, China

Lithium-ion capacitors (LICs) are regarded as the promising energy storage devices owing to their balanced energy and power characteristics compared to both batteries and supercapacitors. To effectively couple the charge storage kinetics of the battery-typed anodes and capacitive cathodes, it is essential to employ high-capacity and high-rate anode materials. Moreover, as one aspect of the sustainable synthesis, the use of heavy metal and critical elements should be avoided. Currently, the mainstream anode material—graphite—suffers from sluggish charge transfer kinetics and potential safety issues due to the unfavorably low Li⁺ intercalation potential (0.01 V vs. Li/Li⁺). To overcome these adverse effects, intercalative Li4Ti5O12 (LTO) with outstanding rate capability and higher insertion potential is used. Nevertheless, the low capacity (175 mAh g⁻¹) and excessively high (1.55 V vs. Li/Li⁺) insertion potential renders it also unsuitable for high-energy LICs. In view of such dilemma between high-energy and safety, and further inspired by the discovery of novel polyanionic material Li2TiSiO5 (LTSO) [Liu et al, Energy Environ. Sci., 2017, 1456-1464], we rationally design a conductive 3D structure consisting of uniformly distributed and aggregation-free LTSO nanoparticles into nanofibrous carbon skeleton [Wang et al, Nano Energy, 2019, 173-181]. The synthetic procedures mainly involve facile and sustainable electrospinning process, followed by a morphology-preserved thermal transformation to convert organic Li, Ti, Si salts in-situ to LTSO and polymer nanofibers to carbon. It should be noticed that such strategy adopts biocompatible polymer precursors and get rid of heavy metal and critical elements. As-fabricated LTSO/C electrodes exhibit high-capacity (241.9 mAh g⁻¹ at 0.2 A g⁻¹), higher than 217.2 mAh g⁻¹ of graphite and 158 mAh g⁻¹ of LTO), superior rate capability (50% retention from 0.1 to 10 A g⁻¹, significantly higher than graphite and similar to LTO), and suitable Li⁺ insertion potential (0.1-1 V vs. Li/Li⁺ to balance between high full-cell voltage and safety). Subsequent kinetic analysis suggests that the high-rate performance probably derives from the pseudocapacitive mechanism, which is highly related to the unique 3D nanoarchitecture based on dispersive LTSO nanoparticles and interconnected conductive carbon framework. As a device level demonstration, the LICs employing LTSO/C anodes with high working potential of 4.2 V are fabricated, which exhibit a high energy density of 105.8 Wh kg⁻¹ and high power density of 28500 W kg⁻¹, effectively bridging the gap between lithium-ion batteries and supercapacitors. We believe that this work may be an essential reference for the rational design and sustainable synthesis of the desired LIC anodes for high-energy, fast, and safe energy storage.

High Cyclability Conversion-Type MoS2/Nanoporous Carbon Anode for Lithium-Ion Batteries Xiao Feng Lim, Viet Thong Le, Jong Hak Lee, Chorng Haur Sow and Barbaros Oezyilmaz; National University of Singapore, Singapore

The current lithium-ion battery technology relies on intercalation-type materials which are highly stable but are limited in storage capacity [1]. Conversion-type materials are a way to greatly increase the energy density of a lithium-ion battery [2]. Molybdenum disulfide (MoS2) is one material that can act as both an intercalation- and conversion-type (via lithium sulfide) anode by controlling the voltage window of cycling [3]. However, it is plagued by problems of pulverization due to the large volume expansion during lithiation [4], poor electrical conductivity [5], and electrolyte dissolution [6], leading to poor cyclability [7]. In this work, we first synthesize MoS2 via a solvothermal route with nanoporous carbon, for strong electrical contact and mechanical support. We further improve the contact between MoS2 and the nanoporous carbon via a thermal treatment. The electrochemical performance shows a long cycling life (800 cycles), due to the structural stability of the nanoporous carbon matrix that minimizes the pulverization and loss of active material via polysulfide shuttling. The improved electrical contact and mechanical support also allowed for high utilization of the active materials. An exceptionally high capacity is achieved due to the lithium sulfide from the conversion of MoS2 and a capacitive contribution from the nanoporous carbon. In addition, an increasing electrochemical activation during cycling results in a significant capacity increment. Detailed material characterization such as scanning electron microscopy (SEM) will also be used to elucidate the origin of the high cyclability.

Understanding the Sodium Battery Testing of Pure Phase SnSb Electrodeposited From an Ethaline Solution Jeffrey Ma and Amy L. Prieto; Colorado State University, United States

Current research on improving state of the art anode technology for Lithium-ion rechargeable batteries is focused heavily on the development of silicon and graphite/silicon composite anodes. However, for beyond lithium-ion research, such as sodium-ion batteries, both silicon and graphite perform poorly. Due to this, anodes that are tin-, phosphorous-, and antimony- based are at the forefront of potential sodium-ion anodes. Of these materials, SnSb has been shown to be a promising material, with a mixture of stable cycling and high energy density.

We have developed the electrodeposition of pure phase, crystalline SnSb from an ethaline solution at room temperature. Electrodeposition is an interesting process as it allows for the study of the anode material’s intrinsic properties without the presence of carbon and binders that are typically used in the slurry-based production of anodes. We will present the sodium battery cycling studies of the electrodeposited SnSb and compare them to Sn-
rich containing SnSb electrodes described in other previously reported electrodeposition processes. The incorporation of Sn is detrimental to the lifetime of battery material, which is a main motivation for the production of pure phased SnSb. We will present and discuss a suite of electrochemical characterization data used to understand the performance of the phase pure material.

Li-S Battery: A Promising Energy Storage Technology Sarish Rehman1, Tom Tranter2, Guobin Wen1, Michael Pope1 and Jeff Gostick1; 1University of Waterloo, Canada; 2University College London, United Kingdom

Lithium Sulfur batteries (LSBs) are of great scientific and commercial interest with potentially five times the energy density of current Li-ion technologies and lower cost. However, the technology suffers problems that have so far prevented their commercialization and wide scale adoption. These include poor cycle-life, limited sulfur utilization, and severe self-discharge during rest and charge. Compounding the problem is the rather complex, multistep reaction pathway that involves reduction from elemental sulfur to form shorter chain species of polysulfides and lithium-polysulfides (LiPS), which can be soluble or insoluble in the electrolyte. So far, modeling has helped to illustrate the processes and species that can be formed inside the cell at various states of charge. However, much more effort is needed to verify these results and supply the models with better data, as many parameters are assumed or fitted. The self-discharge phenomena is the focus of the present study which aims to validate a numerical model with experimental data over long periods of cycling and rest. We shed light on the nature of the LSB’s reversible and irreversible losses and predict their evolution over time.

A Porous N-Doped Carbon 3D Nanoweb-Li2S Cathode Material for High-Performance Lithium-Sulfur Battery Yoongon Kim, Hyunsu Han, Jaejin Bae, Yekyu Kim, Hyunwoo Ahn and Won Bae Kim; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Novel honeycomb-like N-doped carbon three-dimensional (3D) nanowebs (HCNs) have been synthesized through a facile aqueous solution route for use as cathode materials in lithium sulfur batteries. The Li2S@HCN cathode delivers a high discharge capacity of 815 mAh g⁻¹ after 65 cycles at 0.1 C, along with a superior rate capacity of 568 mAh g⁻¹ even at 2 C. The outstanding electrochemical rate performance is ascribed to their unique 3D honeycomb-like nanoweb structure, consisting of nanowires derived from polypyrrole. These properties greatly enhance the electrochemical reaction kinetics by providing continuous electron pathway and hollow channels for electrolyte transport. Nitrogen doping in the carbon nanowebs also considerably improves the chemisorption properties by tuning the affinity between sulfur and oxygen functional groups on the carbon framework. The simple synthesis strategy and resulting unique electrode structure provide a new aspect of nanostructure research for high performance lithium sulfur batteries.

The Search for Solid-State Divalent Ion Conductors Andrew J. Martinolich and Kimberly A. See; California Institute of Technology, United States

Multi-electron redox processes are attractive charge storage mechanisms for next-generation, high energy density
batteries. Multi-electron redox can be achieved via >1 electron redox per transition metal in conventional intercalation-type materials or through conversion mechanisms using divalent cations. Electrodeposition of divalent cations, for example, yield smooth metal deposits compared to Li metal deposited at the same current densities suggesting that divalent metal batteries could be a viable next-generation chemistry. Many challenges remain for divalent-based chemistries, however, including developing and understanding materials that support solid-state divalent ion conductivity. Divalent ion conductivity is an essential fundamental process employed by intercalation electrodes, solid-state electrolytes, and solid-state interfacial layers. To begin understanding the fundamental mechanisms of divalent ion conductivity, we aim to probe divalent ion conductivity in electronically insulating solid-sate host matrices. We will discuss our first attempt at this with a case-study on ZnP2S3. ZnP2S3 supports Zn2+ conductivity with unexpectedly low activation energies (~350 meV) thanks to the flexible [P2S6]4- polyanion that we suggest distorts into the van der Waals gap at the transition state.

Synthesis, Characterization and Investigation of Non-Arrhenius Behavior in Anti-Perovskite Ion Conductors
Fei Wang, Ping-Chun Tsai, Yiliang Li, Lisheng Gao and Yet-Ming Chiang; Massachusetts Institute of Technology, United States

Amongst known families of solid electrolytes of potential interest for solid-state batteries, the anti-perovskites (A3BX) are of interest for the high ionic conductivities observed in certain compositions, and, like perovskites, the compositional flexibility provided by the possibility for ion substitution onto multiple lattice sites. For example, variations in the relative size of ions A, B and X result in changes in the Goldschmidt tolerance factor, or extent of disorder, that are accompanied by changes in the distribution of lithium migration energies. [1]

In surveying transport in this family of ion conductors, we observed a trend wherein numerous compositions show upwards curvature on an Arrhenius plot, indicating a non-constant activation energy. This is unusual as most solids exhibiting non-Arrhenius behavior exhibit a negative deviation. We have synthesized a wide range of Li and Na antiperovskites, and have confirmed non-Arrhenius conductivity with a positive deviation in compositions such as Na3OBr0.6I0.4. This talk will discuss compositional trends related to this behavior, and our attempts to understand the structural origin(s) of this behavior through temperature-dependent X-ray and neutron scattering, calorimetry, and other methods. Implications for the design of solid electrolytes for solid state batteries will be discussed.

This work was supported as part of the Joint Center for Energy Storage Research, an Energy Innovation Hub funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences.

High Performance Aqueous Zinc-Ion Batteries Mediated by Hydrated Intercalation Jaeho Shin and Jang Wook Choi; Seoul National University, Korea (the Republic of)

While a recent fervor for the commercialization of electric vehicle applications has steered the battery industry’s efforts toward high energy density batteries, another significant path for research and development lies with grid-scale energy storage systems (ESSs). ESSs are pivotal in that they can be used to stabilize the power grid through frequency regulation operations. Ideally, power supply should match demand in order to maximize efficiency. However, this is hardly the case in reality because fluctuations in both supply and demand occur due to various reasons. For example, the sporadic nature of renewable energy sources such as wind often results in oscillations in power supply, while certain times during the day demand high levels of power. This mismatch is balanced through the use of ESSs. In order to accommodate such real-time changes, however, ESSs must be highly responsive to perturbations. In other words, high charge/discharge rate capability is critical for such responsiveness, where ESSs can store extra power and discharge when needed in a short period of time. Furthermore, as ESSs are composed of multiple battery modules, a fire may have devastating consequences on its surroundings and/or human lives. Thus, batteries that target ESS applications must meet two crucial requirements: high power density and safety.

In this respect, aqueous zinc ion batteries (AZIBs) are being tapped as potential candidates for ESS applications. AZIBs are promising systems for ESSs in several ways. First, the use of aqueous electrolytes significantly lowers
the risk of fire hazards. Second, the inherently high ionic conductivity of water creates an environment amicable for high rate battery operation. Third, zinc (Zn) is known for its stability in water, rendering its metallic form employable as an anode. Finally, the bivalence of the Zn²⁺ ion opens up possibilities for high capacity. Unfortunately, the use of water as the primary electrolyte solvent ironically entails a critical disadvantage: water splitting. This consists of hydrogen/oxygen evolution reactions at their respective electrodes, the potentials of which sum up to 1.23 V as determined by thermodynamics. Evidently, it is within this narrow voltage window the AZIB must operate. Beyond these boundaries, the irreversible HER/OER steps not only deplete the electrolyte, but also may degrade the electrodes.

In this sense, recent research efforts in AZIBs have primarily focused on discovering new cathode materials suitable for aqueous applications. With Zn generally established as the anode, the cathode becomes the key performance factor. The ideal cathode for AZIBs must meet the following conditions; i) a redox potential within the voltage window, ii) good intercalation kinetics, iii) well-defined ion diffusion channels, and iv) structural stability. Having taken such conditions into account, we have discovered that a mixed-valence vanadium oxide, V₆O₁₃, exhibits promising electrochemical traits such as 93% capacity retention after 2,000 cycles and high rate capabilities of up to 24.0 A g⁻¹. These results were correlated with synchrotron in situ X-ray diffraction (XRD) and X-ray absorption spectroscopy (XAS) experiments to reveal a single phase reaction pathway and reversible redox of vanadium upon Zn (de)intercalation. Interestingly, water plays a crucial role in this process, whereby Zn intercalation is significantly enhanced by means of hydrated intercalation. This intriguing phenomenon was probed via experiments and density functional theory calculations, which highlight the importance of the desolvation energy penalty at the electrode/electrolyte interface as well as the structural implications of co-intercalated water. These results show that V₆O₁₃ is not only a promising candidate for AZIB cathodes, but the reaction mechanisms responsible for such performance could also be extended to future investigations to pave the way for AZIBs.

A Chemically and Electrochemically Bifunctional Mobile Catalyst for Anti-Aging Li-O₂ Batteries Jonghak Kim, Chihyun Hwang, Gwan Yeong Jung, Sang Kyu Kwak and Hyun-kon Song; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Aprotic lithium-oxygen batteries (LOBs) have much higher energy density compared to today’s lithium ion batteries. However, highly reactive superoxide, the discharge intermediate of LOBs, triggers side reactions to deteriorate LOB performances. Also, high overpotential is required to oxidize the discharge product Li₂O₂ during charge due to the non-conductive nature of Li₂O₂. Herein, we present 4-carboxy-TEMPO as a bifunctional mobile catalyst soluble in LOB electrolytes for improving LOB performances. The roles of 4-carboxy-TEMPO is two-fold: (1) the chemo-catalyst to catalyze superoxide disproportionation reaction for suppressing the superoxide-triggered side reactions; and (2) the redox mediator to oxidize the discharge product Li₂O₂ in a kinetically effective way for reducing the overpotential during charge. As expected, the use of the mobile catalyst in LOB cells resulted in the 4-fold increase in cycle life from 50 cycles to 200 cycles, significantly reducing the overpotential during charge. Also, the discharge capacity increased 4-fold.

A Water-Miscible Quinone Flow Battery with High Volumetric Capacity and Energy Density Shijian Jin, Yan Jing, Michael J. Aziz and Roy Gordon; Harvard University, United States

A water-miscible anthraquinone with polyethylene glycol (PEG)-based solubilizing groups is introduced as the redox-active molecule in a negative electrolyte (negolyte) for aqueous redox flow batteries, exhibiting the highest volumetric capacity among aqueous organic negolytes. We synthesized and screened a series of PEG-substituted anthraquinones (PEGAQs) and carefully studied one of its isomers, namely 1,8-bis(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)anthracene-9,10-dione (AQ-1,8-3E-OH), which has high electrochemical reversibility and is completely miscible in water of any pH. A negolyte containing 1.5 M AQ-1,8-3E-OH, when paired with a ferrocyanide-based positive electrolyte across an inexpensive, non-fluorinated permselective polymer membrane at pH 7, exhibits an open-circuit potential of 1.0 V, a volumetric capacity of 80.4 Ah/L, and an energy density of 25.2 Wh/L.

Ultrathin, Flexible, Solid Polymer Composite Electrolyte Enabled with Aligned Nanoporous Host for Lithium Batteries Jiayu Wan, Jin Xie and Yi Cui; Stanford University, United States

The urgent need for safer batteries is leading research to all-solid-state lithium-based cells. To achieve energy density comparable to liquid electrolyte-based cells, ultrathin and lightweight solid electrolytes with high ionic conductivity are desired. However, solid electrolytes with comparable thicknesses to commercial polymer electrolyte separators (~10 μm) used in liquid electrolytes remain challenging to make because of the increased risk of short-circuiting the battery. Here, we report on a polymer–polymer solid-state electrolyte design, demonstrated with an 8.6-μm-thick nanoporous polyimide (PI) film filled with polyethylene oxide/lithium bis(trifluoromethanesulfonyl)imide (PEO/LiTFSI) that can be used as a safe solid polymer electrolyte. The PI film is nonflammable and mechanically strong, preventing batteries from short-circuiting even after more than 1,000 h of cycling, and the vertical channels enhance the ionic conductivity (2.3 ×10^−4 S/cm at 30 °C) of the infused polymer electrolyte. All-solid-state lithium-ion batteries fabricated with PI/PEO/LiTFSI solid electrolyte show good cycling performance (200 cycles at C/2 rate) at 60 °C and withstand abuse tests such as bending, cutting and nail penetration.

10:30 AM EN02.11.02
Revealing the Discrepancy in Capacity Ratio of Graphite to Si Strategical Material Design for Rapid-Charging Lithium-Ion Batteries Kihong Ahn1, Sujong Chae2, Seungkyu Park1 and Jaephil Cho1; 1Ulsan National Institute of Science and Technology, Korea (the Republic of); 2Pacific Northwest National Laboratory, United States

As devices requiring lithium-ion batteries become more diverse and more numerous, not only the energy density but also the customer's demand for power density are increasing. With reported in several papers, the charge rate of a lithium ion battery depends heavily on anode due to the kinetic and thermodynamic reasons such as electrochemical reaction in the vicinity of the interface between the active material and the electrolyte, the low diffusivity and conductivity of lithium ions into inner active materials(Graphite,Si). However, because charging performance (charging rate capability) of Lithium ion batteries decreases drastically with increasing charging rate. In fact, Most researches focused on numerical improvements in charging rate capability, but there was given less consideration for analytic explanation of how the improvement was originated from some reason. Conceptually, in this study, We has been demonstrated that the charging rate capability is improved by designing of the anode active material (SIN@1GnB) and qualitative and quantitatively tried to elucidate how this improvement corresponds with the physicochemical and electrochemical results. As with the step above, we have endeavored to compare the capacity composition on the individual lithiated components which are Graphite and Si or SiN (each capacity contribution of Graphite parts /Si part) of the promising the Si nanolayer embedded Graphite by deconvoluting the lithiated peaks and integrating the peak area through the differential capacity analysis. As a result, at 5C C-rate, there was a remarkable reversal in the Graphite to Silicon capacity ratio which it was 6 to 4, at 5C charged whereas the ratio was 3 to 7 in case of formation C-rate (0.2C) The reversal in this ratio was originated from the drastic reduction in the capacity of the graphite, which was due to the fact that for the same reasons as overpotential(so-called staging kinetics) related to the high resistance and low electronic/ionic conductivity of lithiated Si in itself the anode capacity is more favorable to exhibited by the Stage 2,2L, 3, 4) than the Stage 1 of graphite and. We have strategically designed the SiN@1GnB (SiN nanolayer coated Graphene lumps growth on MCMB).This architecture greatly increases electron / ion migration near the surface by graphene lump ,through the SiN nanolayer, and further accelerates migration of lithium ions toward graphite by the formed Li-Si-N ternary phase. In verification of the materials design strategies by the same method as above, we have demonstrated that there was not reversal of Graphite to Si-N ratio, which was 55 to 45. A differential capacity (dQ/dV) analysis
results also showed that the exhibited capacity by stage 1 and 2 was higher than that of Si, which facilitated the capacity utilization of graphite. Furthermore, by introducing the concept of “effective thickness expansion ratio” and comparing it according to the charging rate, graphite shows a rapid irreversible expansion (~20%) which means the lithium plating at 3C while SiN@IGnB shows the (~7%) negative value of the effective thickness expansion ratio, which means that there was less susceptible to lithium plating on the harsh condition of anode.

10:45 AM EN02.11.03
Stabilizing Silicon Anodes by In Situ Formation of Ternary Phases Binghong Han1, Chen Liao2, Fulya Dogan2, Stephen E. Trask2, Saul H. Lapidus2, Jack Vaughney2 and Baris Key2; 1Exponent, United States; 2Argonne National Laboratory, United States

Replacing the traditional graphite anodes by Si electrodes can greatly improve the energy density of lithium-ion batteries. However, the large volume expansion and the formation of highly reactive Li-Si binary phases during battery operations can cause continuous lithium and electrolyte consumptions as well as the fast decay of Si anodes. In this work, by adding a second metal cation (M) into the electrolyte, we stabilize the Si anodes during the lithiation process through in situ formation of Li-M-Si ternary phases. Firstly, using solid-state nuclear magnetic resonance spectroscopy, we show that the doping of M can dramatically suppress the chemical reactions between the Li-M-Si model compound and common electrolyte solvents. Guided by this discovery, new mixed-salt electrolytes with M cations were prepared and tested with graphite-free Si electrodes, which demonstrated higher capacity, better cyclability, and higher efficiencies in both half-cell and full-cell tests. Post-electrochemistry characterizations demonstrate that adding M salts leads to the co-insertion of M cations along with Li into Si during the lithiation, which stabilized the lithiated silicon anodes by forming more stable Li-M-Si ternaries. The new electrolytes fundamentally change the traditional Li-Si binary chemistry formed during operations while minimally affecting silicon electrochemical profiles and theoretical capacities. This study provides a new and simple approach to stabilize silicon anodes, which can enable the commercial application of Si as the next-generation anodes in lithium-ion batteries.

3D Tortuous Li Anode Design for High Current (30 mA/cm2) and High Capacity (30 mAh/cm2) Li Stripping/Plating Kun Fu; University of Delaware, United States

Lithium metal batteries are promising due to its high energy density and low density. But lithium dendrite caused by the lithium vertical deposition at high current density and energy density could penetrate the separator and the direct contact between lithium anode and cathode causes short circuit of cell, which impede its utilization. To address this challenge, we design a 3D Li metal anode composite with high surface energy artificial framework, which realizes the faster and uniform lithium ions transfer at high current density and a large amount of lithium deposition horizontally inside the artificial framework at high capacity without any lithium dendrite growth. The dendrite-free electrode has long cycle term of over 120 h at high current density of 30 mA/cm2 and capacity of 30 mAh/cm2. This work provides new ways to address the lithium dendrite issue and get longer lifespan at high current and energy density toward the next generation of Li metal batteries.

New Electrolyte for Lithium-Metal Batteries with High-Voltage NMC811 Cathode Xia Cao, Xiaodi Ren, Hongkyung Lee, Chaojiang Niu, Jun Liu, Jie Xiao, Wu Xu and Ji-Guang Zhang; Pacific Northwest National Laboratory, United States

Rechargeable lithium (Li) metal batteries (LMBs) with intercalation cathodes have been revived as promising battery chemistry in recent years due to their superior theoretical energy-densities comparing to the state-of-the-art Li-ion batteries. However, there is still significant barriers to be overcome before large scale commercialization of LMBs because of their limited cycle life and potential safety concerns. Li pulverization during cycling is one of the most critical barriers for safe operation of LMBs. Here we report a new approach to prevent Li pulverization in high-energy LMBs with a Ni-rich LiNi0.8Mn0.1Co0.1O2 (NMC811) cathode during long-term cycling by a highly stable SEI layer enabled by a novel electrolyte. A homogeneous solid electrolyte interphase layer on Li anode is generated in this electrolyte, which is rich in inorganic species and robust against cycling. It successfully minimizes Li loss and pulverization. Furthermore, this electrolyte also enabled the formation of a good cathode electrolyte interphase on the NMC811 cathode, which effectively stabilizes the NMC811 structure. Therefore, very high Li
Coulombic efficiency and great stability has been demonstrated in Li||NMC811 cells adopting this electrolyte. The details of the electrolyte together with post-mortem analysis on Li||NMC811 cells using this electrolyte will be discussed at the presentation.

SESSION EN02.12: Advances in Anodes II

1:30 PM OPEN DISCUSSION

2:00 PM EN02.12.02
Exploring the Elastic Anisotropy of Lithium-Metal Using In Situ Nanoindentation James E. Darnbrough, David Armstrong and Mauro Pasta; University of Oxford, United Kingdom

Solid state batteries with Lithium metal anodes have huge potential as the next high energy-density cells. However, the development of solid state batteries has been hindered by new failure modes not seen in liquid and semi-solid electrolyte systems. A greater understanding of the physical properties of the component parts and the mechanical interaction between them during cycling is required for real battery applications. In order to investigate this we have developed a methodology to test the microstructural and mechanical properties of air sensitive battery-specific materials.

This new approach focuses on in-situ observation of plastic deformation with reference to crystallographic orientation. To demonstrate this we use the example of Li metal, which has previously been shown to have anisotropy in elastic and yield properties. Large single crystal tests and Density Functional Theory (DFT) modelling of the crystal structure have shown the anisotropy but the role of the microstructure and texture has yet to be explored for materials used in Li metal batteries.

In-situ nanoindentation and Electron Backscatter Diffraction (EBSD) allows for testing the mechanical properties of Li metal in specific crystallographic directions. The physical response to load measures elastic modulus, hardness and creep behaviour of the material. Observing the real time development of sink-in around indents is indicative of the dislocation activity caused by the highly localised stress in soft materials.

Strategies for the Stabilization of Metal Anodes for Li and Na Metal Batteries Yang Zhao and Xueliang A. Sun; Western University, Canada

Li-metal batteries (LMBs) and Na-metal batteries (NMBs) are considered as the promising candidates to replace the conventional Li-ion batteries (LIBs) due to their high theoretical energy density. For LMBs and NMBs, Li metal and Na metal are the ultimate choices to achieve their high energy density due to the high specific capacity, low electrochemical potential and lightweight [1]. However, as alkali metals, both Li and Na metal anodes suffer from serious challenges including 1) Li/Na dendrite formations and short circuits; 2) Low Coulombic efficiency (CE) and poor cycling performance; and 3) Infinite volume changes. This presentation mainly focuses on the design of multiple strategies for the stabilization of Li and Na metal anode for LMBs and NMBs.

Solid electrolyte interphase (SEI) layer is one of the key factors for the Li and Na deposition behaviors [2]. We developed different approaches to fabricate artificial SEI with significantly improved electrochemical performances. Firstly, we have demonstrated different ultra-thin protective layers for Li and Na metal anodes by advanced atomic layer deposition (ALD) and molecular layer deposition (MLD) techniques, including Al₂O₃, alucone, and polyurea, et al [3]. More recently, we designed a natural SEI-inspired dual-protective layer for Li metal anode with precisely controlled thicknesses, compositions and mechanical properties [4]. Secondly, we developed the in-situ solution-based methods to fabricate the Li₃PS₄ and Na₃PS₄ as protective layers for both Li and Na metal anodes with significantly enhanced performances and reduced dendrite growth [5].

To address another challenge of volume change, 3D conductive interlayers and hosts have been designed for Li and Na metal anodes. Carbon paper (CP) and modified CP with carbon nanotubes have been used as host/interlayer with excellent electrochemical performance under high current density and high capacity [6].

Final Program 1/13/2020  405
In conclusion, we developed the different approaches, including protective layers fabricated by ALD/MLD and solution methods, interlayers, and 3D skeleton design, for Li and Na metal anodes with enhanced electrochemical performances and reduced dendrite growth. Meanwhile, the ideas have been also applied to solve the practical issues for testing Li and Na metal batteries.

**All-Solid-State Batteries—From Interface to Electrodes**  
Xueliang A. Sun, Changhong Wang, Yang Zhao, Xiaona Li and Jianwen Liang; University of Western Ontario, Canada

The state-of-the-art rechargeable Lithium-ion batteries (LIBs) use liquid electrolytes and are the major choice for current EVs and portable electronic applications. However, these LIBs still suffer from many issues related to safety, lifespan and energy density. Accordingly, solid-state lithium batteries (SSLBs) have recently emerged as a promising alternative energy storage device due to their ability to overcome the intrinsic disadvantages of liquid-electrolyte LIBs and possess a greater volumetric energy density due to the use of solid-state electrolytes (SSEs). However, the interfacial issues between SSEs and electrodes (both cathode and anode) have a significant impact on the stability and lifetime of SSLBs [1-2]. The origin of these interfacial phenomena is the unstable contact and chemical reactions between electrodes and electrolytes to form an interlayer with extremely low electronic and/or ionic conductivities, which restricts the performance of the SSLBs. An artificial, uniform and ultrathin interfacial layer is critical to address these challenges [2]. Atomic layer deposition (ALD) and molecular layer deposition (MLD) are unique coating techniques that can realize excellent coverage and conformal deposition with precisely controllable at the nanoscale level due to its self-limiting nature, which are ideal for addressing the challenges of interface in SSLBs [2].

Our work apply ALD/MLD to rationally design novel coatings to address the interfacial challenges in SSLBs. The goal is to prevent capacity degradation of SSLBs caused by high interfacial resistance and chemical/electrochemical reactions between electrodes and electrolytes (e.g. sulfide-based). We will demonstrate to (i) stabilize the interface between cathode electrodes and electrolytes and prevent the formation of intrinsically high resistance layers, (ii) suppress elemental inter-diffusion during the operation of SSLBs, (iii) fabricate facile ionic transportation channels to facilitate ion exchange between different components of SSLBs, and (iv) buffer volume changes during cycling of SSLBs.

**References:**  
Lithium ion batteries have become the dominant form of energy storage used in consumer electronics and, recently, electric vehicles. However, high costs have prevented widespread deployment of lithium ion batteries for applications other than portable electronics, and the safety issues associated with liquid organic electrolytes remain to be addressed. In order to enable the greater utilization of electric vehicles, allow for grid scale energy storage, and meet the demands of new electronic applications, new materials for high energy density batteries must be developed. High capacity electrode materials like lithium metal have the potential to facilitate these technologies, but lithium metal electrodes are presently limited by significant side reactions, poor quality deposition, and the potential to form hazardous dendrites. Therefore, it is important to develop a clear understanding of the surface reactivity and growth behavior of the lithium metal at the interface with the electrolyte in order to enable stable long-term cycling.

The products that form as a result of electrolyte decomposition reactions at the electrode interface are known to be extremely important in determining the final cell performance. Specifically, fluorinated salts and solvent additives have been shown to enable stable cycling of Li metal anodes. This improvement is ascribed to the formation of LiF in the solid electrolyte interphase (SEI), yet the understanding of how LiF and other SEI compounds are formed and how they affect battery cycling is not complete. In this presentation, in situ spectroelectrochemical techniques including infrared spectroscopy (FTIR), differential electrochemical mass spectrometry (DEMS), and electrochemical quartz crystal microbalance (EQCM), are used to clearly identify components of the Li metal SEI. An understanding of SEI formation with respect to electrochemical potential and time will be discussed. With this understanding we provide new insights into the formation and chemical nature of SEI components that promote stable cycling of lithium metal electrodes.

