transition dipole by systematically studying the temperature dependent absorption and time-resolved fluorescence spectra of CsPbBr₃ nanoribbons and nanoplatelets of varying thickness. To obtain reliable spectroscopic data, we first developed the synthetic procedure producing CsPbBr₃ nanoribbons with high ensemble uniformity of the size and morphology, which exhibit high quantum yield (> 60%). These nanoribbons were stable under laser excitation in vacuum environment exhibiting stable and well-defined fluorescence spectra determined by thickness. From temperature dependent absorption and time resolved fluorescence emission measurements, we observe the GOST effect in nanoribbons and nanoplatelets, manifesting a larger absorption cross-section as well as decreased fluorescence lifetimes. For example, in 3 unit cell-thick nanoribbons the fluorescence lifetime decreases from ~3 ns at 300 K to below 10 ps at 60 K without changing the fluorescence quantum yield significantly. This behavior is similar to that observed in 2 nm thick CdSe platelets where the fluorescence lifetime reaches 150 ps at similar temperatures. These results indicate that few unit cell-thick lead halide perovskite 2-dimensional structures can be superior to their II-VI counterparts where large oscillator strengths are desirable.

Wavelength Tunable Circular Dichroism of Chiral 2D Organic Inorganic Hybrid Perovskite Sunihl Ma¹, Jihoon Ahn¹, Ji-Young Kim², Ji-hoon Kyhm³, Jung Ah Lim⁴, Wooseok Yang⁵, Nicholas A. Kotov² and Jooho Moon¹; ¹Yonsei University, Korea (the Republic of); ²University of Michigan–Ann Arbor, United States; ³Dongguk University, Korea (the Republic of); ⁴Korea Institute of Science and Technology, Korea (the Republic of)

Because 2D organic inorganic hybrid perovskites (OIHP) exhibit desirable optoelectrical properties such as high absorption coefficient, strong quantum confinement effect and highly tunable bandgap, 2D OIHP is considered as promising semiconductors for next generation optoelectronic devices. Additionally, many researches have reported that incorporation of chiral organic cation into the 2D OIHP lattices triggers another intriguing property of OIHP, which is defined as different optical response to left-handed and right-handed light. However, to increase the possibility to develop workable devices such as chiral light emitting diode (LED), wavelength tunability of chiroptical response should be guaranteed. In this study, to obtain wide wavelength tunability of chiroptical phenomenon, chemical composition engineering of 2D OIHP is carried out. Varying the mixing ratio of iodide and bromide anion in (S- or R-C₆H₅CH₂(CH₃)NH₃)₂PbI₄(1-x)Br₄x basically modifies band gap of chiral OIHP, leading to a shift of circular dichroism (CD) signal from 495 nm to 474 nm. It is also found that abrupt crystalline structure transition occurs and CD signal disappears when the 2D organic inorganic hybrid perovskite is transformed to bromide-determinant phase. To obtain material having CD at the wavelength range lower than 474 nm, S- or R-C₁₂H₇CH₂(CH₃)NH₃ with larger spacer group can be adopted. Thereby CD signal can further blue-shift to around 375 nm. Circularly polarized photoluminescence (PL) from our chiral 2D perovskite over a broad wavelength range at 70 K is also confirmed. Such a wide wavelength tunability of chiroptical property will advance the realization of color tunable circularly polarized light-emitting OIHPs.

Single-Step Synthesis of Dual Phase Bright Blue-Green Emitting Lead Halide Perovskite Nanocrystal Thin Films Harshita Bhatia, Julian A. Steele, Cristina Martin, Masoumeh Keshavarz, Guillermo Solís Fernández, Hai'feng Yuan, Guillaume Fleury, Jelle Hendrix, Maarten Roeffaers, Johan Hofkens and Elke Debroye; KU Leuven, Belgium

Metal trihalide perovskites are rapidly redefining the landscape of solid-state semiconductors utilized as active medium in photovoltaics and in light generation. Within this materials space, organic-inorganic hybrid formamidinium lead bromide (FAPbBr₃) has arisen as a promising candidate for efferent light emitting devices, due to its capacity for sharp and bright green light emissions (530 nm). Herein we have applied a facile single-step ligand-mediated method for phase-controlled synthesis of FAPbBr₃ cube- and rod-shaped nanocrystals (NCs), starting from different ratios of precursor agents. Examining their structural and optoelectronic properties – using a combination of synchrotron X-ray diffraction, X-ray spectroscopy, scanning electron microscopy and steady-state and time-resolved photoluminescence (PL) – we reveal the two NC types to fundamentally differ. While the cube-shaped NCs exhibit properties aligning with that of bulk FAPbBr₃, the nanorods exhibit a two-phase microstructure and the co-existence of both a typical cubic perovskite structure alongside the formation of a new low-symmetry monoclinic phase (P2/m). Further, the two-phase nanorods display a bright dual PL emission (peaks centered near 490 nm and 530 nm) and complex luminescence dynamics, properties characteristic of quasi-2D perovskites. The two phase nanorods generation can be assigned to the proton exchange in the presence of excess of FA⁺ during the synthesis.
The Role of Temperature and Concentration on the Morphology of CH₃NH₃PbI₃ and CsPbI₃ Perovskites
Ariany Bonadio, Leonardo Oliveira and Jose A. Souza; Federal University of ABC, Brazil

Halide perovskites have attracted great attention due to their excellent photovoltaic performance. Many growth methods have been developed to prepare these compounds with different morphologies. The identification of their crystal growth mechanism is crucial for understanding their fundamental chemical and physical properties. In this work, we have observed the formation of CH₃NH₃PbI₃ microcuboids and CsPbI₃ microwires via solvothermal method using lead iodide (PbI₂), methylamine (CH₃NH₂) or cesium acetate (CsOAc) as precursors and hydroiodic acid (HI) in isopropyl alcohol solution. We have systematically changed the solution temperature and PbI₂ concentration during the synthesis process. X-Ray diffraction shows that both CH₃NH₃PbI₃ and CsPbI₃ have high crystallinity belonging to the tetragonal (I4/mcm space group) and orthorhombic (Pnma space group) crystal phase, respectively. We have observed that the CH₃NH₃PbI₃ morphology is synthesis parameter dependent changing from small irregular particles to very regular polyhedral shape. We have also observed the presence of hollow spaces and/or hopper-type morphology at high temperature and concentration. CsPbI₃ perovskites present microwire morphology which also depends on synthesis parameter. UV-Vis absorption measurement indicated a band gap energy around 1.5 eV and 2.7 eV for CH₃NH₃PbI₃ and CsPbI₃ samples, respectively. We observed that the optical band gap energy for both compounds is synthesis parameter independent. We discuss the change in the morphology based on Wulff construction.

The Unexpected Role of Composition in Perovskite Diffusion
Kristopher Williams¹, Makhsud Saidaminov², Mingyang Wei², Andrew Johnston², Rafael Quintero-Bermudez², Andrew Proppe², Yi Hou², Grant Walters², Shana O. Kelley², William Tisdale¹ and Edward H. Sargent²; ¹Massachusetts Institute of Technology, United States; ²University of Toronto, Canada

The optimization of perovskite (typically ABX₃) for photovoltaic (PV) performance through mixed cations (A = Cs, methylammonium (MA), and formamidinum (FA)) and halides (X = Br and I) has led to engineered materials comprising six (AjBkC₁-j-kPbXzY₃-z) or more components. The role each of these components plays in increasing the PV performance is not yet well understood.

Here, we use transient photoluminescence microscopy to study the diffusion of carriers in single crystals and thin films for a variety of perovskite compositions (MAPbI₃, CsFAPbBrI, and CsMAFAPbBrI) in order to understand the effects of composition. Unexpectedly, the diffusion of carriers in single crystals was observed to be independent of the perovskite composition. When cast into thin films, however, the same materials showed a marked difference in diffusion constants and lengths. Along with angle-dependent and energy dispersive x-ray data, we determined that the limited transport in some compositions was caused by inhomogeneous crystallization at the grain boundaries. Those compositions containing methylammonium had consistent mixed-halide content across grains, while non-MA-containing compositions showed a gradient in the halide mixture, with higher Br content—and thus a larger bandgap—at the surface of film grains. Such a potential barrier inhibits the movement of carriers from grain to grain and thus their ability to reach electrical contacts.

This work reveals that compositional tuning of perovskites for PV performance has more to do with controlling grain boundary gradients than increasing transport within the bulk material. While most high-performance PV cells contain MA, we show it may be possible to produce high performance PV cells from desirable non-MA perovskites. Theoretical composition yields show current crystallization schemes favor narrow gradients in MA-containing materials, though solvent systems could be engineered to produce homogenous grains in films without the need for MA incorporation.

How Halide Perovskites Relieve Heteroepitaxial Stress?
Eitan Oksenberg¹, Eva L. Unger² and Ernesto Joselevich³; ¹FOM Institute AMOLF, Netherlands; ²Helmholtz-Zentrum Berlin, Germany; ³Weizmann Institute of Science, Israel

Ordered arrays of stable, single-crystal cesium lead bromide (CsPbBr₃) nanowires can be used to study fundamental properties of halide perovskites in a well-defined and simple one-dimensional model system. Specifically, we use
multiple spectroscopy techniques and correlate them with state-of-the-art electron microscopy methods, to reveal, with atomic resolution, large and continuous lattice rotations due to heteroepitaxial stress and lattice relaxation. We show that the lattice distortions give rise to bandgap modulations that are the dominant contributors to an anomalous size-dependent emission spectral shift well beyond the quantum confinement regime. Understanding the lattice behavior in strained perovskite and its effect on the optoelectronic properties of these dynamic materials, from the atomic scale up, is essential to evaluate their performance limits and fundamentals of charge carrier dynamics.

EN09.10.20
On the Interpretation of AC Response Analysis in Metal Halide Perovskite Solar Cells

Rasha A. Awni, Zhaoning Song, Chongwen Li, Cong Chen, Xinxing Yin, Mohammed Razooqi, Xiaoming Wang and Yanfa Yan; The University of Toledo, United States

Perovskite solar cells (PSCs) have emerged as a very promising solar cell technology due to the rapid increase of the power conversion efficiency (PCE). Further improvement in the device efficiency is limited by understanding the device working mechanism that still under debate. Herein, we propose and demonstrate how the interfaces at perovskite/charge selective layer (CSL) play major role. We have employed capacitance/impedance based techniques to understand the AC response, combined with the application of DC potential, and its implications in charge re-distribution in an operating device upon relatively low temperatures. We show that the lateral interfaces can be identified directly through an accurate determining of the equivalent circuit model which fits the capacitance/impedance spectra perfectly at different conditions. Resistance and/or capacitance circuit elements are time independent that cannot describe the large capacitance at low frequencies. However, introducing a time dependent component is necessary to describe the observed transient current behavior that is responsible for the hysteresis in the current–voltage curves. We perform current–voltage and capacitance–frequency simulations to confirm the role of time dependent component. This study provides an important progress in characterizing the electronic and ionic defect properties of perovskite devices.

EN09.10.21
Low Defect Density in Tin-Based Perovskite Crystals for High-Performance Photodetector

Qishun Yao, Binghan Li, Zihao Zhu and Qixi Mi; ShanghaiTech, China

In an effort to explore lead-free perovskite semiconductors, we recently reported [1] all-inorganic CsSnBr3 to have excellent semiconducting properties and thermal stability that are comparable or superior to those of CH3NH3PbI3. However, tin-based perovskites are prone to oxidation and formation of defect states. In this work, CsSnBr3 crystals with shiny and crack-free surfaces were grown by the Bridgman method, and the CsSnBr3 crystal boules were cut and polished into plates. Hall measurements revealed p-type carrier concentrations of 10^{12}–10^{14} cm^{-3} and carrier mobilities around 2×10^{1} cm^{2} V^{-1} s^{-1}, indicating low defect densities in the CsSnBr3 crystals. We further fabricated a 1-mm-thick CsSnBr3 plate into a photodetector with the device structure Al / TQB / CsSnBr3 / Au, where TQB is an organic electron transport material. Without an external bias, the photodetector is responsive to the entire visible spectral range, reaching a peak quantum efficiency of 7% at 700 nm. [2] This functional CsSnBr3 photodetector clarifies undue concerns about bulk defects in this material, and suggests its broader applications in X-ray photodetectors, solar cells, and other optoelectronic devices.