Structural Properties of Nanoconfined Ionic Liquids at Metallic Interfaces for Supercapacitor Application
Antoine Laine1, Jean Comtet2, Antoine Niguès1, Lyderic Bocquet1 and Alessandro Siria1; 1ENS Paris, France; 2École Polytechnique Fédérale de Lausanne, Switzerland

Room Temperature Ionic Liquids (RTILs) are emerging materials for application in energy storage because of their wide physical stability, and large electrochemical window enabling the use of high voltage difference when used as electrolyte in capacitors. From a mechanical point of view, due to their solvent-free nature, the behaviour of RTILs strongly deviates from classical liquid description. The confinement of RTILs down to the nanoscale gives rise to exotic interfacial features resulting from the strong fluid-surface electrostatic interactions, thus highly dependent on the electronic nature of the surfaces. Then the exotic interfacial structural properties of RTILs confined with insulating surfaces have been extensively studied, but still need to be explored for metallic surfaces which are relevant for supercapacitors purposes. Furthermore, with the development of electrodes made of nanoporous materials in order to enhance the capacitance of RTILs based systems, it gets important to take into account the properties of RTILs under strong confinement.

Here, we use a tuning-fork based dynamic Surface Force Tribometer to experimentaly probe the mechanical properties of RTILs confined between extended gold surfaces. Our model sphere-plane geometry enables to probe
the mechanical properties of RTILs confined in a 'slit' for which the size is controlled with nanometric resolution. For strong confinement, 'slit' size under some tens of nanometers, the RTILs undergo a dramatic confinement induced phase transition from a liquid to a solid state. Thus the overall ionic dynamics within this solid interfacial phase may be reduced as the ionic mobility sinks from the liquid to the solid state. By further measuring the mechanical properties of the nanoconfined RTILs, the system exhibits a glassy nature and eventually a shear induced fluidization. Eventually, exploring the mechanical properties of nanoconfined RTILs may enable to provide insights into the dynamics of such solvent-free electrolytes to be used in capacitive applications.

4:30 PM EN02.13.04
The Effects of Electric Field Distribution on the Interface Stability in Solid Electrolytes Rishav Choudhury, Michael Wang and Jeff Sakamoto; University of Michigan, United States

Ceramic solid-state electrolytes could potentially enable Li metal anodes, leading to safer and more energy dense Li-ion batteries. However, it has been hypothesized that electric field amplification at electrode edges can destabilize the interface and lead to short-circuiting under extended cycling. In this study, symmetric Li/ Li6.5La3Zr1.5Ta0.5O12 (LLZO) cells were assembled with Li electrodes of varying geometries to observe the effects on Li electrodeposition. Modeling of the electric field distribution at the electrode/electrolyte interface showed that areas of high electric field were localized at sharp corners but uniformly distributed along regions of low, gradual curvature. To verify this, cells with varying electrode geometries were cycled under galvanostatic conditions until failure and spatial distribution of the degradation was analyzed using optical and electron microscopy. Critical current density was also measured to determine how electric field amplification caused by geometric effects impacts the cell performance. According to the models, isolated regions of high current density/curvature were shown to act as preferred sites for Li filament nucleation. This was experimentally confirmed by localized electrochemical impedance spectroscopy measurements. Non-uniform electric field distributions at the Li/LLZO interface could play a major role in determining cycling capabilities and failure modes of solid-state batteries. This may also have important implications for the manufacturing of Li-ion battery electrodes with geometry being a key consideration for increasing longevity.

4:45 PM EN02.13.05
Role of Solvent-Anion Charge Transfer in Oxidative Degradation of Battery Electrolytes Eric R. Fadel1,2,3, Francesco Faglioni4, Geory Samsonidze2, Nicola Molinari1,2, Boris Merinov5, William A. Goddard5, Jeffrey C. Grossman3, Jonathan Mailoa2 and Boris Kozinsky1,2; 1Harvard University, United States; 2Robert Bosch LLC, United States; 3Massachusetts Institute of Technology, United States; 4University of Modena and Reggio Emilia, Italy; 5California Institute of Technology, United States

Electrochemical stability windows of electrolytes largely determine the limitations of operating regimes of lithium-ion batteries, but the degradation mechanisms are difficult to characterize and poorly understood. Using computational quantum chemistry to investigate the oxidative decomposition that govern voltage stability of multi-component organic electrolytes, we find that electrolyte decomposition is a process involving the solvent and the salt anion and requires explicit treatment of their coupling. We find that the ionization potential of the solvent-anion system is often lower than that of the isolated solvent or the anion. This mutual weakening effect is explained by the formation of the anion-solvent charge-transfer complex, which we study for 16 anion-solvent combinations. This understanding of the oxidation mechanism allows to formulate a simple predictive model that explains experimentally observed trends in the onset voltages of degradation of electrolytes near the cathode. This model opens opportunities for rapid rational design of stable electrolytes for high-energy batteries.
Negative Redox Potential Shift in Fire-Retardant Electrolytes and Consequences for High-Energy Hybrid Batteries
Bruno Ernould, Gabriella Barozzino-Consiglio, Louis Sieuw, Jean-François Gohy and Alexandru Vlad;
Univ Catholique-Louvain, Belgium

Fire-retardant electrolyte formulations have attracted vivid attention recently given the surprising properties observed, with also the potential to solve the grand challenges of alkali-ion batteries: safety, use of metallic anodes and elevated anodic stability. Whereas these chemistries are still extensively studied and correlations are drawn to explain the enhanced electrochemical stability, one essential property - the redox potential - remains poorly characterized.

In this contribution we will report how the strong solvation (or coordination) of lithium cations by organic phosphates, the widely used flame-retardant constituents, induces a negative redox potential shift by as much as half of a volt (-0.5 V). Through a series of complementary 2- and 3-electrode measurements, with different reference electrode chemistries, we demonstrate that the redox potential shift is characteristic of mainly Li-cation (de)solvation processes whereas the redox potential shift of other, non Li-cation (de)solvation processes is negligible. Solvent coordination ratio, cation valence number as well as self-diffusion coefficients are determined via complementary NMR/DOSY methods and correlated with the electrochemical measurements. We will in particular highlight how these processes can impact the developments on high-energy hybrid battery concepts such as higher voltage dual-carbon (dual-ion) or organic batteries as well as the apparent enhancement of the anodic stability. These findings may also trigger the re-evaluation of the electrochemical stability mechanisms of the non-conventional battery electrolyte formulations towards a more realistic picture.

EN02.14.02
Electrochemical Properties of LiNi0.9Co0.1O2 Cathode Material Prepared by Co-Precipitation Using Citric Acid
Jong Dae Lee and Hyun Woo Park; Chungbuk National Univ, Korea (the Republic of)

Ni-rich materials were used as cathode materials for lithium-ion batteries in electric vehicles (EV), plug-in hybrid vehicles (PHEV) and energy storage systems (ESS) due to their high energy density and rate characteristics. Ni-rich cathode materials were prepared by co-precipitation using ammonia. However, ammonia is highly toxic and corrosive, which is considered hazardous when exposed to humans. To resolve the above problems, it is necessary to replace ammonia with an eco-friendly chelating agent. Another problem with Ni-rich materials were related to LiOH/Li2CO3 impurities formed on the surface of cathode material upon exposure to air. The LiOH/Li2CO3 impurities reacts with the LiPF6 electrolyte to form HF, which directly dissolves the transition metal ions of the cathode material, resulting in gas evolution and phase transition from layered to spinel.

In this study, spherical Ni0.9Co0.1(OH)2 precursors were prepared by co-precipitation using citric acid as a chelating agent. The cathode material was prepared by mixing precursor and LiOH H2O and sintering at 680, 700, 720 and 740 °C. The excessive Li on the surface of the synthesized material was removed by washing and the electrochemical performance was investigated. Also, in order to improve the crystallinity of the prepared cathode materials, it was recalcined at 700 °C to investigate its electrochemical characteristics. The particle size distribution, particle shape and crystal structure of the cathode materials were analyzed by SEM and XRD. The prepared precursor had spherical shape and average particle size of Dv(50)=6 µm. The electrochemical performance of the coin cell using a cathode material fabricated by co-precipitation method using citric acid as a chelating agent in LiPF6 (EC:DEC=1:1 vol%) electrolyte was evaluated by the initial charge/discharge, cycle stability, rate capability, and electrochemical impedance spectroscopy (EIS). The initial charge/discharge efficiency of LiNi0.9Co0.1O2 cathode materials prepared by recalcination was decreased, but the cycle capacity (187 mAh/g) and stability (85%) were improved and showed excellent rate capability.

EN02.14.03
Electrochemical Performance of Li2MnO3 / LiMn2O4 Composite Electrode Material for Lithium-Ion Battery
Riki Kataoka, Noboru Taguchi, Toshikatsu Kojima, Nobuhiko Takeichi and Tetsu Kiyobayashi; National Institute of Advanced Industrial Science and Technology, Japan

Li2MnO3, a layered lithium-rich manganese oxide, is one of the potential high-capacity positive electrode materials among the Li containing transition metal oxide materials but its low electrical conductivity restricts its electrochemical activity. We recently found that Li–Mn cation disordering of the Li2MnO3 resulting in the formation of a NaCl-type structure improves electrochemical activity of the Li2MnO3, i.e., a high initial discharge capacity of...
320 mA h g⁻¹. However, its cycling performance is still poor probably due to structural instability, especially, oxygen emission during charging. In this study, we found that the structural stability of NaCl-type Li₂MnO₃ was significantly improved by forming a composite with spinel-type Li₂MnO₄ by mechanical milling. The initial discharge capacity of the composite of Li₂MnO₃ and Li₂MnO₄ in molar ratio of 1:2, was 379 mA h g⁻¹ (more than 1100 Wh kg⁻¹ per active material) which is much higher than those of precursor NaCl-type Li₂MnO₃ (320 mAhg⁻¹) and spinel-type LiMn₂O₄ (298 mAhg⁻¹). This capacity corresponds to about 1.4 and 1.5 mol eq. Li ion insertion, i.e., the obtained electrochemical capacity of the sample cannot be explained by the redox reaction of Mn³⁺/⁴⁺.

The 50th discharge capacity of the composite electrode showed more than 70% of the initial one, while less than 50% for NaCl-type Li₂MnO₃ electrode.

The LiMn₂O₄ component in the composite enhanced the structural stability of NaCl-type Li₂MnO₃, resulting in a restricted oxygen emission from the Li₂MnO₃ domain during charging confirmed by ex-situ XRD analysis and GC-MS. Such a structural stability leads to a better cycling stability and effective utilization of the oxygen redox reaction compared to pure NaCl-type Li₂MnO₃ resulting in the higher reversible capacity.

**EN02.14.04**

**Is Wurtzite-Type LiI Stable at Room Temperature?**

Yudai Omori, Reona Miyazaki and Takehiko Hihara; Nagoya Institute of Technology, Japan

It is widely known that the crystal structures of the most of alkali halides are the rock-salt type. For alkali borohydrides (MBH₄), the rock-salt structures are also stable at room temperature. Because of the high affinity between halide and BH₄⁻ ions, alkali borohydrides form the solid solution with alkali halides for the whole compositional range (for example, NaI-NaBH₄ systems [1]). However, only lithium borohydride is the exceptional; the crystal structure of LiBH₄ is wurtzite [2]. Furthermore, the solid solution of LiI-LiBH₄ is not the rock-salt type but high temperature phase (H.T. phase) of LiI (wurtzite) is stabilized at room temperature, which is clear difference from the other MBH₄-MI systems [3].

At the present stage, the solubility limit of LiBH₄-LiI systems is under controversial. The solubility limit of LiI into LiBH₄ was reported to be 33 mol% when the samples was synthesized by sintering at 543 K [3]. On the other hand, 50 mol% of LiI could dissolve in H.T. phase of LiBH₄ by mechanical milling [4]. Although, the rock salt structure is the stable phase of LiI at room temperature, it was reported that hexagonal phase of LiI was observed at the temperature below 273 K [5], which is the same structure with H.T. phase of LiBH₄. Thus, it is expected that the solubility limit highly depends on the fabrication procedure and/or temperature. The purpose of this research is investigating the solubility limit of LiI-LiBH₄ systems fabricated by low temperature milling.

All of the samples were fabricated in Ar filled glove box. LiI-LiBH₄ systems were fabricated by ball-milling at low temperature. LiBH₄ and LiI were purchased from Aldrich Co. Mechanical milling was carried out by using chrome steel pot (45ml) and 10 pieces of balls (10 mm in diameter). First, the given molar ratio of LiI and LiBH₄ were mixed in the mortar and encapsulated in the air-tight milling pot. Subsequently, the samples were kept at 213 K for one hour. Then, mechanical milling was performed at 400 rpm for 5 minutes. After milling, samples were cooled at 213 K again. Above cooling and milling cycles were repeated for 60 times, which resulted in the total milling time of 5 hours. The crystal structures of the samples were characterized by XRD measurement. The measurement was conducted at room temperature. The Li⁺ ion conductivities were measured by AC impedance method with Li electrodes. For the conductivity measurement, the powder samples were pelletized at ca. 150 MPa for 30 seconds. The thickness and diameter of the pellets were ca. 2 mm and 10 mm, respectively.

From XRD measurements, it was indicated that 2LiI·LiBH₄ (LiI : 67 mol%) is single phase of the hexagonal structure. Because LiI concentration is larger than 50 mol%, it can be said that LiBH₄ is not the host lattice but BH₄⁻ ions were introduced to the hexagonal modification of LiI. More specifically, this result indicates that wurtzite-type LiI was stabilized at room temperature. Further increase of the LiI concentration yielded to the two phase mixture of hexagonal (LiBH₄-LiI system) and rock-salt (unreacted LiI) structures. It should be noted that relative peak intensity of rock-salt LiI was reduced when LiI-LiBH₄ systems were fabricated by low temperature ball milling. Therefore, it is suggested that low temperature milling is the effective method for the stabilization of the hexagonal phase of LiI at room temperature.

High Reversible Energy Density in Mn-Rich Electrode Materials by Enabling Cation/Anion Redox Reaction

Junghwa Lee and Byoungwoo Kang; Pohang University of Science and Technology, Korea (the Republic of)

Since the commercialization of Li-ion battery (LIB) in 1990s, it has been an essential energy storage technology for powering advanced portable electronics and now has been becoming a key enabler for transforming our society into sustainable energy paradigm by deploying electric vehicles and grid-scale applications for renewable energy sources. To realize this transformation, tremendous efforts have gone to develop high capacity electrode materials with low cost and high abundant raw materials. From now on, almost all Li-ion cathode materials are composed of only few transition metals such as Ni and Co, which are electroactive in layered cathode materials such as LiCoO$_2$ and Li(Ni, Mn, Co)O$_2$, causing constraints on their resources and availability. To replace Ni or Co with cheap and abundant Mn, developing Mn-rich electrode materials with high energy density will be very attractive. Recent study reports that Mn-rich electrode materials with disordered-rocksalt structure can achieve higher energy density than conventional layered materials by using Mn$^{2+}$/Mn$^{4+}$ double redox that was enabled by a fluorination process and high valent dopants. However, they still suffer from sluggish Li diffusion caused by fully cation-disordered structure and can be still lack of practical implementation.

In a departure from previous approaches, we take a strategy of enhancing reversible oxygen redox reaction for increasing energy density in Mn-rich materials by controlling of the atoms solubility. The resulting Mn-rich material can achieve the highest energy density, ~1100 Wh/kg among reported Mn-rich materials and deliver superior rate capability, up to 10C rate (3A/g). Interestingly, the superior rate capability with very high discharge capacity in the resulting material indicates that the Co-free Mn-rich material can be kinetically comparable to other only TM redox materials, contrary to previous observation in Mn-based materials. We believe that the findings in this study can unlock the potential of Mn-rich electrode materials and will provide new avenues for the design of electrode materials that have high energy density and that can be practically implemented for high performance Li-ion batteries.

First-Principles Modelling of Li$^+$, Na$^+$ and Mg$^{2+}$ Mobility in Bronzes and Other Complex Oxides

Kit McColl, Ian Johnson, Jawwad Darr and Furio Corà; University College London, United Kingdom

High Li$^+$ mobility in electrode materials is required for high power Li-ion battery applications, enabling rapid charging and discharging rates. However, many conventional Li-ion electrode materials display slow ionic diffusion rates, leading to low capacity at high (dis)charging rate in bulk particles. Understanding and realising high ionic mobility in solids is also crucial for emerging sodium-ion and magnesium battery technologies, due to the larger size and high charge density of Na$^+$ and Mg$^{2+}$ respectively. For instance, mobility of Mg$^{2+}$ in many oxides is extremely poor, and achieving reversible Mg$^{2+}$ intercalation in oxide cathodes with both high capacity and high voltage at room temperature represents a major challenge in Mg battery development.

Transition metal oxides built from corner-sharing octahedra and the tetragonal/hexagonal tungsten bronze structure, but with empty interstitial sites reminiscent of ReO$_3$, have emerged as exceptional high-power Li-ion intercalation electrodes. Some materials in this family exhibit excellent capacity retention at high rates, which can be achieved in bulk particles without nanosizing. [1]

The corner-sharing framework of ReO$_3$ undergoes correlated distortions and rotations upon Li$^+$ intercalation, which stabilise the Li$^+$ ions and limit their mobility. [2] In contrast, bronzes that allow high-rate intercalation comprise some degree of edge-sharing among polyhedra in the $ab$ crystallographic plane. These provide structural rigidity, limiting framework distortions, and leading to ions occupying ‘frustrated’ intercalation sites. [1,3] Mobility of ions is enhanced when moving between frustrated sites, due to a smoothing of the potential energy surface. [4]

Here we present results of hybrid-exchange DFT calculations on a range of materials with bronze-type structures, including ReO$_3$, T-Nb$_2$O$_5$, V$_2$O$_5$, V$_6$Nb$_9$O$_{35}$, and Mo$_{2.5+y}$VO$_{12+y}$. [5] These materials display a range of structural features and connectivity including differently sized channels, $c$-axis separation, and elemental composition. We compare the behaviour of Li$^+$, Na$^+$ and Mg$^{2+}$ ions, thus exploring the effects of both varying ionic size and charge on intercalation and mobility.
Our calculations reveal that the smaller Li and Mg ions adopt frustrated coordination sites in some of the frameworks, whilst Na ions typically occupy stable sites with high coordination number due to their larger size. Low energy migration pathways exist between some sites for Li$^+$ and Mg$^{2+}$, indicating bronzes can be used to achieve high mobility for these ions. We also identify high energy regions in certain structures through which ions are unlikely to move, and thus represent bottleneck for ionic mobility under ambient temperature conditions. We can therefore begin to establish design principles for achieving high ionic mobility in bronzes for Li-ion battery materials and intercalation chemistries employing other charge-carrying ions.

Compositional Tuning of Solution-Processable Sulfide Solid Electrolytes for All-Solid-State Lithium-Ion Batteries

Yong Bae Song, Dong Hyeon Kim, Hiram Kwak and Yoon Seok Jung; HYU, Korea (the Republic of)

The application of high-energy lithium-ion batteries (LIBs) has been expanded from mobile electronics to electric vehicles (EVs) and energy storage systems (ESSs). However, accidents of the explosion of LIBs not only for small-scale ones but also large-scale ones such as EVs happened frequently in recent years. Accordingly, the safety issue of conventional LIBs, originating from the use of organic liquid electrolytes, has emerged as a serious concern. In this regard, all-solid-state batteries (ASSBs) are one of the most promising next-generation battery systems. Especially, ASSBs employing sulfide solid electrolytes show outstanding performance, compared with those fabricated using oxide or polymer solid electrolytes. Sulfide solid electrolytes have a critical advantage of deformable property besides the high ionic conductivity, enabling intimate contacts with active materials by the simple cold pressing process. Furthermore, several sulfide solid electrolytes such as Li3PS4Cl and Li1-Li2SnS4 are reported to be fully dissolved in solvents without side reactions and to be recovered by eliminating solvents and the subsequent heat-treatment, i.e., solution-processable, which allows to directly coat solid electrolytes onto active materials or to infiltrate conventional LIB composite electrodes with solid electrolytes. Thus, the solution process of solid electrolytes could be an effective protocol to realize the scalable production of ASSBs with high energy density. Unfortunately, only a few candidates of solution-processable sulfide solid electrolytes (e.g., (LiI-)Li4SnS4, Li6PS5X (X = Cl, Br, I), (NaI-)Na3SbS4, Na4-xSn1-xSbxS4) have been reported so far. Moreover, the decrease of ionic conductivity after the solution process by approx. an order of magnitude is common.

In this presentation, compositional tuning of arylgrodite sulfide SEs via the solution process and its resulting electrochemical performances for ASSBs are presented.

Electrochemical Characteristics of Nb-Sb Compounds for Li-Ion Battery Anodes

Dongkeun Yu, YeonHo Jang, Ki-Hun Nam and Cheol-Min Park; Kumoh National Institute of Technology, Korea (the Republic of)

The accelerating development of portable electronic devices and electric vehicles increases the demand for better secondary batteries. Rechargeable Li-ion battery (LIB) is a representative secondary battery system, displaying a large energy density and high power. On the other hand, because conventional graphite anodes have a small theoretical capacity and slow rate-capability, the development of Li-alloy-based anodes is required for the realization of high-performance LIBs. Therefore, various Li-alloyable materials have been pursued for increasing the anode capacity. Among the Li-alloyable materials, many studies have focused on Sb-based systems because of its high gravimetric (Li3Sb: 660 mAh g⁻¹) and volumetric capacities (~4370 mAh cm⁻³). Although Sb-based systems have a higher energy density, they suffer from poor cycling behavior because a large volume change occurs during discharge/charge. Therefore, many studies have focused on Sb-based intermetallics and their nanostructured composites to alleviate or minimize the volume change that occurs during cycling.

In this study, to enhance the electrochemical behavior of the Sb, the intermetallic Nb5Sb4 compound was synthesized by a simple solid-state method and tested its electrochemical properties for use as LIB electrodes. The reaction mechanism of intermetallic Nb5Sb4 compound was examined during Li insertion/extraction using various ex-situ analytical tools, such as X-ray diffraction (XRD) and Nb K-edge extended X-ray absorption fine structure (EXAFS) and differential capacity (dQ/dV) plot. Additionally, the intermetallic Nb5Sb4 compound was tested as high performance Sb-based anodes for Li-ion battery.

Enhanced Sn-Based Alloy Anodes in High Performance with Metal Carbides Matrix for LIBs

Do-Hyeon Kim, Taehyun Kim, Dongkeun Yu and Cheol-Min Park; Kumoh National Institute of Technology, Korea (the Republic of)

As the development of electric vehicles and portable electronic devices accelerates, the needs for improved secondary batteries have risen considerably. A rechargeable Li-ion batteries (LIBs) are a representative energy storage system due to its high operating voltage and energy density. However, commercial graphite anodes in LIBs
show relatively good electrochemical performance, it has a low theoretical capacity and slow rate capability. Among the representative Li-alloy-materials (Si, Ge, Sn, P, and Sb), which exhibit higher theoretical capacities than commercial graphite anodes, the Sn-based anodes are considered as alternative anode materials due to higher conductivity and volumetric capacity than that of the other anode materials.

To design an easily manufactured, large energy density, highly reversible, and fast rate-capable Li-ion battery (LIB) anodes, Fe-Sn intermetallic compounds were synthesized, and their potential as anode materials for LIBs were investigated, including ex situ X-ray diffraction (XRD), extended X-ray absorption fine structure (EXAFS) analyses at the Fe K-edge, along with a differential capacity plots (DCPs). Among the Fe-Sn intermetallic compounds, FeSn2 was selected on the basis of the electrochemical performances. To improve the electrochemical performance of FeSn2, it was modified using various transition metal carbides of TiC, WC, and SiC, which acted as a buffer matrix against the volume expansion during cycling. Furthermore, carbon black was used to manufacture FeSn2/TiC/C nanocomposite for stable cycling. The easily manufactured FeSn2/TiC/C nanocomposite for the Sn-based Li-ion battery anodes showed large energy density (first reversible capacity of 572 mAh g⁻¹), high reversibility (first coulombic efficiency of 74.3%), long cycling behavior (95% capacity retention after 200 cycles), and fast rate capability (approximately 458 mAh g⁻¹ at 3C rate).

3-V Cu-Al Rechargeable Battery in Aprotic Electrolyte—A Battery with Only Metal Foils Huimin Wang¹ and Denis Y. W. Yu¹,²; ¹School of Energy and Environment, City University of Hong Kong, China; ²Center of Super-Diamond and Advanced Films (COSDAF), City University of Hong Kong, China

To meet increasing demands for energy storage, many recent battery researches are devoted to new electrode chemistries and reaction mechanisms that promise substantial increase in energy density. Traditional positive electrode materials for lithium-ion batteries such as LiCoO₂ and LiFePO₄ rely on the redox reaction of the transition metal within the structure for charge-discharge. Though, the capacity is low because of their small charge-to-mass ratio. To break away from conventional thinking, here, we turn inexpensive Cu and Al foils, the common current collectors, into active materials as positive and negative electrodes, respectively, that undergo electrochemical reactions and charge transfer to store energy. The electrochemical reactions at the electrodes are given by

Cathode: Cu (s) ↔ Cu⁺ + e⁻
Anode: Al (s) + e⁻ + Li⁺ ↔ AlLi (s)

Here, we are successful in constructing a 3 V Cu-Al full cell the battery by coupling a Cu foil as the positive electrode with an Al foil as the negative electrode in LiTFSI-based aprotic electrolyte. During cycling, the charge transfer on the Cu electrode is achieved by stripping and deposition of Cu/Cu⁺, while that on the Al electrode is carried out by the alloying and dealloying reactions between Li and Al. TFSI⁻ anions migrate through the anion exchange membrane to balance the charge. Stable cycle performance is possible with the use of a highly concentrated electrolyte - a 3 V cell exhibits excellent cycle stability for more than 200 cycles in 6M LiTFSI DMC electrolyte.

Raman spectroscopy, electrochemical impedance spectroscopy (EIS), field emission scanning electron microscopy (FE-SEM) and X-ray photoelectron spectroscopy (XPS) were conducted on the Cu-Al cells and electrodes to further understand the reasons for the improved performance in the highly concentrated electrolyte. We found that the highly concentrated electrolyte suppresses Cu cross-over with the formation of large solvation structure, which also promotes smooth and non-dendritic Cu-metal plating, enhancing the long-term stability of the cell. XPS measurements show that an SEI derived from TFSI⁻ effectively passivates the surface of the Al electrode during initial cycling, leading to excellent capacity retention. Besides AEM, other common membranes, for example polypropylene, are also being examined as alternatives. More investigations on the interactions between the membrane and the solvation structure of electrolyte are underway.

Our findings demonstrate a novel 3 V battery that can be easily fabricated by putting two common metal foils (Cu and Al) together without any active material coating. Our Cu-Al battery can give a volumetric energy density of the range of 79-156 Wh L⁻¹, comparable to that of state-of-the-art all-vanadium redox flow batteries, and has potential to be used for future grid storage applications.
The Influence of Anode/Cathode Capacity Ratio on Cycle Life and Potential Variations of Lithium-Ion Capacitors

Roya Naderi¹,²,³ and Jim P. Zheng⁴,⁵,¹; ¹Florida State University, United States; ²Materials Research Society Student Chapter at Florida State University, United States; ³Aero-Propulsion, Mechatronics and Energy (AME) Center, United States; ⁴Florida A&M and Florida State University College of Engineering, United States

Lithium-ion capacitors (LICs) incorporate the fundamental features of intercalation battery materials and double-layer capacitor materials, to bring together the desirable combination of high energy and power densities, long cycle life and materials stability. But, the presence of battery materials in anode also contribute towards LIC’s long-term capacity fade, based on its extent of utilization. This work studies the importance of anode to cathode capacity ratio, and its influence on the electrodes potential variation and capacity decay behaviors. In a LIC system based on activated carbon (AC) and hard carbon (HC), we show that increasing the HC:AC capacity ratio from 1.1 to 3, boosts the capacity retention of the LIC by 10% after 2,000 cycles at 1C rate, and by 28% after 20,000 cycles at 60C rate. During the intermittent EIS and 3-electrode galvanostatic tests at 0.25C rate, lower anode over-potential is observed for LIC with larger anode to cathode capacity ratio. Pointing towards a reduced charge transfer and Warburg diffusion resistances, based on the potential at which the anode was operating. We show that for LICs with different anode to cathode capacity ratios, the difference in cell impedances originates from the difference in anode potential or degree of lithiation, and anode inter-planar distance expansions and contractions. The 1C and 60C rates long term tests, and intermittent EIS and 3-electrode tests at 0.25C rate were all in agreement that LIC with larger HC:AC capacity ratio had a better electrochemical performance.

Copper Doped NCM622 Cathode Material with Increased Capacity

Zifei Meng, Bin Chen, Mengyuan Chen, Xiaotu Ma and Yan Wang; Worcester Polytechnic Institute, United States

As the most expensive and important part of Li-ion batteries (LIB) is the cathode, developing high performance cathode material is vital for large-scale application of next generation LIB. NCM cathode materials have been used commercially due to its high energy density. For example, LiNi₀.₆Mn₀.₂Co₀.₂O₂, a kind of Ni-rich NCM cathode, has higher capacity, which have emerged as an ideal cathode material for LIB. However, its capacity is not high enough to reach the theoretical capacity, so the capacity of NCM622 still needs to be improved. Element doping is an efficient way to improve the electrochemical properties of cathode materials, and several mono- and multi-valent doping cations have been used to dope NMC622. Here, Cu-doped NCM622 cathode (CuNCM) was prepared by a coprecipitation process. The cyclic voltammetry profile showed the obvious wider peak than the virgin NCM. From XRD results, the strongest peak shifted to higher angle and the lattice parameter is smaller in the refinement. The specific capacity of CuNCM is 186 mAhg⁻¹ and 180.5 mAhg⁻¹ in first cycle at 0.1C and 0.33C between 3 to 4.3 V, which is 14 mAhg⁻¹ higher and 17 mAhg⁻¹ than the virgin NCM respectively.

Novel Silane-Based Matrices for Silica-Mediated Electrolyte-Binder Coatings in All-Solid-State Hybrid Ceramic Electrolytes for Lithium-Metal Batteries

Jordan Aguirre; Temple University, United States

In the context of Lithium Batteries (LB), Lithium Metal Batteries (LMBs), are considered a promising technology for meeting increased capacity and power demands, both for intermittent, renewable energy sources, and Electric Vehicles (EVs). With LMBs come particular challenges and obstacles, among which dendrite growth has been a significant concern for the LB research community. Fruits of research efforts have included exploring general strategies for preventing/stopping dendrites. This has been traditionally attempted with solid electrolytes that are either strong enough to halt dendrite advancement (high modulus materials), or prevent excessive concentration gradients (single-ion conductors).

In the latter category the highest Li⁺ conductivities are often found in inorganic materials such as ceramics, glasses or glass-ceramics. Conductivities are usually 1-2 orders of magnitude below traditional liquid electrolytes, though some systems have comparable conductivities. With the choice of a hard, inflexible electrolyte comes the challenge of impedance contributions from the electrode-electrolyte interface, as well as instability against the anode and even cathode.

A possible solution to the larger issue of ceramic electrolytes’ brittleness and fragility is to use them in a pulverized form, and combine with an appropriate binder. Binders generally are softer and able to conformally adhere to the
electrodes, solving the electrode-electrolyte interface, and grain boundary problems.

While this should be a straightforward solution, binders and ceramics tend to have dissimilar properties, such that there is lack of intimate contact, thus shifting the interfacial problem to the ceramic-binder interface. If unaddressed, ionic conduction happens preferentially in the organic binder, which almost inevitably has inferior ionic conductivity, and the ironically supposed compatibilizing component becomes the rate-limiting step. It is within this smaller context that this work takes place, seeking to develop a suitable electrolyte-binder interface.

Currently, a silica (SiO$_2$) mediated electrolyte-binder coating is being developed for a commercial, proprietary lithium ion conducting glass-ceramic (LICGTM) electrolyte, functionalized with opportune moieties. A silylated SiO$_2$ layer includes Li-solvating poly(ethylene oxide) (PEO) chains, as well as 2 different immobilized, pendant anion groups. The plan is to explore these moieties' effects on maintaining suitable conductivity values and minimizing concentration gradients at the interface, as well as avoiding dual ion conduction, as would be the case for LiX-based systems.

The formation of the silylated coating is achieved by a modified sol-gel method, starting with hydrolyzable silicon alkoxides (also known as silanes), with at least one group being non-hydrolyzable, and incorporating one of the above mentioned moieties.

In the case of silanes with PEO, these are referred to as monopodal (one silane group on one end of PEO) or dipodal (one silane group on both ends) PEG-silanes, while silanes with pendant anions (PA) are referred to as PA-silanes. Combinations of different silanes in different feed ratios have been explored, along with the incorporation of LiTFSI as a lithium source in select compositions. The alkoxides employed are either commercially available, or synthesized.

In this initial work, the bulk properties of these coatings have been explored. These have included thermal characterization by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC), as well as electrochemical characterization by temperature-dependent conductivity through electrochemical impedance spectroscopy (EIS). Ongoing work has included bulk EIS characterization LICGTM wafers with different thicknesses of SiO$_2$.

Magnetic Resonance Characterization and Transport Studies of Sodium-Ion Based Electrolytes for Electrochemical Energy Storage

Daniel J. Morales$^{1,2}$, Sophia Suarez$^3$, Stefano Passerini$^4$ and Steven Greenbaum$^2$; $^1$CUNY Graduate Center, United States; $^2$CUNY Hunter College, United States; $^3$CUNY Brooklyn College, United States; $^4$Karlsruhe Institute of Technology, Germany

In this work, Nuclear Magnetic Resonance (NMR) Diffusometry was used to investigate the transport properties of sodium electrolytes for two different materials systems. Variable-Temperature PFG NMR was performed on samples of NaPF$_6$ salt dissolved in glycol dimethoxy ethers (glymes), a novel electrolyte for use in Electric Double-Layer Capacitors (EDLCs), as well as NaPF$_6$ in mixtures of Ethyl Carbonate (EC), Propylene Carbonate (PC), Diethyl Carbonate (DEC), and Fluoroethylene Carbonate (FEC), at various concentrations. Self-diffusion Measurements for $^1$H, $^{19}$F, and $^{23}$Na were taken from 0-60°C, and ionic conductivities were calculated from the Nernst-Einstein relation:

$$\sigma_{\text{NMR}} = \frac{F^2[C]}{RT} \times (D_{\text{cation}} + D_{\text{anion}})$$

Where is the ionic conductivity, F is Faraday’s constant, R is the ideal gas constant, T is the temperature in Kelvin, C is the molar concentration, and $D_{\text{cation}}$ and $D_{\text{anion}}$ are the self-diffusion coefficients for the cation and anion, respectively. The results indicate significant ion pairing effects which increase with both increasing temperature and decreasing glyme molecular mass. We have also investigated ionic liquid-based Na electrolytes, and these results will be discussed in the context of practical use for Na-ion electrolytes for commercial energy storage.

In Situ Formation of Functional Material for Impeding Diffusion of Lithium Polysulfides and Mechanism Study for Enhancing the Performance of Lithium-Sulfur Battery

Junhwan Ahn, Tae-sun You and Dong-Won
Kim; Hanyang University, Korea (the Republic of)

Li-ion battery (LIB) has promoted the growth of global market such as portable electronic devices, personal mobilities, unmanned aerial vehicles and long-range electric vehicles. Over two decades of dedicated researches and developments, the energy density of LIB has increased about 2 times since its commercial release. However, it has been mostly achieved by the improvement in battery manufacturing technologies, and only little change has been made in active materials and their chemistry, reaching their own theoretical limitations. In this regard, exploring next-generation energy storage materials that satisfies high energy density and low cost is essential. Extensive studies on next-generation energy storage materials have narrowed down some candidate materials and sulfur has shown the most promising results among them. Its advantages such as its high theoretical capacity, natural abundance, non-toxicity and low cost render sulfur an attractive choice. However, lithium-sulfur battery suffers from rapid capacity fading and shuttling phenomena caused by reaction intermediates called lithium polysulfides (Li$_2$S$_x$, 4 $\leq x \leq$ 8). Low electronic conductivity of sulfur and reaction products also compels introduction of large amount of conducting carbon, lowering practical energy density of lithium-sulfur battery. Many efforts for encapsulating sulfur using polar conductive matrices (doped carbon, conducting polymers) have been made to alleviate these problems, however, most of the approaches are proven to be effective only for few hundreds of cycles. Instead of exploring bulky heavy materials for lithium-sulfur battery, we propose highly reactive electrolyte additive, which can immediately react with lithium polysulfides to form thin solid layer and results in effective blocking of migration of lithium polysulfides to anode side. Chemical composition of the material formed in-situ as well as its electrochemical property was investigated and possible reaction mechanism, corresponding cell performance and desirable structure of additive will be suggested.

EN02.14.18
Large Three-Dimensionally Interconnected Mesopore Carbon and Solid Polymer Electrolytes for All-Solid-State Flexible Supercapacitors with Ultra-High Energy Storage Performance

Kyunggook Cho$^1$, Hee Soo Kim$^2$, Seongsu Jang$^1$, Won Cheol Yoo$^2$ and Keun Hyung Lee$^1$; $^1$Inha University, Korea (the Republic of); $^2$Hanyang University, Korea (the Republic of)

All solid-state supercapacitors (SCs) have received significant research interest as a shape deformable power supply device owing to the recent progress in portable, lightweight, and flexible electronics/optoelectronics. SCs typically exhibit fast power delivery rates, long life cycles, a wide range of operating temperatures, and good operational safety compared to rechargeable batteries. However, their low energy density limits the use of SCs in broader applications. To overcome the low energy density of the SCs, we employed three-dimensionally interconnected large mesoporous carbons (49 nm) to electrochemically stable ionic-liquid (IL) based solid polymer electrolytes (referred to as ionic gels). Precisely designed large mesopores interconnected through windows provide effective transport pathways for the electrolyte ions, while the well-developed micropores render a large active area for capacitive charge storage. The resulting SCs showed excellent energy storage performance such as specific capacitance of 323 F g$^{-1}$ and record-high energy density of 179 Wh kg$^{-1}$. Furthermore, the high energy and power densities obtained in this work exceed the upper bound of Ragone plots constructed based on aqueous-, organic-, and IL-based EDLCs reported to date. We also demonstrated the flexible all-solid-state SCs with an outstanding energy storage density (115 Wh kg$^{-1}$) that are suitable for bendable and foldable electronic devices. We believe these results provide design principles for developing high-performance SCs using electrochemically stable but dynamically slow ILs or IL-based solid electrolytes.

EN02.14.19
Electrochemical Properties of LiMn$_2$O$_4$ under High Pressure

Yosuke Ishii, Mayuko Kameoka, Shun Yoshitani and Shinji Kawasaki; Nagoya Institute of Technology, Japan

Owing to their highest energy density compared to other commercially available energy storage devices, rechargeable lithium-ion batteries (LIBs) are indispensable device in modern society. In addition to the daily applications, LIBs are also expected to be used for cutting-edge fields such as deep-see, space, and other planets. In order to extend the application filed of LIBs, understanding of electrochemical behavior of LIBs at extreme environments is required. In addition, basic understanding of effects of pressure for battery operation is very important to improve reliability and safety of LIBs. Here, we report Li-ion storage properties of LiMn$_2$O$_4$ electrodes under extremely high-pressure condition up to 100 MPa.

In order to perform electrochemical experiments under high-pressure condition, we developed a two-electrode-type
cell in this study. The cell was immersed in an insulating silicone-oil (pressure medium) and hydrostatic pressure generated by a hand-pump was applied through a free-piston. Galvanostatic charge-discharge tests, galvanostatic intermittent titration measurements (GITT), and electrochemical impedance spectroscopy (EIS) were performed. In the measurements, a Li-metal foil, and LiMn$_2$O$_4$ coated on Al foil (LiMn$_2$O$_4$ : carbon black : PVdF = 6 : 3 : 1 in weight ratio) were used as anode and cathode, respectively. A mixture of ethylene carbonate (EC) and diethyl carbonate (DEC) solution (EC : DEC = 1 : 1 in volume ratio) containing LiClO$_4$ (1 mol L$^{-1}$) was used as the electrolyte. A glass-fiber filter was used as separator. All test cells were constructed in high-purity Ar-filled glovebox.

We confirmed that the reversible capacity of LiMn$_2$O$_4$ electrode at 25°C was not changed up to 100 MPa. In the meantime, plateau potentials corresponding to Li-insertion/extraction reaction was changed by the pressure. It was found that charge transfer resistance of the LiMn$_2$O$_4$ was clearly decreased with increasing pressure. It was also found that the thermal stability of LiMn$_2$O$_4$ was dramatically improved under high pressure condition: Under 100 MPa condition, the LiMn$_2$O$_4$ electrode showed good cyclability even at 55°C. On the other hand, reversible capacity of the electrode was dropped within 2 cycles at 0.1 MPa-55°C condition. These results indicate that LiMn$_2$O$_4$ cathode has great potential for special batteries for high-pressure application (deep-sea exploration etc.).

EN02.14.20
Rational Engineering of Silicon–Carbon Materials for Lithium-Ion Batteries—Influence of the Carbon Coating Graphitization Degree
Joseph Schwant1, Giorgio Nava1, Matthew G. Boebinger2, Matthew T. McDowell2 and Lorenzo Mangolini1; 1University of California, Riverside, United States; 2Georgia Institute of Technology, United States

Since its introduction, the research community has been engaged in efforts to replace the state-of-the-art graphite anode used in commercial Li-ion batteries with novel high-capacity materials. Among several candidates, silicon-core carbon-shell nanoparticles -NPs- are considered one of the most promising choices due to their good electrochemical performance and high gravimetric and volumetric storage capacities. Although a wide range of different Si-C nanocomposites have been proposed over the years, establishing a rational understanding of how the material structure and properties influence the battery performance is far from trivial. For instance, the influence of the presence and quality of the carbon (i.e. graphitization degree) on the electrochemical performance of the synthesized materials is still not well understood. We have investigated a novel approach to address this question through a modified Chemical Vapor Deposition -CVD- approach that enables a fine and precise tailoring of carbon coating graphitization degree on Si NPs. Our composite Si-C materials are produced by starting from the same raw silicon nano-powders, which allows for direct comparison of carbon shell contributions as the silicon cores are identical. The NPs are coated in a conformal layer of amorphous carbon resulting from the thermal cracking of C$_2$H$_2$ at 650 °C. After removing C$_2$H$_2$ from the reaction zone, the temperature is increased to 1000°C in Ar permitting controlled graphitization of the C-shell. Notably, both TEM and Raman analysis have shown no detectable presence of silicon-carbide in the synthesized materials. The as-produced composites have been tested in Li-ion battery half-cell assemblies. Both the amorphous-C-coated and graphitic-C-coated Si NPs exhibit a high first cycle coulombic efficiency of 87% with capacities around 1800 mAh g$^{-1}$. However, after 100 cycles the amorphous-C-shell rapidly decays to a capacity retention of 34% while the graphitic-C-shell drastically enhances the cycling stability showing a capacity retention above 71%. To explain this phenomenon, we then observed the lithiation process through in-situ TEM measurements. Highly graphitic carbon markedly improves the structural stability of the composite particles and strongly favours the passage of lithium ions into the silicon core with respect to a purely amorphous carbonaceous material. This interpretation is confirmed by EIS analysis, displaying a stark reduction of both SEI and Charge Transfer impedances for a carbon layers with high a graphitization degree. Finally, we demonstrate that the silicon-graphite composites produced also work as a functional “drop-in” additive in graphite dominant anodes. The addition of 10% in wt of the Si-based active material enables the fabrication of electrodes with areal capacity around 3 mAh/cm$^2$, gravimetric capacity 60% higher than the one of a pure graphite electrode, first cycle CE of 90% and capacity retention of 81% over 100 cycles.

EN02.14.21
TiO$_2$ as a Stable Catalyst-Support for Lithium–Oxygen Batteries
Gwang-Hee Lee and Dong-Wan Kim; Korea University, Korea (the Republic of)

Lithium-oxygen batteries (LOBs) can achieve a large energy density (> 3500 Wh/kg) through the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER) during the discharge and charge processes. In the LOBs,
the oxygen-cathodes can improve the efficiency of discharge-discharge cycle through effective ORR and OER. Carbon is used as a support for the catalyst applied to the conventional air electrode. However, the carbon-electrolyte interface causes side-reactions such as the formation of by-products and then exhibits a large overpotential between charge-discharge. Therefore, a carbon-free catalyst supports capable of suppressing side-reactions is required. Transition metal oxides have attracted interest to replace carbon-based catalyst supports. This work investigated the Ti\textsubscript{4}O\textsubscript{7} crystal structure as a chemically/physically stable catalyst support. Initially, anatase-TiO\textsubscript{2} was synthesized by sol-gel synthesis method. Thereafter, in order to control the anatase-TiO\textsubscript{2} phase to the Magnéli-Ti\textsubscript{4}O\textsubscript{7} phase, reduction heat treatment was performed in an H\textsubscript{2} gas atmosphere. Magnéli-Ti\textsubscript{4}O\textsubscript{7} has the best electrical conductivity among titanate crystal structures. The electric conductivity of Magnéli-Ti\textsubscript{4}O\textsubscript{7} is improved due to oxygen vacancies with Ti\textsuperscript{3+} cations on the (110) surface plane. Therefore, since the characteristics that can efficiently transfer electrons to the catalyst are obtained, Magnéli-Ti\textsubscript{4}O\textsubscript{7} can exhibit excellent charge-discharge performance with the stable charge-discharge overpotential than anatase-TiO\textsubscript{2}.

We investigated the phase transition of Magnéli-Ti\textsubscript{4}O\textsubscript{7} with anatase-TiO\textsubscript{2} through XRD, TEM, XPS, etc. In electrochemical properties such as cyclic voltammetry and galvanostatic cycle tests, Magnéli-Ti\textsubscript{4}O\textsubscript{7} was proved an excellent catalyst support through the introduction of RuO\textsubscript{2} catalyst.

Energy storage systems can be the most plausible solution since we are on the verge of a global energy crisis due to the rapid dissolution of fossil fuels. Finding environmentally benign fossil fuel replica with a broad performance spectrum is still a very encouraging field of research. In recent times, a tremendous effort related to the energy storage device has been put by our research groups. Few-layer graphene (FLG) achieved via mechanical exfoliation method from agricultural waste biomass: peanut shell. We have explored that the electrochemically deposited three-dimensional graphene oxide (ErGO) has a crucial role to act as binder-free electrode material for supercapacitor application. A facile electrochemical method can have advantages to grow reduced graphene oxide-polypyrrole hybrid platform on a pristine nanoporous gold chip for microsupercapacitor (MSC) application with outstanding cycle life.

Recently, electrochemical followed by laser-induction have shown the advancement for the fabrication of conductive and robust and flexible metal-free MSC. The LIG film on flexible substrate was patterned with the aim to develop on-chip flexible MSC, which offers large working voltage of 1.2 V in aqueous solid electrolyte. The MSC, without any metal current collector, interestingly shows unique electrical-double layer behavior and unprecedented cycling stability. Notably, the retention of initial capacitance after 1,00,000 continuous cycle was 100\% and after 150 days was more than 99\%, respectively. This study provides an effective strategy to build up metal-free supercapacitor with exceptional life cycle and facilitates progress toward a sustainable energy future.

Energy & Environmental Science, 2019, DOI: 10.1039/C9EE01458F

3D printing is an additive manufacturing (AM) technique that has attracted extensive attention for both industry and academia because it enables direct printing of multifarious, delicate, and complex structures in a low-cost, adjustable and scalable way. 3D printing also provides a facile route to fabricate advanced architectures and systems for a broad range of applications: energy, biotechnology, microfluidics, electronics, and engineered composites. In this work, we demonstrated electrical double layer supercapacitors using 3D printed activated carbon-based porous materials. Supercapacitors typically show intermediate characteristics of conventional electrolytic capacitors and secondary batteries and have outstanding advantages such as rapid charge/discharge rates, high efficiency, a wide operating temperature range, and a semi-permanent lifetime. The porous carbon-based electrode inks developed in this work were printable in various shapes: lattice, rectangular, circle, pyramid, spiral and so on. They can also be
stacked in multiple layers to increase electrode surfaces for capacitive energy storage. For the device fabrication, multi-stacked/interdigitated electrodes were designed and generated and the resulting energy storage performance was studied. As an electrolyte layer solid-state polymer gel electrolytes consisting of ionic liquid and host polymer networks were employed. To evaluate the electrochemical performance, cyclic voltammetry measurements were performed at various scan rates and the devices showed the reversible energy storage characteristics in the investigated operating voltage window. In addition, galvanostatic charge/discharge properties of the supercapacitors were examined at various current densities and the devices exhibited triangular shaped charge/discharge profiles.

**Improving Fluorinated Separator Membranes Performance for Lithium-Ion Batteries by Surface Micropatterning**

Renato Gonçalves¹, Teresa Marques-Almeida¹, Daniel Miranda², Maria Silva¹, Vanessa Cardoso¹, Carlos Costa¹ and Senentxu Lanceros-Mendez³⁴; ¹Universidade do Minho, Portugal; ²Polytechnic Institute of Cavado and Ave, Portugal; ³BMC Materials, Basque Center for Materials, Applications and Nanostructures, Spain; ⁴IKERBASQUE, Basque Foundation for Science, Spain

The constant technological development and the increasing mobility lead to the necessity of new ways of energy generation and storage [1]. Lithium ion batteries are increasingly used in portable devices and show some advantages when compared to other battery systems, due to higher energy storage, high capacity and higher number of charge-discharge cycles. Membrane separators are one of the key components of battery systems, the most important characteristics of these membranes being porosity, ionic conductivity, good mechanical properties and chemical stability [2]. Poly(vinylidene fluoride) (PVDF) and (vinylidene fluoride) (VDF) copolymers such poly(vinylidene fluoride – co – trifluoroethylene) (PVDF-TrFE) are known for its excellent chemical resistance, mechanical properties and outstanding electroactive properties [3].

In the present work, porous poly(vinylidene fluoride-cotrifluoroethylene) (PVDF-TrFE) separators with different patterned surfaces constituted by arrays of hexagons, lines, zig-zags and pillars microstructures and their influence on battery performance. In addition, computer simulations allow to deeper understae the influence of the patterned surface on battery response.

The discharge capacity efficiency of batteries with zig-zag micropatterned separators is the largest among the patterned separators, being 804% higher than the one for batteries with non-patterned separators.

**Two-Dimensional SiOₓ Nanosheets-Zero-Dimensional Silicon Nanoparticles Hybrid for High Capacity Lithium Storage Materials**

Hyun Dong Yoo, Soohwan Kim, Dong Jae Chung, Hyun Jong Kim and Hansu Kim; Hanyang University, Korea (the Republic of)

Si based anode materials for lithium-ion batteries have high theoretical capacity(3,580 mAhg⁻¹), but they have critical limit for commercial use because of their poor cycle performance associated with severe volume changes during lithium insertion and desertion. Our previous work, two-dimensional(2D) SiOₓ nanosheets electrode showed highly stable cycle performance and excellent dimensional stability because of physical nature of 2D nanostructure such as short diffusion length and abundant pore formed between stacked 2D nanosheets. However, their low reversible capacity has been a drawback to compete with other commercial material. In this work, we suggested 2D SiOₓ nanosheets and 0D Si nanoparticles hybrid materials using abundant intra-nanosheets pores in the stacked 2D SiOₓ nanosheets. The hybrid material delivered much improved reversible capacity more than 825 mAhg⁻¹ with higher initial efficiency compared to those of 2D SiOₓ nanosheets without sacrificing other anodic performances.

**High-Performance Lithium-Ion Battery Anodes Based on SiN, Nanoparticles from Gas-Phase Synthesis**

Stefan Kilian¹, Lisong Xiao¹, Christof Schulz¹² and Hartmut Wiggers¹²; ¹University of Duisburg-Essen, Germany; ²Center for Nanointegration Duisburg-Essen (CENIDE), Germany

With the current target of numerous countries to push electro mobility to the mass market, the demand for high performance batteries has increased drastically. Currently, the next goals on the roadmap are to achieve sufficient mileage and to reduce charging time of electrical vehicles. To accomplish these goals, the energy density as well as rate capability of lithium-ion batteries (LIBs) needs to be increased.
Silicon is widely recognized as the most promising component in high-capacity anode materials for next-generation lithium-ion batteries (LIBs) owing to its natural abundance, relatively low working potential, and its high theoretical storage capacity of 3579 mAh/g. However, the practical application of Si-based anodes is severely hindered by its low intrinsic electrical conductivity and its large volume change (>300%) during charging and discharging. The resulting mechanical stress causes rapid pulverization of the silicon and insulation and disconnection of the active material from the current collector. These failure events can cause rapid degeneration of the Si electrode and is especially prominent for silicon particles exceeding the size of a few hundred nanometres. Thus, recent research mainly focuses on nanostructures and nanocomposites that can tolerate the volume change.

A very promising way to stabilize silicon in LIB anodes is the incorporation of nitrogen, which has been shown to significantly improve the cycle performance. We therefore developed a gas-phase synthesis method based on the pyrolysis of monosilane in ammonia-rich atmosphere. Production rates are as high as 30 g/h and can be easily scaled. Based on this technology we are able to synthesize high-performing SiNx nanoparticles for lithium-ion battery anode. Moreover, their electrochemical properties can be designed by adjusting the synthesis parameters, thus affecting Si/N stoichiometry, particle morphology, size, and crystallinity.

We further demonstrate that SiNx nanoparticles with medium nitrogen content show significantly enhanced cycling performance of LIB-electrodes compared to pristine silicon. They show an initial specific discharge capacity as high as 1400 mAh/g and a highly stable cycle performance with a capacity retention of 96% after 100 cycles and over 80% after 500 cycles. Rate capability tests show that more than 60% of their capacity can be retained at a charging/discharging rate of 10 C. These results imply that silicon-rich SiNx based LIB electrodes are promising candidates for high-performance lithium-ion batteries with very high durability.

EN02.14.27
Highly Ordered Mesoporous Niobium Nitride for High-Performance Anode Material in Potassium-Ion Batteries Jae-Hyuck Park1,2, Jisung Lee3, Seongseop Kim1, Eunho Lim4, Jinwoo Lee3 and Yung-Eun Sung1,2; 1Seoul National University, Korea (the Republic of); 2Institute for Basic Science, Korea (the Republic of); 3Korea Advanced Institute of Science and Technology, Korea (the Republic of); 4Korea Research Institute of Chemical Technology, Korea (the Republic of)

Although Lithium-ion batteries (LIBs) have been regarded as fascinating energy storage device, the scarcity and high cost of lithium resources intrigue researchers’ interest in the next-generation batteries such as Potassium-ion batteries (KIBs) which have similar electrochemical characteristic of LIBs and use abundant potassium resources. However, to date there are still significant problems about searching suitable anode materials for KIBs because of hazardous of potassium metals and unstable cycle performance of carbonaceous materials due to large ionic size of potassium. Herein, we report ordered mesoporous niobium nitride/N-doped carbon composites hybrids (m-NbN/NC) as anodes for KIBs with superior cyclability and rate capability. The electrode delivers reversible capacities of 143 mA h g⁻¹ at 0.01 A g⁻¹ and 49 mA h g⁻¹ at 1 A g⁻¹. More impressively, the capacity retention of 100% at 0.5 A g⁻¹ after 2000 cycles could be achieved. In situ X-ray diffraction and ex situ SEM analysis indicates that m-NbN/NC electrode retains its structural integrity during potassiation and is accompanied by small strain, which is ascribed to high proportion of surface-controlled reaction. This work may suggest feasible new class of anode materials for ultra-stable KIBs.

EN02.14.28
All Printed Flexible Micro-Supercapacitors Based on Carbon Nanotubes Current Collectors and Exfoliated Manganese Oxide Nanoshhets Electrodes João Coelho, Lorcan Mckeon and Valeria Nicolosi; Trinity College Dublin, Ireland

In the last few years the concept of self-powered systems (SPS) has gained momentum in the fields of portable flexible technology. SPS usually refers to devices that are powered up by harvesting energy from external sources, such as solar radiation and body movement.[1] In a society where portable devices become an indispensable part of modern life, the development of SPS is of major importance.[2] These systems not only reduce the pressure on the electrical grid, but also help society moving towards sustainable and renewable energy sources. When integrated with energy storage devices, such as batteries and supercapacitors, SPS are also capable of storing energy under normal circumstances, thus assuring energetic self-sufficiency, even when surrounding conditions are less favourable for energy harvest.[1] In fact, the development of energy autonomous SPS is anticipated to bring
unforeseen ubiquitous innovations in our daily lives. Current thin-film batteries, still suffer from several technical disadvantages, as their energy per volume tends to rapidly decrease in the micrometre scale.[2] Moreover, they also raise safety concerns. On the other hand, micro-supercapacitors are highly desired as power sources for flexible devices as they present an enhanced power density, optimal cyclability, long shelf life and capability of direct on-chip integration.[2–4] However, to be fully integrated into wearable and flexible technologies, supercapacitors need to be flexible enough to undergo large mechanical deformations, without compromising their performance.[5] Commercially available supercapacitors do not present the most suitable configuration for devices meant to be bent or even rolled up, due to the presence of rigid components and the constant risk of harmful electrolyte leakage. The transition from current supercapacitor technology to fully printed, planar, ultra-thin and light supercapacitors will be disruptive.

In this work, inks based on carbon nanotubes (CNTs) and two dimensional manganese oxide nanosheets (MnO₂) processed by liquid phase exfoliation will be used as promising material platforms for flexible in-plane printed micro-supercapacitors. Owing to their superior mechanical and electrical properties, CNTs were implemented as highly efficient current collectors, thus removing the need for bulky and heavy metallic components. UV-Vis analysis revealed that the electrical conductivity of CNT films, as thin as 12 nm, is suitable for supercapacitor applications. Energy storage active materials, such as 2D - manganese oxide nanosheets, were then printed on top of the CNT films. Preliminary cyclic voltammetry experiments exhibited a characteristic supercapacitor behaviour. In order to maximize the exploitation of these devices properties, optimized inks, formulations and printing patterns will be carefully designed and characterized.

The proposed combination of liquid phase exfoliation and printing technologies will open the venue for the large-scale manufacture of ultra-light and thin flexible energy storage devices.

Structural and Chemical Evolution of nSi-cPAN Electrodes after Extensive Cycling Harvey Guthrey¹, Chun-Sheng Jiang¹, Andrew G. Norman¹, Se-Hee Lee², Nathan Arthur Dunlap² and Mowafak Al-Jassim³; ¹National Renewable Energy Laboratory, United States; ²University of Colorado Boulder, United States

Coating silicon nanoparticles (nSi) with cyclized polyacrylonitrile (PAN) is one approach to address the large volume expansion of silicon when used as an electrode material in solid-state batteries. This also enables the use of industrial processing techniques and inexpensive materials that can provide high active material mass loading with large reversible capacity. While previous studies have demonstrated success in using these materials to maintain high energy densities over long cycling life, comprehensive characterization is still needed to supply critical details needed for further optimization and extension to different material systems. In this work we focus on analysis of solid-state sheet style electrodes (nSi-PAN) and the interface with the LPS (Li₂S-P₂S₅) solid electrolyte. This analysis was performed in cross-section after fracturing and polishing the exposed surface using Ar⁺ ion milling. All sample preparation and subsequent characterization was performed without exposure to atmosphere so that no unintentional oxidation of the material would obscure true material properties. Devices were studied in the initial uncycled state and also at full delithiation after extensive cycling. SEM-based EDS mapping has revealed that there are changes in the spatial distribution of the nSi particles after cycling devices extensively. Additionally, sulfur from the solid electrolyte appears to have migrated into the nSi-PAN layer after cycling. No sulfur was observed in this layer prior to device cycling. A more complete understanding of how these changes relate to device performance was attained by correlation with electronic characteristics (scanning spreading resistance microscopy (SSRM)) and
The Effect of Li Salt Concentration on the PEO-Base Solid Polymer Electrolyte

Jae Hyun Kim and Anupriya Arul; DGIST, Korea (the Republic of)

To achieve improvement in the performance and energy density of lithium ion batteries, there is a high demand for novel electrolytes. Solid polymer electrolytes (SPEs) are now becoming increasingly attractive for LIBs because of their excellent properties such as high safety, easy fabrication, low cost, high energy density, good electrochemical stability and excellent compatibility with lithium salts. Polymers may also act as hosts for ions.

PEO is a polyether compound with low toxicity and is thus used in a variety of applications. PEO can complex with lithium salts (Li⁺) to form polymer electrolytes. Its ethylene oxide (EO) units have a high donor number for Li⁺ and high chain flexibility, which are responsible for ion transport. The ions can move in the space provided by the free volume of the polymer host, and conductivity is thus possible above the glass transition temperature (Tg) of the polymer where the polymer molecules are free to move. The ionic conductivity displays a diffusive liquid-like behavior in the solid electrolyte. The design criteria for PEO-based electrolytes is the suppression of PEO crystallinity to increase the percentage of amorphous phase of PEO for ion transport. Various strategies have been employed to improve the ionic conductivity of PEO based electrolytes.

The challenging and critical issue with solid polymer electrolytes are to improve the ionic conductivity, interfacial contacts between electrodes and electrolytes and electrochemical stability window

In order to above requirements, recent research in PEO-based solid-state electrolytes (SSEs) has focused on the design of additive for solid polymer electrolytes (SPEs). The additives include ionic liquid, oxide particles, etc. The addition of ionic liquid and organic solvent could serve as the plasticizers, which were found to be efficient on improving the ionic conductivities of SPEs. On the other hand, various modification methods of SPEs by introducing oxide particles have been published. It was reported that the addition of oxide nanoparticles to the SPEs, such as SiO₂, TiO₂, Al₂O₃, LAGP, YSZ can improve ionic conductivity. Researchers attributed the enhanced ionic conductivity to that the highly dispersed nanoparticles be able to inhibit the recrystallization of polymer segment and further accelerate Li⁺ transport. The nanoporous materials such as nanosized mesoporous SiO₂ and metal–organic framework (MOF) can be used to achieve high Li ion conductivities. One material containing porous channel was used as an additive to a high ionic conductivity composite electrolyte.