Unraveling Charge Carrier Dynamics in Perovskite Solar Cells Using Bias-Dependent Time-Resolved
Photoluminescence Esma Ugur, Jafar I. Khan, Mingcong Wang, Erkan Aydin, Stefaan De Wolf and Frederic Laquai; King Abdullah University of Science and Technology, Saudi Arabia

Their unique optical and electronic properties make metal halide perovskites very attractive for photovoltaic and other optoelectronic applications. Meanwhile, the power conversion efficiency (PCE) of metal halide perovskite solar cells (PSCs) has reached more than 24%. Despite this impressive progress for solution-processed photovoltaic devices, performances of the PSCs are still limited by the open-circuit voltage (V_{oc}) and fill factor (FF) which are both controlled by the charge carrier dynamics. Thus, understanding the intrinsic limitations of these materials and the working mechanism of solar cells is vital to push the device efficiencies closer to the radiative Shockley-Queisser limit. Time-resolved optical spectroscopy of perovskite thin films and perovskite/charge transport layer interfaces allows identifying the photophysical processes in the absence of electric fields. On the other hand, bias-dependent photoluminescence on devices allows distinguishing between two competing processes: field-induced spatial charge separation and nonradiative charge recombination. Here, we study how the photoluminescence intensity and radiative decay in n-i-p PSC devices change when applying an external bias. We performed bias-dependent time-resolved photoluminescence (TR-PL) measurements at room-temperature in vacuo to reduce environmentally-induced and temperature-dependent photophysical changes during the PL measurements. We observe a gradual decrease of the PL intensity at V > V_{oc}. On the other hand, for V < V_{oc} no change of the PL is observed compared to the unbiased device. We will discuss how interface engineering using 2D perovskites with different cations alters charge carrier dynamics of PSCs under external bias.

Interplay of Symmetry, Phonons, Electronic States and Excitons in Low Dimension Perovskites and Nanostructures Jacky Even; INSA, France

The presentation will describe some of the recent experimental and theoretical results for various classes of layered halide perovskites. Basic symmetry analysis of their electronic states will be proposed introducing simplified layered structures and compared to the case of 3D bulk materials and colloidal quantum dots (QD). The exciton fine structure, electron-phonon interactions, quantum and dielectric confinement effects will be further analyzed. The presentation will address the ongoing debate about the nature of the exciton ground state in perovskite QD.

8:45 AM *EN09.11.03
Exciton Recombination and Annihilation in Pure-Phase Phenylethylammonium Based 2D-Layered Hybrid Perovskite Crystals Emmanuelle Deleporte1, Géraud Delport1, Gabriel Chehade1, Ferdinand Lédée1, Hiba Diab1, Gaëlle Trippé-Allard1, Jacky Even2, Jean-Sébastien Lauret1 and Damien Garrot3; 1ENS Paris-Saclay, France; 2INSA-Rennes, France; 3UVSQ, France

Over the past few years, organic-inorganic halide 3D perovskites were found to present remarkable optoelectronic properties. A great attention has been paid to perovskite thin films, as an ideal building block for PV and LED devices. On the other hand, the study of single crystals has proven necessary to unveil some of the intrinsic properties of these semiconductors [1,2]. While the 2D-layered perovskites, forming self-assembled natural quantum well structures where the perovskite layer is separated by large organic cations, have been known for decades, they are attracting growing interest, for their strong photoluminescence properties, their chemical versatility and their low sensitivity to external degradation mechanisms due to UV light and moisture. Due to the quantum and dielectric confinements, 2D-layered perovskites exhibit high oscillator strengths and robust excitons, making them particularly relevant for light-emitting devices, and in the past, several works have been done to demonstrate the strong coupling regime at room temperature between excitons and photon modes in vertical microcavities [3,4] or in the distributed feedback geometry [5], or between excitons and plasmons [6]. More recently, 2D perovskites have proved to be interesting also for photovoltaics with efficiencies around 15 % and a better stability than their 3D counterpart [7]. Nevertheless, many of the fundamental photophysics properties of these 2D-layered perovskites, in particular the recombination dynamics of the excitons, remain to understood.

Pure-phase monocrystalline thin films of Ruddlesden-Popper phenylethylammonium-based 2D-layered perovskites of formula (C_{6}H_{5}C_{2}H_{4}NH_{3})_{2}(CH_{3}NH_{3})_{n-1}Pb_{n}I_{3n+1} are produced using the “Anti-solvent Vapor assisted Capping Crystallization” method [8]. The exciton recombination dynamics of the phases n = 1, 2, 3, 4 is investigated using time-resolved micro-photoluminescence (PL) in a large range of power excitation. The PL dynamics is highly dependant of the fluence due to the competing effect of traps saturation and exciton-exciton annihilation. At low
fluence, emission mechanism is excitonic, dominated by defect-assisted recombination. At high fluence, the dynamics is dominated by exciton-exciton annihilation, the order of magnitude of the annihilation rate is evaluated.

Uniaxial Expansion of the 2D Ruddlesden-Popper Perovskite Family for Improved Environmental Stability
Ioannis Spanopoulos1, Ido Hadar1, Weijun Ke1, Qing Tu1, Michelle Chen1, Hsinhan Tsai2, Yihui He1, Gajendra Shekhawat1, Vinayak Dravid1, Michael Wasielewski2, Aditya D. Mohite3, Constantinos Stoumpos1 and Mercouri G. Kanatzidis1; 1Northwestern University, United States; 2Los Alamos National Laboratory, United States; 3Rice University, United States

The unique hybrid nature of 2D Ruddlesden-Popper (R-P) perovskites has bestowed upon them not only tunability of their electronic properties but also high-performance electronic devices with improved environmental stability as compared to their 3D analogs. However, there is limited information about their inherent heat, light and air stability, and how different parameters such the inorganic layer number and length of organic spacer molecule affect stability. To gain deeper understanding on the matter we have expanded the family of 2D R-P perovskites, by utilizing pentylamine (PA)$_2$(MA)$_{n-1}$PbnI$_{3n+1}$ (n = 1-6, PA = CH$_3$(CH$_2$)$_4$NH$_3^+$, C$_5$) and hexylamine (HA)$_2$(MA)$_{n-1}$PbnI$_{3n+1}$ (n = 1-4, HA = CH$_3$(CH$_2$)$_5$NH$_3^+$, C$_6$) as the organic spacer molecules between the inorganic slabs, creating two new series of layered materials in single crystal form, for up to n = 6 and 4 layers, respectively.[1] The increase in the length of the organic spacer molecules does not affect their optical properties, however it has a pronounced effect on the air, heat and light stability of the fabricated thin films. We fabricated films on various substrates, and performed extensive environmental stability tests, evaluating their air, heat and light stability, both with and without encapsulation. Multiparameter, invaluable information was extracted from these studies, which showed that for the same number of layers the PA based materials, exhibited improved heat, light and air stability (e.g. stable for 450 days in air), as compared to BA, HA and 3D analogues. Furthermore, we verified for the first time that hybrid halide perovskites are inherently heat and light stable in the absence of moisture, a most critical finding for their potential commercialization. Lastly, evaluation of the out of plane mechanical properties of the corresponding materials showed that their soft and flexible nature can be compared to the current commercially available polymer substrates (e.g. PMMA), rendering them suitable for fabricating flexible and wearable electronic devices, expanding their utilization beyond photovoltaic applications.

Using Nonlinear Absorption to Reveal Hidden Carrier Dynamics in Lead-Halide Perovskites
Thomas Winkler1;2, Sean Bourelle1, Angus Mathieson1 and Felix Deschler3;1, 2University of Cambridge, United Kingdom; 3University of Kassel, Germany; 1Technical University of Munich, Germany
While the stimulated emission of light was postulated by Albert Einstein over 100 years ago, its nonlinear counterpart has only been observed in a handful of experiments so far. We recently discovered that nonlinear coherent amplification of an ultraviolet femtosecond laser pulse can occur in a piece of optically excited sapphire [1]. The nonlinear, two-photon stimulated emission holds promises for laser technologies, microscopy and laser-spectroscopy as it is inherently nonlinear, providing temporal/spatial focusing and control over selection rules.

Here, we discuss our recent experimental efforts to expand the nonlinear stimulated emission from the ultraviolet into the infrared regime. To that extent, we utilize novel lead-halide layered (2D) and bulk (3D) metal-halide perovskite semiconductors, which demonstrated promising properties for photovoltaic and optoelectronic devices [2,3]. With band gap energies in the visible spectrum and long carrier lifetimes, they are an ideal sample system to explore two-photon stimulated emission in an ultrafast pump-probe experiment.

We will also discuss, how we utilize the special selection rules in nonlinear absorption and emission to reveal population and carrier dynamics of dark states in 2D and 3D perovskites. By performing ultrafast linear- and circular polarized pump-probe measurements in the single and two-photon regime, we resolve the dynamics of bright and dark states separately.

9:45 AM EN09.11.06 Complexities of Contact Potential Difference Measurements on Metal Halide Perovskite Surfaces Fengyu Zhang1, Florian Ullrich2, Scott Silver1, Ross Kerner1, Barry P. Rand1 and Antoine Kahn1; 1Princeton University, United States; 2Technische Universitat Darmstadt, Germany

Understanding the electronic structure of metal halide perovskite (MHP) surfaces and interfaces is of considerable interest for the development of MHP based devices. A number of techniques, including ultraviolet and X-ray photoemission spectroscopy (UPS, XPS), contact potential difference (CPD) measurements, and Kelvin probe force microscopy (KPFM), have been applied to gather information on these surfaces and interfaces.[1-2] However, standard photoemission spectroscopy, such as UPS and XPS, only probes the top few nm of the film and cannot distinguish between flat bands and band bending occurring over several tens of nanometers. Furthermore, photoemission can induce non-equilibrium conditions of surface photovoltage (SPV) and unwanted band-flattening, providing distorted information on the equilibrium position of the Fermi level. Therefore, contactless, non-invasive, and non-destructive, Kelvin probe (KP) based CPD measurements serve as an important complementary technique to sort out some of these issues.[3] CPD measurements in the dark and under illumination (SPV measurements) provide valuable information on work function changes caused by the generation of electron-hole pairs near the surface/interface and on charging and discharging of surface/interface defect states upon illumination. Yet, CPD measurements can also be skewed and lead to erroneous results owing to changes in chemical composition and electronic structure of the surface under illumination.[4-5] Obtaining accurate SPV signals can therefore be challenging when working on perovskite surfaces, which are sensitive to, and degrade under, irradiation. Care must be taken to distinguish SPV signal and reversible band flattening as a result of photo-excitation, which occurs over short time scales (μs), from the long-term changes in surface work function due to surface reorganization or changes in stoichiometry (irreversible, or slowly reversible over hours), e.g., when the perovskite film surface undergoes degradation and decomposition during the CPD or SPV measurement. We present here a vacuum-based study[5] of the surface potential and response to illumination of two different types of perovskite films, methylammonium lead bromide (MAPbBr3) and the 2D Ruddlesden–Popper phase butylammonium lead iodide (BA2PbI4, n = 1), using KP-based CPD and SPV measurements. We show that supra-band gap illumination of both MAPbBr3 and BA2PbI4 leads to halide loss from the surface of the material, accompanied by a contamination-induced modification of the KP work function.[6] If undetected, this can lead to misinterpretations of the MHP surface potential. Repetitive calibration of the tip work function with HOPG is necessary to ensure reliable results. In contrast to MAPbBr3, BA2PbI4 exhibits a significant SPV corresponding to a partial flattening of an upward surface band bending. Our results illustrate the effectiveness of the Kelvin probe-based technique in providing complementary information on the energetics of perovskite surfaces and the necessity to monitor the work function of the probe to avoid erroneous conclusions when working on these materials.

Novel Low-Dimensional Tin and Antimony Halide Compounds and Their Unconventional Applications

Maksym V. Kovalenko1,2; 1ETH Zurich, Switzerland; 2Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The spatial localization of charge carriers to promote the formation of bound excitons and concomitantly enhance radiative recombination has long been a goal for luminescent semiconductors. Zero-dimensional materials structurally impose carrier localization and result in the formation of so-called self-trapped excitons. We present fully inorganic, perovskite-derived zero-dimensional SnII material Cs4SnBr6 and a general series of Cs4-xAxBr6-yIy (A=Rb, K; x≤1, y≤1) that exhibit room-temperature broadband photoluminescence centered with quantum yields (QYs) of 10-20 % [1]. The emission peak of these materials ranges from 500 nm to 620 nm. We also present the synthesis, the structure as well as electronic and optical properties of a family of hybrid one- and two-dimensional tin (II) bromide compounds comprising guanidinium [G, C(NH2)3+] and mixed cesium-guanidinium cations: G2SnBr4, CsGSnBr4, and Cs2GSn2Br7 [2]. G2SnBr4 has a one-dimensional structure that consists of chains of corner-shared [SnBr5]2- square pyramids and G cations situated in-between the chains. G2SnBr4 is a luminescent phase with a broad emission band resulting from trapped excitonic states. In addition, we will discuss similar antimony-based compounds [3], which benefit from higher chemical robustness as compared to 0D Sn halides.

We will also present several unconventional applications of such metal halide luminophores, which harness molecular-like, moderately fast and single exponential radiative recombination kinetics. In particular, we show that the strong temperature dependence of the photoluminescence of low-dimensional tin-halides is ideally suited for remote thermography and thermal imaging [4]. The lifetimes values can be varied over several orders of magnitude by adjusting the temperature (up to 20 ns °C-1) and the sensitive range spans up to one hundred centigrade, and is tunable from -100 to 110 degC going from [C(NH2)3]2SnBr4 to Cs4SnBr6 and (C4N2H14I)4SnI6. Through the implementation of cost-effective hardware for fluorescence lifetime imaging, based on time-of-flight technology, these thermoluminophores have been used to record thermographic videos with high spatial and thermal resolution.