These results indicated the porous nanoparticles may be a relatively effective additive to increase the ionic conductivity than the nonporous particles, which is mainly attributed to the pores creating more space charge regions to facilitate Li⁺ transport. The implanted materials with rich nanoporous structure can effectively promote the formation of an Li⁺ enrichment area through the adsorption effect. In the newly formed percolated interface between additives and polymer, the continuous area could act as a high-speed pathway for fast lithium ion diffusion.

In this study, we mixed PEO and Si and Al based 3-dimensional nanoporous oxide structures (NOPSs) to make composite solid electrolytes. Because the choice of lithium salt also plays a crucial role in solid polymer electrolyte, lithium hydroxide (LiOH) and lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) were used to investigate the effect of different kind of Li salt on the Li ion conductivity. The most important requirement of lithium salt is their solubility in polymer matrix. We varied the drying temperature of the composite solid state electrolytes. The drying temperature range is from 25 °C to 60 °C. We also changed the ration of EO:Li. Different molar concentration of PEO is utilized such as, EO:Li = 16:1 & 18:1 ratios. The best lithium ion conductivity was obtained in the temperature of 50 °C.

Enabling Rapid Charging Lithium-Metal Based Rechargeable Batteries through Suppression of Dendrite Growth and Ion Depletion in the Electrolyte via Surface Acoustic Wave-Driven Mixing

An Huang1, Haodong Liu1, Ofer Manor2, Ping Liu1 and James Friend1; 1University of California San Diego, United States; 2Technion–Israel Institute of Technology, Israel

Lithium metal is an attractive material for use as anodes in batteries due to its high electronegativity, low density, and high energy density. Because it is unstable during recharging, with non-uniform Li deposition that leads to porosity, dendrites, and dead Li, rechargeable lithium metal batteries have been unrealistic for nearly fifty years with
serious safety problems and low Coulombic efficiency. Over this time, research on electrolyte additives, solid-state electrolytes, artificial SEI modifications, and separators have produced modest improvements, but none that have justified considering lithium metal batteries over lithium-ion batteries in rechargeable applications. Battery stability, ionic conductivity, and interfacial issues remain key challenges.

Nonuniform lithium deposition during charging occurs due to a Li ion depletion layer adjacent to the anode, especially at modest to high charge rates of 1C or above. By including a small, 100 MHz surface acoustic wave device into the lithium metal battery that produces intense acoustic waves in the electrolyte, rapid submicron boundary layer mixing flow may be generated during charging. This flow largely eliminates the Li ion depletion layer, and because the SAW device is small, solid state, and requires only 10 mWh/cm² during battery charging, there is a realistic possibility of incorporating this technology into current batteries under consideration for an electric vehicle, consumer device, and medical applications. The elimination of the ion depletion layer furthermore allows high-rate charging, as we will demonstrate in our electrochemistry and morphological results. The underlying physics will be explained using a closed-form model formed from intermediate asymptotics, and will show the crucial impact of the Peclet number in avoiding the ion depletion layer.

EN02.14.32
Improved Ionic Conductivity Achieved via Sr Doping with Amorphous LLTO as Solid Electrolyte Yubin Zhang¹, Daxian Cao², Hongli Zhu² and Yan Wang¹; ¹Worcester Polytechnic Institute, United States; ²Northeastern University, United States

Amorphous Li₀.₃₅La₀.₅₅TiO₃ (LLTO) shows great promise for solid electrolyte in all-solid-state Li-ion batteries (ASSLiB), amorphous LLTO thin films have also been successfully synthesized by sol-gel process in our previous work. The ionic conductivity can reach up to 1.88*10⁻⁵ S/cm at 30 °C. However, one key requirement for solid electrolyte is high ionic conductivity. In order to further increase the ionic conductivity to fit the demand of ASSLiB, doping method was applied in our research. In specific, Strontium (Sr) was introduced as dopant. The ionic conductivity of Li₀.₃₅La₀.₅Sr₀.₀₅TiO₃ (LLSTO) is one order’s higher than LLTO. In this study, we successful prepared amorphous LLSTO thin film via sol-gel procedure, moreover, differences are introduced with Sr ratio in order to understand the relationship of ionic conductivity change and structure difference. We also proved the LLSTO came with promising electrochemical stability window and stability in contact with Lithium metal. In this case, we are able to better reveal the fundamental relationship between structure and ionic conductivity in a variety of solid-state electrolytes and Li-ion transport mechanism.

EN02.14.33
Fabrication of the Guest Li⁺ Ion Conductors Based on NaI-NaBH₄ System Reona Miyazaki¹, Yasuto Noda² and Takehiko Hihara¹; ¹Nagoya Institute of Technology, Japan; ²Kyoto University, Japan

Solid electrolytes for the all-solid-state lithium batteries have been mainly developed based on Li compounds in which the host Li⁺ ions are the main conduction species. On the other hand, our group has been focused on the “Li-free” compounds as the base materials for the solid electrolytes, where the foreign ions, or “guest Li⁺ ions” play a major role for the ionic conduction. From our previous research, it has been shown that NaI, NaBr and KI become guest Li⁺ ion conductors via forming the solid solution with LiBH₄ (6 mol%) [1-3]. While the guest Li⁺ ions are the major conduction carriers, the contribution of the host Na⁺ ion conduction in NaI-LiBH₄ systems was proven to be quite small [4]. The solid solutions of NaI-LiBH₄ were fabricated by mechanical milling of NaI and LiBH₄, however, it was suggested that the as-milled samples include unreacted LiBH₄ as the secondary phase [5]. The difference of the crystal structures would be one of the reasons for the slow kinetics for the formation of the solid solution (rock-salt and wurtzite structures for NaI and LiBH₄, respectively). Therefore, it is expected that the fraction of the secondary phase can be reduced if the guest Li⁺ ions in NaI lattice are introduced by the doping of LiI (rock-salt structure). In the present work, both BH₄⁻ and Li⁺ ions are doped into NaI by the mechanical milling of NaI, NaBH₄ and LiI all of which are the rock-salt type compounds. The guest Li⁺ conduction properties in NaI-NaBH₄-LiI systems will be also presented.

NaI, NaBH₄ and LiI were purchased from Aldrich Co. The mechanical milling was conducted with 10 pieces of balls in a chrome still pot (45 ml). First, several composition of NaI-NaBH₄ solid solutions were fabricated with the different f/BH₄⁻ ratios. Subsequently, LiI was milled with NaI-NaBH₄ systems in a given molar ratio. The concentration of Li⁺ and BH₄⁻ ions were changed by adjusting the doping amount of LiI and NaBH₄, respectively. The crystal structures of the obtained samples were analyzed by XRD measurement using Cu Kα radiation source.
The local structure around guest Li+ was investigated by 7Li NMR measurement. For the conductivity measurement, the powder sample was pelletized under ca. 400 MPa, resulting in the dense pellet with the thickness of 1 mm. Stainless steel was used as the both sides of electrodes and the three layered cell was sealed into air-tight cell. Electrical conductivity of the sample was measured by AC impedance methods from the frequency range between 1 MHz and 1 Hz. From the results of 7Li NMR measurement for NaI-NaBH4-LiI systems, it was clearly confirmed that the fraction of the secondary phase was successfully reduced by using LiI as the starting material. The Li+ conductivity is increased by the reduction of the secondary phase; the conductivity of 9(15NaI-NaBH4)-LiI was reached to be 1.5 × 10⁻⁵ S/cm at room temperature while the conductivity of the sample with unreacted LiBH₄ (9NaI-LiBH₄) was remained to 3.0 × 10⁻⁶ S/cm. The conductivity results of the samples with the different cation and anion ratios will be presented at the meeting.

MXenes' Terminations Engineering and Intercalation for Energy Storage Applications
Frederic Le Goualher, Liu Zheng and Martial Duchamp; Nanyang Technological University, Singapore

The sharp growth of the energy storage business - 30 % in the US in 2018, dominated by lithium ion battery - urges to find new alternatives for fast, safe and reliable devices. Existing solutions rely either on batteries or supercapacitors: the former stores energy with a high density but suffer from slow energy delivery and irreversible capacity fading; the latter stores less energy but higher power densities, with charging times of seconds to minutes and excellent cyclability.

But what if we could combine the best of both worlds?

This promise may be kept by using new pseudocapacitive materials known as MXenes. They are a rapidly growing family of transition carbides and/or nitrides with the general formula Mₙ₊₁XₙTₓ (n = 1, 2 or 3; M = transition metal, e.g. Ti, V, Nb, Mo; X = C and/or N; T = surface termination, e.g., -OH, -F, =O). Their potential in energy storage devices has already been intensively studied since their discovery in 2011. They exhibit a 2D layered structure, a very high conductivity, can intercalate ions or molecules in order to trigger or enhance ion insertion, show low diffusion barriers for Li+ ions or other multivalent ions. Another key aspect is that they use fast surface redox reactions to store more energy than traditional electrical double layer capacitors and at a higher rate than traditional batteries.

But the real potential of MXenes lies in their versatility. Researchers primarily focused on finding new Mₙ₊₁Xₙ chemistries, with great success. But another way to control their performances is to engineer surface terminations: they are introduced during the synthesis process and strongly influence Fermi's level density of state. Conductivity is thus strongly impacted as well as electrochemistry. Removing them or finding strategies to modify them is of great importance and can lead to boost performances.

In addition, intercalating molecules and/or ions between MXenes sheets is another mechanism that can be used. Interplanar distance and thus, storage capabilities, will be modified. We could think that 'the wider, the better' but this would be a false assumption. Indeed, as it has recently been proven, solvent plays a key role in this mechanism. A balance has to be found.

In this study, we demonstrate that for a given battery electrolyte, it is possible to enhance electrochemical storage in MXenes by choosing the right intercalant. Our results showed a 30 % improvement in performances by finding the correct balance between inter planar distance and ion insertion (with or without solvation shell). Moreover, we will also evaluate the impact of surface terminations modifications on battery performances and provide insight using electron microscopy.

EN02.14.35
Ideal Li-Metal Anodes with *Ex Situ* Artificial Layers for the Realization of Highly Stable Lithium-Metal Batteries Jung-In Lee and Soojin Park; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

The new technological breakthrough of battery systems is essential to spurring the development of energy-storage systems with a high energy density for electric vehicles and various electronic devices, albeit many advances since the commercialization of Li-ion batteries in 1991. At present, the employment of Li metal as a battery anode has attracted enormous attention because of its high capacity (3860 mA h g⁻¹), lightweight (0.59 g cm⁻³), and a low working voltage as crucial factors to fabricate high energy density batteries (e.g., Li-air batteries, Li-S batteries, and Li-metal batteries). Nonetheless, there are serious problems hanging over the system including the volume expansion and dendrite growth of Li anodes, safety issue, unstable interphase between Li metal and electrolytes, low round-trip efficiency, and short cycle life. Thus, it is necessary to seek a solution for suppressing the Li dendrites and then finally leading to advancing the development of practical Li metal batteries. In this work, we propose practical approaches for enhancing the electrochemical performances of Li metal batteries using two ways. One is a Li₂TiO₃ layer, (LT) which has the 3D pathway inside the particles for Li-ions, along with a simple, secure, and scalable fabrication method. The other is a polymer layer on a Li metal surface, which transports Li ions and screens Li metal from oxygen and moisture. Additionally, these works include indisputable evidence for verifying the superiority of these ways and practical demonstrations of full cells using high-energy cathodes.

EN02.14.36
The Impact of Charging Pulse on the Diffusion-Induced Stress on a Thin-Film Electrode Pavan Kumar Polkampally¹, Ashish Vineet¹, Jay Krishan Dora¹, Debashis Khan², Tarun K. Kundu¹ and Sudipto Ghosh¹; ¹Indian Institute of Technology, India; ²Indian Institute of Technology BHU, India

All solid-state thin film batteries are promising candidates for applications ranging from medical implants to micro-power sources for portable electronic devices. The structural durability and reliability of thin film batteries depend on the volume change in the electrodes. In order to make further improvements in the thin film battery technology, an in-depth understanding of the electro-chemo-mechanical processes involved in these batteries is necessary. To enhance the cyclic performance of thin film batteries, a fully coupled diffusion-stress modeling in continuum scale with various operating conditions are essential. In this work, we have incorporated coupling of diffusion and stress in a Si thin film and analyzed the impact of the nature of charging pulse on the evolution of hydrostatic and principal stresses.

EN02.14.37
Synthesis and Characterization of V₂O₅ Microstructures as Advanced Cathode Material for High-Performance Lithium-Ion Batteries Hemlata Dhoundiyal, Mukesh C. Bhatnagar and Pintu Das; Indian Institute of Technology Delhi, India

In recent time transition metal oxide vanadium pentoxide (V₂O₅) is considered as an excellent energy storage device material for Li-ion batteries (LIBs) with reference to its high charge storing capacity, low cost, rich layered structure, and abundant material. With respect to its rich layered structure, which can reversibly accept the intercalation and deintercalation of Li-ions in the process of charging and discharging of LIBs. In this study, we report a simple hydrothermal procedure to synthesize the porous microstructure of V₂O₅ as a cathode for LIBs with subsequent annealing temperature. The structural analysis stands for the orthorhombic phase of V₂O₅ and other suboxides phase of vanadium are absent. The RAMAN analysis justifies the layered structure of V₂O₅. The morphological study of V₂O₅ shows the flower-like three-dimensional micro flowers (having diameter ~1.2 to 2.6µm) self-assembled by Nanorods. In electrochemical cyclic voltammetry measurement three cathodic peaks were observed corresponds to 3.27V, 3.05V, and 2.08V as Li/Li⁺ refer to three crystal phase α-V₂O₅ to β- Li₀.₅V₂O₅; β- Li₀.₅V₂O₅ to δ-Li₂V₂O₅ and δ -Li₂V₂O₅ to γ-Li₂V₂O₅ respectively. And also three anodic peaks correspond to Li-ion deintercalation. Which indicate the good reversibility of the electrode. In this report, V₂O₅ micro flowers deliver very high specific discharge capacity of 290mAhg⁻¹ and after 50cycles the capacity reduced to 198mAhg⁻¹ cycled between the voltage range 2.0-4.0V at the current rate 0.1C.

EN02.14.38
Hierarchical Porous Nickel-Doped Vanadium Dioxide (B) Nanobelts with Ultrahigh Rate Capability and Long Cycle Life for Aqueous Rechargeable Zinc-Ion Batteries Yi Cai, Rodney Chua and Madhavi Srinivasan;
Nanyang Technological University, Singapore

Recently, aqueous rechargeable zinc-ion batteries (ARZIBs) have attracted great attention as compared to commercial lithium-ion batteries due to their unique advantages of high intrinsic safety (non-flammable water-based electrolyte) and low cost. [1-3] Over the past few decades, much progress has been focused on the exploration of suitable cathode materials. Among them, vanadium dioxide (B) has been considered as a potential cathode for ARZIBs owing to its unique double layers of V₂O₆ type with tunnels, which can facilitate rapid zinc-ions de/insertion processes. [4] However, the reported VO₂ (B) displays a high initial capacity but noticeable capacity fading and especially declines drastically at a high current rate. Compositing VO₂ (B) with an electrically conductive matrix has recently been introduced as an effective way to improve the power capability. However, it can only improve the external electric conductivity and the usage of expensive carbon (graphene) negates the cost advantage of vanadium oxides. Therefore, it is of great importance to construct novel VO₂ (B) electrode materials with excellent electrochemical performance.

Herein, we report an alternative approach to designing and engineering a hierarchical porous Ni-doped vanadium dioxide (B) nanobelts for ARZIBs. The as-synthesized samples were characterized by X-ray diffraction (XRD), Raman spectroscopy, scanning electron microscopy and transmission electron microscopy (TEM). The existence of Ni dopant was confirmed by the X-ray absorption near-edge structure studies (XANES) and X-ray photoelectron spectroscopy analysis. Electrochemical studies indicate that the Ni-doped VO₂ nanobelts electrode exhibits superior cycling stability and ultrahigh rate capability with long cycle life, which is significantly higher than that of the undoped VO₂ (B). This can be attributed to the utilization of Ni dopant to electrical wiring the electroactive material, the intrinsic conductivity of VO₂ can be effectively increased. In-operando XRD measurements coupled with ex-situ TEM micrographs taken at specific potentials were exploited to gain a further understanding into the structural evolution upon cycling and ions storage mechanism. The results of the study can potentially open the doors for the widespread application of constructing other elemental doping materials as cathodes with high rate capability and long cycle life for aqueous rechargeable batteries.

Phase Transformation of Copper Hexacyanoferrate Cathode in Aqueous Zn-Ion Battery Joohyun Lim¹, Rajib Sahu¹, Kevin Schweinar¹, Gholnecheh Kasiri², Katharina Hengge¹, Dierk R. Raabe¹, Fabio La Mantia² and Christina Scheu¹; ¹Max-Planck-Institut für Eisenforschung GmbH, Germany; ²Universität Bremen, Germany

Prussian blue analogs (PBAs) are polynuclear transition metal cyanides with the general chemical formula of AMₙ[Mₙ(CN)₆]xH₂O, where A represents monovalent cations and M transient metal cations. The PBAs have been considered as promising electrode materials for multivalent metal-ion batteries as well as monovalent metal-ion batteries because of their robust and large 3D channel framework.¹ In particular, copper hexacyanoferrate (CuHCF) has shown promising performances in aqueous Zn-ion batteries with specific energy and power comparable to organic Li-ion batteries.² However, the CuHCF suffers from decreasing capacity upon cycling. The exact mechanism of the CuHCF upon Zn ions insertion is still difficult to understand.

Here, we investigate the change of the CuHCF cathode in aqueous Zn-ion battery in terms of morphology, chemical composition, and oxidation state. Advanced electron microscopy techniques such as scanning electron microscopy, (scanning) transmission electron microscopy, energy dispersive X-ray spectroscopy, electron energy loss spectroscopy, and focused ion beam are applied in order to unravel the underlying mechanism. We observed the formation of wire and cubic morphologies of the Zn₅Cu₆HCF upon cycling the CuHCF cathode in Zn ions-containing electrolytes. A substitution mechanism is proposed to explain the increasing Zn content of the cathode material while simultaneously the Cu content is lowered during the Zn-ion battery cycling. The detailed degradation
mechanism and its relationship with the electrochemical performance will be discussed.

EN02.14.40
Visualization of Inhomogeneity Formation on the Cathode Materials of Lithium-Ion Battery by X-Ray Micro-Diffraction Chao Li, Mark Wolfman and Jordi Cabana; University of Illinois at Chicago, United States

Layered transition metal oxide family of cathode materials for Lithium-ion battery (LIB) has been exclusively studied due to their high theoretical capacities and chemical stability. Their performance is limited by the capacity degradation during cycling as irreversible reaction occurs. The irreversible reaction resulting from the crystal structural change of the cathode materials is due to the movement of lithium ions between electrodes while cycling at different rates. As a result, different phases can be observed by X-ray Powder Diffraction (PXRD). In order to understand the mechanism of different phases formation during cycling, it is necessary to locate the regions where the inhomogeneity is formed within the cathode. LiNi0.80Co0.15Al0.05O2 (NCA) was used as an example to develop an ex-situ methodology by using X-ray Microdiffraction (μ-XRD) at the scale from 1mm to 100µm to visualize the distribution of inhomogeneity within the cathode by generating a map of distribution of unit cell parameters of crystal lattice. Applying this approach, NCA has been examined under different discharging rates (C/10, C/5, C/2, 1C and 5C) with different sizes of lithium anode. The maps clearly show the distribution patterns of rate-depend inhomogeneities due to kinetic limitation within the cell. This methodology will be further developed to investigate the inhomogeneity formation on secondary particles.

EN02.14.42
Investigation of the Interface Structure between a Solid Electrolyte and a Battery Electrode through Neutron Reflectometry Patrick Kim and Joseph A. Dura; National Institute of Standards and Technology, United States

Lithium phosphorus oxynitride (LiPON) has attracted significant interest in solid-state batteries, due its wide potential window, high ionic conductivity, and fairly good mechanical stability. However, several issues which are associated with the formation of an interfacial layer between LiPON and battery electrodes (e.g. LiCoO2) and the structural degradation of electrodes significantly affect the electrochemical performances in solid-state batteries. Several techniques (such as HRTEM, STEM, SEM etc.) have been employed to look into the interfacial layer between solid-state electrolytes and electrodes; but it was technically difficult to analyze the same spot of sample without damage, due to its high energy beam. In operando neutron reflectometry (NR) is a non-destructive technique which enables the investigation of the evolution of nanometer-scaled interfacial layers as a function of working potential. In addition it is very sensitive to the light elements such as Li and H, which facilitates the qualitative analysis of thin films. Due to these fascinating characteristics, it has been used to study the by-products (e.g. solid electrolyte interphase) formed at the interface of battery electrodes. Through this study, we investigated the interface of LiCoO2 electrode before and after sputtering LiPON via NR and studied how Li-impregnated solid-state electrolyte affects the structural characteristics of LiCoO2 electrode. Moreover, we looked into the structure and composition of the co-diffused layer between LiPON and LCO using NR. These results may explain the reason for the capacity fade and power fade of solid-state batteries. In future work, we will explore the possibility that a thin layer of Al2O3 can improve the structural integrity of each LiPON and LCO. These fundamental studies will lead us to understand the inherent problem of solid-state batteries and provide guidelines to design the suitable electrode for thin film solid-state batteries.

EN02.14.43
Nitrogen-Doped Graphene/CNTs/Li2S Composites as Cathode for High-Performance Lithium-Sulfur Batteries Gaind P. Pandey, Joshua Adkins and Lamartine Meda; Xavier University of Louisiana, United States

Lithium sulfide (Li2S) is one of the most promising cathode materials for the next-generation advanced lithium-ion batteries as it allows for the use of lithium-free metal-based high capacity lithium-ion anodes such as silicon-based anode etc. It has high theoretical capacity (1167 mA h g⁻¹) and large energy density to match with high capacity metal anodes. However, Li2S suffers from poor rate performance and short cycle life due to its insulating nature (very low electronic and ionic conductivity) and shuttle effect of lithium polysulfides during charge-discharge.
cycles. In this work, we report a facile and scalable ball milling synthesis method to synthesize nitrogen-doped graphene/carbon nanotubes (CNTs)/Li$_2$S composites with 80 wt% Li$_2$S loading. In this composite cathode, two-dimensional (2D) N-doped few layer graphene nanosheets and one-dimensional (1D) CNTs provides efficient channels for electron transfer and ionic diffusion, and leads to a low solubility of polysulfides in electrolytes during charge-discharge cycles. The N-doped Graphene/CNTs/Li$_2$S composites cathode yields an exceptionally high initial capacity of 847 mAh g$^{-1}$ after 3 cycles at the C/20 rate based on the mass of Li$_2$S. The mass loading of active material (Li$_2$S) was ~4 mg cm$^{-2}$ in the cathode. The cell also shows good cycling stability with an average decay rate of 0.23% per cycle over 150 cycles at C/3 rate, and improved rate capability of 470 mAh g$^{-1}$ at C/2 rate. The reported facile and scalable synthesis method of N-doped Graphene/CNTs/Li$_2$S composites cathode with high Li$_2$S content presents promising application potentials in high-performance lithium-sulfur batteries.

EN02.14.44  
Electrospun Nanofibric Network of Ca$_2$Fe$_2$O$_5$ as Durable Anode for Advanced Li-Ion Batteries  
Sandeep K. Sundriyal$^1$ and Yogesh Sharma$^2$; $^1$Indian Institute of Technology, Roorkee, India; $^2$Indian institute of Technology, Roorkee, India

Recently, iron based metal oxides have attracted much attention for advanced lithium ion batteries (LIBs) anode. However, rapid capacity fading and poor rate capability caused by drastic volume variations during cycling process hinder their practical applications. To circumvent these issues, one dimensional nanofibric architecture consisting voids/gap present in between individual nanoparticles may play a vital role to prevent the volume variation during long term cycling. In this regard, nanofibers of Ca$_2$Fe$_2$O$_5$ have been fabricated by facile, environment friendly and cost-effective electrospinning technique, and thoroughly characterized by FE-SEM, TGA, XRD, XPS and BET. Further, the advantages and importance of Ca$_2$Fe$_2$O$_5$ nanofibers as LIBs anode is demonstrated by cyclic voltammetry (CV), galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS). Ca$_2$Fe$_2$O$_5$ nanofibers exhibit remarkable lithium storage performance such as high initial reversible capacity (650(±10) mAh.g$^{-1}$), excellent cyclic stability (600(±10) mAh.g$^{-1}$ up to 100 cycles) and good rate capability. Moreover, Nanoparticles of Ca$_2$Fe$_2$O$_5$ were also investigated as LIBs anode, however, nanoparticles performance are found to be inferior to the nanofibers. The better performance of Ca$_2$Fe$_2$O$_5$ nanofibers is attributed to the unique features of nanofibric architecture such as one dimension, porous, high aspect ratio and presence of voids/gap between interconnected nanoparticles.

N-doped, Microporous Carbon Coating Synthesized via Carbonization of Electrospray-Deposited Metal-Organic Framework for Lithium-Sulfur Battery  
Clayton T. Kacica and Pratim Biswas; Washington University in St. Louis, United States

Next-generation battery technologies with higher capacities and longer lifetimes compared to current lithium-ion batteries (LIBs) are vital for portable devices and electric vehicles. Lithium-sulfur batteries have received significant attention due to their ultrahigh theoretical capacity of 1675 mA g$^{-1}$ and the environmental availability and benignity of sulfur. However, several issues currently prevent their more widespread utilization, including the low electronic conductivity of sulfur (S$_8$) and its lithiated products (Li$_2$S$_x$). Additionally, the “shuttle effect” resulting from the soluble intermediate polysulfides Li$_2$S$_n$ (4 ≤ n ≤ 8) formed during charging and discharging in organic electrolytes has been shown to cause rapid capacity fade and battery failure.

Various strategies have been utilized to mitigate these issues, such as forming composites with conductive and adsorptive hosts to confine sulfur. However, the shuttle effect and resulting electrode instability has yet to be eliminated. Herein, we designed a metal-organic framework (MOF) derived N-doped microporous-carbon coated electrode consisting of sulfur and nanostructured titanium dioxide (S-TiO$_2$). The N-doped carbon coating is formed from the carbonization of an electrospray deposited Zn-MOF, and possesses a suitable pore size to prevent polysulfides from passing while not inhibiting the movement of Li$^+$. Meanwhile, the TiO$_2$ nanostructures provide efficient electron pathways to enhance the high-rate performance of the electrodes. The resultant electrodes deliver a high specific capacity and excellent rate performance.
Development of Novel Polymer Electrolyte for 3D Printed Free Form Factor Battery

Nishani Jayakody1, Steven Greenbaum1, Diana Golodnitsky2, Heftsi Ragones2, A. Vinegrad2 and G. Ardel2; 1Hunter College of CUNY, United States; 2Tel Aviv University, Israel

The high areal-energy and power requirements of advanced microelectronic devices favor the choice of a lithium-ion system, since it provides the highest energy density of available battery technologies. Several attempts have been made to produce primary and secondary thin film batteries utilizing printing techniques. These technologies are still at an early stage, and most currently printed batteries exploit printed electrodes sandwiched with self standing commercial polymer membranes, produced by conventional extrusion or papermaking techniques, followed by soaking in aqueous or non-aqueous liquid electrolytes.

In this work we report on the development and fabrication of novel 3D-printed solid-state or quasi-solid electrolytes by fused filament fabrication (FFF). The electrolytes are composed primarily of polyethylene oxide (PEO) and polyethylene glycol (PEG) which are known ionic conductors, and polylactic acid (PLA) for enhanced mechanical properties and high temperature durability. Flexible quasi-solid-state printed electrolyte plasticized by the ionic liquid (IL) 1-Butyl-1-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide (PYR14TFSI) with 0.3M concentration of LiTFSI exhibited an ionic conductivity of 2.8 × 10–4 S/cm at 60°C.

The 3D printed electrolytes were characterized by means of SEM imaging, differential scanning calorimetry (DSC) and electrical impedance spectroscopy (EIS). We have also investigated the charge transport dynamics in this printed electrolyte material by pulsed field gradient diffusion nuclear magnetic resonance (NMR) using the probe nuclei 1H, 7Li, and 19F, corresponding to the PYR14, Li, and TFSI ions. All ionic diffusivities in the IL-plasticized PLA/PEO/PEG electrolyte were reduced compared to their values in the IL with 0.3M LiTFSI, even though the ionic conductivity exhibited an acceptable value. Interestingly, a sample consisting of the IL LiTFSI mixture imbibed into the PLA matrix exhibited no reduction in ionic diffusivity compared to the liquid sample.

These results pave the way for a fully printed battery, which enables free-form-factor geometries and is far superior in terms of safety compared to standard Li ion batteries which contain volatile liquid electrolytes.

Reduced TiO2 as a Stable Cathode Material for Sodium-Air Batteries

Christopher J. Franko, Z. Blossom Yan and Gillian R. Goward; McMaster University, Canada

Sodium-based battery chemistries have potential for use as competitive energy storage alternatives to Li-ion batteries (LIBs), largely due to the low cost and wide availability of raw sodium materials compared to their lithium counterparts (150 USD t⁻¹ vs 5000 USD t⁻¹ for Na and Li carbonate respectively).1 Unfortunately, the development of Na-ion batteries (NIBs) has been limited by the intrinsic gravimetric barriers that come from moving toward Na-based intercalation. Na-air batteries (NABs) on the other hand, do not suffer from these barriers, reaching high theoretical capacities of 1108 Wh kg⁻¹.2 The comparatively high energy density of the NAB arises from a fundamentally different cell chemistry, where energy is gained through chemical synthesis rather than intercalation. Typically, a sodium metal anode is oxidized upon discharge to give Na⁺ ions which travel across a liquid electrolyte toward a porous carbon cathode, where O₂ gas is reduced to form either sodium superoxide (NaO₂) or sodium peroxide (Na₂O₂) in competing oxygen reduction pathways. Although theoretical gravimetric capacity is high in these batteries, cell lifetime is hindered by the oxidative instability of the carbon cathode toward NaO₂, forming sodium carbonate in a parasitic side reaction (Na₂CO₃).³

In this work, titanium dioxide (TiO₂) is investigated as a starting material for alternative cathode substrates in long cycle life, chemically stable, NABs. Electrically insulating TiO₂ is reduced via hydrogen gas to produce highly conductive single phase Ti₄O₇. The stability of Ti₄O₇ toward NaO₂ is confirmed by monitoring a ground mixture of the two by solid state ²³Na magic angle spinning nuclear magnetic resonance (MAS NMR), where no reaction is observed. A comparison mixture of NaO₂ and graphitic carbon is also monitored, and a distinct reaction to form Na₂CO₃ is seen.

Porous, carbon-free, Ti₄O₇ electrodes are fabricated and tested in Swagelok style Na-air cells. Cells are discharged, halted, stripped, and have their cathodes removed to examine the electrochemical products formed. ²³Na MAS NMR is used at spinning speeds of up to 40 kHz and at fields of up to 19.9 T in tandem with the multiple quantum MAS (MQMAS) pulse sequence to give optimal separation of the complex electrochemical mixture. Both NaO₂ and Na₂O₂ are detected by form on the Ti₄O₇ cathode, and are found to be relatively stable over time when compared to the carbon-based system. Continuous wave, x-band, electron paramagnetic resonance (EPR) is also used to characterise NABs. Both NaO₂ and Ti₄O₇ resonances are visible in the EPR spectrum of discharged cathodes. The EPR signature
of Ti₄O₇ is measured before and after an oxidative stress test where the cathode is kept at 4 V (Na/Na⁺) in an oxygen atmosphere to mimic the most extreme conditions faced in the NAB, and little to no change is observed. The long-term cycle life of Ti₄O₇ NABs is tested by monitoring capacity retention of cells over 50 charge/discharge cycles with varying cut-off voltage windows. Measurable improvement is seen over the carbon system. Ti₄O₇ is shown to be a highly stable cathode material for NAB systems, while tandem ²³Na MAS NMR and EPR are proven to be an encompassing toolkit for the disentanglement of the complex chemistries found in metal-air batteries.

**Thermal Stability in High Nickel Layered Oxides**

Carol M. Kaplan, Hui Zhou, Anshika Goel, Natasha Chernova and M. Stanley Whittingham; Binghamton University, United States

Layered oxides are among one of the leading cathodes for lithium ion batteries due to their high energy density. They are one of the more attractive options for use in electric vehicles which makes their safety a top priority. It is well known that layered oxides produce oxygen upon heating which can lead to exothermic reactions within the cell aiding in thermal runaway. This presentation will discuss the thermal stability of the high nickel layered oxides LiₓNi₀.₈Mn₀.₁Co₀.₁O₂ (NMC) and LiₓNi₀.₈Co₀.₁₅Al₀.₀₅O₂ (NCA) in different charged states. The effect of composition of the layered oxides as well as their interaction with the electrolyte components will be explored in order to isolate the cause of the thermal output present upon heating. Differential scanning calorimetry (DSC) was used to study the exothermic reaction between the cathode materials and the electrolyte. To further understand these reactions, the individual components of both the cathode and the electrolyte were studied to identify what interactions were causing the heat release. X-ray diffraction (XRD) was used after DSC to identify products of the reaction to gain better insight on what is going on within the cell. While high nickel content in layered oxides is known to destabilize the material, the onset temperatures for these reactions is not below 200°C and the total heat released does not exceed 1400 J/g. By using a more stable electrolyte, the total heat released drops to roughly 400 J/g.

**Garnet-Rich Composite Solid Electrolytes for Dendrite-Free, High-Rate, Solid-State Lithium-Metal Batteries**

Chaoyi Yan; North Carolina State University, United States

Composite solid electrolytes (CSEs), which are composed of inorganic fillers and organic polymers, show improved safety and suppressed lithium dendrite growth in Li-metal batteries, as compared to flammable liquid electrolytes. However, the performance of current CSEs is limited by the agglomeration effect, with low content of inorganic Li⁺-conducting fillers and ineffective Li⁺ transport between the inorganic fillers and the polymer matrix. We therefore set out to design a CSE toward high-performance, solid-state Li-metal batteries based mainly on inorganic Li-conductors, with supplementary polymer content for improving interfacial contact. A new type of CSE with enriched inorganic Li-conductors and well-percolated network was introduced utilizing one dimensional L₆₂.₉₃La₃Al₀.₂₄Zr₂O₁₂ (LLAZO) nanofibers to provide long-range and fast Li⁺ conduction. Additionally, acrylate functional groups (CH₂=CHCOO⁻) were covalently bonded on the surface of LLAZO nanofibers, which enabled the chemical grafting of functional monomers directly from the nanofiber surfaces. In the resultant composite electrolytes, silane-decorated LLAZO nanofibers (s@LLAZO nanofibers) were cross-linked along with polymerization of monomers. This controlled fabrication of composite structures led to a well-percolated network, forming continuous, 3-dimensional, and fast Li⁺ conductive pathways within the CSE. The silane coupling agent significantly prevented the inhomogeneous distribution of inorganic Li⁺ conductors and enhanced the interaction between the LLAZO nanofibers and the polymer matrix, which improved the mechanical strength of CSE, favored the amorphization of polymer, and reduced the activation energy of Li⁺ conduction between the filler and polymer.
Consequently, the silane coupling agent successfully eliminated the agglomeration effect, and the introduced CSEs (LLAZO nanofibers > 60 wt.%) exhibited higher ionic conductivity, larger lithium transference number, and wider electrochemical stability window. Excellent cycling stability and extraordinarily high rate capability (up to 10C) was demonstrated in the all-solid-state Li-metal batteries with LiFePO4 and high-voltage Li[Ni0.3Mn0.3Co0.4]O2 cathodes at ambient temperature. This novel design of CSEs with s@LLAZO nanofibers paves the way for a new generation of improved functioning all-solid-state Li-metal batteries.

**Tunable D-spacing of Ammonium Vanadium Bronze for High-Performance Rechargeable Aqueous Zinc-Ion Batteries** Jianwei Li; University College London, United Kingdom

Driven by safety concern and cost-efficient demand of the commercial market, Rechargeable aqueous zinc-ion batteries (ZIBs) has drawn many attentions in last few years due to high energy/powder hubs and eco-friendly features for facile massive production and large-scale applications. However, considering the highly reversible and superior capacity of ZIBs, the researches of vanadium-based cathode materials are still in its infancy and suffering from a deficient investigation of zinc ion diffusion kinetics and deep insight of intercalation mechanism within a crystallographic configuration. Herein, we elaborately fabricated tunable d-spacing expansion of ammonium vanadium oxide (NVO) with various amount of ammonium ions as cathode material in ZIBs. The hydrogen bond of NH4+ within interlayer of V2O5 framework possesses superior behaviour on zinc ion diffusion as “lubricant” like water molecule which is highly different from metal pre-intercalated V2O5 in previous reports. Thus, the as-obtained NVO presented 252 mAh g\(^{-1}\) at a high current density of 10A g\(^{-1}\) with excellent retention of 95% after 1000 cycles. The electrochemical reaction kinetics, structure evolutions and zinc storage mechanism are discussed in detail. This work may stimulate future exploitation of vanadium-based cathodes in ZIBs and bring more insights into the mechanisms of zinc-ion storage.

**A Safe and Fast-Charging Lithium-Ion Battery Anode Using MXene Supported Li3VO4** Nian Liu and Haochen Yang; Georgia Institute of Technology, United States

During fast charging, the commonly used Li-ion battery anode material, graphite, has a significant shortcoming: its discharge potential is too low to guarantee the safety of batteries. Li3VO4 (LVO), an alternative anode material, has a safe discharge potential window of 0.5 V to 1.0 V vs. Li+/Li and high theoretical capacity (~394 mAh/g). However, the poor conductivity of LVO (~10\(^{-10}\) S/m) constrains its further applications. This presentation will show our recent efforts embedding LVO uniformly onto a multilayered material, Ti3C2Tx MXene, by a sol–gel method. The Ti3C2Tx MXene nanolayers with high electrical conductivity (2.4 × 10\(^5\) S/m) served as a scaffold to load LVO nanoparticles. The LVO/Ti3C2Tx MXene composite exhibited remarkable electrochemical performance in terms of rate capability and long-term cycle stability in comparison with bare LVO and commercial graphite anodes. The LVO/Ti3C2Tx MXene composite delivered an initial capacity of ~187 mAh/g and 146 mAh/g after 1000 cycles at 5C, compared to bare LVO (an initial capacity of ~41 mAh/g and ~40 mAh/g after 1000 cycles at 5C) and graphite (~71 mAh/g after 1000 cycles at 5C). We believe this work opens new possibilities of anode materials for safe and fast-charging Li-ion batteries. This presentation is based on our recent publication: *J. Mater. Chem. A*, 2019, 7, 11250-11256

**https://doi.org/10.1039/C9TA02037C**
A novel and facile polymer-assisted chemical solution (PACS) method is successfully developed for the synthesis of LiMn$_2$O$_4$, LiMn$_{1.5}$Ni$_{0.5}$O$_4$ and LiNi$_{0.5}$Co$_{0.2}$Mn$_{0.3}$O$_2$ (NCM523) with unique morphology and nanoparticle nature as cathodes for lithium-ion batteries. PACS uses polymers polyethyleneimine and ethylenediaminetetraacetic acid to bind with metal salts, such as metal nitrate. PACS is unique compared with other solution methods in that water-soluble polymers bind with the metal ions to prevent them from hydrolysis. Therefore, these metal-polymer solutions are stable for years. The compositions and particle sizes of cathode materials can be tuned by simple controlling different heating temperatures from metal-polymer solutions. At low heating temperature of 550 °C, LiMn$_{2-x}$Ni$_x$O$_4$ nanoparticles are covered by a thin layer of carbon from in situ incomplete depolymerization of the polymers. The LiMn$_{2-x}$Ni$_x$O$_4$ cathode exhibited better durable rate capability with 100% of the capacity retained (∼100 mAhg$^{-1}$) after 400 cycles at 10 C rate. However, for NCM materials, higher calcination temperature of above 800 °C is necessary for layered structure formation with a lower degree of Ni/Li cation mixing thus for better electrochemical performance. As compared with the NCM prepared at 800 °C, the sample heated at 900 °C exhibits a higher initial discharge specific capacity of 189 mAh g$^{-1}$ being charged to 4.5 V at a current rate of 0.05 C, and better cyclability at 4.3 V cutoff voltage and a current density of 1 C.

**Short-Range Order and Li Transport in Fluorinated Disordered Rocksalt Cathode Materials** Bin Ouyang$^1$, Nongnuch Artrith$^2$, Zhengyan Lun$^1$, Zinab Jadidi$^1$, Daniil Kitchaev$^3$, Huwen Ji$^1$, Alexander S. Urban$^2$ and Gerbrand Ceder$^1$; $^1$University of California, Berkeley, United States; $^2$Columbia University, United States; $^3$University of California, Santa Barbara, United States

The discovery of Li-excess disordered rocksalt (DRX) materials has opened up a diversified chemical space for the development of low-cost high-energy-density cathodes. However, because of the Li excess, DRX oxide materials typically suffer from unsatisfactory capacity retention due to irreversible oxygen loss, a problem which can be mitigated by fluorination as it lowers the average cation charge states and makes more transition metal capacity available. In this work, we use ab-initio models to understand the short-range order and Li transport in fluorinated DRX (F-DRX) across different cation chemistries and fluorine contents. We find that the percolation of Li in F-DRX is governed by both Li-F attractions and cation mixing. To provide rational design principles for F-DRX, a synthesis map that combines expected electronic capacity, 0-TM percolation, and synthetic accessibility of fluorinated DRX materials is presented. Finally, we experimentally verify the fluorination effect in DRX materials and propose several promising F-DRX systems that combine high capacity and good cycle life.

**Developing High-Ni Layered Cathodes for Li-Ion Batteries through Synthesis by Design** Feng Wang, Mingjian Zhang, Chong Yin and Jianming Bai; Brookhaven National Laboratory, United States

There has been considerable interest in developing low-cost, high-energy electrodes for batteries. However, synthesizing materials with the desired structure and properties has proven difficult due to the complexity of the reaction involved in chemical synthesis. Additional challenge comes from the fact that synthesis is often undertaken under non-equilibrium conditions and, hence, the process is hard to be predicted by theoretical computations. In situ, real-time probing of synthesis reaction allows for identification of intermediates and determination of thermodynamic/kinetic parameters governing kinetic reaction pathways, thereby enabling synthetic design of materials with desired structure and properties. In this presentation, we will report our recent results from in situ probing and synthetic control of local structural ordering during synthesis of high-Ni layered LiNi$_{1-x}$Mn$_x$Co$_2$O$_4$ ($x>0.7$). Findings from this study, along with its implication to designing surface-stabilized high-Ni layered oxide cathodes, will be discussed.

9:00 AM EN02.15.04
**Cycling and Structural Evolution of KNb$_3$O$_7$ and NaNb$_3$O$_7$ as Li-Ion Battery Electrode Materials** Megan M. Butala$^{1,2}$ and Igor Levin$^2$; $^1$University of Florida, United States; $^2$National Institute of Standards & Technology, United States

As batteries are employed in larger numbers and for increasingly diverse applications, there is interest in alternative electrode materials, especially with improved safety, availability, and cost relative to the layered materials employed in commercial Li-ion batteries (LIBs). Early transition-metal oxides, one class of promising alternatives, have
demonstrated compelling performance for high-rate LIBs and even multivalent-ion-based energy storage. However, as this family of compounds is chemically and structurally distinct from the layered and olivine materials employed in commercial LIB electrodes, we are just beginning to understand the origins of their promising charge storage capabilities.

To bring new understanding to this class of materials and how they store charge, we analyze the cycling and structural evolution of KNb$_3$O$_8$ and related NaNb$_3$O$_8$, which comprise complex layers of edge- and corner-sharing [NbO$_6$] octahedra. On the first discharge, these materials react with 2 moles of Li per mole of Nb, resulting in relatively disordered products. Only half of the first discharge capacity is reversible on charge, yet long-range order is recovered and the structures of charge products resemble the initial materials. Using ex situ and operando XRD and PDF, we describe the evolution of the structure, focusing on changes in the [NbO$_6$] layers during cycling and the role of the counteration.

Our findings on how these materials store charge and their unexpected recovery of long-range order can inform the selection and design of new materials for energy storage, with relevance for early transition-metal oxides as well as conversion electrodes.

9:15 AM *EN02.15.05
Single Crystal Ni-Rich Cathode for Advanced Li-Ion Batteries Jie Xiao; Pacific Northwest National Lab, United States

Lithium ion battery (LIB) has been intensively investigated in recent years for vehicle electrification and its cost has been significantly reduced. For the long-range electrical vehicles, however, the cell energy and durability still need to be further improved to go beyond that of conventional Li-ion batteries. Among different cathode materials, Ni-rich NMC (LiNi$_{1-x}$Mn$_{x}$Co$_{1-x-y}$O$_2$, x $\geq$ 0.6) has a specific capacity greater than 200 mAh g$^{-1}$, high operating voltage (ca. 3.8 V) and low cost, and is therefore deemed as one of the most promising cathode candidates for next-generation Li-ion batteries.

Unlocking the full potentials of Ni-rich NMC cathodes demands to push the limit of this class of materials to achieve good cycling stability at elevated voltages to extract maximum reversible capacity, prevent Ni-catalyzed electrolyte decomposition, structural degradation and cracking during cycling, improve thermal stability and reduce moisture sensitivity, as well as overcome practical limitations to maximize the accessible capacity in the full cells. Although fundamental understandings of Ni-rich cathode have been deepened, an effective method to address the cathode problems is still lacking and even the failure mechanism of Ni-rich cathode is arguable. There is still a significant knowledge gap between materials research and cell-level need of the materials properties. For example, although many attractive attributes have been displayed from nano-sized cathode materials, the direction towards higher energy cathode is the opposite i.e., micron-sized large particles with high tap density and press density when being calendared into electrodes. The desired particle size, morphology and tap density of Ni-rich NMC that will benefit the porosity control and the electrochemical performances of the thick electrodes are not well studied from the synthesis point of view. The synthesis approach that help to extract greater than 210 mAh/g capacity from Ni-rich NMC without increasing the cutoff voltage is also critical and a necessity in improving the energy of next-generation Li-ion batteries which are, however, not well studied.

This talk will discuss the synthesis, understanding and implementation of single crystal Ni-rich cathode in lithium ion batteries. While polycrystalline is the common form of traditional LiNi$_{1/3}$Mn$_{1/3}$Co$_{1/3}$O$_2$, single crystal is preferred when Ni content becomes dominant (>70%) in the cathode material. Single crystal Ni-rich cathode may have reduced gas evolution, reduced sensitivity to moisture, lower surface area and increased tap density, all of which will play a key role for high performance advanced Li-ion batteries.

9:45 AM BREAK
Can a Glassy Interface Suppress Li Filaments in Ceramic Solid-State Electrolytes?  
Andrew S. Westover and Nancy J. Dudney; Oak Ridge National Laboratory, United States

Electric vehicles, consumer electronics, and the possibility of electric aviation demand energy storage with extremely high specific and volumetric energy densities. Incorporating Li metal as the anode in a Li ion battery to make Li metal batteries has the potential to fill this demand. To integrate Li metal into a battery, an electrolyte that is chemically stable with Li, and can suppress Li dendrites is required. Some of the most promising electrolytes are the ceramic electrolyte which have good ionic conductivity and electrochemical stability but are particularly prone to penetration by Li filaments. The glassy electrolyte Lipon on the other hand has a moderate ionic conductivity but can completely suppress Li filaments. The aim of this research is to answer the question: if ceramic electrolytes had a glassy interface like Lipon could they suppress Li dendrites at high current densities? To test this hypothesis, we deposited a Lipon layer on the surface of lithium lanthanum zirconium oxide (LLZO) and lithium aluminum titanium phosphate (LATP) ceramic electrolytes and cycled Li metal at increasing current densities. The answer to this question gives us great insight into the origin of Li filament formation and what is needed to suppress them in solid-state electrolytes with high ionic conductivities.

Inorganic Lithium Conductors for All-Solid-State Batteries—The Link between Crystal Chemistry, Transport Properties, Electrochemical and Chemical Stabilities in the Li2S - P2S5 System  
Omer U. Kudu1,2, Theodosios Famprikis1,3,4, Marc David Braida5, Thierry Le-Mercier5, Benoit Fleutot1,2 and Christian Masquelier1,3,2; 1Université de Picardie Jules Verne, France; 2Réseau sur le Stockage Électrochimique de l’Énergie (RS2E), France; 3ALISTORE European Research Institute, France; 4University of Bath, United Kingdom; 5SOLVAY R&I, France

Requirements for higher energy density and better safety in demanding applications such as grid storage and electric vehicles call for next-generation battery technologies. All Solid State Batteries (ASSBs) might enhance the safety and the energy density of conventional LIBs by removing flammable organic electrolytes and allowing the use of metallic lithium anodes [1]. In this context, solid sulfide-based solid electrolytes have drawn a lot of attention owing to their high ionic conductivities (10^-2 – 10^-4 Scm^-1 at RT) [2–5]. Few compositions in the Li2S – P2S5 binary system, particularly Li3PS4 and Li7P3S11, are being heavily investigated as glass-ceramic materials synthesized by mechanochemistry and subsequent annealing [4]. However, varying ball-milling parameters and annealing procedures were rarely systematically investigated [5].

In this work, we will report on the synthesis of various materials in the Li2S – P2S5 system (Li3PS4, Li7P3S11, Li2P2S6, …) via a systematic synthesis approach: the individual effects of pre-selected ball-milling and subsequent annealing parameters will be presented, as characterized in details through X-ray and neutron diffraction, and various techniques of spectroscopy such as Raman, NMR and complex impedance. The latter technique is quite powerful to discriminate between crystalline and amorphous contributions to the total ionic conductivity, which may be strongly affected as well by the relative amounts of local units such as P2S6^4-, P2S7^4- and PS4^3- in the material. Additionally, the chemical stabilities in air and the electrochemical stability windows of the aforementioned materials were assessed with the help of specialized experimental setups. These results will be comparatively presented along with the discussion of the link between the electrochemical and the chemical stabilities and the structure.

The vast majority of solid-state electrolyte (SSE) materials are unstable in contact with lithium metal, and (electro)chemical reactions between SSEs and lithium result in the formation of an interphase region [1]. Understanding the growth kinetics and chemo-mechanical consequences of interphase formation is key for controlling solid-state interfaces, which may enable the use of a wider variety of SSE materials within lithium metal batteries. Here, we investigate NASICON-structured L1+xAlxGe2-x(PO4)3 (LAGP), as well as sulfide-based SSEs. For LAGP, multi-modal \textit{in situ} investigation of interfacial reactions combined with electrochemical experiments reveal how the formation of the interphase is linked to cell failure. \textit{In situ} transmission electron microscopy (TEM) shows that the reaction of LAGP with lithium is similar to a conversion reaction, in which lithium insertion causes amorphization and volume expansion of ~130\% [2]. The interphase is a mixed ionic-electronic conductor, resulting in continuous growth. \textit{In situ} X-ray tomography experiments of operating LAGP-based cells reveal that the growth of the interphase causes fracture of the SSE, and quantification of the crack network shows that the extent of fracture with time is directly correlated to impedance increases within the cell [3]. Finite-element analysis is used to model stress evolution during interphase formation, and the initial fracture locations predicted from modeling correspond well to experimental observations. Interestingly, we have found that interphase growth trajectories can be modulated through the deposition of interfacial protection layers. Controlling the morphology of the interphase with protection layers results in the ability to extend cycling stability of symmetric cells from ~30 hours with unprotected SSEs to >1000 hours with protected materials. Overall, these results provide fundamental insight into interfacial transformations in SSEs, and they show that control over interfacial transformation processes could enable a wider variety of materials to be used in solid-state lithium metal batteries.

This work was supported by the Nanostructures for Electrical Energy Storage (NEES) center, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award number DESC0001160.

11:00 AM EN02.16.05
First Principles Modelling of Defect Chemistry and Electronic Properties of Lithium Garnets Alexander Squires¹, Daniel W. Davies², David O. Scanlon¹,⁴,⁵, Aron Walsh²,⁶,⁵ and Benjamin J. Morgan¹,⁵; ¹University of Bath, United Kingdom; ²Imperial College London, United Kingdom; ³University College London, United Kingdom; ⁴Diamond Light Source, United Kingdom; ⁵The Faraday Institution, United Kingdom; ⁶Yonsei University, Korea (the Republic of)

One of the key challenges in the development of high energy-density solid-state lithium batteries is the development of an electrolyte that is chemically stable with respect to a lithium metal anode. Lithium-rich garnets have been shown to possess the required electrochemical stability window to interface with lithium during battery cycling and consequently are highly promising candidate solid-state battery electrolytes [1,2]. Despite this, garnet-based batteries are yet to achieve commercialisation. Questions remain around how best to optimise lithium conductivity in the garnet framework to make them truly competitive with conventional liquid electrolytes, and how to prevent the formation and propagation of lithium dendrites, which cause batteries to fail by short circuit.

A number of recent works have suggested that defect chemistry of lithium garnets is non-trivial, with experimental evidence for the presence of oxygen vacancies in the as-synthesised materials [2]—This raises questions about both the native defect chemistry, and how native defect chemistry interacts with extrinsic dopants used to control lithium content in an attempt to optimise conductivity. Other work has suggested that electronic conductivity in lithium garnets is the reason behind ruinous dendrite formation [3]; in this work it was proposed that electronic conductivity facilitates the reduction of lithium within the garnet structure, causing dendrites to nucleate within the electrolyte, rather than propagating out from the anode. As the defect and electrical properties of semiconductors are inextricably linked, we have used first principles techniques to investigate both in this work, in an attempt to determine to what extent these can be controlled by synthetic design.

We have used hybrid density functional theory calculations to determine defect formation energies in the prototypical lithium garnet Li₇La₃Zr₂O₁₂ (LLZO). We use these defect formation energies to solve for grand canonical defect and carrier concentrations self-consistently as a function of chemical growth conditions [4].

Analysis of these results suggests that the defect chemistry of LLZO is indeed more complex than previously suggested. We report potential synthesis regimes in which the charge introduced by donor doping to control lithium content is compensated by the formation of LiZr anti-sites as opposed to the expected lithium vacancy [6]. Calculation of electronic charge carrier concentrations, in addition to further first principles analysis of dielectric response and charge carrier effective mass, allow for us to estimate electronic conductivities using the Feynman polaron mobility model [7]. These results provide insight into the nature of electronic conductivity and the extent to which synthetic control can be used to minimise electronic conductivity, finding that under the range of temperatures LLZO is typically synthesised under, charge carrier concentrations can vary by 6 orders of magnitude. This work may aid in understanding what synthesis regimes reduce electronic conductivity, with the potential consequence of inhibiting dendrite formation.

Phonon Contributions to Ionic Transport—A Guide to Achieving High Performance Solid Electrolytes
The application of solid-state ionic conductors is vast, ranging from next generation solid-state Li-ion batteries, to solid oxide fuel cells and different families of sensors. However, the realization of these applications is mostly impeded by the slow diffusion of ions in the lattice. One of the factors that directly impact the conduction of ions in solid materials is the vibration of atoms in the lattice. In the classical theory of diffusion, the effect of these vibrations only enters the formulations through a set of proxy parameters such as the attempt frequency. Such oversimplification of the vibrational effects neglects all the individual contribution that each phonon/mode of vibration can have on the hopping of ions between different lattice sites. In this study, we introduce a formalism that allows us to better understand the effect of individual phonons on the diffusion of ions through the lattice. Specifically, after calculating the modes of vibration for different configurations of the system using lattice dynamics calculations, we determine their contribution to the ionic diffusion using (i) molecular dynamics simulations and (ii) Nudge Elastic Band calculations. Our obtained results on the example structure of Ge-doped Li3PO4 revealed that >90% of the Li-ion diffusion in the lattice originates from the vibrational modes with frequencies in the 10-15THz region. Analyzing the distribution of eigen-vectors for these contributing modes shows that the P atom in all these vibrations is frozen and does not participate in the vibrations. Such a high resolution understanding of the contribution of phonons to the ionic conduction opens new gates for (i) improving the performance of the existing electrolytes by engineering the vibrations of phonons in their respective structures, and (ii) searching for better performing solid-state ionic conductors, using methods such as high-throughput computational approaches.

Can Battery Material Morphology be Controlled by a Guided Synthesis Approach? Pallab Barai, Juan C. Garcia, Tim Fister, Hakim Iddir and Venkat Srinivasan; Argonne National Laboratory, United States

New battery materials hold the key for an electrified future by enabling electrification of transportation and integration of storage on the electric grid. While there is a robust and growing effort to accelerate the discovery of new materials, the next frontier is identifying synthesis pathways to ensure that these materials can be made. Recently, new approaches focused on precision synthesis have gained a lot of attention in the materials field, including battery materials. While the focus of much of these efforts is around developing predictive routes to synthesis materials of a specific crystal structure, it has been clear for decades that the morphology of the material plays an equally crucial role in its behavior. An example is the layered LiNi0.5Mn1.5CoO2(NMC) layered oxide. In these materials the high reactivity of the cathode with respect to the electrolyte remains a key challenge that impedes their performance. It is well-established that the reactivity of these materials depends strongly on crystal facet, suggesting that shielding some primary particle facets from solution could be critical. Cathode secondary particle porosity can aid with fast-charging but also expose greater surface area to reaction. Graded secondary particles, wherein the outer regions are designed to be less reactive while the interiors are designed to be more energetic, have been advanced as an approach, but ensuring that the right gradation is achieved and the right structure is exposed to the electrolyte requires careful morphology control. Finally, while coatings (e.g., Al2O3) are known to protect the cathode surface, their coverage tends to differ on different facets. Controlling the reactivity of these materials requires control over the morphology of the cathode material in addition to the structure. Therefore, synthesis routes need to be tuned to achieve the right morphology, in addition to obtaining the right crystal structure.

Over the last two years we have been developing a methodology to link synthesis conditions to particle morphology with the aim of using predictive approaches to guide synthesis. The focus of the research has been around (i) linking synthesis conditions to morphology during the co-precipitation of the NMC-hydroxide precursor and the sintering to the lithiated oxide and (ii) linking the sintering of Li7La3Zr2O12(LLZO) solid electrolytes to the density of the final
structure. The methodology involves simulations at multiple scales to bring focus to preferred crystal orientation during synthesis, growth of primary and secondary cathode particles, understanding grain growth and grain boundary movement, and the formation of dense structures as a function of process conditions. The models are complemented with in situ synchrotron x-ray methods and other techniques to provide physical insights and use as comparisons to the models.

This talk to summarize the approach, and describe the physical insights that have been gained in these two material classes. Further, the talk will describe the various opportunities in this emerging new area in battery synthesis.

2:00 PM OPEN DISCUSSION

2:15 PM EN02.17.03
Investigation of the Transport in Li(Ni1/3Co1/3Mn1/3)O2 as Cathode Active Material in a Single Secondary Particle Set-Up Markus S. Friedrich, Simon Burkhardt, Janis K. Eckhardt, Matthias T. Elm and Peter J. Klar; Justus Liebig University Giessen, Germany

Lithium ion batteries (LIBs) are today's state-of-the-art power supplies for portable electronic devices as well as for electrical and hybrid vehicles. In addition, LIBs are a promising technology to store the excess energy generated from renewable energy sources which would otherwise be wasted. To meet the requirements of such applications, an optimization of the overall performance, i.e. life-time, cyclability, and energy as well as power density, of such batteries is crucial [1]. A deeper understanding of the transport in the active material used in the electrodes of the LIBs is key to such optimizations. State-of-the-art LIBs usually contain layered structured transition metal oxides, such as Li(Ni0.5Co0.5Mn1−x−y)O2 (NCM), as cathode active material (CAM) [2] [3]. To investigate the properties of such CAMs conventionally composite electrodes are prepared. In this composite electrodes micrometer sized spherical secondary particles (diameter of 10 to 30 µm) of the CAM, built from a complex porous network of nanometer sized single crystalline primary particles, are embedded in a network of organic binder and conductive agents. These additives might influence or superpose the properties of the pure active material [4].

To investigate the transport properties in the pristine active material we developed a technique that allows to perform electrochemical measurements on single particles of CAMs. The investigated NCM material was of the composition Li(Ni1/3Co1/3Mn1/3)O2 (NCM111). The particles were arranged in trap holes, formed via photolithographical structuring a photosist, on top of a noble metal coated substrate. The setup, on one hand, allowed us to perform experiments with ion-blocking electrodes [5] and, on the other hand, to assemble Lithium ion batteries, that contain a single secondary particle of NCM as cathode active material (SCAMP-LIB). We performed cycling experiments, cyclic voltammetry, and impedance spectroscopy on single secondary particles and agglomerates of NCM111 secondary particles. To resolve the influence of the measurement set-up systematically, different set-ups have been investigated. We found clear evidence, that the secondary particle’s diameter, and therefore its porosity, has an influence on the impedance of the cell system. Furthermore, it was possible to estimate the diffusion coefficient of Lithium ions in the bulk NCM111 during delithiation. This estimated diffusion coefficient was a few orders of magnitude lower than those reported by other groups [6][7]. We found clear evidence, that the investigated material undergoes severe surface degradation during cyclization.

Nevertheless, the presented method is a promising way to study the transport in pristine CAMs. The technique can be further improved by the application of solid electrolytes in the cell system or a controlled arrangement of many single secondary particles to achieve a better model of a real electrode.