Low-Dimensional Hybrid Perovskites Containing an Organic Cation with an Extended Conjugated System
Dirk J. Vanderzande1,2, Wouter Van Gompel1, Roald Herckens1, Laurence Lutsen2, Martijn Mertens1 and Paul-Henry Denis1; 1University of Hasselt, Belgium; 2imec, Belgium

Organic-inorganic hybrid perovskites allow for creating a wide variety of structures: from a 3D structure using small organic building blocks to essentially 2D layered structures using larger organic building blocks. This opens an avenue towards a quite new class of organic-inorganic nano-composites in which the inorganic perovskite sheet acts as a template for the self-assembly of organic chromophores confined between the sheets of the inorganic layer. Consequently, an organization can be obtained for the organic chromophores that resemble the order observed in a single crystal. The number of inorganic sheets can easily be tuned by changing the stoichiometry of the organic small and large building blocks. In this way, a fluent transition of electro-optical properties can be achieved of the inorganic part from confined 2D structures to strongly delocalized quasi-3D structures. We will discuss the structures obtained so far.

The use of carbazole ammonium salts in 2D hybrid perovskites leads to materials for solar cells with enhanced photoconductivity and stronger resistance toward moisture yielding solar cells with strongly enhanced stability compared to the 3D MAPI perovskite material [1].

Also, the use of pyrene ammonium salts to synthesize 2D hybrid perovskites has been explored and initial results on the structure and optoelectronic properties will be discussed. Transitions between 1D and 2D structures were observed by specific modification of the stoichiometry of the components and also in function of temperature [2]. In combination with the introduction of extra secondary interactions in the organic layer, a material is obtained with an exceptionally low bandgap. This was realized by intercalating strong electron acceptor molecules (e.g. TCNQ and TCNB) in the organic layer. The pyrene chromophore acting as a donor together with TCNQ leads to the formation of an organic charge transfer complex between the inorganic sheets [3, 4].

In more recent work we are exploring mono tethered oligo-thiophene ammonium salts as building blocks for low dimensional hybrid perovskites. In this way, a new group of truly organic-inorganic hybrid materials is disclosed with possibly new applications for thin film electronics.

11:30 AM EN09.11.10
Computational Design of Perovskites—The Case of Ba2AgIO6, a Low Band-Gap Solution Processable Oxide Double Perovskite
George Volonakis, Nobuya Sakai, Henry J. Snaith and Feliciano Giustino; University of Oxford, United Kingdom

Over the last seven years we have witnessed the rise of lead-halide perovskites for optoelectronic applications such as photovoltaics, sensors and light-emitting diodes. Well before that, oxide perovskites have been extensively investigated and are today pivotal in many technological applications. Yet, a rational connection between these two important classes of materials is missing. In this talk, we will employ a computational design strategy to explore this missing link and demonstrate that for each halide perovskite there are several lookalike oxide perovskites with similar optoelectronic properties. As a proof of concept, we will also report on the synthesis of Ba2AgIO6, the oxide
analog of Cs₂InAgCl₆.
We will begin by showcasing recent efforts towards new materials that do not contain Pb, for which computational
design approaches from first-principles have been extensively successful and revealed another class of compounds;
the so-called halide double perovskites. Five inorganic crystals have been since synthesized and characterized;
Cs₂Bi₄AgCl₆, Cs₂Bi₄AgBr₆, Cs₂Sb₄AgCl₆, Cs₂Sb₄AgBr₆, and Cs₂In₄AgCl₆. Among these, Cs₂Bi₄AgBr₆ has the narrower
indirect band gap of 1.9 eV, and Cs₂In₄AgCl₆ is the only direct band gap semiconductor, yet with a large gap of 3.3
eV. All of them exhibit low carrier effective masses and consequently, are prominent candidates for opto-electronic
applications such as photovoltaics, light-emitting devices, sensors, and photo-catalysts. We will outline the
computational design strategy that lead to the synthesis of these compounds, and particularly focus on the insights
we can get from first-principles calculations in order to facilitate the synthesis, improve their opto-electronic
properties and the in-silico identification of compounds with properties that are similar to the lead-halide
perovskites. This rational design approach allows us to further develop a universal analogy concept that can be used
to identify analogs between oxide and halide perovskites. This new concept of analogs led us to identify a new oxide
double perovskite semiconductor, Ba₂AgIO₆, which exhibits an electronic band structure remarkably similar to that
of our recently discovered halide double perovskite Cs₂AgInCl₆ but with a band gap in the visible range at 1.9 eV.
We report the successful synthesis of Ba₂AgIO₆ by solution processes and we perform crystallographic and optical
characterization. We show that Ba₂AgIO₆ and Cs₂AgInCl₆ are both analogs of the well-known transparent conductor
BaSnO₃, but the significantly lower band-gap of Ba₂AgIO₆ makes this new compound much more promising for
oxide-based optoelectronics and for novel monolithic halide/oxide devices.

Twin Domains in CH₃NH₃PbI₃ Thin Layers as a Strain Relaxation Mechanism—The Ferroelasticity of Halide
Perovskites Aicha Asma Medjahed1, Pia Dally2, Tao Zhou3, Noella Lemaitre2, Stephane Cros2, Solenn Breson2,
David Djurado1, Peter Reiss1 and Stephanie Pouget4; 1CEA Grenoble/IRIG/SyMMES, France; 2CEA-LITEN/DTS/SMPV/LMPO, France; 3ESRF, France; 4CEA-Grenoble/IRIG/MEM, France

Over the past ten years, a steep rise in the efficiency of metal halide perovskite solar cells has been observed. With
the technological giant leap comes an impressive number of synthetic routes that lead to crystalline thin films used
in devices. In the case of MAPbI₃ (MA = CH₃NH₃), using chlorinated precursors has attracted high interest as the
morphological, structural and electronic properties of the resulting layers are improved when using PbCl₂ as a lead
source. The absence of chlorine in the final perovskite layer has been explained by the large ionic radii difference
between chlorine and iodine, making alloy formation impossible. However, halide exchange between MAPbI₃ and
MAPbCl₃ has already been observed when exposing MAPbI₃ (MAPbCl₃) to a MACl (MAI) solution, without any
alloying and despite the large lattice parameter mismatch (6.275 Å and 5.66 Å for MAPbI₃ and MAPbCl₃
respectively, in the cubic phase).

Here, the structure and microstructure of MAPbI₃ thin layers synthesized from PbCl₂ and MAI precursors and
optimized for devices in terms of efficiency and aging are studied. X-ray diffraction (XRD) measurement at room
temperature on these layers surprisingly reveal the presence of MAPbCl₃ phase in the film and a double texturation
along [hh0] and [00l] MAIPI directions. By in-situ XRD study of the annealing process, we unravel the role of
MAPbCl₃ as a crystallization intermediate for MAPbI₃ thin film. Three stages are observed: for the first one,
MAPbCl₃ and MAPbI₃ coexist in the layer, the intensity of the former decreasing in favor of the latter, and the
MAPbI₃ cell being under an important and increasing compressive strain (up to 0.55%). The second stage is
characterized by the formation of PbI₂, MAPbI₃ degradation phase, as a mechanism to partially relax the strain.
During the last stage, MAPbCl₃ disappears and MAPbI₃ strain is suddenly released, with no further evolution of
degradation phase. When completely removing the chlorinated phase from the layer through careful annealing, PbI₂
cannot be avoided but the double texture is no longer observed at room temperature. This two-fold texture is the
signature of twin domains present in the MAPbI₃ crystallites. Considering the ferroelastic behavior of MAPbI₃
which supposes that the response to an external strain is a structural perturbation, the twin domains find their origin
in the strain caused by the coexistence of MAPbI₃ and MAPbCl₃ in the layer. To gain further insight into the
relation between the strain levels and the twin domains, we studied the behavior upon temperature of the two
population of crystallites in layers presenting different levels of strain.
In summary, we identified one crystallization path of MAPbI₃ thin layers through ionic exchange and we characterized the strain in the layer induced by this process. We report here the XRD signature of the ferroelastic character of MAPbI₃ that have been documented only by local probes so far. Through in-situ and temperature dependent measurements, we unraveled the direct correlation between strain and twin domains.

SESSION EN09.12: Defect Science, Ion Migration and Polarization
Session Chairs: Laurent Lombez and Omer Yaffe

Ion and Electron Conductivity in Hybrid Perovskites in Bulk and at Interfaces Joachim Maier; Max Planck Institute for Solid State Research, Germany

The measurement of ionic and electronic conductivities and their dependencies on the control parameters (stoichiometry, doping level, temperature) are discussed in terms of defect diagrams. The major stoichiometric parameter is the iodine partial pressure that has a significant influence on the properties. As far as the dopants are concerned, extrinsic (Na, oxygen) and native frozen defects are considered [1,2].

While these results show far-reaching similarities to typical oxide perovskites, the finding that under illumination not only the electronic but also the ionic conductivity is greatly enhanced, is surprising. The relevance of this effect on photo-degradation but also on photo-demixing in perovskite mixtures is set out [3].

In addition to bulk properties, interfacial effects are investigated in the light of mixed conductivity. It is shown that the space charge effects at MAPI/Al₂O₃ and MAPI/TiO₂ interfaces are determined by ionic excess charges rather than electronically dominated. Such phenomena are well studied in the case of mixed conductivity and ionically conducting solids (nanoionics) [4], but provide a paradigm change in understanding and probably also in designing relevant photoactive interfaces.

Ion Migration and Operational Stability of Perovskite Solar Cells Qing Zhao; Peking University, China

The large amount of ionic bonds in the perovskite and the distorted lattice structure make the material possess a large number of mobile ions, and the migration of these ions is considered to be the main cause of device instability. The effect of ionic transport on the physical properties of CH₃NH₃PbI₃ perovskite films was investigated by using an in-situ fluorescence imaging system under light and electric field. It was found that prolonged ion migration can cause irreversible changes in perovskites with a large number of defect states near the electrodes, indicated by quenched fluorescence. With higher humidity (> 30%RH), ion migration is enhanced, even lead to morphology change of the film. It indicates that water molecules facilitate the ion migration in perovskites, which may explain the moisture-related burn-in degradation in perovskite solar cells. To quantitatively study the ion migration in perovskites and the effect of composition, moisture and light, perovskites were tested under different light intensity and temperatures using a cryogenic system. The electronic conductivity and the ionic conductivity are extracted via Galvanostatic and IV scanning measurement. The temperature-dependent relationship of the conductivity is summarized and analyzed. Further, the electronic and ionic transport properties of the material can be obtained by using Arrenhenius equation fitting, e.g. energy level of defects, carrier scattering mode and activation energy of ion migration. The corresponding results are as follows: light and water molecules can reduce the activation energy of ion migration by several times, and the substitution of organic cations by inorganic cations (Cs⁺) can greatly inhibit ion migration, especially under light; we demonstrated a solution-processed CsPbI₃Br solar cell can exhibit tremendous improvement on long-term operational stability under continuous steady-state operation, showing 1500
h operational stability under continuous light illumination at MPP tracking. The excellent long-term stability of CsPbI2Br indicets the importance Cs+ in the inhibition of ion migration in perovskite solar cells.

Ion migration behavior in mixed cation hybrid perovskite film is systemically investigated. Phase segregation and ion migration is identified in CsFAMA system by a combination of in situ photoluminescence scan and Galvanostatic measurement. Near the anode/cathode side, visible PL red/blue shift can be observed under synergetic effect of light and electric field. The Phase segregation was found to be correlated with the halide migration in the film. To combine the high efficiency of CsFAMA and the high stability of inorganic CsPbX3, we put forward a new structure to construct a CsPbBr3-clusters passivated perovskite film. In this structure, CsPbBr3 forms as cluster, suppresses ion migration and passivates CsFAMA grains. CsFAMA films with 3% mol of CsPbBr3 additive demonstrate enhanced PL lifetime, decreased defect state density, larger activation energy of ion migration, and suppressed phase segregation. As a result, the passivated PSCs exhibit around 20% stabilized power conversion efficiency without ‘burn-in’ exponential decay, with a champion open circuit voltage of 1.2 V for 1.62 eV bandgap perovksite. Furthermore, the target device achieves significantly extended long-term operational stability by remaining 90% of the initial efficiency after 500 h continuous operation under maximum power point (MPP) and light illumination. More importantly, under both continuous full-sun illumination, MPP operation and thermal stress (65 °C), the passivated planar type PSCs using TiO2 as electron transport layer and Spiro-OMeTAD as hole transport layer demonstrate a 125 h device lifetime (T80).

Identifying Degradation Mechanisms at Oxide and Noble Metal Interfaces in Halide Perovskite Devices Ross Kerner1,2 and Barry P. Rand1; 1Princeton University, United States; 2National Renewable Energy Laboratory, United States

While an ITO/MAPbI3/Au or ITO/FAPbI3/Au device appears uncomplicated, the degradation mechanisms are non-trivial to fully elucidate. In this study, we identify defect mediated, thermal and voltage-induced degradation reactions between the acid salts methylammonium and formamidinium at the ITO/perovskite interface that are exacerbated by O2-plasma treatments relative to UV-ozone. Thermally induced reactions catalyzed by the perovskite/Au interface are also discussed. Moreover, we systematically deconstruct electrically stressed devices to characterize cathodic and anodic electrochemical reactions at both the ITO and Au electrodes within a voltage window of -1.5 to 1.5 V. For example, the acidic etching of ITO can be cathodically induced near room temperature influencing impurities, electronic properties, and stability. At the Au electrode, exceeding a threshold voltage can anodically oxidize iodide to produce a small amount of triiodide which serves as an excellent lixiviant to facilitate the dissolution of Au as AuI or [AuI2]- species, transport these species through the perovskite layer, and electroplate neutral Au at the cathode. Our results illustrate that, for a single device, a variety of degradation pathways are possible with the dominant mechanism highly dependent on the specific temperature and bias regime as well as detailing how device stability can be affected by processing, reverse bias, and bias history. Finally, we believe our observations and approach to be pedagogical for experimental design aiming to uncover degradation mechanisms in more highly engineered perovskite devices.