New Power Technologies for Venus Atmospheric and Surface Missions Ratnakumar V. Bugga1, John-Paul Jones1, Michael Pauken1, Keith Billings1, Channing Ahn1, Brent T. Fultz1, Kerry Nock2, Abhijit Shevade1, Dharmesh Bhakta1, Eric Raub1 and James Cutts1; 1California Institute of Technology, United States; 2Global
**Aerospace Corporation, United States; 3Eagle Picher Technologies, United States**

*In-situ* exploration of Venus is seriously hampered by its severe environment, which is benign (28°C) at an altitude of 55 km, but rapidly becoming more hostile at lower altitudes, with temperature increasing initially at ~10°C/km eventually to reach ~465°C and the pressure attaining 90 bars at the surface. These challenging conditions have limited Venus in-situ exploration missions to high altitude balloons at 55 km (above the clouds) that lasted for 48 h, or even shorter duration of 2h for surface missions, even when the batteries were enclosed in thermal chamber. Both these types of missions were implemented using primary batteries. There is a need for more long-duration in-situ missions for a better understanding of the Venus atmosphere across the cloud layers and below, and even to the surface, as recommended by the Venus Exploration Analysis Group (VEXAG). Two types of mission concepts, i.e., i) long-duration variable-altitude balloons with extended range below the clouds, and ii) landers with lifetimes of a few days have gained particular interest. This talk will describe new power technology for a variable altitude balloon (VAB) that we have been developing under NASA-NIAC (NASA Innovative and Advanced Concepts) program for sustained Venus atmospheric exploration. The probe mission concept utilizes: i) Photovoltaics (PV), regenerative solid oxide fuel (SOFC), hydrogen storage bed for on-demand storage or release of hydrogen, and a balloon filled with hydrogen and with hydrogen buoyancy-based altitude control system. This novel architecture enables generation of fuel from in-situ resources at high altitudes, power at low altitudes, and provides transport gas for the balloon. In addition to this VAB, we have been developing high-temperature primary batteries for Venus surface missions under NASA’s HOTTech program. These batteries are based on lithium alloy (e.g., Li-Al) anodes, molten salt electrolytes based on binary/ternary mixtures of alkali metal halides, cathodes consisting of transition metal sulfides and designs similar to the aerospace thermal batteries.

Transitioning Garnet Li-Ion Electrolyte into Manufacturable Li Metal Solid-State Batteries  
Jeff Sakamoto1,1, Regina García-Mendez1, Michael Wang1 and Arushi Gupta2; 1University of Michigan, United States; 2University of Michigan–Ann Arbor, United States

There is tremendous interest in making the next super battery, but state-of-the-art Li-ion technology works well and has inertia in several commercial markets. Supplanting Li-ion will be difficult. Recent breakthroughs in Li metal solid-state electrolytes could enable a new class of non-combustible solid-state batteries (SSB) delivering twice the energy density (1,200 Wh/l) compared to Li-ion. Garnet-type ceramic electrolyte with the nominal formula Li7La3Zr2O12 (LLZO) satisfies many of the criteria necessary to enable Li metal electrodes. However, technological and manufacturing challenges remain. The discussion will consist of recent milestones and attempts to bridge knowledge gaps to include:

- Stability and kinetics of the Li metal-LLZO interface
- Stability and kinetics of the catholyte-LLZO interface
- Manufacturing and scale-up of thin film ceramic constructs and cells.

Despite the challenges, SSB technology is rapidly progressing. Multi-disciplinary research in the fields of materials science, solid-state electrochemistry, and solid-state mechanics will play an important role in determining if SSB will make the lab-to-market transition.

Integration of Porous Semiconductor Nanocomposites in Advanced Energy Storage Systems—An Industrial Compatible Synthesis Process  
Arthur Dupuy1, Aude Roland2, Stéphanie Sauze3, Mohammad Reza Azizyan1,
The extension of Internet connectivity and interrelating physical devices, known as Internet of Things (IoT), has become an increasingly growing topic of research over the past few years. Because of rapid progresses in this filed, it is expected that successful implementation of IoT will revolutionize everyday human life within the coming decades. Therefore, it has become inevitably necessary to redesign the current power supplies to integrate them directly into the production line [1]. This has motivated many researchers for enhancing solid-state and on-chip storage systems, such as supercapacitor and lithium-ion battery [2]. In this respect, the significant specific capacity (4200 mAh/g) and high lithium-ion diffusion coefficient of silicon (Si) made it an attractive candidate for storage applications. However, it has been extensively discussed and proved that Si suffers from a low life cycle and large volume expansion. Nanostructuring of Si has been one of the viable solutions to reduce the stress during lithiation. As a matter of fact, porous silicon has been a favourable candidate as on-chip anode for supercapacitor [3], high power density [4] and high energy density device [5]. Although downsizing the active material can prevent volume expansion stress, it also increases specific surface, leading to formation of solid electrolyte interface, which is the origin of irreversible capacity. On this subject, functionalization of the semiconductor surface by carbon has been one of the most compelling alternatives for limiting SEI formation and the first cycle irreversible capacity. Compared to silicon, germanium (Ge) has better electrons and holes mobilities, faster Li-ion diffusion rate, lower charge/discharge potential, and an isotropic volume expansion less significant than silicon during lithiation process. Similar to porous silicon, macro- and mesoporous Ge anodes have shown outstanding performances, but they have been produced by an unscalable and expensive process; the thermal reduction synthesis. In parallel, progresses in the electrochemical etching of Ge provided conditions for the synthesis of low-cost and scalable porous layers [6]. Concerning graphene functionalization based on CVD technique, Ge offers a good catalytic surface, because of the low miscibility of carbon into Ge, to grow a graphene-like coating with higher quality compares to silicon. In this study, we have investigated a mesoporous Ge on-chip anode that was synthesized by electrochemical etching, and we have compared the improvement of the electrode life cycle and rate capability once the active material was coated with graphene-like layer grown by CVD. A coulombic efficiency above 98% was achieved and 1000 mAh/g capacity was reached during over 400 cycles for the graphene-coated porous Ge nanocomposite on-chip anode. In this presentation, we will discuss the crucial parameters and experimental conditions that allowed us to achieve such high-performance devices and will present a new type of anode which can reach a wide range of power density value.

improve the life of Li metal anodes, and that these properties are synergistic.

The final structure for use as a Li metal coating is a dynamic, single-ion-conducting network (DSN) with room temperature Li ion conductivity of $3.5 \times 10^{-5}$ S cm$^{-1}$. When cut, the material self-heals at room temperature in 12 hours. Molecular dynamics simulations combined with DFT calculations show that the labile bonding between the anionic centers and the coordination ligands impart the dynamic self-healability and high ionic conductivity. When used as a coating on Li metal, 1 mAh cm$^{-2}$ of lithium can be reversibly plated and stripped at rate of 0.5 mA cm$^{-2}$ for a record high 300 cycles with a high coulombic efficiency of 96.5%. In contrast to other lithium coatings, synthesis of DSN emerges from a facile, scalable, one-pot process with only hydrogen gas as the by-product. Furthermore, the coating can be directly applied to Li metal via a dip-coating process at a cost of only 0.02 $ cm^{-2}$. Using this scalable approach, a DSN-coated Li metal anode was used in a high-voltage NMC-532 full-cell with all commercial components. The coated Li metal anodes show dramatically increased cycle life (160+ cycles) over uncoated Li (<100 cycles). The rational design of these scalable coordination polymers offers a promising approach to enable next-generation batteries with Li metal anodes.

Time-Temperature-Transformation-Conductivity (TTTC) Diagrams for Li-Garnet Films from Solution Processing – Giving Manufacturing Guidelines and Insights on Phase Stabilization
Yuntong Zhu1, Zachary D. Hood1, Won Seok Chang2, Lincoln J. Miara3 and Jennifer L. Rupp1; 1Massachusetts Institute of Technology, United States; 2Samsung Advanced Institute of Technology, Korea (the Republic of); 3Samsung Research America, United States

Li-garnets have been considered as the candidate ionic conductors for multiple new technological applications, including all-solid-state batteries1 and very recently, electrochemical gas sensors,2 owing to their wide electrochemical stability window, high room temperature Li-ion conductivity, and good thermal stability. Very recently, research advancements have demonstrated the possibility of transferring Li-garnets to their thin-film forms with various crystalline and poly-amorphous states,3 giving room for researchers to redesign the structural and transport properties with alternatives of low-temperature film processing for grain-boundary-free polyamorphous Li-garnets to compete with state-of-the-art electrolytes, such as LiPON, and prevent dendrite penetration.3-4 Despite the promises, there is still a lack of understanding on the crystallization kinetics and its effects on Li-ion transport properties. In this study, garnet-type Li$_7$La$_3$Zr$_2$O$_{12}$ (LLZO), is processed as thin films by spray pyrolysis. The crystallization and phase transitions of the LLZO thin films were studied by DSC together with Raman spectroscopy and in situ TEM. Johnson-Mehl-Avrami-Kolmogorov (JMAK) crystallization theory and Kissinger analysis are applied here, for the first time, to study the fundamentals of the crystallization involving chemical reactions and enthalpy changes during the phase formation process of LLZO. We develop Time-Temperature-Transformation-Conductivity (TTTC) diagrams for Li-garnet films to connect the transport properties with phase formation kinetics. Inspired by the TTTC diagram, crystallization temperature for the cubic phase LLZO is successfully lowered via an isothermal annealing step. Role of structural compaction on ionic conductivity is discussed for the crystalline and poly-amorphous LLZO and compared to the structure-transport characteristics of other Li-glass conductors. Our methodology and results highlight a new opportunity of tuning Li motion and lowering the crystallization temperature by precisely controlling the processing history with a cost-effective processing method. The insights from this work are expected to serve as fundamental guidelines for understanding the processing-structure-property relationships of amorphous and crystalline Li-garnet. Technologically, the work demonstrates new opportunities to stabilize amorphous and crystalline cubic films at low temperatures, and sets process temperature windows for next-generation solid-state batteries.

Advanced Microfabrication Process for All Solid-State Thin-Film Batteries

Arnaud Bazin, Francoise Geffraye, Sami Oukasi, Séverine Poncelet, Christophe Secouard and Raphael Salot; CEA-LETI, France

Over the last years, the continuous miniaturization of nomadic electronic systems such as sensors, actuators or medical devices, has put a focus on the growing need for miniaturized energy sources with high power densities. All solid-state thin film batteries have proved to be of particular interest for such applications as they can be directly integrated onto the device. Moreover, the absence of liquid electrolyte is particularly advantageous in terms of safety, particularly for the numerous medical applications that are emerging today.

In this work we propose to present our latest progress on microfabrication process for thin film batteries. Microbatteries are manufactured on 8 inches silicon wafers using standard semiconductors processes such as physical vapor deposition, photolithography and etching. The fabrication process flow is carried out in a clean room environment using the TINY platform. Lithium based materials are particularly challenging when it comes to patterning processes due to their high reactivity. Moreover, the need for higher battery capacity induces an increase of the materials thickness, which brings also great challenges in terms of process development.

Microfabricated thin film batteries presented in this work are composed of the following layers (bottom-up):
- Platinum as current collector, LiCoO2 as the cathode, LiPON as solid electrolyte, Silicon as anode and Titanium as anodic current collector and redistribution layer.
- In order to improve the capacity of the battery, the thickness of the LiCoO2 cathode is increased up to 20 µm, leading to a high defectivity in the film due to coating process limitations. We propose to optimize the patterning process to cope with the high defect density.
- After fabrication, the wafer is thinned down to about 50 µm in order to obtain a total thickness of less than 100 µm for the battery. Wafer dicing is then carried out to obtain single batteries ready to be tested and integrated in the final component.
- The 5.3 millimeter square batteries demonstrate excellent electrical performances with a discharge capacity of 20µAh (680 µAh.cm-2, galvanostatic cycling, 3-4.2V potential range, 0.2C rate). The average capacity loss is limited to 0.1%/cycle, with a state of the art coulombic efficiency of 99%.

Liquid Electrolyte with a High Dielectric Constant for Stable Operation of Lithium-Metal Anode

Ju Young Kim, Dong OK Shin and Young-Gi Lee; ETRI, Korea (the Republic of)

Lithium metal is considered one of the most promising anode materials for realizing high volumetric and gravimetric energy density, owing to the high specific capacity (~3860 mAh g−1) and the low electrochemical potential of lithium (~3.04 V vs. the standard hydrogen electrode)[1]. However, undesirable dendritic or mossy lithium growth and corresponding instability of the solid electrolyte interphase prevent safe and long-term use of lithium metal anodes[2-3]. This work presents an easy electrolyte approach to improve the performance of lithium metal batteries by tuning the dielectric constant of the liquid electrolyte. Electrolyte formulations are designed by changing the concentration of ethylene carbonate to have various dielectric constants. This study confirms that high ethylene carbonate content in a liquid electrolyte enhances the cycling performance of lithium metal batteries because the electric field intensity applied to the electrolyte is reduced in relation to the polarization of the electrolyte and thus allows smooth lithium plating by the formation of stable solid electrolyte interphase. We believe that this approach provides an important concept for electrolyte system design suitable for lithium metal batteries.

Highly Active Metal Pyrites Catalysts for a Low-Cost, High-Performance Polysulfide/ferrocyanide Redox Flow Battery Yifan Dong¹,², China University of Geosciences, China; ²University of Wisconsin, United States

Polysulfide is a promising redox couple employed in various aqueous redox flow batteries (RFB) for large scale electrochemical energy storage due to its high solubility and low cost. However, polysulfide has much lower rate constant in comparison with other commonly used redox couples in RFB. Therefore, efficient electrocatalysis is a key to achieving high performance for polysulfide-based RFB. Here we first systematically investigated the electrocatalytic activity of various pyrite phase metal disulfides (FeS₂, CoS₂, NiS₂) as thin film electrodes towards polysulfide redox reactions under steady state condition. Then we further demonstrated a high-performance polysulfide/ferrocyanide RFB using optimized high surface area NiS₂ nanostructures grown on carbon paper as the electrode. The NiS₂/carbon paper electrode showed a high exchange current density of 9.3 mA cm⁻² and was able to achieve a current density of 38.6 mA cm⁻² at an over potential of 100 mV. An aqueous polysulfide/ferrocyanide RFB employing NiS₂/carbon paper as anode and plain carbon paper as cathode was further evaluated by constant current cycling test and electrochemical impedance spectroscopy to demonstrate high charging-discharging cycling performance and low charge transfer impedance.

**EN02.19.03**
Room-Temperature, Ambient-Pressure Chemical Synthesis of Amine-Functionalized Hierarchical Carbon–Sulfur Composites for Lithium–Sulfur Battery Cathodes Changju Chae, Youngmin Choi and Sunho Jeong; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Recently, the achievement of newly designed carbon–sulfur composite materials has attracted a tremendous amount of attention as high-performance cathode materials for lithium–sulfur batteries. Compared with commercialized lithium-ion batteries, the Li–S batteries possess a characteristic advantage in storing an electrical energy (2.6 kWh/kg). To date, sulfur materials have been generally synthesized by a sublimation technique in sealed containers. This is a well-developed technique for the synthesizing of well-ordered sulfur materials, but it is limited when used to scale up synthetic procedures for practical applications. In this study, we design a room-temperature, ambient-pressure chemical synthetic method by which to obtain multistacked, amine-functionalized carbon–sulfur composite materials. By an aqueous chemical conversion from sodium thiosulfate (Na₂S₂O₃), sulfur layers are deposited on preformed two-dimensional carbon templates, which are synthesized through the electrostatic interaction between negatively charged graphene oxides and positively charged amine-terminated multiwalled carbon nanotubes. It is demonstrated that stable cycling performance outcomes are achievable with a capacity of 730 mAhg⁻¹ at a current density of 1 C with good cycling stability by virtue of the characteristic chemical/physical properties of composite materials. The critical roles of conductive carbon moieties and amine functional groups inside composite materials are clarified with combinatorial analyses by X-ray photoelectron spectroscopy, cyclic voltammetry, and electrochemical impedance spectroscopy.

Development of Novel and Versatile Polyl Method to Synthesize High-Performance Cathode Materials Hyeseung Chung¹, Antonin Grenier², Zachary W. Lebens-Higgins³, Peter Ercius⁴, Minghao Zhang¹ and Shirley Meng¹; ¹University of California, San Diego, United States; ²Stony Brook University, The State University of New York, United States; ³Binghamton University, The State University of New York, United States; ⁴Lawrence Berkeley National Laboratory, United States

To develop high-performance cathode materials in Li-ion batteries, diverse synthetic methods have been explored with the overall goal of producing a product with controlled morphology and without local compositional and crystallographic inhomogeneities. Polyl method is a promising synthetic technique, when properly designed, that can offer these advantages. The unique properties of polyl solvent allow for monodispersed nanoparticle morphology while maintaining scalability for industrial applications. In this work, we introduce this novel synthesis method to produce cathode materials with three different crystal structures - layered LiNi₀.₃Mn₀.₃Co₀.₄O₂, spinel
LiNi_{0.5}Mn_{1.5}O_{4}, and olivine LiCoPO_{4}. Each of the synthesized material shows high crystallinity and competitive electrochemistry due to stable surface structure. After confirming the versatility of this synthetic method, our study extends to the detailed synthesis reaction mechanism that explores nanoscale dynamics occurring during polyol synthesis. With a combination of in situ and ex situ characterizations, including STEM/EELS, soft XAS, synchrotron XRD, and pair distribution functions (PDF) analysis, we directly observe the structural and chemical transformation during each step of the reaction. Our work highlights the deep insights in designing and optimizing synthesis procedure for cathode materials and possibly a wide range of intercalation compounds in the future.

*Ab Initio* Non-Covalent Interaction Energies to Quantify Structure-Property Relationships in Lithium-Conducting Oligomers

Somesh Mohapatra, Bo Qiao, Ryoichi Tatara, Jeffrey Lopez, Graham M. Leverick, Yoshiki Shibuya, Yivan Jiang, Jeremiah A. Johnson, Yang Shao-Horn and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Polymer electrolytes for lithium ion batteries offer superior mechanical stability and lower risks than liquid organic solvents, but are challenged by a lower ionic conductivity. The addition of secondary modifications to the polymer backbone opens up an additional degree of freedom for design to enhance the transport properties, by modulating the polymer-ion and counterion interactions. In this work, we explore how non-covalent interactions govern the interplay between conductivity and viscosity of a series of ethylene-oxide oligomers with secondary modifications. DFT calculations were used to quantify the additional non-covalent interactions introduced by the secondary modifications. A multi-dimensional regression was then fit to experimental conductivity and viscosity data at different temperatures. The binding energies of the secondary site towards lithium ion, counteranion, glyme, and the same secondary site through intermolecular interaction were used as the inputs to the regression. Since all inputs to the predictor are available from affordable simulations, this multi-dimensional free energy relationship was then used to screen for new secondary sites that maximize conductivity, which were then realized in the lab and shown to have 13% higher molar conductivity than baseline at room temperature.

Liquid Phase Sintering Effect of Composite-Electrode Containing Li_{2.2}C_{0.8}B_{0.2}O_{3} Solid Electrolyte for All-Solid-State Batteries

Seokhee Lee; Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

All-solid-state batteries have received significant attention around the world because of high safety, reliability and energy density. Up until now, all-solid-state batteries are produced by vacuum deposition techniques, such as RF-sputtering like physical vapor deposition (PVD) or pulsed laser deposition (PLD), and thermal evaporation. These batteries are developed to use micro-batteries because their specific capacities are only between 5 and 100 μAh cm⁻², depending on the thickness of electrode. The main challenge facing all-solid-state batteries is to enhance the surface capacity influenced by the thickness of electrode. However, many attempts to increase the electrode thickness have not been successful because of micro-cracks between the components by stress generated at the solid electrode-electrolyte interface. In addition, strong kinetic limitations due to the low mobility of the ions and electrons in the increased electrode is also another problem. To overcome these problems, a composite-electrode made of multifunctional materials should be used as electrode. The composite-electrode contains the electrochemically active material, solid electrolyte, and conducting additive to transport electrons and ions in the electrode.

In this study, a Li_{2.2}C_{0.8}B_{0.2}O_{3} solid electrolyte is used for Li⁺ conduction pathway in the composite-electrode because it has a low melting point (> 500 °C) and is expected to act as a bonding material at the interface resulted from liquid phase sintering. Moreover, the composite-electrode with a strong mechanically framework was fabricated by a simple one-step spark plasma sintering (SPS) technique. To apply composite-electrode of all-solid-state batteries, optimized parameters are scrutinized, such as SPS conditions to protect decomposition of active material and the composite-electrode formulation (active material/solid electrolyte/electrical conductor ratio) to ensure good ionic and electronic percolation. The composite-electrode was very dense with very few voids as a result of the microstructure analysis. The Li_{2.2}C_{0.8}B_{0.2}O_{3} solid electrolyte was in close contact with the active materials due to liquid phase sintering. A Li-ion conduction path was formed along the electrode particles. In order to analyze the effects of liquid phase sintering systematically, the electrochemical performance of the composite-electrode is discussed in detail.
Development of Highly Heat-Resistant Battery Separator Based on Boron Nitride Nanotubes

Kentaro Kaneko, Keisuke Hori and Suguru Noda; Waseda University, Japan; Waseda Research Institute for Science & Engineering, Japan

A separator is a key component for the safety of batteries. The conventional separator is made of polypropylene (PP), that has a shut-down function by closing its pores at an elevated temperature. But its fundamental thermal stability is low; it shrinks largely over melting point (PP: 160 °C), resulting in direct contact and short circuit between cathode and anode. We here propose and report a highly heat-resistant separator based on boron nitride nanotube (BNNT), which has high chemical and thermal stabilities (stable in air up to 900 °C) [1].

Self-supporting BNNT papers (thickness: 25 µm) were fabricated by dispersion and filtration without using binder. Similarly, self-supporting electrodes based on carbon nanotube (CNT) with lithium cobalt oxide (LCO) and graphite for cathode and anode, respectively, were fabricated [2]. The cathode/separator/anode stack was prepared, heated to and kept at a given temperature for 10 min. After cooled down, the insulation between the cathode and anode was checked. Then the charge-discharge test was performed by fabricating a 2032-coin cell using the stack and fresh electrolyte.

The PP separator shrank significantly, resulting in short-circuit at 225 °C. In contrast, the BNNT separator showed little thermal shrinkage and kept insulation even at 500 °C. Furthermore, the stack with BNNT showed no degradation after heating in the charge-discharge test. This showed that BNNT separator as well as the CNT-based electrodes worked without problem after heating at 500 °C.

Controllable Electrochemical Fabrication of KO₂-Decorated Binder-Free Cathodes for Rechargeable Lithium–Oxygen Batteries

Wei Yu, Dengyun Zhai, Ce Wen Nan and FeiYu Kang; Tsinghua University, China

Understanding the electrochemical property of superoxides in alkali metal oxygen batteries is critical for the design of a stable oxygen battery with high capacity and long cycle performance. In this work, a KO₂-decorated binder-free cathode is fabricated by a simple and efficient electrochemical strategy. KO₂ nanoparticles are uniformly coated on the carbon nanotube film (CNT-f) through a controllable discharge process in the K–O₂ battery, and the KO₂-decorated CNT-f is innovatively introduced into the Li–O₂ battery as the O₂ diffusion electrode. The Li–O₂ battery based on the KO₂-decorated CNT-f cathode can deliver enhanced discharge capacity, reduced charge overpotential, and more stable cycle performance compared with the battery in the absence of KO₂. In situ formed KO₂ particles on the surface of CNT-f cathode assist to form Li₂O₂ nanosheets in the Li–O₂ battery, which contributes to the improvement of discharge capacity and cycle life. Interestingly, the analysis of KO₂-decorated CNT-f cathodes, after discharge and cycle tests, reveals that the electrochemically synthesized KO₂ seems not a conventional electrocatalyst but a partially dissolvable and decomposable promoter in Li–O₂ batteries. In general, tailoring a promoter-loaded binder-free cathode by a simple electrochemical process in a battery provides a feasible route to construct a multifunctional electrode not only for the alkali metal oxygen battery but also for other energy devices, such as sulfur batteries and ion batteries.

Understanding Low-Temperature Cycling of Lithium-Metal Anodes

Akila C. Thenuwara, Pralav P. Shetty and Matthew T. McDowell; Georgia Institute of Technology, United States

Efficient operation of batteries at low temperature is crucial to enable technological development in the areas of electric aircraft, interplanetary space exploration, and advanced robotics. For these high energy applications, Li metal batteries are the superior choice as they can deliver significantly higher specific energy than conventional Li-ion cells with graphite anodes. However, the electrochemical behavior of Li metal anodes at low temperatures is largely unknown. In this work, we investigate the effect of sub-zero temperatures on electrochemical behavior, morphological evolution, and solid-electrolyte interphase (SEI) formation of Li metal anodes in carbonate and ether solvents. We find that electrolytes containing carbonates tailored for low-temperature operation exhibit severe transport limitations at low temperatures, while ether-based electrolytes show promising Li cycling ability down to -80 °C. Interestingly, ex situ investigation after cycling revealed that distinct Li morphologies form at different temperatures, which is likely due to different nucleation and growth behavior, as well as differences in SEI.
chemistry and structure. Detailed SEI characterization by x-ray photoelectron spectroscopy and cryogenic electron microscopy reveal distinct structures of the SEI formed at room temperature compared to temperatures less than -40 °C. These results provide a fundamental understanding of how Li metal anodes behave at low temperatures, which could enable high-energy batteries for a range of operating conditions and environments.

EN02.19.11
Boost-Up Electrochemical Performance of MOFs via Confined Synthesis within Nanoporous Carbon Matrices for Energy Storage and Conversion Applications Min Seok Kang, Hyuna Kyung and Won Cheol Yoo; Hanyang University, Korea (the Republic of)

Utilizations of metal-organic frameworks (MOFs) for electrochemical applications are significantly limited by insulating nature and mechanical/chemical instability. One promising approach for the deployment of conventional MOFs in electrochemical applications is to fabricate MOF-based hybrids (MBHs) with conductive materials, which facilitate effective electron transfer via conductive additives between MOFs. Herein, we present a facile method for effective filling of Cu- and Ni-HKUST-1 (Cu-/Ni-MOF) inside 3D ordered mesoporous carbon (24nm, mC), 3D ordered N-doped macroporous carbon (300 nm, NMC), and 3D ordered macroporous carbon (300 nm, MC), denoted as MOF@mC, MOF@NMC, and MOF@MC, respectively. The MOF@carbon matrix (MOF@CM) composites were intended for use as electrodes for electrical double layer capacitors (EDLCs) and Li-S battery (LSB) and as electrocatalysts for the oxygen reduction reaction (ORR). EDLC performance of MOFs can be significantly improved by facilitating electron transfer through 3D conductive CM, reducing the electron pathway within insulating MOF using CM with small pores, and choice of metal center with pronounced faradaic nature. Ni-MOF@mC exhibited superior specific surface area normalized are capacitance (26.5 μF/cm²), exceeding most carbons and MOF-based EDLCs and outstanding long-term stability (91%@5000th). Furthermore, Cu-MOF@mC resulted in pronounced ORR activities, excellent methanol tolerance, and long-term stability. For LSB, Cu-MOF@mC presented superior performances compared to Ni-MOF@mC probably due to more preferential coordination bonding of S toward Cu center. It is clearly demonstrated that conventional MOFs can be utilized for EDLC, ORR, and LSB when conjugated with a 3D-connectednano-sized CM.

EN02.19.12
High-Performance Garnet-Based Lithium-Metal Batteries with Optimized Electrolyte/Electrode Interfaces Bingkun Hu, Wei Yu, Bingqing Xu, Liangliang Li and Ce Wen Nan; Tsinghua University, China

Garnet-type solid electrolytes are suitable for solid-state batteries with a lithium metal anode due to their high ionic conductivity, good stability against the lithium metal, and wide electrochemical window. The interfaces between the garnet electrolytes and the anode/cathode play an important role in the performance of garnet-based lithium metal batteries. In this study, at first, we applied some metal or alloy coating layers on the surface of garnet-type LixLi1/2La2/3Er1/3Ta2/3O2 (LLZTO) pellets that were synthesized by pressureless solid-state sintering and assembled LiFePO4|| LLZTO||Li cells. These LLZTO-based cells showed a long cycle life with a large current density of a few hundreds of μA/cm² at room temperature and an excellent rate performance, because the interfacial resistance between the electrolyte pellets and the Li anode was significantly reduced by 1-2 orders and the lithium dendrite growth was suppressed. The microstructure and composition of the interfacial layers formed at the LLZTO/Li interfaces were systematically investigated by high-resolution TEM and XPS. Next, based on the optimized LLZTO/Li interface above, the interface between the garnet electrolytes and the cathode was studied. Ionic liquid was adopted to improve the contact between the LiCoO2-based cathode and LLZTO. With an optimal cathode composition, LiCoO2||LLZTO||Li solid-state cells were fabricated and the influence of the concentration and type of Li salts in the ionic liquid on the performance of these cells was studied. The cells can be steadily cycled at room temperature. It is worth noting that our cathode design is applicable for other active materials when they are combined with garnet electrolytes. Our work provides proper interfacial optimization methods for garnet-based lithium metal batteries and paves the way for developing high-performance solid-state batteries.

EN02.19.13
Enhancement of Electrochemical Performance in Boron-Doped Si Micron-Rod aNode Fabricated Using a Mass-Producible Lithography Method for a Lithium-Ion Battery Sungjun Cho, Gun Young Jung and Kwangsup Eom; Gwangju Institute of Science and Technology, Korea (the Republic of)

Studies on the high specific capacity of silicon (Si) based anodes for lithium ion batteries (LiBs) have recently been
conducted, despite a large volume being expanded during electrochemical cycling\cite{1}, which is a significant problem. Although a variety of Si structures have been incorporated into the anode to prevent this problem\cite{2}, such structures have difficulties in terms of mass production. Herein, we present a new way to repetitively produce micron Si rods at different boron (B) doping levels using laser interference lithography (LIL) and metal assisted chemical etching (MACE), enabling the mass-production of multiple Si rods at low cost. The micron rod shaped Si anodes showed a higher rate capability and capacity retention than powdery Si particles. These characteristics are attributed to an increase in the surface-to-volume ratio, and a short radial lithium (Li) ions diffusion path, leading to alleviated pulverization during the de/lithiation process. In addition, the effects of the B-doping level on the electrochemical battery performance are studied for the first time. In particular, lightly B-doped Si rod (~10^{15} atoms cm^{-3}) anodes exhibit the highest capacity and cycling performance, showing a high initial coulombic efficiency (CE) of 98.1% and a capacity fading rate of 0.11% during 500 cycles owing to the high kinetics of de/lithiation relevant to the phase transition and diffusion. Through a CV analysis, it was confirmed that the lightly B-doped Si rod have a low over-potential, implying outstanding kinetics for the de/lithiation process. Whereas the heavy B doping hinders the de/lithiation kinetics because a number of Li atoms are trapped from the outermost side of the Si rods even after being fully delithiated with an increase in B-doping densities. This study provides a new approach for easy and rapid preparation of the electrode material and elucidates the dependence of the electrochemical performance on the level of B doping.

Polyethylene Oxide/Garnet-Type Li_{6.4}La_{3}Zr_{1.4}Nb_{0.6}O_{12} Composite Electrolytes with Improved Electrochemical Performance for Solid-State Lithium Rechargeable Batteries
\textit{Chen Liu}; Shenzhen University, China

Next generation lithium batteries require new electrolytes with good safety, excellent ionic conductivity, high electrochemical stability and good cycling performance. Herein, we first report a solid composite polymer electrolyte comprises of Li_{6.4}La_{3}Zr_{1.4}Nb_{0.6}O_{12} fillers and polyethylene oxide matrix. The ionic conductivity of the solid composite electrolyte is significantly improved to 1.4 × 10^{-3} S cm^{-1} (60 °C) and the electrochemical window is enhanced to 5.2 V, respectively, by incorporation of Li_{6.4}La_{3}Zr_{1.4}Nb_{0.6}O_{12} powder at a weight ratio of 0.5:1 with respect to polyethylene oxide. The solid batteries employing the composite electrolytes are able to work at room temperature and have a capacity retention of 99% after cycle. The performance improvement is primarily due to the combined functions of each component in the composite: (i) the incorporation of fillers effectively decreases the crystallinity of PEO, providing more amorphous region for ion conduction; (ii) Li_{6.4}La_{3}Zr_{1.4}Nb_{0.6}O_{12} serves as a fast ion conductor in the composite and enhance the electrochemical stability; (iii) the polymer matrix forms intimate surface contact with fillers and electrodes, reducing the bulk and interfacial resistance. The composite polymer electrolyte in this work would be a competitive alternative for the next generation solid state lithium rechargeable batteries.

EN02.19.16
Phase Change Materials Encapsulated in Reduced Graphene Aerogel Beads for Lithium-Ion Battery Thermal Management
\textit{Jinliang Zhao} and \textit{Jinglei Yang}; Hong Kong University of Science and Technology, Hong Kong

Over last few decades, lithium ion battery (LIB) has been extensively explored and has dominated the power source market for portable electronic devices since Sony Co launched their first LIB in 1992. Recently, as a result of depletion of coal fuels, it triggered cleaner and more sustainable energy technology development including the invention of electrical vehicles (EVs), hybrid electrical vehicles (HEVs) and plug-in hybrid electrical vehicles (PHEVs). The challenges of developing EV, HEV and PHEV are short calendar and cycle lifetime, high weight, high volume and safety issues. LIBs provide the solutions for these technologies due to its high gravimetric and volumetric energy density, rechargeability, temperature stability and capability of scale-up. In most cases, a certain
Recent researches on the production and utilization of renewable energy (solar, wind, geothermal, etc.) have attracted attention as environmental pollution problems caused by depletion and use of fossil energy are emerging. The development of the renewable energy sector is essential to build an energy storage system (ESS) to secure the elasticity of energy production and consumption. Therefore, although lithium-ion battery systems widely used today are in the spotlight, the development of new material-based battery systems is required for long-term demand response and stability of supply and demand. Na-ion batteries have similar electrochemical mechanisms to Li-ion batteries and are actively being studied as candidates for energy storage systems due to their abundant amount and price stability. Na$_3$V$_2$(PO$_4$)$_3$ (NVP) is one of the promising cathode materials among Na ion storage materials due to its excellent structural and thermal stabilities due to its strong polyanion network. However, it is difficult to secure a reversible capacity close to the theoretical capacity (117.6 mAh g$^{-1}$ at 3.4 V vs. Na/Na$^+$) owing to NVP's poor electrical conductivity. There have been many attempts to improve the mass and charge transport of NVP materials by decreasing the NVP particles size or introducing conductive materials. In particular, many attempts have been made to synthesize carbon-NVP composites by forming carbon coatings using hydrocarbons, organic solvents, organic acids and surfactants on the surface of NVP. However, these methods require a high carbon weight of at least 10% to achieve high rate performance. Recently, the use of graphene or graphene oxides enabled ultra-high speed movement with a relatively small amount of carbon (less than 5%), but the use of related materials limits the practicality of using Na-ion battery systems instead of lithium.

In this study, we have developed carbon-containing Na$_3$V$_2$(PO$_4$)$_3$ (NVP) as an active cathode material for Na-ion batteries using carbon-methyl cellulose (CMC) and sucrose as dual carbon sources. The interaction between CMC and sucrose formed a porous structure (surface area: 58.998 m$^2$ g$^{-1}$) with increased sp$^2$ carbon species, promoting mass and charge transport. The specific capacity (104.99 mAh g$^{-1}$) of the carbonized CMC/sucrose NVP (CS-NVP) was obtained close to the theoretical capacity (117.6 mAh g$^{-1}$). Also, CS-NVP exhibited stable cyclability with a specific capacity of 75.04 mA g$^{-1}$ at a rate of 20 C.
**EN02.19.18**

**Electrochemical Property of Yb-F-S Multiple-Anion Compounds**  Shintaro Tachibana¹, Kazuto Ide², Takeshi Tojigamori², Hisatsugu Yamasaki², Yukinari Kotani² and Yuki Orikasa¹; ¹Ritsumeikan University, Japan; ²Toyota Motor Corporation, Japan

Fluoride-ion batteries using solid-state electrolytes are expected as one of the candidates for next-generation rechargeable batteries [1]. For fluoride-ion batteries, the ion carrier is monovalent fluoride ion, which can realize the multi-electron reactions of counter cations in active materials of fluoride compounds. However, it is far from practical use mainly due to lack of solid electrolytes which have high ionic conductivity and a wide electrochemical potential window like lithium-ion conductors. The previously reported fluoride-ion conductors such as PbSnF₄ [2] and La₀.₉Ba₀.₁F₂.₉ [3] contain one type of anion, fluoride ions. To our best knowledge, there is no report on the solid electrolyte materials containing multiple-anion compounds. Fluoride-based multiple-anion compounds have the potential to exhibit abundant functionality (electrical, optical, and magnetic properties, etc.) because of a variety of crystal structures [4]. However, their stability of fluoride compounds is low because the activity of fluorine in the air is extremely low compared to that of oxygen. Therefore, in many cases, controlling the synthesis atmosphere is required, resulting in few research examples of multiple-anion compound using fluoride ion.

In this study, we prepared Yb-F-S compounds containing fluoride and sulfides ions as anions by solid-state reaction under vacuum. In order to identify the phase of the prepared samples, powder XRD measurement was performed. F K-edge and O K-edge XAS measurements were performed at BL-2 in Ritsumeikan University SR Center. Electrochemical impedance spectroscopy and the two-probe conductivity measurement were performed. In addition, the charge-discharge properties of the prepared compounds were examined.

The synthesized sample contains the ytterbium fluoride sulfide as the main phase and ytterbium oxyfluoride as an impurity. One of the reasons for the appearance of this impurity is that the oxygen source which was initially contained in the starting materials could not be removed during the synthesis process and remained in the resulting sample. Electrochemical measurements indicate that the prepared compound exhibits electric conductivity. This is because ytterbium ion in this compound is a mixed valence state with divalent and trivalent.

**Ion Transport in Sputter-Deposited Li₂O and Li₂S Thin Films**  Simon Lorger, Dieter Fischer, Robert E. Usiskin and Joachim Maier; Max Planck Institute for Solid State Research, Germany

Dense thin films of Li₂O and Li₂S grown by r.f. sputtering are found to exhibit ionic conductivities at 25 °C that are multiple orders of magnitude higher than expected from the bulk defect chemistry. The enhancement appears not to be due to the substrate - film interface, nor to doping, nor to the presence of impurity phases. Instead, the evidence points to higher-dimensional defects as enabling the faster ion transport. The resulting conductivity values are consistent with those typically observed from composite SEI layers that contain Li₂O or Li₂S. This work may help explain the rate-limiting process for ion transport through some SEI layers.

**EN02.19.20**

**N-doped Nanoporous Carbon Coated Graphite as a Anode Material for Lithium-Ion Batteries**  Junyoung Kim, Dong Young Rhee and Min-Sik Park; Kyung Hee University, Korea (the Republic of)

Lithium-ion batteries (LIBs) have been successfully utilized as a main power source for various energy storage applications owing to their high energy density and excellent power characteristics. Unfortunately, current LIBs cannot fulfill the requirements of the rapidly growing electric vehicle (EV) market due to their limited energy density based on conventional electrode materials [1]. Therefore, the development of advanced materials for LIBs has become very important. In practice, graphite is the most popular anode material of commercialized LIBs owing to a low reaction potential (~0.2V vs. Li/Li⁺) and a high reversibility toward Li⁺ intercalation and de-intercalation.
However, the practical use of graphite in EV applications is hindered by poor rate capability and cycle performance because Li\(^+\) intercalation into graphite is allowed only through the edge-plane of graphite so that uncontrollable metallic Li is deposited on the surface of graphite anode under high-rate cycles [2]. In this respect, it is crucial to develop a robust design of graphite to make it more suitable for EV applications. With a purpose of improving the rate capability and cycle performance of graphite, herein, we propose a bi-phasic graphite decorated with N-doped nanoporous carbon (NPC) nanoparticles. It can be obtained by a direct growth of ZIFs (Zeolitic Imidazolate Framework) on the surface of graphite followed by a carbonization process. The large specific area and high electrical conductivity of NPC offer additional reaction sites of Li\(^+\) as well as promote charge-transfer reactions [3-4]. Furthermore, the porous structure of NPC is advantageous for securing the tortuosity of electrode and facilitating Li\(^+\) migration in the electrode during cycles. Based on the electrochemical and structural analyses, further discussion on the positive effects of NPC decoration on the rate capability and cycle performance of graphite will be presented.

Fluorinated-O\(_2\) Selective Membranes as Gas Diffusion Electrodes for Metal-Air Batteries
Gizem Cihanoglu and Ozgenc Ebil; Izmir Institute of Technology, Turkey

Fluctuation of oil prices and the effects of global warming have resulted in increased research in alternative energy storage and conversion systems, especially in battery technologies. Development of cost effective and environmentally safe battery technologies for a variety of applications ranging from small portable electronic devices to electric vehicles are also driven by increased public awareness of fire, explosion and toxicity risks associated with today’s Li-ion batteries. Metal-air batteries are considered as cheaper and safer alternative to Li-ion batteries due to their theoretically higher energy densities (1000-13000 Wh kg\(^{-1}\)) for a wide range of applications. However, metal-air batteries have not reached their full potentials as they suffer from limited capacity and lifetime mostly due to catalyst corrosion, anode passivation and corrosion, electrolyte loss and pore clogging leading to performance loss and reduced cycle life.

Here we present an improved Gas Diffusion Electrode (GDE) based on CVD deposited hydrophobic and oxygen selective polymeric thin films as gas diffusion layers to increase energy and power densities of metal-air batteries. Oxygen selective and highly hydrophobic copolymer thin films containing tetravinyltetramethylecyclohexasiloxane (V4D4), 2-(perfluorohexylethyl) acrylate and 2-(perfluoroalkyl)ethyl methacrylate were fabricated via Initiated-CVD. Fabricated copolymer films minimize the accumulation of excess water and prevent flooding of GDE during battery operation. In addition, higher oxygen permeability leads to higher current densities resulting in improved battery performance.

EN02.19.22
Direct Analysis of Lithium in LIB Cathode Using Soft X-Ray Emission Spectrometer
Yusuke Uetake\(^1\), Shunsuke Asahina\(^1\), Natasha Erdman\(^2\), Tamae Omoto\(^1\) and Hirokazu Munakata\(^3\); \(^1\)JEOL Ltd., Japan; \(^2\)JEOL USA, United States; \(^3\)Tokyo Metropolitan University, Japan

Both distribution and composition of Lithium in a charged cathode affect the capacitance and the efficiency of Lithium ion battery (LIB). Auger Electron Microscopy (AES) is one of the common methods to analyze distribution and composition of Lithium in the battery with high spatial resolution by using focused electron beam for surface analysis of the specimen. Since the energy of Auger electrons is a few electron volts, it is possible to analyze with surface sensitive information. In addition, AES is also capable of providing depth profiling by using Ar ion sputtering, making AEM a quite useful method for LIB analysis. However, there are issues with AES analysis for LIB. The Auger electrons are very sensitive to the electrostatic field on the surface. The user should therefore create a condition of ‘floating’ Cathode with respect to the specimen holder during AES analysis. Otherwise, the Cathode will discharge Lithium ion during the analysis.

Currently we are focusing our efforts on using SXES (Soft X-ray Emission Spectrometer) method, which was...
Recently developed, this method allows analysis of characteristic X-ray of Lithium by charging on the sample surface. The SXES is installed on Field Emission SEM (Scanning Electron Microscope) that is able to detect soft X-rays with high spatial resolution. The acquisition energy range of SXES is less than 250 eV, which means that this SXES enables the use of low landing voltage with small interaction volume for X-ray excitation such as 2 kV or below. Such setup makes SXES a surface analysis method like an AES. In addition, using SXES is sufficient to generate soft X-rays with low landing energy such as 2 kV, which suppresses the charging of the sample by the irradiated electrons.

JEOL FE-SEM (JSM-7200F) equipped with SXES (SS-94000) was used for analyzing Lithium distribution in LIB Cathode. Sample was prepared in a glove box and transferred without air exposure into the SEM to avoid any oxidation. The soft X-ray spectra were acquired at an accelerating voltage of 2 kV and a beam current of 40 nA. As a result, a characteristic X-ray of a Lithium peak around 48 eV was detected from the surface of fully charged LIB cathode.

In this study, we will report that we examined the distribution of Lithium by direct analysis from the surface of charged Lithium ion battery cathode using SEM-SXES.

**EN02.19.23**  
**Surface Coated Graphite Anode with Non-Stoichiometric Metal Oxides for Lithium-Ion Batteries**  
Dong Young Rhee, Junyoung Kim and Min-Sik Park; Kyung Hee University, Korea (the Republic of)

Recently, lithium ion batteries (LIBs) have been considered as the most suitable power source for various energy storage applications. In the LIBs, graphite is widely used as a commercial anode material because it offers a low reaction potential (~0.2 V vs. Li/Li⁺) and high theoretical capacity (~372 mAh/g) [1]. However, because of the layered structure of the graphite, graphite does not offer sufficient cycle performance and rate-capability for practical use in electric vehicles (EV) applications [2]. Therefore, it is of great importance to develop advanced anode materials with improved electrochemical performance in this research field. To overcome these technical limitations, various structural modifications of the graphite have been proposed to make it more favorable for securing a long term cycle stability as well as excellent power characteristic. In this respect, we focused on advantages of non-stoichiometric metal oxides with distinctive electronic properties because they can play an important role as a functional additive for improving the electrochemical performance of the graphite [3]. Herein, we propose a new material design with a core-shell structure in which graphite core is encapsulated by a functional surface layer (shell) composed of non-stoichiometric MeOₓ and amorphous carbon. The functional layer can be successfully introduced on the surface of graphite by a simple solution process combined with a carbothermal reduction using MeO₂ nanoparticles and coal-tar pitch precursors. Tailoring the surface structure of graphite with a functional layer is effective for suppressing structural degradation and lowering the overpotential at the surface of graphite even at high current densities. In addition, cycle performance of the proposed anode material can be notably improved compared with commercial graphite. Based on a range of structural and electrochemical analyses, fundamental roles of the functional layer on the surface of graphite will be discussed.

**Mesoporous Carbon as a Potential Reservoir of Metallic Li**  
Seung Hyun Choi, Junyoung Kim and Min-Sik Park; Kyung Hee University, Korea (the Republic of)

During the last decade, lithium ion batteries (LIBs) have shown great promise as a potential power source for various application such as portable electronic devices and electric vehicles (EVs) [1]. Responding to growing demand for high-energy LIBs, it is crucial to develop materials which provide a higher energy density than commercial materials currently available.

Li metal has been considered as a future anode material for LIBs because of its extremely high theoretical capacity (~3,860mAh/g) and low redox potential. Despite these benefits, the practical use of Li metal is limited by several technical issues as follow; i) inevitable growth of dendritic Li and ii) infinite volume changes during cycling are...
regarded as drawbacks causing rapid performance degradation and safety issues [2]. Recently, porous carbon materials with well-distributed pore that can serve as Li storage reservoir have been proposed to suppress unfavorable volume changes [3-4]. Herein, we design a disordered mesoporous carbon (DPC) as a potential Li storage material, allowing a dual-phase reaction (i.e. lithiation and metallization). It can be synthesized via a direct carbonization of silica-embedded zeolitic imidazolate frameworks (SEZIFs) combined with a chemical etching process. The DPC exhibits a great potential for accommodating a large amount of metallic Li thanks to its highly mesoporous structure. In practice, we confirm that Li can be reversibly stored in the structure based on various electrochemical and structural analyses. Furthermore, a correlation between pore structure and Li storage behavior is thoroughly investigated to examine the feasibility of DPCs as the next generation anode for high-energy LIBs.

[S8 | Li-Doped Graphite] Cells for Long-Cycle-Life Li-S Batteries Yusuke Ushioda1, Yuki Ishino1, Keitaro Takahashi1, Kohei Inaba1, Tatsuya Kawamura1, Masayoshi Watanabe2 and Shiro Seki1; 1Kogakuin University, Japan; 2Yokohama National University, Japan

Recently, demands of renewable energy are increasing with against lack of energy resources. However, power generation of renewable energies (solar and wind-power) drastically change with meteorological variation, and have poor stability of output performances. Therefore, large-scale and high-energy-density energy storage devises are strongly desired for power system stabilization, and lithium-sulfur (Li-S) batteries are expected as the one candidates. Main advantages of Li-S batteries are low-cost of elemental sulfur (S8) and their high capacity (1,672 mAhg⁻¹). On the other hand, intermediate compound of positive electrode material with charge-discharge process (Li2Sₓ) can be easily dissolved into electrolyte solution with significant degradation of cells. Moreover, lithium dendrite grows up at the Li metal and causes internal short-circuit. In this study, to prevent the Li dendrite, Li-incorporated negative electrode, such as C6Liₓ (Li-doped graphite electrode) was proposed as a stable electrode. C6Liₓ electrodes were prepared by reconstructed process of electrochemical cells (C6 | electrolyte | Li). In order to improve the efficiency of Li dope process, we investigated the electrolyte species (glyme and sulfolane) and composition dependencies for electrochemical performances. Moreover, preparation process of cells (annealing temperature) affected electrical coulombic efficiency. In the presentation, we will also report Li-S battery performances of [S8 | electrolyte | Li-doped C6 (C6Liₓ)] cells, and their related applied systems.

EN02.19.26
Optimization of NMC Electrode for High-Voltage Lithium Batteries Maciej J. Boczar1, Hui Wang2, Dominika A. Ziolkowska1 and Andrzej Czerwinski1; 1University of Warsaw, Poland; 2University of Louisville, United States

In recent years, lithium-ion cells have been introduced into electric vehicles. Presently, one of the most promising cathode materials for lithium batteries industry are mixed manganese nickel cobalt oxides (NMCs) due to their high specific capacity and high cycle stability. In this work, we present how the application of different electrolyte mixtures influences safety and stabilizes the NMC cathode material with upper cutoff potential exceeding 4.2 V. Next, we will demonstrate all-solid-state battery (ASSB) design using S-based solid electrolyte. The structure and morphology of the materials will be examined using Raman spectroscopy, scanning electron microscopy, X ray powder diffraction and specific surface area by (BET). Electrochemical measurements are carried out in three-electrode Swagelok® systems with Li metal as counter and reference electrodes and a working electrode composed of NMC active material. In order to determine the optimal potential window of NMC without a significant specific capacity drop electrolytes based on LiPF6, LiTFSI, LiTDI and LiBOB in various organic solvents were tested. Those cells are characterized by chronopotentiometry and cyclic voltammetry. As most of the batteries with liquid electrolyte are flammable and unstable and therefore are not a reliable solution for various applications, especially in higher voltage systems, we present an alternative design characterized by higher safety and energy density thanks to application of S-based solid electrolytes to our exemplary ASSB system.
Thin layered ASSB design will be possible thanks to our recently discovered liquid synthesis approach of producing lithium thiophosphates. This new generation of all-solid-state batteries creates new possibilities. It may be attractive, efficient and safer for several energy storage systems, especially for automotive industries due to the large potential window, higher energy density, and its inflammability.

EN02.19.27

Engineering the Cathode-Li Garnet Interface—How Phase Stabilities and Temperature Windows in Processing Affect Solid-State Battery Performances Kunjoong Kim and Jennifer L. Rupp; Massachusetts Institute of Technology, United States

Solid State Batteries offer safe alternatives to classical Lithium-ion batteries (LIBs) due to the non-liquid nature of the electrolyte and give perspective to assure both, high energy and power densities. Despite the fast-growing field of solid-state batteries, the high-temperature manufacturing of the battery cell components and co-assembly of solid electrolyte/cathode interfaces define largely by structures and kinetics the battery characteristics for technology. Till date, interface fabrication in Li-garnet (LLZO) based cathode/electrolyte interface is reported for high-temperature sintering (600-1050 °C) and also implicate its electrochemical storage capability. However, interfacial resistances for the Li⁺ transfer between the active material and the LLZO electrolyte and corresponding overpotential are still high which limits overall performance. Through this work, we focus on fabrication and characterization of all solid state cathode/LLZO electrolyte interfaces using most popular oxide cathode material, LiFePO₄, and LiCoO₂. Critical discussion is placed on how to enhance contact quality at low temperature in the co-assembly manufacturing vs. phase stability. We highlight the need to control the number of the reaction site and assure efficient electro-ionic percolation pathway by comparing classic co-sintered and infiltration manufactured cathode/electrolyte assemblies, and also discuss the findings towards other three-dimensional composite cathodes processed with and without additives. Ultimately, this work provides guidelines on the phase stability of LLZO and cathode interfaces, and temperature window for processing depending on the manufacturing route (classic sintering vs. infiltration) for the engineering of future solid-state batteries based on Li-garnets for safe energy storage.

**EN02.19.29**

**N, S-Codoped and Size-Controlled Porous Carbon Derived from MOF-5 as Lithium-Sulfur Battery Cathodes**
Geonho Kim, Seoyeah Oh and Jiwon Kim; Yonsei University, Korea (the Republic of)

Lithium-sulfur batteries have been actively studied as one of the future energy storage devices because they have higher theoretical capacity values compared to commercial lithium-ion batteries. Since sulfur is abundant in nature, it is low in price and environmentally safe. However, when sulfur is used as an anode material for lithium-sulfur batteries, it often lowers the conductivity and the reaction intermediates (ex. Li₂S, Li₂S₂) cause expansion in volume. The reaction intermediates also show high solubility in electrolytes reducing the cell cycles. Porous structured carbon with high content of sulfur can suppress volume expansion and also improve conductivity. Porous carbon can easily be synthesized by carbonization of metal-organic framework (MOF) with controllable porosity facilitating charge transfer. Heteroatom doping can also enhance the conductivity and prevent dissolution of polysulfide into electrolytes due to an electronegativity of the doped atoms.

Herein, we synthesized MOF-5 derived N, S-codoped porous carbon via microwave-assisted solvothermal method. The microwave-assisted solvothermal process can drastically reduce the time (<30min) required for heteroatom (N, S) doping compared to conventional solvothermal methods (several hours). When thiourea was used as a doping source, 1~3 at% and 2~5 at% of N and S in porous carbon were obtained, respectively. Furthermore, when it was used as a cathode of Li-S battery, it showed high initial capacity of ~1300 mAhg⁻¹ and excellent cell cycle retention of 60% at 0.1 C after 150 cycles. In addition, the crystal size of MOF was controlled by stirring speed. As a result of controlling the stirring speed from 0 to 300 rpm, it was confirmed that the crystal size of the MOF changed to a size of about 10 μm to 100 μm (higher speed results in smaller crystal size). As a result of reduced-size crystal applied to Li-S battery, the initial capacity was improved to ~1400 mAhg⁻¹ at 0.1C compared to ~1000 mAhg⁻¹ at 0.1C for non-stirred MOF. Therefore, we can greatly improve the performance of Li-S batteries by optimizing structure and composition of porous carbon which can contribute to commercialization of Li-S batteries.

**EN02.19.30**

**Nano-Electrodes for Na-Ion Batteries—New Insights from Ab Initio Calculations**  
Arianna Massaro, Ana B. Munoz-Garcia and Michele Pavone; University of Naples "Federico II", Italy

Na-ion batteries (NIBs) [1] are attracting widespread interests as convenient alternatives to current state-of-the-art Li-ion batteries (LIBs) [2] for large-scale grid energy storage applications [3]. Despite similar working principles, the larger sodium ion needs different component materials than LIBs, especially at the negative electrode [4]. In this context, recent studies have proposed new electrodes based on nano-structured materials like TiO₂ anatase nanoparticles, and the reported results are very promising in terms of both performance and stability [5]. However, a deep comprehension of the surface-related mechanism for insertion/de-insertion of Na into the specific materials surface/interface termination is still missing. Within this context, in this contribution we report state-of-the-art first-principles calculations on two prototypical systems that can be applied as nano-electrodes in NIBs, namely the TiO₂ anatase nanoparticles, and the MoS₂-Graphene hybrid 2D heterojunction [6].

First, we rationalize the adsorption and insertion of Na at the different (101), (100) and (001) surface termination of TiO₂ anatase nanoparticles, and the MoS₂-Graphene hybrid 2D heterojunction. Our results provide an unambiguous explanation of recent relevant experiments. Second, we will highlight the potentiality of molybdenum disulfide 2D nano-layer supported on Graphene for the inclusion and diffusion of the sodium cation at such hybrid interface.

In conclusion, the new insights on the structural features that determine the observed electrochemical behavior can be easily exploited further for the design of new and more effective nano-structured electrodes for NIBs. Authors wish to thank European Union (FSE, PON Ricerca e Innovazione 2014-2020, Azione I.1 “Dottorati Innovativi con caratterizzazione Industriale”), for funding a Ph.D. grant to Arianna Massaro.

Flow Batteries Using Manganese, Cerium and Related Redox Couples
Alex Bates\textsuperscript{1}, William Paxton\textsuperscript{2}, Joshua M. Spurgeon\textsuperscript{2}, Mahendra Sunkara\textsuperscript{1} and Sam Park\textsuperscript{1}; \textsuperscript{1}University of Louisville, United States; \textsuperscript{2}Conn Center for Renewable Energy, United States

Grid-scale implementation of redox flow batteries (RFBs) has been hindered by the availability of cost-effective redox couples within the solvent window of aqueous electrolytes. Vanadium is the predominant active species in RFBs because it is highly reversible over many cycles and it possesses multiple oxidation states, allowing it to be used in both sides of the battery (positive electrolyte: \( V^{5+} \leftrightarrow V^{4+} \), negative electrolyte: \( V^{2+} \leftrightarrow V^{3+} \)). However, the cost of vanadium is too high, resulting in a high capital cost that is not competitive for grid-scale energy storage. While other redox active species are frequently reported, such as Fe, Cr, and Br, there are few that are compatible with the aqueous solvent window while utilizing graphite electrodes, commonly used in the standard RFB configuration.

In this presentation, boron-doped diamond (BDD) is shown to be an exceptional alternative to the standard graphite electrode by enabling a wide range of redox couples that are more cost effective, environmentally friendly, and sustainable, while also offering improved efficiencies and energy densities than the current state-of-the-art. Diamond has proven itself to be a superior material for a variety of applications and its utility in electrochemistry has become increasingly apparent over the past decade. In addition to diamond’s ability to resist fouling and corrosion in extreme environments, it’s most critical advantage for flow batteries is it’s extremely high overpotential for both hydrogen and oxygen evolution (-1 V to 2.5 V, respectively). This large solvent window enables the use of redox couples that would occur with common electrodes, such as graphite or platinum, in either the hydrogen or oxygen evolution regime. Despite these advantages, it has not been until now, that BDD has been considered for use in RFB technology. This has led to the identification of several additional relevant redox couples that were previously out of reach. This research represents a monumental advancement of RFB technology and could be the solution to grid-scale energy storage challenges.

Two-Dimensional Metal Chalcogenides for Li-Ion Battery Applications
Meiying Liang and Valeria Nicolosi; Trinity College Dublin, Ireland

Metal chalcogenides (MCs), including metal sulfides and metal selenides, have attracted tremendous attention for energy storage applications and development of rechargeable lithium-ion batteries due to their unique physicochemical properties (e.g. high electrical conductivity, good thermal stability, earth abundance, etc.).\textsuperscript{[1-3]} Especially, MCs possess higher theoretical specific capacities for rechargeable lithium-ion batteries compared to traditional intercalation electrode materials. In addition, metal chalcogenides tend to be more electrochemically reversible as compared to metal oxide counterparts due to their faster charge transfer kinetics. Recently, as an alternative anode material for replacing currently commercialized graphite or carbon-based anode materials, many kinds of layered inorganic materials are investigated because of their large theoretical capacity. Similarly large numbers of layered MCs are explored as intercalation anode materials for lithium-ion batteries. However, there is still a plenty of room for the development of new efficient anode materials from non-layered MCs such as two dimensional (2D) MC nanosheets operating in terms of non-intercalative mechanism, since only a few studies are carried out for this type of materials.\textsuperscript{[3,4]}

In this work, 2D MCs nanosheets (such as GaS, GaSe, GaTe and InSe) were prepared via LPE approach. And their application as anodes of Li-ion batteries was investigated in detail. Among these 2D MC nanosheets, InSe displays the most excellent rate capability and high specific capacity (926 mAh g\textsuperscript{-1} and 595 mAh g\textsuperscript{-1} at 50 mA g\textsuperscript{-1} and 2 A g\textsuperscript{-1}, respectively). In addition, it shows exotic cycling stability. The capacity of it has increased with the increase of cycling numbers, which means the quality of a battery will be improved when the battery is used. This work opens up vast opportunities for InSe and other families of MC nanosheets to be scalably processed into flexible conductive composite films with a broad range of applications such as wearable electronics, optoelectronics, and other energy storage systems.
Improved Cyclability of Nickel Rich Layered Oxides

Nils Wagner\textsuperscript{1,2}, Julian Tolchard\textsuperscript{1}, Artur Tron\textsuperscript{1}, Sidsel Hanetho\textsuperscript{1}, Harald Pollen\textsuperscript{2} and Paul Dahl\textsuperscript{1}; \textsuperscript{1}SINTEF Industry, Norway; \textsuperscript{2}Norwegian University of Science and Technology, Norway

Secondary Li-ion batteries are the battery concept with the highest energy density both per volume and weight currently on the market and have driven the electric mobility transition. A difficult compromise between energy density and safety has to be found for electric vehicle (EV) Li-ion chemistries. The most common positive electrode for EV applications is based on the LiNi\textsubscript{x}Mn\textsubscript{y}Co\textsubscript{z}O\textsubscript{2} (NMC) system, as this is the only system that can meet the power and range requirements. Increasing the Ni content with NMC oxides results in higher capacity values but is detrimental to the capacity retention and the thermal stability. This work explores a simple acidic co-precipitation route as a "one-pot" synthesis for high energy layered oxide cathodes by oxalate precipitation, adapted from a method described by Zhen Chen \textsuperscript{[1]}. This versatile synthesis route allows for the preparation of single phase high Nickel oxides such as LiNi\textsubscript{0.8}Mn\textsubscript{0.1}Co\textsubscript{0.1}O\textsubscript{2} (NMC 811), and more complex composites such as LiNi\textsubscript{0.8}Co\textsubscript{0.15}Al\textsubscript{0.05}O\textsubscript{2} decorated LiNi\textsubscript{0.8}Mn\textsubscript{0.08}Co\textsubscript{0.12}O\textsubscript{2} in core-shell structure with improved capacity retention compared to NMC 811. This study further includes the implementation of protective surface coatings to further improve the cycle-life and increase the thermal stability of Ni rich layered oxides by lowering the reactivity of the material surface. Most reported coating methods rely on expensive fluidised bed atomic layer deposition. \textsuperscript{[2-4]} Here we compare FB-ALD with wet chemical methods that can be implemented into the material synthesis.