Equivalent Circuit Modeling of Hybrid Perovskite Interfaces and Implications for Device Physics Davide Moia1,2, Ilario Gelmetti3,4, Phil Calado1, Alessandro Senocrate2, Gee Yeong Kim2, Jenny Nelson1, Joachim Maier2 and Piers Barnes1; 1Imperial College London, United Kingdom; 2Max Planck Institute for Solid State Research, Germany; 3Universitat Rovira i Virgili, Spain; 4Institute of Chemical Research of Catalonia (ICIQ), Barcelona Institute of Science and Technology, Spain

Clarifying the connection between the mixed ionic-electronic conducting properties and the observed huge capacitive/inductive behavior and current-voltage hysteresis in hybrid perovskites based devices is critical to the advance of the field. Here, we discuss the observation that changes in electronic charge transfer processes, such as recombination, at interfaces of hybrid perovskite solar cells due to mobile ion redistribution can give rise to apparent capacitive behavior.[1,2] This capacitive effect differs from the chemical capacitance, which accounts for bulk polarization effects, and traditionally describes the capacitive behavior of mixed conductors.[3,4] It is also not simply associated with an accumulation or depletion of charges in the active layer, and cannot therefore be adequately described with a conventional capacitor. We identify the bipolar transistor as a most appropriate circuit element to reproduce analytically the observation of ionically-gated electron transfer at interfaces. We include transistors into an equivalent circuit model that couples ionic and electronic carrier dynamics[1]. We propose that
the huge capacitive and/or inductive behavior[5] observed for thin film perovskite solar cells is best described by electronic currents that are in fact an amplified version of the ionic current. The resulting model yields good fits to the experimental impedance spectra and can reproduce large perturbation transient measurements such as hysteretic current-voltage characteristics.[6] Since the model emphasizes the importance of ionic transport in the perovskite layer and of the space-charge behavior at interfaces in these devices, we perform an electrode material and thickness dependence analysis of perovskite devices. Our results help elucidating the space charge situation at perovskite/metal interfaces and clarify the relative contributions of chemical capacitance and of interfacial ionically-gated electronic charge transfer to the capacitive behavior of hybrid perovskite based devices.

**Suppressing Defects in Perovskites for Highly Efficient Tandem Solar Cells**

Kai Zhu; National Renewable Energy Laboratory, United States

Perovskite solar cells (PSCs) have become a competitive photovoltaic (PV) technology with rapid progress of efficiencies reaching above 24% for single-junction devices. The bandgap tunability through perovskite composition engineering is attractive for developing ultrahigh-efficiency tandem solar cells, including perovskite/perovskite, perovskite/silicon, or perovskite/thin-film absorber (e.g., CIGS). In this talk, I will discuss our recent progress on suppressing defects in perovskites covering both the wide-bandgap (~1.7–1.8 eV) and low-bandgap (~1.2–1.3 eV) perovskite compositions. For wide-bandgap PSCs, the challenge is to reduce the voltage deficit, which requires strategies for suppressing defect density. For low-bandgap PSCs based on Sn–Pb mixed perovskite films, key challenges lie at both the material and device levels. The high defect density associated with oxidation of Sn2+ to Sn4+ and formation of Sn vacancies significantly limits carrier lifetime and charge collection. I will discuss these challenges and show our recent progress on the general approaches to reduce defect density in perovskites for both low- and wide-bandgap perovskite films. The precursor chemistry and growth conditions affect significantly the physical and optoelectronic properties of perovskites. Applications of perovskite absorbers in highly efficient tandem devices will be discussed.

**Dependence of Resistive Switching Performance on Composition Engineering of One-Dimensional Imidazolium Lead Iodide**

Eun-Suk Choi, June-Mo Yang, Seul-Gi Kim, So-Yeon Kim and Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Demand for high-density memory semiconductors, which are essential to build large capacity for artificial intelligence and the Internet of Things, has been increasing day by day. PbI2 based resistive switching memories have been proposed as one of next generation memories because of low operating voltage, high on/off ratio and possibility of multi-level storage as nonvolatile memory. We report here resistive switching memory characteristics of imidazolium lead iodide depending on molar ratio of PbI2 to imidazolium iodide (ImI). It also proved experimentally and computationally to show the optimum performance for structural reason at any ratio composition. The stoichiometric composition results in hexagonal structure of (ImI)PbI3 which has molar ratio of PbI2:ImI = 1:1 analyzed by X-ray diffraction. The structure forms one-dimensional face-sharing [PbI3] chain.
Bipolar resistive switching characteristics having forming process are observed regardless of mixing ratio at low SET/RESET operating voltage of 0.2V and -0.2V, respectively. ON/OFF ratio is increased from $10^6$ to $10^9$ as ImI content is increased due to the increased HRS associated with pronounced insulating characteristics by ImI. Whereas, the stoichiometric (ImI)PbI$_3$ exhibits 5 times longer endurance ($10^3$) and one order of magnitude longer retention time ($10^4$ s) as compared to other compositions. Multilevel data storage also appeared by changing the compliance current. Conduction mechanism is investigated I-V measurement depending on temperature. Low resistance state (LRS) and high resistance state (HRS) are associated with Ohmic conduction and Schottky conduction, respectively. Density functional theory (DFT) calculation shows that defect formation energy of iodine vacancy is estimated to be low indicating that (ImI)PbI$_3$ has enough concentration of iodide vacancy for the filament formation and Further energy barrier calculations reveal that iodide migration preferentially occurs along 1-dimensional [234] crystallographic direction rather than interlayer [130] direction with lower energy. A good performance of (ImI)PbI$_3$-based memristor is thus related to the low defect formation energy of iodide vacancy and the preferential growth of the filament along 1-dimensional chain. These results suggest that (ImI)PbI$_3$-based memristor is potential candidate for next-generation memory application.

New, Lead-Free, Polar Oxynitride Semiconductors with Band Gaps Spanning the Visible Spectrum Steven T. Hartman, Arashdeep S. Thind and Rohan Mishra; Washington University in St. Louis, United States

Lead-halide perovskites have emerged as a new class of high-performance semiconductors with applications in solar cells, solid-state lighting, and photocatalysis. Some of their excellent properties, including high charge carrier mobility and defect-tolerance, can be attributed to the presence of the heavy-metal lead with Pb 6s$^2$ states at the band edge. However, lead-halide perovskites suffer from stability issues due to the generally weaker metal-halide bonds when compared to metal nitrides and oxides, which are more robust. On the other hand, metal oxides and nitrides typically have large band gaps that make them unattractive for solar energy harvesting and visible-light optoelectronics.

In this work, we will present new, stable quaternary oxynitrides, designed using first-principles density-functional-theory calculations, with predicted band gaps ranging from 1.6 to 3.3 eV, spanning the entire visible spectrum, that can act as alternatives to lead-halide perovskites. These semiconductors were predicted from a high-throughput computational search of the expansive $ABO_{3-x}N_x$ composition space, where A and B are inorganic cations, with B being a p-block metal with its s-states at either the valence or conduction band edge of the resulting compound. Several of these oxynitrides are on the convex hull of competing phases, indicating thermodynamic stability against decomposition, while others are slightly metastable. Their band structures feature a very disperse conduction band, similar to many transparent conducting oxides. The smaller electronegativity of nitrogen with respect to oxygen reduces the band gap substantially compared to oxides. In addition, some of these new compounds have a ferroelectric polarization as high as 16 μC/cm$^2$. The spontaneous polarization in such semiconductors can be expected to efficiently separate electrons and holes, leading to improved efficiency in solar cells.

The combination of a narrow, tunable band gap, high electron mobility, and ferroelectric polarization in one material would allow for several exciting applications. For example, the ferroelectric BiFeO$_3$ is known to show the bulk photovoltaic effect, but with poor power conversion efficiency and low current density due to a combination of wide band gap and low electron mobility. The new polar oxynitrides, presented here, are expected to overcome these challenges.

4:30 PM EN09.12.08
Ferroic-Ionic Effects on Photovoltaic Hybrid Organic-Inorganic Perovskites Yongtao Liu$^{1,2}$, Liam Collins$^3$, Anton V. Ievlev$^1$, Alex Belianinov$^1$, Stephen Jesse$^1$, Kai Xiao$^1$, Mahshid Ahmadi$^1$, Bin Hu$^2$, Sergei Kalinin$^1$ and Olga S. Ovchinnikova$^1$; 1Oak Ridge National Laboratory, United States; 2The University of Tennessee, Knoxville, United States

Despite the remarkable performance of hybrid organic-inorganic perovskites (HOIPs) in solar cell, light emission, and photodetector, it remains to require further advances in fundamental understandings of HOIPs photophysics. Recently, the discovery of ferroic twin domains in HOIPs has initiated contentious discussion on the ferroic nature of HOIPs. Given the interconnected nature of defect chemistry, ionic states, and ferroic properties, the effects of ferroic domains on the optoelectronic properties of HOIPs can no longer be ignored. Ferroelectric polarization— which has yet to be unambiguously established despite considerable effects to do so—is thought to facilitate the dissociation of photoinduced electron-hole pairs, benefitting photovoltaic action. Alternate to ferroelectricity,
ferroelasticity was also proposed in these materials. Here, we systematically studied the piezoelectric response of multiple CH$_3$NH$_3$PbI$_3$ thin films that exhibit twin domains and have different crystallographic planes parallel to the substrate. In doing so, we demonstrate that the piezoelectric contrast between twin domains along studied orientations is below 1 pm/V. Therefore, the ferroelectricity (if there is) along these orientations is < 1 pm/V. By applying electric biases, we find that the domain changes are governed by ion redistribution and structural deformation under electric biases. This indicates that the biases induced domain evolution in these materials is different from classical ferroelectric materials, where the ferroelectric polarization switching is the major driver. The ion redistribution and structural variation point to the potential effects of twin domains on solar cell operation. In addition, we for the first time reveal the photoluminescence (PL) variations in CH$_3$NH$_3$PbI$_3$ twin domains, indicating the different optoelectronic properties between domains. Density functional theory (DFT) simulation further indicates that the photogenerated electrons and holes show preferential distributions in the ferroelastic twin domains due to strain and chemical inhomogeneity between domains. In turn, this preferential charge distribution results in different lattice strain, alternating the behaviors of the ferroelastic twin domains in CH$_3$NH$_3$PbI$_3$. In-situ X-ray diffraction and band excitation piezoresponse force microscopy (BE-PFM) measurements present experimental evidence of the interaction between charge carriers and ferroelastic twin domains. This work provides an in-depth understanding of the effects of twin domains on optoelectronic properties of HOIPs, which are helpful for further improving the optoelectronic performance of HOIPs.

4:45 PM EN09.12.09
Giant Isotope Effect on Phonon Dispersion and Thermal Conductivity in Methylammonium Lead Iodide Perovskite Mahshid Ahmadi$^1$, Kunlun Hong$^2$, Panchao Yin$^2$, Songxue Chi$^3$, Yao Cai$^3$, Luke Daemen$^2$, Raphael Hermann$^2$, Hsin Wang$^2$, Andrew May$^2$, Mark Asta$^3$ and Michael Manley$^2$; 1University of Tennessee, United States; 2Oak Ridge National Laboratory, United States; 3University of California, Berkeley, United States

Organic-inorganic halide perovskites (OIHPs) are strong candidates for high-performance low-cost solar energy, light emission and detection applications$^{1,3}$. Despite extensive research, they remain far from well understood, particularly the role of phonons and organic molecule dynamics on the optoelectronic properties. It is known that there is a strong coupling between the dynamics of cation off-centering/orientation in the cage of octahedral and the inorganic framework tilting$^{4,5}$ but a full accounting of how this impacts thermal transport and the long-charge carrier lifetimes that help enable high power conversion efficiencies$^6$ is still elusive. A hot-phonon bottleneck effect has been shown to significantly extend the cooling time of hot charge carriers in OIHPs, which thermalize first through carrier-optic-phonon scattering, followed by optic phonon decay to acoustic phonons, and finally to the thermal conduction. To better understand the fundamental physics of these processes, it is informative to adjust the lattice dynamics independent of electronics by changing isotopes. In this work, we make use of the large 2:1 mass ratio of deuterium to hydrogen to alter the hydrogen-related dynamical modes of the organic molecules. Even though deuteration does not change the overall mass density of the lattice significantly, we find using neutron scattering that deuteration results in a large 20-50% softening in the longitudinal acoustic (LA) phonons near zone boundaries$^7$. This softening of the LA phonon occurs as the liberation modes of NH$_3$ and CH$_3$ soften and push down on the zone boundary LA phonons via mode anticrossing. This anticrossing behavior demonstrates that there is strong coupling between these hydrogen-controlled molecular modes and the LA phonons. The observed zone boundary softening of the LA phonons causes a significant fraction of the LA-phonon density of states to have a reduced group velocity$^8$ owing to a decrease in the propagation velocities of the LA phonons caused by the phonon softening. Finally, we use first-principles calculations to show that light- or X-ray-induced lattice expansions/distortions$^{11,12}$ associated with improved performance produce relatively small changes to these phonons, indicating that previous x-ray measurements$^3$ are not strongly biased by the probe and that these phonon properties are likely retained under operating conditions. Our findings highlight the importance of phonon-molecular mode interactions in organometallic halide perovskites and suggest a route to enhance hot-carrier properties by tuning the hot-phonon bottleneck.

EN09.13.01
Improvement in Printable Mesoscopic Perovskite Solar Cells via Thinner Spacer Layer
Qifei Wang¹² and Hongwei Han¹²; ¹Huazhong University of Science and Technology, China; ²Wuhan National Laboratory for Optoelectronics, China

In recent years, the perovskite solar cells (PSCs) based on printable triple mesoscopic structure develop rapidly showing a certified power conversion efficiency (PCE) of 15.6% for the lab-scale device, 10.4% for 100 cm² and an AM 1.5 sunlight stability of over 10000 h.

The mesoporous ZrO₂ (mp-ZrO₂) layer plays an important role in separating the mesoporous TiO₂ (mp-TiO₂) and the carbon layer, whose thickness closely relates to the open-circuit voltage (VOC) and PCE. However, thicker mp-ZrO₂ layer needs more perovskite solution to fill in and causes problems in the cost and reproducibility of devices.

To reduce the thickness of the mp-ZrO₂ layer, two directions can be taken into account. One is to select a more insulating material to replace ZrO₂. The other one is to modify the TiO₂ with proper materials to decrease the recombination between the TiO₂ and the carbon layer. Herein, we choose Al₂O₃ as a modification material on TiO₂. Through simple spraying pyrolysis method, a thin layer of Al₂O₃ is deposited on the surface of the TiO₂ layer. The insert of Al₂O₃ does not change the pore-filling situation or the crystallization of perovskite in the mesoporous scaffold, but accelerates the injection of electrons and reduces the recombination of light-induced carriers. For the thickness of ZrO₂ layer decreases with the help of Al₂O₃, the usage of solvent and PbI₂ is also reduced, which could protect the environment and are benefit for human's health. The modified TiO₂ makes the device both more cost-efficiently and environment-friendly. We support modifying TiO₂ with Al₂O₃ through spraying pyrolysis method improves the performance of devices in all aspects and reduces the usage of raw materials, which would make sense in the commercialization of printable mesoscopic PSCs.

EN09.13.02
Influence of Quantum Confinement and Charge Transport Layers on Hybrid Perovskite Carrier Dynamics through THz Emission Spectroscopy
Kyle Virgil, Jina Lee, Qin Yang, Griffin Mead, Geoffrey Blake and Harry A. Atwater; California Institute of Technology, United States

Designing hybrid perovskite optoelectronics which are simultaneously robust, scalable, and highly efficient relies on characterizing their intrinsic charge transport phenomena. We present investigations into picosecond carrier dynamics of sub-micron thick halide perovskite films in the terahertz (THz, or far-infrared) regime. Terahertz emission spectroscopy (TES) is employed to discern the influence of perovskite quantum confinement and electron/ hole transport layers on photocurrent generation. Notably, we observe THz emission from a range of 2D halide perovskites. Emission was observed down to “n=1” perovskite layer architectures like butylammonium lead iodide (BA₂PbI₄). These results suggest significant photo-Dember charge separation within 2D perovskite layers, brought upon by a difference in excited electron-hole mobilities. Using this response, we can interrogate carrier dynamics.
dynamics within the 2D perovskite planes and near interfaces with typical charge transport layers like PCBM, Spiro-OMeTAD, TiO2, etc. Comparing material parameters extracted from systematically varied THz emission spectra allows us to further analyze the relationship between photoexcited carrier transport and local perovskite environment. This work offers non-traditional insights to help guide the rapid development of perovskite solar cells, and strengthens our foundational knowledge of hybrid perovskite materials. Cohesively optimizing perovskite potential through diverse scientific frontiers is necessary to achieve the revolutionary energy technology of our future.

**EN09.13.03**

*Ultrafast Carrier Dynamics of Thin-Film Perovskite Solar Cells*  
*Exian Liu¹, Kanishka Kobbekaduwa¹, Pan P. Adhikari¹, Kai Zhu² and Jianbo Gao¹; ¹Clemson University, United States; ²National Renewable Energy Laboratory, United States*

Despite notable achievements of perovskite solar cells have been made for efficiency improvement by optimizing the device structure, and film morphology and structure, the fundamental photophysics of perovskite solar cell, especially the photoexcited carrier dynamic process including relaxation, transport, recombination, and trapping remains unclear. Most studies on solar cell physics were carried out with steady-state measurements, while its ultrafast carrier dynamics has not been demonstrated so far.  

Aim to elucidate ultrafast carrier dynamics *in-situ* solar cells with more than 20 % power conversion efficiency, in this talk, we present the carrier dynamics *in-situ* organic-inorganic halide perovskite solar cell using ultrafast photocurrent spectroscopy with sub-40 picosecond time. With comprehensive investigation on temperature-dependent, voltage-dependent and laser power-dependent photocurrent of this solar cell, we elucidate the photoexcited carrier relaxation and recombination process from sub-40 picosecond to microsecond. This study establishes the novel characterization approach for *in-situ* solar cells, in addition to addressing the fundamental desirable questions including carrier lifetime, mobility, trap density, and carrier transport mechanisms.

**EN09.13.04**

*Tailoring Structural Disorder and Crystal Orientation in 2D Perovskite Thin Films for High-Efficiency Optoelectronics*  
*Siraj Sidhik¹, Wenbin Li¹, Austin Fehr¹, Yafei Wang¹, Mercouri G. Kanatzidis², Jacky Even³, Jean-Christophe Blancon¹ and Aditya D. Mohite¹; ¹Rice University, United States; ²Northwestern University, United States; ³Univ. Rennes, France*

Two-dimensional (2D) halide perovskites are solution-processed hybrid organic-inorganic materials with unique structure and photo-physical properties, which has led to several proof-of-concept high efficiency optoelectronic devices such as photovoltaics and light emitting devices with technologically relevant stability. Despite several 2D perovskite crystals of different phase and composition have been synthetized, only a few have been successfully integrated into efficient and stable optoelectronic devices. The main challenges consist in both reducing the amount of structural disorder (i.e. a single 2D perovskite phase and high degree of orientation of the crystalline grains) and optimizing the 2D layer orientation for directional transport. More precisely, the designprinciples for controlling the phase purity, orientation and crystallinity of 2D perovskite thin film needs to be established. In this work, we propose a systematic approach to understand and control the phase purity, crystallinity and orientation of 2D perovskites of different phase (Ruddlesden-Popper, Dion-Jacobson and Alternating Cation) and varying perovskite thickness. Our approach consists in fabricating the thin films with different 2D perovskites using solvent engineering strategies, and subsequently performing correlated structural (GIWAXS) and physical (optical and electrical) characterization of the films to determine their degree of purity, orientation and crystallinity. Finally, we demonstrate proof-of-concept optoelectronic devices that validate these findings and pave the path for tuning the structure and properties of 2D perovskite thinfilms for low cost, high efficiency and stable devices.

**EN09.13.06**

*The Working Principle of Hybrid Perovskite Single Crystal Detector for Gamma-Ray Photon Counting*  
*Fangze Liu¹, Michael Yoho¹, Hsinhan Tsai¹, Kasun Fernando¹, Jeremy Tisdale¹, Shreetu Shrestha¹, Kevin Baldwin¹, Aditya D. Mohite², Sergei Tretiak¹,¹, Duc Vo¹ and Wanyi Nie¹; ¹Los Alamos National Laboratory, United States; ²Rice University, United States*

Gamma-ray spectroscopy that quantifies the gamma-ray energies is a critical technology used in many disciplines such as astrophysics, nuclear material detection and medical diagnosis. Recently, organic-inorganic lead halide
Optically Switchable Photoelectron Injection from Perovskite Nanorods for Wavelength-Distinguishable UV

Perovskite materials have received intense interest as solid state gamma ray detectors owing to their intrinsic properties such as high effective atomic number, low defect density and excellent transport property. Specifically, chlorine-doped methylammonium lead tribromide (MAPbBr$_3$-Cl) and methylammonium lead triiodide (MAPbI$_3$) single crystals have shown energy resolutions of about 10% for various gamma ray energies from 60 keV ($^{241}$Am) to 662 keV ($^{137}$Cs). [1, 2] While those demonstrations are highly promising, the device operational mechanism of the hybrid perovskite detectors are greatly under explored, and the electrical pulses generated from the gamma-ray photon are not well understood which are essential for further detector optimization and construction of gamma-ray spectra.

Here we report the working mechanism of solid-state gamma-ray detectors made from MAPbBr$_3$-Cl single crystals. Specifically, we build devices with high or low work function contacts that collect only p-type (holes) or n-type carriers (electrons). Detailed device characteristics reveal that the main source of the dark noise in MAPbBr$_3$-Cl crystals originates from the thermally injected electrons from the impurity to the conduction band edge. As a result, only p-type device can observe clear gamma-ray induced electrical pulses from several radioactive sources with different amplitudes that correspond to gamma-ray photons at various energies. In addition, we discover the unusually long rise time (100 micron second) of pulses at room temperature can be greatly reduced at lower temperature. This suggests the long rise time arises from the slow structural dynamics under bias, such as interfacial ion migration. Our study reveals the operational mechanism and paves the way for material optimizations to improve the performance of hybrid perovskite-based gamma-ray detector.

Optically Switchable Photoelectron Injection from Perovskite Nanorods for Wavelength-Distinguishable UV Photodetector

Ultraviolet (UV) radiation has given rise to high-speed, wide-coverage and non-line-of-sight wireless optical communications due to its small susceptibility to solar background interference and flexibility of transmitter/receiver orientations such as pointing, acquisition and tracking. For a wireless UV communication, function generator produces pattern-controlled electrical signals that contain characteristic information on the intensity and on-off frequency of UV lights, which are emitted by transmitter and subsequently detected by receiver to realize the relay of information. Moreover, UV radiations with different wavelengths are employed in communication systems so as to enable bidirectional and high-capacity optical transmission, where large distinction between UV wavelengths is demanded for minimized inter-channel interference. Therefore, developing a photodetector that can accurately identify UV intensity variation, while simultaneously distinguishing UV photons in different wavelengths is highly desirable for acquiring and decoding the information embedded in UV carriers. Owing to the suitable bandgaps and superior charge transport properties, lead halide perovskites (e.g. MAPbCl$_3$, CsPbCl$_3$, FAPbI$_3$) have realized high-performance UV photodetectors. Nonetheless, such photodetectors were never able to differentiate UV photons with different energies due to indiscriminate, unidirectional transport of photogenerated charge carriers in 1) prototypical p-in photodiode structures, 2) lateral photoconductor structures with external voltage biases, and 3) devices utilizing metal electrodes with much discrepant work functions for guided carrier migration. In addition, photodetectors need to be sufficiently sensitive to accurately detect UV photons with temporally varying flux based on superior photoelectronic properties (e.g. large free carrier density, high mobility), since optical information can also be ciphered in the oscillating intensities. As such, it is intriguing both at scientific and technological levels to develop UV photodetector that permits multidirectional carrier transport in perovskite materials with radically improved optoelectronic properties, so as to observe perturbed photocurrent responses and to eventually elucidate the energies and intensities of UV photons. Here, with the presence of LiCl additive in formamidinium chloride (FACl) solution, as-grown LiCl:FAPbCl nanorods demonstrated greatly enhanced crystallinity and UV photoresponse as compared to pristine FAPbCl nanostructures without LiCl additive. Most importantly, LiCl:FAPbCl nanorod film exhibits unprecedented distinguishability to UV lights with different energies and oscillating intensities, via unipolar/bipolar and periodically oscillating photocurrents. This work could advance the fundamental understanding of photoinduced...
carrier processes in halide perovskites and facilitate the development of novel UV-based optical communications.