Neutron Depth Profiling (NDP) Technique for Studying Dynamic Short-Circuit Behaviors in Garnet-Based Solid-State Batteries

Chengwei Wang, Weiwei Ping, Howard Wang and Liangbing Hu; University of Maryland, United States

Wide electrochemical window, high ionic conductivity, and excellent stability to the lithium metal make the garnet-based solid-state electrolytes (SSEs) attractive for solid state lithium metal batteries. However, the hazard of short-circuit in garnet-based solid-state batteries has encumbered the cycle life and capacity of the full cells with the blurred reason and mechanism. In this work, we report a dynamic short-circuit process in the garnet-based solid-state batteries and study the mechanism with in situ neutron depth profiling (NDP) technique. The quantitative NDP measurements could perceive the transferring Li ions within the cell sensitively, which can forecast and confirm the dynamic behavior of the short-circuit in the garnet-based batteries. A real-time Li accumulation monitoring system of CNT/NMC/garnet/Li is also designed to reveal the charging problem in the garnet-based full cells. The voltage drops of the CNT monitoring electrode during the charging process of NMC/garnet/Li full cell indicate the Li accumulation on the garnet surface through Li dendrite inside garnet bulk, while the flat and smooth voltage profile of the CNT electrode during the discharging process demonstrates the disappearance of the short-circuit. The results indicate that this dynamic short-circuit behavior is mainly due to the low ionic conductivity and high electronic conductivity of garnet SSEs. Increasing ionic conductivity while decreasing electronic conductivity is the key to
achieve electrochemically stable garnet SSEs for solid state batteries.

New Insights into the Relationship between Structure and Transport Properties of Oxide Glasses  
Mirza C. Beg and John Kieffer; University of Michigan, United States

Combining a recently developed variant of transition state theory (TST) for ionic transport in amorphous structures with molecular dynamics (MD) simulations facilitates unprecedented insights into the local and medium-range structure of these glasses. Realistic structural models of network glasses are generated using MD simulations based on a reactive force field, which allows for the accommodation of dynamically variable coordination numbers for a given network former and dynamic charge transfer upon formation or breakage of covalent bonds. The TST model, which relies on mean-field statistical measures, allows us to identify the size of the spatial region affected by the activated ion hopping process. In combination with MD simulations, we can identify the specific molecular configurations that participate in the jump process and onto which the thermal energy for activation must be focused. Thus, MD simulations allow us to observe the behavior of all atoms involved in the ionic transport process, and identify the underlying mechanisms in the context of glass structure, its chemical character, and its bonding topology. This knowledge is used towards the development of a materials design criteria for solid-state electrolytes. (Acknowledgement: NSF-DMR 1610742.)

High Entropy Materials as Anode and Cathode for Advanced Li-Ion Batteries  
David Stenzel, Abhishek Sarkar, Qingsong Wang and Ben Breitung; Karlsruhe Institute of Technology (KIT), Germany

In recent years, a new class of high entropy materials has gained scientific interest besides the already known high entropy alloys, namely, the “high entropy oxides” (HEOs). These compounds are based on the concept of entropy stabilization of crystal structures in oxide systems by embedding multiple metal cations into single-phase crystal structures. The interactions among the various metal cations lead to interesting and often unexpected characteristics. Some of the compounds show electrochemical and structural properties, which improve the capacity retention of conversion materials for Li-ion batteries. Another promising material class are the high entropy oxyfluoride systems (HEOFs), showing great potential to be part of next generation cathode materials. The modular building approach for these high entropy materials allows tailoring the composition to develop customized electrode materials, e.g. with reduced Co content.

In our report we present different approaches, which utilize the high entropy concept, for novel high entropy electrode materials. The compounds (Co0.2Cu0.2Mg0.2Ni0.2Zn0.2)O and Li(Co0.2Cu0.2Mg0.2Ni0.2Zn0.2)OF are used as anode and cathode materials, respectively. By replacing, adding or subtracting elements, the electrochemical properties can be tailored and the influence of different elements evaluated.

Investigations of Ionic Conduction Mechanism and Charge-Discharge Property of  
Polyether/Li7La3Zr2O12(LLZO) Composite Solid Electrolytes  
Masaki Kato, Shiro Seki and Koji Hiraoka; Kogakuin University, Japan

Li-ion secondary batteries are widely used in many applications from various of electric devices, including mobile phones and electric vehicle to large scale power storage system due to high capacity, cycle ability and in/out put ability. Conventional electrolytes of Li-ion battery are mainly used flammable organic liquid electrolyte such as ethylene carbonate (EC), propylene carbonate (PC) and dimethyl carbonate (DMC). Not only performance improvement of batteries but also securing of essential safety of Li-ion batteries are also important. All solid-state Li
ion battery can solve the safety problem and higher energy density by stacking, weight saving of device by thinning of electrolyte layer are also possible. Our group focused on solid polymer electrolyte with high flexibility and oxide-based inorganic solid electrolyte with high ionic conductivity and chemical stability in air. We prepared polymer/inorganic composite solid electrolyte has high autonomy at thinning by using polyether-based solid polymer electrolyte and cubic-Li$_7$La$_3$Zr$_2$O$_{12}$(LLZO), one of the most candidate Li-ion conductive inorganic electrolyte with garnet structure. Preparation of samples and cell were carried out in Ar-filled groove box. LiN(SO$_2$CF$_3$)$_2$ and DMPA (photo initiator) were dissolved in polymer-based macromonomer solution ([Li] / [O] =0.1, amount of O was based on oxide unit from polyether and DMPA is 1000ppm based on weight of macromonomer). Cubic-LLZO were mixed in weight ratio of macromonomer: LLZO = 1: x (x =0, 0.2, 0.33, 0.42, 0.5, 0.6, 0.66) and a little acetonitrile were added to the solution to obtain homogeneous solution. The solutions were vacuum dried over 12h. The solutions were casted on glass plate and covered by two glass plate and 0.5mm teflon spacer. Composite solid electrolyte films were fabricated by radical polymerization under UV at 5 min. Ionic conductivity, Li/electrolyte interfacial behavior using Li/Li symmetrical cell, Li ion transport number were measured by AC impedance method (VSP, Bio-logic). Temperature dependence of ionic conductivity and Li/electrolyte resistance were carried out and Li-ion transport number were also measured at 333K. We consider that there are two Li ion conduction pass of polymer phase and LLZO particle in polyether/LLZO composite system from changing of impedance spectra. Li-ion conduction in LLZO particle and grain boundary is more preferentially than polymer phase because of ionic conductivity and amount of Li-ion career are much higher than polymer phase. Thermal properties of polyether/LLZO composite solid electrolytes were measured by differential scanning calorimetry (THRMO PRO EVO2, Rigaku). Heat capacity changes with glass transition of polymer electrolyte were observed -243K. All solid-state Li batteries were prepared using LiCoO$_2$ for positive electrolyte and Li metal for negative electrolyte. Charge-discharge measurements were performed in the operating voltage 4.2~2.5V and 0.05C rate at 333K and showed initial capacity of 120mAh/g. We will present about charge-discharge property and ionic conduction mechanism of polyether/LLZO composite system in detail on conference.

Developing Low-Potential Prussian Blue Analogues

Samuel J. Wheeler and Mauro Pasta; University of Oxford, United Kingdom

Prussian blue analogues (PBA) are some of the most promising cathode materials for sodium-ion and potassium-ion batteries operated in both aqueous and non-aqueous electrolytes. They have an open-framework structure that exhibits minimal structural change during ion insertion/extraction and enables fast ionic conduction. This leads to high power and long cycle life electrodes. However, the excellent properties of PBA cathodes can only be fully utilised in a full cell with an anode of comparable performance. One pathway to high performance anodes is to develop low-potential PBA materials by tuning the composition. This has successfully led to the development of anodes based on manganese hexacyanomanganate with a reduction potential of ~0.70 V vs. SHE.

In search for lower potential PBA compositions we recently reported a thorough characterisation of manganese hexacyanochromate which has a reduction potential of ~0.86 V vs. SHE, giving full cell voltages against common PBA cathodes approaching 2 V. This material had a modest specific capacity of 63 mAh g$^{-1}$, much lower than its theoretical value (~170 mAh g$^{-1}$) due to high vacancy and water content, and only one transition metal being electrochemically active. Improving its capacity is a scientific challenge as the material is unstable in the reduced state in water, which prevents the use of common strategies to reduce the vacancy and water content during synthesis. In my talk, I will present our efforts to improve the specific capacity and stability of low-potential Prussian blue analogues by exploring the wider transition-metal hexacyanochromate composition space and by developing novel synthetic strategies.

EN02.19.39
Phosphorene Based Composites as Anode Material for Potassium-Ion Battery Rishabh Jain, Prateek Hundekar and Nikhil Koratkar; Rensselaer Polytechnic Institute, United States

Potassium ion battery has recently gained considerable interest in energy storage systems. We report, for the first time, phosphorene as an anode material for K ion battery. Phosphorene showed very high initial capacity of 865 mAhg\(^{-1}\) which is attributed to alloy formation with potassium (K\(_{3-x}\)P) but also lead to tremendous increase in volume (200%). This lead to delamination of phosphorene anode which lead to very quick decay in specific capacity. In order to prevent huge loss in capacity decay, we investigated two different type of materials as buffer layer: reduced graphene oxide (2D) and single walled carbon nanotubes (1D). Phosphorene composite with reduced graphene oxide in proportion of 1:3 showed high specific capacity of 762 mAh g\(^{-1}\) and 72% capacity retention after 100 cycles. In comparison to that phosphorene composite with single walled carbon nanotubes (1:3) showed capacity retention of 40%. Phosphorene/reduced graphene oxide (P/rGO) also showed high rate capability (~400 mAhg\(^{-1}\) at 1C) and stable cycle life up to 300 cycles. Furthermore, P/rGO using spherical potassium cobalt oxide (s Koch) as cathode showed almost similar specific capacity (~400 mAhg\(^{-1}\) at 1C) and a long cycle life (100 cycles).

EN02.19.40
Reassessing the Charge Transfer Transition of Layered LiMO\(_2\) Electrodes Christopher Savory\(^1\), Aron Walsh\(^2\), Benjamin J. Morgan\(^3\) and David O. Scanlon\(^1\); \(^1\)University College London, United Kingdom; \(^2\)Imperial College London, United Kingdom; \(^3\)University of Bath, United Kingdom

Ab initio modelling is a useful tool in the study of battery electrodes, able to support experimental findings and predict new phases and behaviours, providing a suitable and accurate method is used. Regular Density Functional Theory (DFT) functionals such as the commonly used PBE, however, are impacted by the ‘self-interaction error’ which severely impacts the accuracy of calculations involving the highly-correlated 3d valence electrons in transition metals.\(^1\)

Historically, the study of battery cathodes using DFT has been improved through the addition of ‘U’ parameters, which correct for the self-interaction error,\(^2\) however these parameters require tuning to experimental measurements on the specific system in question, while also need to be varied during intercalation (with changes in oxidation state) and can be highly sensitive to changes in transition metal composition. This makes them unideal for the description of complex cathode systems such as NMCs and as a predictive tool for new systems.

Additionally, with the increased development behind the theory of anionic redox, accurate assessment of the charge transfer transition, which standard DFT tends to underestimate, is crucial.\(^3\) Minimally-parameterised hybrid DFT functionals such as HSE06 are routinely used to accurately predict the band gaps of semiconductors, however previous studies have highlighted disagreement between hybrid DFT and the band gap of LiCoO\(_2\) recorded from XPS-BIS, as well as overestimation of its predicted intercalation voltage.\(^4,5\)

In this study, we address this issue, demonstrating through a combination of HSE06 and high-level quasiparticle self-consistent GW calculations that the perceived value of the LiCoO\(_2\) charge transfer transition is underestimated, and that HSE06 represents an accurate, transferable standard method for describing the structural and electronic properties of LiMO\(_2\) cathode materials (M=Mn, Co, Ni). We also consider the issue of dispersion effects on estimated intercalation voltages, and explore the impact of the reassessed charge transfer gap on the defect chemistry of these materials, with a view to wider study of degradation and anionic redox in NMC cathodes.

EN02.19.41
Highly Porous Carbon in Multiscale as a Lithium-Sulfur Battery Cathode Seoyoung Yoon, Jihyeon Park and
Porous carbon is known for its strong mechanical stability, excellent electrical conductivity, high surface area and porosity. Therefore, it is utilized in various fields such as electrodes for electrochemical reactions or supports for gas storage. When applied as an electrode, its porous structure provides increased active sites and efficient electrolyte infiltration resulting in an enhanced performance of batteries. More specifically, porous structure reduces volume expansion of a cathode minimizing deformation and shuttle effect caused by migration of intermediates during reduction-oxidation reaction via sequestrating intermediates inside the pores. Furthermore, multiscale porous structure with macro-, meso-, and micro-pores allows an effective ion diffusion and charge transfer by shortening the ion diffusion path.

Herein, we synthesized metal organic framework (MOF) derived multiscale porous carbon by varying the ratio of more than one solvent and MOF-5 precursor, respectively. Dimethylformamide (DMF) and water were used as solvents, whereas benzene-1,4-dicarboxylic acid (BDC, C₆H₄(COOH)₂) and zinc nitrate hexahydrate (Zn(NO₃)₂·6H₂O) were MOF-5 precursors. Varying the ratios of solvents and ligand to metal led to changes in morphology of MOF via competition between water and BDC ligands for coordination with [Zn(NO₃)₂]⁶⁺ units. Afterwards, carbonization of MOF resulted in porous carbon with high specific surface area (837~2990 m²/g) and porosity (pore volume of 0.582~3.281 cc/g). Batteries with the controlled porous carbon as an electrode showed a broad range of performances: an initial capacity was 1123 mAh/g when water to DMF ratio was 11:1 and the metal-ligand ratio was 1:6, and the coulombic efficiency maintained over 98% even after 200 cycles. We believe a facile way to synthesize multiscale porous carbon with both meso- and micro-pores can pave a way for many other application areas including energy/conversion devices, catalysis, and gas storage.

Molecular Level Insight into the Lithium Coordination Structure and Lithium Transport Properties in Polyether-Based Polymer Electrolytes

Koki Yamada, Ryansu Sai, Yu Katayama and Hiromori Tsutsumi; Yamaguchi University, Japan

There has been much effort to develop solid-state electrolytes, including polymer electrolytes, with high energy and power densities, long cycle lives, and safety for next-generation lithium batteries. However, the ionic conductivities of current polymer electrolytes are orders of magnitude less than those of liquid electrolytes, and they are still insufficient for practical battery applications. In this study, a series of polyether-based polymers having different number of cyanoethoxy side chains are newly synthesized and compared. The contribution of the cyanoethoxy group to the Li⁺ coordination structure as well as electrolyte properties, such as the ionic conductivity and lithium transference number, are studied by various (electro)chemical and spectroscopic techniques. Here, we verify that the molecular structure of the repeating monomer unit of the polymers (i.e. the number of the cyanoethoxy group on the main chain) alter the Li⁺ coordination structure, which in turn affects the thermal stabilities and ionic transport properties. The result thus indicates the importance of the Li⁺ coordination structure in the polymer electrolyte in order to understand electrolyte properties. Our findings pave the way toward a design strategy for polymer electrolytes with improved conductivity, based on the Li⁺ coordination structure that has been experimentally identified.

Polymer Based Solid State Electrolyte for Safe Energy Storage Application

Samuel Danquah, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Polymer solid electrolyte such as polyethylene oxide (PEO) could influence solid-state battery chemistries with desirable performance and safety due to their high ionic conductivity of 10⁻⁴ S.cm⁻¹ (65°C - 78 °C), low glass transition temperature, flexibility and its stability with lithium metals and conductive with lithium salt. In addition, it is environmentally stable and has an electrochemical window wide enough to overpower surplus electronic transport. However, limited thermal stability of PEO makes it more challenging for commercial use, which consequently, hinders the fast charging and discharging behavior of the battery. This work investigates the synthesis of polyethylene oxide solid electrolyte by a simple melting technique. A remarkable reduction of the interfacial impedance was noticed at room temperature. The structure and surface morphology of PEO was characterized by X-ray diffraction (XRD) and FESEM, respectively. Interestingly, field emission scanning electron microscope (FESEM) images show a porous nature of the electrolyte which promotes the movement of lithium ions through the
The electrochemical performance of the battery shows outstanding performance with large charge storage capability. The battery shows improved capacitance with higher number of charging and discharging cycles. This improvement in the rate ability is a result of the reduction in the interfacial impedance. This work is supported by the NSF-CREST (CREAM) Grant Number HRD 1547771, and NSF-CREST1 (CNBMD) Grant number HRD 1036494.

**Thin Solid Composite Electrolyte with Three-Dimensional Interconnected Structure**

Xi C. Chen¹, Max J. Palmer¹, Marm Dixit², Sergiy Kalnaus¹, Andrew S. Westover¹, Kelsey B. Hatzell² and Nancy J. Dudney¹; ¹Oak Ridge National Laboratory, United States; ²Vanderbilt University, United States

Composite solid electrolytes consisting of a processible soft polymer phase and a highly conductive hard ceramic phase are promising in enabling lithium metal anode to achieve high energy and power density. In order to achieve energy density goals, the electrolyte film must be thin (< 30 μm). In previous work, we discovered that composite electrolytes with high ceramic loadings suffer from low ionic conductivity due to a large interfacial resistance for ion transport across the polymer-ceramic interface.¹⁻² In a composite electrolyte where discrete ceramic particles are dispersed in the polymer host, ions do not transport through the ceramic phase due to large interparticle resistance.

Here we introduce an approach that creates a 3D interconnected structure of the ceramic with greatly reduced interparticle resistance.³ Furthermore, we fabricate a solid composite electrolyte film that is thin (20-30 μm in thickness), ionically conductive, and mechanically robust. Without the use of plasticizers, our composite film has an ionic conductivity of approximately 0.03 mS/cm at 30°C. Ion conduction path in the composite electrolyte is investigated by synchrotron X-ray tomography and finite element analysis.

**Accurate Sub Nanometer Thin, Pristine 2D Channels for Electrochemical Applications**

Gangaiah Mettela, Pawin Lamprasertkun, Ashok Keerthi, Robert Dryfe and Radha Boya; University of Manchester, United Kingdom

Electric double layer capacitors (EDLC) are energy storage devices which fall between dielectric capacitors and batteries.¹ EDLC store the energy by ion adsorption on the electrode surface, and the criteria for a high performance electrode is high surface area to maximise the charge storage. In spite of numerous studies on porous electrodes particularly involving carbon, there still remains a lack of understanding on the precise relationship of confinement to EDLC, due to the distribution of pore sizes, and uncontrolled surface charge on electrodes.² A fundamental study establishing the relation between the capillaries/pore size in electrode to EDLC is a potential way to improvise the performance of a capacitor. We have fabricated sub nm thin channels through a modified of the fabrication method reported by Radha et al.³ Briefly, three components, namely- top, channel and bottom are assembled through the van der waals interactions. The thickness of the channels has been varied from 0.68 nm to a few nm, while channel length is of a few tens of microns. The obtained channels possess ultra-smooth pristine surfaces, nearly free from the rough edges. The specific capacitance and cation size effect of the electrolyte have been studied.

Thermal and Electrochemical Characterization of Adiponitrile (ADN) LiXF₆ (X = P, As, Sb) Cocrystals

Laura Sonnenberg, Birane Fall, Stephanie Wunder and Michael J. Zdilla; Temple University, United States

Cocrystals of adiponitrile (ADN₂LiXF₆ (X = P, As, Sb) can be formed by dissolving the LiXF₆ salts in excess ADN at elevated temperature and cooling to room temperature, resulting in the formation of cocrystals. The cocrystals all have the same crystal structure. Temperature-dependent ionic conductivities (σ) and lithium ion transference numbers, tₐ⁺, show that tₐ⁺(Sb) > tₐ⁺(As) > tₐ⁺(P), that is there is a greater contribution from the Li⁺ ion to the conductivity as the anion becomes larger (greater mass). Thermogravimetric analysis data indicate that the ADN is removed first (T_d ~ 100 °C) and that it comes off at the same temperature as ADN for LiPF₆ but at a higher temperature (T_d ~ 150 °C) for LiAsF₆ and LiSbF₆. Further, the residual weight loss of the anion increases as the anion size increases in mass. DSC data for (ADN) LiXF₆ indicates no melting of the sample below the T_d. However, there is a small melt and crystallization of the ADN. As previously observed, this is attributed to liquid regions around the co-crystallites. Similar DSC results are observed for the LiAsF₆ and LiSbF₆.

Improving Electrochemical Performance of LiNi₀.₈Mn₀.₁Co₀.₁O₂ Cathode by a Li-Nb-O Combined Coating/Substitution for High-Energy-Density Lithium-Ion Battery

Fengxia Xin, Hui Zhou, Xiaobo Chen, Carol M. Kaplan, Natasha Chernova, Guangwen Zhou and M. Stanley Whittingham; Binghamton University, United States

High-nickel NMCs are very attractive high capacity cathode material for practical applications, especially in automotive industry. However, many obstacles caused by the high nickel content, such as high surface reactivity, structural instability, etc., must be overcome before this type of compounds can become the material of choice for application. Through a wet chemistry method, a Li-Nb-O coated and substituted co-modified NMC 811 was prepared by single step treatment. The Li-Nb-O coating/substitution not only supplies a protection on surface but also optimize the material itself by Nb⁵⁺ incorporation. With this treatment, the 1st capacity loss was significantly reduced (13.7 vs. 25.1 mAh/g), which can contribute at least 5% increase on the energy density of full-cell level. In addition, both rate (158 vs. 135 mAh/g at 2C) and cycling (89.6 vs. 81.6% after 60 cycles) performance were greatly enhanced as well.

Acknowledgement: This work was supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Office of Vehicle Technologies of the U.S. Department of Energy, through the Advanced Battery Materials Research Program (Battery500 Consortium).

Simultaneous Exfoliation and Functionalization of Graphene for Supercapacitors

Yuling Zhuo; University of Manchester, United Kingdom

Aryl diazonium salts have been widely reported in the research of surface chemistry and they are believed to increase the specific capacitance of pristine graphene electrodes by introduction of pseudocapacitance as well as increased surface area due to prevention of graphene restacking. In this work functionalized graphene for use in supercapacitors was prepared by a two-step process, where graphene was functionalized with two different aryl diazonium salts (4-nitrobenzenediazonium tetrafluoroborate (NBD) or 4-bromobenzenediazonium tetrafluoroborate (BBD)) simultaneously during electrochemical exfoliation. Characteristic peaks identified from Raman and X-ray photoelectron spectroscopy demonstrate that the simultaneous functionalization and exfoliation of the graphene with NBD and BBD was successful. Cyclic voltammetry, galvanostatic charge-discharge measurements and electrochemical impedance spectroscopy were performed to study the electrochemical properties of the functionalized graphene electrodes. It was found that graphene NBD functionalized for 30 minutes (N30) exhibited superior energy storage properties with 5 times increase in specific capacitance compared to pristine graphene.

**Bismuth Nanowire Array Electrode for a Dual-Function Battery for Desalination and Energy Storage** Jun-Bin Wu¹, Shih-Hsun Chen², Shao-Sian Li¹ and Pochun Chen¹;¹ National Taipei University of Technology, Taiwan; ²National Taiwan University of Science and Technology, Taiwan

With the increasing demands of the green energy and fresh water, it is necessary to develop a more efficient approach to provide sustainable resources for human use. Seawater is an abundant resource to produce clean water and to store energy by desalination process. Among several types of desalination, electrochemical salt removal is a promising approach to separate dissolved salt ions from seawater and to selectively store sodium and chloride ions in cathode and anode. The development of desalination batteries depends critically on the discovery of high performance chloride-storage electrodes. Among all types of anode materials, bismuth-based electrodes, with a comparable theoretical specific capacity, as new high efficient electrode materials for chloride storage.

In this study, we designed and fabricated bismuth nanowire arrays with various aspect-ratios serving as chloride-storage electrodes by a template-assisted process. Chloride ions can be efficiently stored in the high-aspect-ratio bismuth nanowire structures in the form of BiOCl. We characterized and evaluated the bismuth nanowire array electrodes for application of seawater desalination. We carried out linear sweep voltammetry (LSV) and galvanostatic charging/discharging tests for half-cell reactions of bismuth nanowire array electrode to examine its chlorination/dechlorination behavior. In addition, we discussed the effects of the dimensional parameters of the bismuth nanowire arrays and the surface treatments on the bismuth nanowire arrays.

**Modeling the Mechanisms of Dendrite Growth and Suppression in Lithium-Ion Batteries** Zhuolin Xia¹, Feiyang Yu² and Dilip Gersappe¹;¹ SUNY-Stony Brook, United States; ²Columbia University, United States

The choice of an anode material for Li-Ion batteries is critical, since the formation of dendrites, which will result in safety problems and self-discharge, usually occurs on the anode. Thus, the choice of anode materials, the charge-discharge conditions and the additives inside of the electrolyte is critical to the formation of dendrites. Here, we focus our study on the use of Li metal anodes. To study the process of dendrite formation on Li anodes, we have developed a Lattice Boltzmann model. The model is used to study the mechanism of these processes, and the effects of applied potential and morphological features on the local concentration distribution and structure evolution. Our model is also able to capture the effect of charge-discharge cycles on the morphology of the anode. We also study the effect of pulsing on the formation of dendrites in the battery. These results can be used to build a relationship between design parameters and battery performance in order to improve the stability and the capacity of the battery.

**Abuse Tolerant 300 Wh/Kg High Energy Density Li-Ion Batteries** Jun Wang, Xiangyang Zhu, Hong Yan, Ryan Laplante, Jongho Jeon, Jordan Rubio, Qiguo Chen, Yao Chen, Kitae Kim, Maha Hammoud and Derek C. Johnson; A123 Systems LLC, United States

Rechargeable Li-ion batteries with energy density ≥ 300 Wh/kg (650 Wh/L) have become increasing important to extend driving range beyond 250 miles per charge for electric vehicles. While cell level energy density target may be achieved with commercial grade high nickel content (≥80%) NCM cathode when paired with Si/graphite composite anode, how to ensure such high nickel chemistry can deliver on cell safety requirements is a major hurdle to the vehicle electrification roadmap. Therefore, a number of techniques have been studied in order to improve Li ion battery safety at component level, such as active materials engineering and safer electrolyte formulation. The main purpose of this research is to demonstrate a technology path which can deliver cell level energy density of 300 Wh/Kg as well as meet very stringent abuse tolerance tests including nail penetration, overcharge, hotbox and crush. Due to intrinsically low first cycle columbic efficiency of the Si/graphite anode, prelithiation emerges as an indispensable process to reach 300 Wh/Kg energy density target. Cell safety is primarily achieved by combining A123’s for proprietary safety technologies with commercially available cathode materials such as NCM 811. As expected, the composite cathode materials exhibited improved thermal stability as onset temperature shifted to higher degree with split exothermal peaks as revealed by differential scanning calorimetry (DSC) characterization. Subsequent validation experiments conducted through production intent large format cell testing confirmed the
effectiveness of the A123 safety technologies while maintaining target energy density, as cells without those safety additives failed nail penetration (Hazard level 5.0) whereas those with safety additives passed convincingly (Hazard Level 3.0). Not surprisingly, this study also demonstrates that nail penetration, the most challenging one among all abuse tolerance tests, shows a strong dependence on testing conditions such as size and speed of the nail. Those results shed light on how high energy density Li ion batteries (≥300 W/kg) can be made safe through innovative engineering of commercial NCM cathode materials.

The Exploration on the Promising Performance of Epitaxial Li$_{1-x}$CoO$_2$ Thin Film  
Justin S. Pearson, Heshan Yu, Ren Yaoyu and Ichiro Takeuchi; University of Maryland, United States

Li$_{1-x}$CoO$_2$ (LCO) is a promising material for the application in lithium batteries as cathodes as well as the new type of transistor devices. Fabricating the epitaxial LCO thin films is considered to be a potentially effective method to raise the ionic conductivity and to optimize the interface between the solid electrolyte and electrode. In order to improve the performance of the LCO, the high-quality epitaxial thin films with different orientations, e.g., (104), (110), and (001) were grown on (100), (110), and (111) - oriented SrTiO$_3$ substrates utilizing the Pulsed Laser Deposition (PLD) technique with deposition temperature of 650 – 700 °C, respectively. By tuning the oxygen pressure and laser repetition precisely, the epitaxial LCO thin films with different grain sizes were fabricated. As shown in the X-ray diffraction results, the crystallization varies with changing oxygen pressure, e.g. intensity of the LCO diffraction peaks of each orientation firstly increases with raising oxygen pressure from 50mTorr to 150mTorr and then decreases at higher pressure. The surface geometry mapped by AFM and SEM also reveals that the grain size is the maximum at 150mTorr and would decrease with both raising and reducing the oxygen pressure. This may be related to the different growth modes: the level of interaction between the ablated material and the oxygen environment effectively enhanced the diffusion and growth of the film until the interactions increased past a critical point to change the growth mode leading to smaller uncoalesced grains at higher pressure. In order to maximize the grain size, the laser frequency is then carefully tuned at the most promising oxygen pressure of 150 mTorr. There exists approximately an order of magnitude change in the grain size with changing repetition. The grain size could be almost 1 micron with the laser frequency of 2Hz. Recently, the Lithiation and de-lithiation process is taken in a sealed cell at room temperature to investigate the function of the LCO with different grain sizes.

Ionic Liquid-Polymer Interaction in Fully Zwitterionic Ionogels Using Thermal Analysis  
Andrew G. Clark, Morgan Taylor, Matthew Panzer and Peggy Cebe; Tufts University, United States

In this study, the thermal properties of a group of zwitterionic copolymers containing ionic liquid designed for electrochemical energy storage are investigated using temperature modulated differential scanning calorimetry (TMDSC) and thermogravimetry (TG). Investigating the thermal properties will reveal how the zwitterionic moieties affect transition phenomena and interact with ionic electrolytes. Sulfo betaine vinylimidazole (SBVI) and 2-methacryloyloxyethyl phosphorylcholine (MPC) were dissolved in the commercial ionic liquid EMI TFSI in varying molar ratios and subsequently polymerized to produce fully zwitterionic random copolymers. TG reveals two degradation steps at 290 °C and 390 °C due to MPC degradation, and one step at 350 °C due to SBVI degradation. TMDSC at 5 °C/min was used to identify the glass transition of these materials, showing a decrease in $T_g$ from 60 °C to 10 °C with increasing addition of SBVI. A melting endotherm at -18 °C was observed on heating, attributed to the presence of residual ionic liquid. The solid state heat capacity of the polyzwitterions with ionic liquid was measured and compared to predictions assuming additivity of the heat capacities of the ionic liquid and polyzwitterions. The assumption of additivity was valid for only a few of the polyzwitterion compositions, suggesting that some of these materials were still in the liquid or partially liquid state, even down to -80 °C.

Transition-Metal-Mediated Instability of LiNi$_{0.5}$Mn$_{1.5}$O$_4$ Spinel by In Situ Neutron Scattering  
Yan Chen and Ke An; Oak Ridge National Laboratory, United States

Transition metal (TM) substitution has been widely applied to tune the complex oxides crystal structures to create high energy density electrodes materials in high performance secondary rechargeable lithium-ion batteries. The LiNi$_{0.5}$Mn$_{1.5}$O$_4$ spinel, which is obtained by substituting one fourth of the Mn with Ni in the LiMn$_2$O$_4$ spinel, is a candidate cathode material for electric vehicle applications because of its high operating voltage and large energy