EN09.13.08
Template Stripping of Perovskite Thin Films for Dry Interfacing and Surface Structuring

Alexander Hernandez Oendra, Eva De Leo, Stefan M. Koepfli, Jan Winkler, Aurelio Rossinelli, Andreas Riedinger, David J. Norris and Ferry Prins; ETH Zurich, Switzerland

Metal-organic halide perovskites, with the chemical formula CH$_3$NH$_3$PbX$_3$ (X = I, Br, Cl), benefit from unique material properties that include continuous band-gap tunability, high carrier mobility, low non-radiative carrier recombination rates, and simple deposition approaches.1-3 Thanks to these advantages, perovskite thin-film devices are promising candidates for photovoltaic and light-emitting technologies.4 To facilitate the integration of perovskite thin films into such optoelectronic device architectures, a need exist for simple and efficient fabrication methods. Here we present a template-stripping technique to produce ultra-flat and flexible perovskite thin films.5 Spin-coated CH$_3$NH$_3$PbBr$_3$ perovskite thin films can be mechanically cleaved from a silicon template using an epoxy adhesive to expose ultra-flat perovskite surfaces with root-mean-square roughness down to 2.7 nm. The flatness and flexibility of these films enable new processing strategies based on dry interfacing. To demonstrate this, we interface perovskite thin films with plasmonic hole arrays. Through the interaction of the perovskite film with surface plasmon polaritons at the perovskite-metal interface, we are able to obtain a six-fold enhancement of the outcoupling of the perovskite film’s emission in the out-of-plane direction. In addition, by using prepatterned silicon templates, we show that our template-stripping method can produce structured perovskite surfaces with micrometer-sized structures.

Based on these demonstrations, we envision that our template-stripping approach can be utilized for the straightforward integration of perovskite materials into optoelectronic devices.

Role of Temperature and Antisolvent in Rapid Single Crystal Growth Using Inverse Temperature Crystallization

Ramashanker Gupta$^{1,2}$, Tulja B. Korukonda$^3$, Shailendra K. Gupta$^3$, Bhanu P. Dharmiya$^3$, Priyanka Chhillar$^3$, Govind Gupta$^1$, Ritu Srivastava$^1$, Sandeep Pathak$^3$ and Vinay Gupta$^4$; $^1$CSIR-National Physical Laboratory, India; $^2$Academy of Scientific and Innovative Research, India; $^3$Indian Institute of Technology Delhi, India; $^4$Madsar Institute, United Arab Emirates

Perovskite (ABX$_3$) materials show remarkable solar cells power conversion efficiency (PCE) of ~22% in past years.1 The applications of perovskite material have spread into different areas such as optoelectronic devices, LEDs, Lasers, X-ray detectors.2 The perovskite detector based on single crystal have been mostly used single-crystal grown by inverse temperature crystallization method. Perovskite (ABX$_3$) material has demonstrated extraordinary optoelectronic properties in polycrystalline thin films as well as in single crystals. Among various method of methyl ammonium lead iodide (MAPbI$_3$) perovskite single crystal growth, the inverse temperature crystallization has been proven to be the best in terms of crystal growth and optoelectronic properties.

In this work, the mechanism of MAPbI$_3$ single crystal growth have been studied via changing the three parameters such as growth temperature, precursor composition and anti-solvent. After varying these parameters, we got success in growing a single crystal of 1 cm at room temperature (RT). The acetonitrile (ACN) which acts as an anti-solvent in the precursor solution influences the temperature of crystallization. Besides this, ACN is also improving the solubility of MAI in GBL solvent and its presence affect the growth of crystals. The optimized ACN concentration provides adequate nucleation density to form a crystal. The higher amount of ACN concentration is unfavourable for single crystal growth because it enhances the concentration of nucleation sites. In RT crystal nucleation the availability of active ions tenability is required, which is obtained by adding more ACN and increase the solution molarity (M). Further increase in ACN concentration leads to the formation of several nucleation sites, which retards the single crystal growth. By optimizing the ACN concentration and other parameters, we got a meta-saturation state which helped in the growth of single crystal at RT.
The crystal growth striations were observed at a higher temperature (HT). The striations were absent in the RT case. The variation in growth rate between the consecutive layers is the cause behind striation formation. The heat dissipated by the previous layer opposed the flow of ions, which helped in the formation of the consecutive layers. This phenomenon is also affected by the growth rate. Finally, conventional crystals were synthesized successfully at different temperatures ranging from high to room temperature. These RT crystals showed significantly similar structural and photophysical properties as compared to the crystals grown at higher temperatures.

Electronic Stability of Lead Halide Perovskites Studied via Time Resolved Microwave Conductivity Min Ji Hong and John G. Labram; Oregon State University, United States

Photovoltaic devices based on Lead Halide Perovskites (LHPs) have drawn significant attention due to their outstanding performance in optoelectronic devices. Despite being processable from solution at low temperature, perovskite solar cells have demonstrated certified power conversion efficiencies (PCE's) in excess of those of polycrystalline silicon. However, LHPs exhibit poor stability under ambient environmental conditions and hence restrict commercialization for a long-term use. As the material's electronic properties (mobility and carrier lifetime in particular) are directly related to the device performance, developing an extensive understanding of the stability of optoelectronic properties is crucial for future applications.

Several previous studies have investigated the stability of LHP based devices in air. However almost all studies of electronic properties are carried out via electronic devices, and hence include the implicit encapsulation electrodes and transport layers provide.

In this work, we present electronic properties of solution processed hybride halide perovskite thin films studied via Time Resolved Microwave Conductivity (TRMC) under two different conditions: (1) Extended exposure to elevated temperatures and (2) Extented exposure to ambient (air) conditions. TRMC is a technique enabling direct evaluation of a material's mobility without any contacts, and in the absence of interfacial effects. This study enables us to make unambiguous statements on material stability in these compounds, which could be highly informative for LHP-based optoelectronic applications.

EN09.13.11
Phase Engineering in 2D Ruddlesden–Popper Perovskite Solar Cells Shuang Yu1, Yajie Yan1, Kaibo Zheng2 and Ziqi Liang1; 1Fudan University, China; 2Technical University of Denmark, Denmark

Recently, two-dimensional (2D) Ruddlesden–Popper (RP) perovskites have attracted broad attention for the excellent moisture resistance and tailorable composition.[1] However, compared with the 3D perovskite, the quantum confinement effect restrains interphase exciton splitting and charge transport owing to the incorporation of an insulating organic spacer layer. Meanwhile, randomly oriented 2D octahedral sheets inside thin film greatly hinder the charge carrier transfer along the vertical direction of the photovoltaic device. Phase engineering in 2D RP perovskites may offer a promising avenue to these obstacles.[2] Our recent studies have revealed that spontaneously generated 3D phases within 2D perovskite grain boundary not only promote the exciton splitting at the interface of 2D phases but also provide an additional channel for charge transport in device. These 3D phases can be introduced by two different approaches\(^\text{\textdagger}\): either the molecular design of organic spacer or the optimization of perovskite thin film processing.

Firstly, we employed the shorter branched isobutylamine (iso-BA) to replace linear n-butylamine (n-BA) and generate two aliphatic systems of \((n\text{-BA})_2(\text{MA})_3\text{Pb}_4\text{I}_{13}\) and \((\text{iso-BA})_2(\text{MA})_3\text{Pb}_4\text{I}_{13}\) 2D perovskites \((n = 4)\). It was found that the iso-BA 2D perovskite exhibit remarkably enhanced optical absorption and crystallinity along with preferably aligned orientation than n-BA analogue.[3] The resulting solar cells exhibit high PCEs of 10.63% and 8.82% with hot-casting and room-temperature processing, respectively. Transient transport studies establish the formation of 3D phases in iso-2D perovskite, which in turn accelerates charge/energy transfer and reduces charge accumulation caused by the unbalanced transfer rate, thereby significantly increasing the PCE.[4]
Second, among aromatic organic spacer based 2D perovskite system, we introduced S-bearing thiophene-2-ethylamine (TEA) to displace phenylethylamine (PEA). The intensive interaction between S and Pb atom not only stabilizes 2D inorganic lattices but also disrupts their long-range ordering which distorts the lattices and creates the nucleation sites for the formation of 3D phases. As a result, the best cell based on (TEA)2(MA)3Pb4I13 yield a prominent stable PCE of 11.2% without any photocurrent hysteresis. Importantly, the unencapsulated device display excellent ambient stability by preserving 80% efficiency after 270 h storage in air with 60 ± 5% relative humidity at 25 °C.

Third, by utilization of NH4Cl additive and DMSO solvent, we demonstrate their favorable synergistic effects on 2D (PEA)2(MA)3Pb4I13 perovskites fabricated at room temperature, which enable to passivate trap states within 3D phase (NH4Cl) and promote the 2D/3D inter-phase charge transfer (DMSO). The optimal cell delivers an impressive PCE (n = 4) of 13.41% with eliminated hysteresis. These findings highlight the importance of 3D phase engineering to modulate the charge carrier dynamics and improve optoelectronic properties of 2D RP perovskites, which offer an effective approach toward commercialized perovskite solar cells with high efficiency and excellent stability.

Improvement of Film Quality of Solvent-Supported EDTA-Blended SnO2 Based Planar Perovskite Solar Cell in Low Temperature Process Jihyun Kim, Hye Ri Jung, Bich Phuong Nguyen, Yeon Soo Kim and William Jo; Ewha Womans University, Korea (the Republic of)

In recent years, SnO2, which is an electron-selective layer (ESL) of a planar-type perovskite solar cell (PSC), has attracted attention as a promising substance. While SnO2 has many advantages, SnO2 films contain surface defects that can degrade electronic properties by trapping charge carriers. Herein, we fabricate n-i-p planar-type PSCs with ethylene diamine tetraacetic acid (EDTA)-blended SnO2 (E-SnO2) ESL and investigate the effect of selecting a mixture of solvent, on the solar-cell performance is discussed. We gain better crystallinity, uniform morphologies, higher carrier mobility and enhanced interfacial quality of PSCs with solvent-mixed E-SnO2 ESL compared to traditional SnO2 ESL. The electrical properties of PSCs based on solvent-mixed E-SnO2 ESL using Kelvin probe force microscopy (KPFM) and a conductive atomic force microscope (c-AFM) are examined and the work function and local current of the surface are measured. We also investigate the potential distribution of the cross-sectional area of PSCs. By using KPFM, we can compare the band structure and explain the carrier transport mechanism between the solvent-mixed E-SnO2 ESL and the PSC interface. These photovoltaic performances, optical and electronical properties offer the potential to improve device operation by optimizing solvent-mixed E-SnO2 ESL quality.

EN09.13.13
Preparation of Halide-Dependent Perovskite Heterostructure for Advanced Interface with Exfoliated MoS2 and WS2 Hye Ri Jung and William Jo; Ewha Womans University, Korea (the Republic of)

Heterostructure consist of organolead halide perovskite and 2D transition metal dichalcogenides (TMDs) was reported to exploit as a high-performance photodetector and a stable perovskite solar cell. TMDs assisted the effective carrier transfer in the interfaces with its high charge mobility and facilitated well aligned band structure for providing the advanced device design. In that point, fabrication and investigation of the charge transport mechanism and the band alignment in various heterostructures is significant for understanding the interfacial properties between the halide-dependent perovskites and TMDs. We fabricated the heterostructure with exfoliated MoS2 and WS2 with organolead lead halide perovskites, and conductive atomic force microscopy was used thereafter to display the electrical contacts of the heterostructure. Photocurrent also enhanced in the heterostructures by enhanced charge
transport in the interface. Furthermore, Kelvin probe force microscopy was conducted to demonstrate the band alignment in the different type of heterojunction. We propose the efficient heterostructure from the charge transport mechanism and the band structure in the various junctions depending on the halide-dependent perovskites and TMDs.

EN09.13.14
CVD Patterning of Lead Iodide Thin Film and Hybrid Perovskite Conversion Geemin Kim, Sol An, Myungwoong Kim and Naechul Shin; Inha University, Korea (the Republic of)

Organic-inorganic hybrid perovskites (OIHPs), i.e., such as methylammonium lead iodide perovskites (CH$_3$NH$_3$PbI$_3$) have demonstrated distinguished optoelectronic properties for a variety of applications including photovoltaics (PV), light emitting diodes (LED), and photodetectors, etc. To this end, solution-based crystallization of OIHPs has been widely employed to prepare perovskite thin films desired for the device fabrication process. Attracted interests due to their enormous potential in photovoltaics (PV) application, such as Solar cell, light emitting diodes (LED), and photodetectors. Most applications are based on the polycrystalline thin film which synthesized via dissolution & recrystallization in organic solvent. However, it has limitations such as irregular morphologies with randomly oriented grains, which cause large grain boundaries which deteriorate carrier lifetime and diffusion length. Despite the versatility of solution-based synthesis, however, the as-prepared perovskite films exhibit relatively irregular surface roughness implying the existence of randomly-oriented crystal domains and large density of grain boundaries, which ultimately reduce the device performance and lifetime. Moreover, the device fabrication based on the typical “top-down” lithography remains difficult to apply due to the general instability of OIHPs to the solvents involved in the process. However, it has limitations such as irregular morphologies with randomly oriented grains, which cause large grain boundaries which deteriorate carrier lifetime and diffusion length.

In this study, we report the CVD patterning of lead iodide (PbI$_2$) thin films on a micro-scale pre-patterned Si substrate by P(NBOC-r-GMA) polymer, followed by conversion into CH$_3$NH$_3$PbI$_3$ using methylammonium iodide (CH$_3$NH$_3$I) vapor. Detailed analysis of PbI$_2$ film growth on the polymer patterns suggests that the surface energy difference between polymer and Si promotes the selective deposition of PbI$_2$ precursor onto hydrophilic Si surface with a uniform thickness of about 100 nm. We observe the formation of [0001]-oriented PbI$_2$ nanoplatelets are preferred on Si surface, and the selectivity and surface coverage of patterned PbI$_2$ thin films can be controlled via modulation of growth temperature. The patterned PbI$_2$ films maintain their morphology after perovskite conversion by virtue of vapor-solid intercalation. We also demonstrate photodetector arrays based on the patterned CH$_3$NH$_3$PbI$_3$ crystalline thin films and confirm the potential for the various optoelectronic applications. Our results highlight the advantage of CVD patterning of perovskite materials in large scale production for various optoelectronic applications.

EN09.13.15
Spatially Extended Gap States Induced Up-Conversion Photoluminescence Xixiang Zhu$^1$, Hengxing Xu$^1$, Yongtao Liu$^{1,2}$, Jia Zhang$^1$, Miaoqang Wang$^1$, Ilia Ivanov$^1$, Olga S. Ovchinnikova$^1$ and Bin Hu$^1$; $^1$University of Tennessee, United States; $^2$Oak Ridge National Laboratory, United States

Quasi-2D Ruddlesden-Popper perovskites have demonstrated interesting optical properties in down-conversion regime. In our work, we found the infrared-to-visible up-conversion photoluminescence (PL) peaked at 521 nm occurring in quasi-2D perovskite [(PEA)$_n$(MA)$_{4-n}$Pb$_5$Br$_{16}$ with n = 5] films by using infrared CW 980 nm laser beam to excite the gap states at room temperature. With increasing the CW laser intensity, the up-conversion PL intensity is almost quadratically increased with the power dependence factor of 1.7. This presents an evidence to show that the up-conversion PL is essentially a two-photon process occurring through the gap states. Furthermore, the two-photon up-conversion PL shows a strong dependence of n value in the 2D perovskites. As lowering the n value, the up-conversion PL signal is dramatically decreased, becoming negligible when the n value is lower than 3. Simultaneously, the gap states are non-detectable in optical absorption when n < 3. This verifies that the gap states are indeed responsible for generating the two-photon up-conversion PL. Moreover, it was found that the two-photon up-conversion PL shows an appreciable dependence of magnetic field through spin mixing mechanism. This provides direct evidence that the gap states are essentially spatially extended states to enhance two-photon up-conversion PL in 2D perovskites.

EN09.13.16
Surface Passivation, Thermal Stability and Temperature-Dependent Photoluminescence of CH$_3$NH$_3$PbI$_3$ and
**Double Perovskite Cs₂AgBiBr₆ Nanocrystals**

Yangning Zhang, Cherrelle J. Thomas and Brian A. Korgel; University of Texas at Austin, United States

CH₃NH₃PbI₃ (MAPI) nanocrystals with tetragonal crystal structure and cuboidal shape terminated by (110) and (002) facets and double perovskite Cs₂AgBiBr₆ nanocrystals with cubic double perovskite crystal structure and cuboidal shape terminated by {001} facets were synthesized. Oleylamine and oleic acid are used in the synthesis of both nanocrystals and their interactions with the nanocrystal surfaces were studied and compared using ¹H nuclear magnetic resonance (¹H NMR) spectroscopy and nuclear Overhauser effect (NOESY) spectroscopy. Oleylamine and oleic acid both cap the MAPI nanocrystals, while only oleylamine bonds to Cs₂AgBiBr₆. In the synthesis of Cs₂AgBiBr₆ nanocrystals, oleic acid promotes the ionic metathesis reaction, but does not serve as a capping ligand. It could be substituted with diisoctylphosphinic acid to produce nanocrystals with similar size, cuboidal shape, uniformity, cubic double perovskite crystal structure, and optical properties. Superlattices of MAPI and Cs₂AgBiBr₆ nanocrystals were assembled and studied with grazing incidence small- and wide-angle X-ray scattering (GISAXS and GIWAXS) with *in situ* heating. MAPI nanocrystals undergo a tetragonal-to-cubic phase transition at 55-60°C similar to bulk films and begin to degrade at 90°C, when PbI₂ begins to form. Both hexagonal and rhombohedral phases of PbI₂ are observed as thermal degradation products. *In situ* photoluminescence (PL) shows that the emission energy increases with increasing temperature and decreases in intensity. In contrast, the PL peak wavelength of Cs₂AgBiBr₆ nanocrystals does not change with increasing temperature. Also, GISAXS and GIWAXS showed that Cs₂AgBiBr₆ nanocrystals are more stable, up to 250°C. At this temperature, the nanocrystals sinter, but the Cs₂AgBiBr₆ crystal orientation remains the same on the substrate.

**EN09.13.17**

*Revealing the Origin of Luminescence Center in 0D Cs₄PbBr₆ Perovskite* Zhaojun Qin¹,², Shenyu Dai³,², Viktor G. Hadjiev²,², Chong Wang⁶,², Lingxi Ouyang⁴,², Lixin Xie²,², Yizhou Ni²,², Chunzheng Wu¹,², Guang Yang²,², Shuo Chen²,², Liangzi Deng²,², Qingkai Yu¹, C. W. Chu²,²,⁶, Guoying Feng¹ and Jiming Bao²,²; ¹University of Electronic Science and Technology of China, China; ²University of Houston, United States; ³Sichuan University, China; ⁴Yunnan University, China; ⁵Texas State University, United States; ⁶Lawrence Berkeley National Laboratory, United States

As a zero-dimensional all-inorganic perovskite with excellent optical properties, Cs₄PbBr₆ has attracted considerable attention as well as intensive debates, especially two opposing mechanisms of its highly efficient green photoluminescence (PL): embedded CsPbBr₃ nanocrystals versus intrinsic Br vacancy states. Here, we provide sensitive but noninvasive methods that can identify CsPbBr₃ nanocrystal inclusions in Cs₄PbBr₆ as dominant green PL source in this compound. We first synthesized both green PL emissive and non-emissive Cs₄PbBr₆, obtained the complete Raman spectrum of Cs₄PbBr₆ and assigned all Raman bands based on density functional theory simulations. We then used correlated Raman-PL as a passive structure-property method to identify the difference between emissive and non-emissive Cs₄PbBr₆ and revealed the existence of CsPbBr₃ nanocrystals in emissive Cs₄PbBr₆. Finally, we used molecular dynamics simulations based on density functional theory. The resolution of this long-lasting controversy paves the way for device applications of low-dimensional perovskites, and our comprehensive optical technique integrating structure-property with dynamic response can be applied to other materials to understand their luminescence centers.

**EN09.13.18**

*Impact of Nuclear Disorder on the Urbach Energy in Halide Perovskites* Christian Gehrmann and David Egger; Technische Universität München, Germany

Halide perovskites (HaPs) are intriguing optoelectronic materials and promising candidates for efficient solar-cell devices. In particular, HaPs exhibit small Urbach energies and sharp optical absorption edges allowing for efficient collection of sunlight in thin-film photovoltaic devices. On the other hand, HaPs also exhibit complex nuclear dynamics and structural effects, including anharmonicity and disorder, which is unusual for efficient optoelectronic materials. Moreover, since small Urbach energies indicate a low amount of disorder, the aforementioned optoelectronic properties are difficult to rationalize. Using first-principles methods, we study the disorder potential induced for electronic states in various paradigmatic HaPs. To account for the complex nuclear motions at elevated temperatures, we used molecular dynamics simulations based on density functional theory. With this approach, we take into account anharmonicity in the lattice dynamics to all orders in the Taylor expansion of the crystal potential. We find that correlations in the disorder potential are dynamically confined to atomic distances, and that the massive
nuclear motions of A-site and X-site ions dynamically shortens them. This length-scale of the correlations in the disorder is similar to the one reported for usual inorganic semiconductors, and we show that the dynamic shortening of the disorder leads to favorable distributions of band edge energies. We conclude that sharp optical absorption edges and small Urbach energies, which are highly desired properties of any solar absorber material, are enabled by this dynamic mechanism.

EN09.13.19
Self-Patterned CsPbBr₃ Nanocrystals for High-Performance Optoelectronics Bin Xin and Iman Roqan; King Abdullah University of Science and Technology, Saudi Arabia

All-inorganic lead halide perovskites are promising materials for many optoelectronic applications. However, two issues that arise during device fabrication hinder their practical use, namely inadequate continuity of coated inorganic perovskite films across large areas and inability to integrate these films with traditional photolithography due to poor adhesion to wafers. Herein, for the first time, to address these issues, we show a room-temperature synthesis process employed to produce of CsPbBr₃ perovskite nanocrystals with two-dimensional (2D) nanosheet features. Due to the unique properties of these 2D nanocrystals, including the “self-assembly” characteristic, and “double solvent evaporation induced self-patterning” strategy are used to generate high-quality patterned thin films in selected areas automatically after-drop-casting, enabling fabrication of high-performance devices without using complex and expensive fabrication processing techniques. The films are free from micron size cracks. In a proof-of-concept experiment, photodetector arrays are used to demonstrate the superior properties of such films. We provide evidence of both high responsivity (9.04 A/W) and high stability across large areas. The photodetectors fabricated on flexible substrate exhibit outstanding photo-response stability. Advanced optical and structural studies reveal the possible mechanism. Our simple and cost-effective method paves the way for the next-generation nanotechnology based on high-performance, cost-effective optoelectronic devices.

EN09.13.20
First-Principles Theory Investigation on Structural and Photoelectronic Properties of Formamidinium Lead Halide Perovskites Yang Zhao; Huazhong University of Science & Technology, China

Formamidinium lead halide perovskites have attracted wide attention as photoelectronic conversion materials due to the high photoelectronic conversion efficiency (PCE), low cost and simple synthetic process. The structural, electronic and optical properties of mixed formamidinium lead halide perovskites FAPbIₓClₓ₋ₓ (FA = NH₂CH=NH₂⁺, x = 0 ~ 3) have been investigated by the first-principles theory. Our results show that FA cations lie along [001] direction in the trigonal FAPbX₃ (X = Cl, Br, I). However, the direction is slightly shifted owing to the distortion of PbX₆ (X = Cl, I) octahedrons in the mixed FAPbIₓClₓ₋ₓ. The Pb—I bond distances (0.315 ~ 0.334 nm) are larger than Pb—Cl bond distances (0.282 ~ 0.302 nm). With the increase of I/Cl ratio, the lattice parameters and volumes of FAPbIₓClₓ₋ₓ increase. The FA cations play a crucial role in balancing the crystal structure, but they do not participate into the process of frontier orbital transition directly. They just play the role of charge donors to contribute ca. 0.76 e to PbI₃ framework. FAPbIₓClₓ₋ₓ are direct band-gap semiconductors, with the direct bandgap nature at Z (0, 0, 0.5) symmetry point. The valence band maximum (VBM) is composed of antibonding orbitals of I 5p (Cl 3p) and a few Pb 6s orbitals, and the conduction band minimum (CBM) is composed of Pb 6p orbital. There exists a combined covalent and ionic bonding mechanism between Pb and I (Cl) ions. As the I/Cl ratio increases, the band gaps decrease and the absorption spectra are red shifted. FAPbI₃ has an ideal band gap of 1.53 eV. It exhibits the superior absorption spectrum especially in the range of 300 nm to 500 nm, which elucidates that FAPbI₃ has great potential as the photoelectronic conversion material. Our results could provide theoretical guidance for the experimental design and synthesis of perovskite solar cells.

EN09.13.22
Investigation of Electrode Electrochemical Reactions in CH₃NH₃PbBr₃ Perovskite Single-Crystal Field-Effect Transistors Junzhan Wang; University of Cambridge, United Kingdom

Optoelectronic devices based on metal halide perovskites, including solar cells and light-emitting diodes, have attracted tremendous research attention globally in the last decade. Due to their potential to achieve high carrier
mobilities, organic-inorganic hybrid perovskite materials can enable high-performance, solution-processed field-effect transistors (FETs) for next-generation, low-cost, flexible electronic circuits and displays. However, the performance of perovskite FETs is hampered predominantly by device instabilities, whose origin remains poorly understood. Here, perovskite single crystal FETs based on methylammonium lead bromide are studied and device instabilities due to electrochemical reactions at the interface between the perovskite and gold source-drain top contacts are investigated. Despite forming the contacts by a gentle, soft lamination method, evidence is found that even at such “ideal” interfaces, a defective, intermixed layer is formed at the interface upon biasing of the device. Using a bottom-contact, bottom-gate architecture, it is shown that it is possible to minimize such a reaction through a chemical modification of the electrodes, and this enables fabrication of perovskite single crystal FETs with high mobility of up to ≈15 cm² V⁻¹ s⁻¹ at 80 K. This work addresses one of the key challenges toward the realization of high-performance solution-processed perovskite FETs.

EN09.13.23
Raman Scattering Obtained from Laser Excitation of MAPbI₃ Single Crystal Hagit Aviv, Tal Ben Uliel and Yaakov R. Tischler; Bar-Ilan University, Israel

Finding renewable energy sources is of paramount importance to meet the increasing global energy demand whilst minimizing the impact on the environment. The research community has focused on solar energy as it is endlessly available, and have ranked the methylammonium lead iodide (MAPbI₃) as the most promising candidate amongst perovskite solar cells. Despite its high efficiency, the MAPbI₃ is sensitive to humidity, light, and temperature, its instability affects primarily on the crystalline structure and eventually leads to degradation. Three crystalline structures are known for this material, orthorhombic, tetragonal, and cubic which exist in different temperatures. Here we report on several processes detected from laser excitation of MAPbI₃ single crystal at ambient conditions. A phase transition from tetragonal to cubic phase was induced by excitation of over 15 mW laser power. The phases were characterized by LF-Raman and PL, taken simultaneously with the increase of exciting laser power and the spectral changes were assigned to the structural differences. In addition, Raman stimulation of iodine vapors signal was observed, those vapors were generated from the core of the focus wherein the highest temperature lead to degradation. The stimulated Raman phenomenon was enabled due to the unique properties of the MAPbI₃ single crystal and revealed viability to use this material for additional applications in other research fields.

EN09.13.24
Why Introducing MA⁺ Cations in Mixed Halide Perovskites Matters—An Atomistic Perspective Giuseppe Fisicaro, Antonino La Magna, Alessandra Alberti, Emanuele Smecca, Giovanni Mannino and Ioannis Deretzis; CNR Institute for Microelectronics and Microsystems, Italy

Mixed halide perovskites containing a compositional mixture of formamidinium (FA⁺) and methylammonium (MA⁺) ions are the actual standard for obtaining record-efficiency perovskite solar cells. Although the compositional tuning that brings to optimal performance of the devices has been largely established, little is understood on the role of even small quantities of the MA⁺ ions in boosting the efficiencies of primarily FA⁺-based hybrid perovskite solar cells. In this study, we use Car-Parrinello molecular dynamics in large supercells containing different ratios of FA⁺ and MA⁺ ions. Our analysis shows that the introduction of MA⁺ cations in the perovskite crystal reduces the orientational disorder of the FA⁺ cations and leads to a lowering of the vibrational intensity of the inorganic lattice. The charge asymmetry of the MA⁺ cation within the inorganic cage plays a key role for such ordering process, as it accelerates the reorganization of the organic molecules towards energetically more favorable configurations. Such structural/vibrational optimization facilitates the transport of the photogenerated carries and, in conjunction with the higher thermal stability of FA⁺-based perovskites, it should be at the origin of the enhanced photovoltaic properties of mixed FA⁺-MA⁺ perovskites.

Ovchinnikova², Sergei Kalinin² and Mahshid Ahmadi¹; ¹University of Tennessee, Knoxville, United States; ²Oak Ridge National Laboratory
Laboratory, United States

Electrochemical reactivity at the hybrid perovskite interfaces remains one of the most complex phenomena affecting their applications, both via stability of hybrid perovskite structures and via enabling novel functionalities such as sensing [1, 2]. However, exploration of these phenomena is severely limited by the intrinsic complexity of the hybrid perovskite electrochemistry [3, 4], presence of multiple mobile ionic species, and possible role of the environmental species at the triple-phase junctions [5]. Here we report the in-situ studies of electrochemistry of hybrid perovskite-metal interface via time- and voltage-resolved time of flight secondary ion mass spectrometry (ToF-SIMS) measurements of lateral perovskite heterostructures. ToF-SIMS data allows visualizing lateral chemical composition along the surface and its time evolution with light and bias. The machine learning workflow combining Hough transform and non-negative matrix factorization is developed to extract the salient features of associated chemical changes. These data are further compared to the time-resolved Kelvin Probe Force Microscopy measurements. Furthermore, the non-negative tensor decomposition is used to separate the time- and voltage-dynamics in the multidimensional data sets. Our in-situ characterizations provide a comprehensive information on the chemical nature of moving species, ion accumulation, and interfacial electrochemical reactions.

SESSION EN09.14: Emerging Properties and Frontier Phenomena of Halide Perovskites

Puzzling Perovskite Photoconductivity Dynamics Revealed by Scanned Probe Measurements of Electric Force Gradients, Dissipation and Impedance Spectra John A. Marohn1, Ali M. Tirmzi1, Ryan P. Dwyer1, Rachael Cohn1, Jeffrey A. Christians2, David T. Moore2, Fangyuan Jiang2, Jake Precht2, Rajiv Giridharagopal2 and David S. Ginger2; 1Cornell University, United States; 2National Renewable Energy Laboratory, United States; 3University of Washington, United States

We recently undertook a rigorous treatment of the interaction of a charged cantilever with an electrically conductive sample having significant sample impedance. The results were surprising. Starting from an electromechanical model of the cantilever-sample interaction, we used Lagrangian mechanics to derive coupled equations of motion for the cantilever position and charge [1]. Using this approach we derived equations describing the cantilever frequency shift and friction observed in Kelvin-probe and electric-force microscopy experiments. A key player in our theory is the transfer function describing the voltage drop across the tip-sample gap; this transfer function depends on the tip-sample capacitance and the complex sample impedance (i.e., sample capacitance and resistance). Our central new finding is that the cantilever frequency and dissipation measure the real and imaginary parts, respectively, of this transfer function. We show how scanned-probe, broadband local dielectric spectroscopy measurements enable us to characterize the local sample impedance. Our new treatment enables us to clearly understand, for the first time, how both sample capacitance and resistance contribute to the frequency shift and dissipation observed in electrical scanned-probe microscope experiments. We have used these insights to study light-induced conductivity and capacitance in a series of 3D perovskite [2,3] and 2D [4] perovskite and organic photovoltaic films as a function of time, temperature, and substrate. Many, though not all, of the perovskite samples show a conductivity which rises...
promptly upon illumination and recovers slowly in the dark. This recovery shows an activated temperature
dependence with a large activation consistent with ion or vacancy motion. These findings are generally consistent
with the Kim-Maier picture that light creates vacancies [5].

Excitonic Properties of Lead Halide Perovskites under Weak Magnetic Field—Implication of Strong Exciton-
Phonon Coupling Yasuhiro Yamada1, Hirofumi Mino1, Kenichi Oto1 and Yoshihiko Kanemitsu2; 1Chiba
University, Japan; 2Kyoto University, Japan

Lead halide perovskites APbX3 [A = Cs+, CH3NH3+ (MA+), and CH(NH2)2+; X = I−, Br−, and Cl−] have attracted
attention both from the viewpoint of fundamental physics and device applications such as solar cells and light-
emitting devices because of their unique optoelectronic properties. To clarify the origin of the advanced features of
this class of materials, we have so far studied the photoresponses of lead halide perovskite thin films, single crystals,
and perovskite-based devices, revealing unique carrier recombination dynamics.1-5) In addition, the recent researches
have suggested the polaron formation is the key mechanism for the unique nature of halide perovskites. However,
the impact of electron-phonon interaction on the band-edge optical properties are still under discussion.
Magneto-reflectance spectroscopy is one of the most powerful tools to derive the band-edge optical parameters of
semiconductors including exciton binding energy, reduced mass, effective dielectric constant, etc. However,
previous magneto-optical studies on lead halide perovskites have estimated the exciton binding energies by
employing extremely strong pulsed magnetic fields exceeding 100 T. This approach was difficult for the accurate
determination of exciton binding energy at zero magnetic field. Moreover, previous theoretical works have suggest
that special attention is needed for the excitonic properties under strong magnetic field in the case of strong exciton-
phonon interaction. Therefore, the measurements with high-quality crystals under weak magnetic fields are essential
for an accurate estimation.

In this work, we performed high-sensitivity measurements using circular dichroism of reflectance at low
temperatures (1.5 K) under relatively weak magnetic fields (< 7T), where the cyclotron energy is sufficiently small
compared with the LO phonon energy and exciton binding energy. We successfully observed the higher-order
exciton states (1s, 2s, and 3s) of a MAPbBr3 single crystal, which enabled us to determine exciton binding energy
accurately. The estimated exciton binding energy is much smaller than that of previous work under strong field. In
the presentation, we will discuss the discrepancy between the data of low- and strong magnetic field in conjunction
with the strong exciton-phonon interaction. Also, the results of different halide perovskites will be compared.

Part of this work was supported by JST-CREST (Grant No. JPMJCR16N3) and JSPS KAKENHI (19K03683).

Final Program 1/13/2020 941
Non-Radiative Recombination in Metal Halide Perovskites—Thin Films vs Bulk Crystals

Martin Ledinsky1, Ales Vlk1, Zdenek Remes1, Jan Valenta2, Tereza Schonfeldova1, Jakub Holovsky1,3, Zdenka Hajkova1, Lucie Landova1,3, Erkan Aydin4, Stefaan De Wolf4 and Antonin Fejfar1; 1Institute of Physics AS CR, Czechia; 2Charles University, Faculty of Mathematics and Physics, Czechia; 3Faculty of Electrical Engineering, Czech Technical University in Prague, Czechia; 4King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Metal-halide perovskites show many interesting properties important for its use in optoelectronic devices, such as solar cells. One of the prime characteristics is their very low deep defect density, leading to relatively low non-radiative losses. This is directly translates into a high density of photo-generated carriers in these films resulting in a very high open-circuit voltage ($V_{OC}$).1 However, although excellent power conversion efficiencies (PCEs) have been reported (>24%), the remaining $V_{OC}$ losses are an open challenge to maximize the PCE. To reveal the correlation between electronic quality and the perovskite solar cells we report here on a set of spectroscopic measurements.

First, we probed the temperature dependence of the absorption spectra of methylammonium lead iodide and bromide (CH$_3$NH$_3$PbI$_3$/Br$_3$), both for films and bulk crystals. We extracted the Urbach energy, $E_0$, as the reciprocal value of the slope of the absorption at the band edge, when plotted in a logarithmic scale. Its value depends on the material disorder and generally correlates well with the loss in $V_{OC}$ of optimized cells, compared to their bandgap.2,3 We found a strong decrease in $E_0$ upon cooling, accompanied by a slow decrease in their optical band gap energy. Values measured for films and bulk crystals were highly comparable, indicating bulk-like properties of perovskite films.

Next, from the theoretical $E_0$ temperature dependence, we obtained the average energy of electronically active phonon states to be about 100 cm$^{-1}$, which implicates that the dynamic disorder of halide perovskite films and single crystals is mainly caused by cage vibrations.4 We were able to calculate the density of active static defects in perovskites from the temperature dependence as well. Its value is very low for all characterized materials in comparison with other materials used for solar cells, including bulk monocrystal semiconductors like GaAs or crystalline silicon. Thin methylammonium lead iodide films doped by Cs and/or Rb reveal an even lower deep defect density, which is in agreement with the overall superior properties of finalized cell based on these materials.

Finally, we found a strong correlation between the $V_{OC}$ deficiency of finalized solar cells and $E_0$ measured by PL spectroscopy. We will show these results in combination with measurements of the quantum yield PL efficiency and correlate these with non-radiative $V_{OC}$ losses in the solar cell. These results will help to establish more practical efficiency limits of perovskite solar cells by taking into account the $E_0$, not only the Shockley-Queisser radiative based limit, which considers just the bandgap of active material.

Direct X-Ray Detection by Stable and Radiation Hard Perovskite Thin Films

Beatrice Fraboni1,2, Andrea Ciavatti1,2, Laura Basiricò1,2, Satyaprasad P. Senanayak1 and Henning Sirringhaus3; 1University of Bologna, Italy; 2INFN, Italy; 3University of Cambridge, United Kingdom
The demand for large area high-energy radiation detection systems combining high sensitivity and low-cost fabrication, has pushed the research in the last ten years to develop and design both novel materials and device geometries. Despite organic semiconductors have attracted a great attention, their low atomic number strongly limits the high-energy radiation absorption and, blending the organic solution with high Z nanoparticles is necessary to maximize their radiation absorption. Hybrid organic-inorganic perovskites have been recently proposed as alternative materials for X- and γ-photon direct detection, thanks to their high Z atoms, combined with high charge mobility.

In this work we report on thin film X-ray detectors made of solution processed Cesium-containing triple cation perovskite, namely Cs0.05(MA0.17FA0.78)Pb(I0.8Br0.2)3 (CsFAMA), where cesium (Cs) has added to mixed organic cations (methylammonium (MA) and formamidinium CH3(NH2)2 (FA)) and mixed halides (I and Br). We demonstrate how X-ray detectors based on solution processed CsFAMA film possess a high sensitivity, with values up to 80 µC mGy⁻¹ cm⁻³ in short-circuit conditions, and up to 380 µC Gy⁻¹ cm⁻² when operated under low (i.e. 4V) bias conditions: two orders of magnitude higher than previously reported perovskite thin films and comparable to perovskite single-crystal at 50V operating bias [1]. We performed radiation hardness tests and verified that the detectors are still properly working after receiving a total dose of 10 Gy in few minutes. Indeed, the combination of thin films and long carrier diffusion length allows in perovskites the efficient collection of photogenerated charges, even in presence of defects or radiation-induced traps, resulting in a higher radiation tolerance than thicker films and single crystals. Finally, we characterized perovskites thin films with enhanced stability in air. Remarkably, the electrical performance of the final detectors is still unaffected after 50 days of storage in air, with degradation of X-ray sensitivity limited to 15%.

In the light of the above discussed state-of-the-art, we reckon that thin film perovskite devices: i) surpass the state-of-the-art performance of inorganic large area detectors (a-Se and poly-CZT); ii) can overcome the scalability limitation of thick layers and single crystals; iii) allow to envisage battery-operated wearable detectors thanks to their low voltage operation. Our studies confirm the great potential of perovskite thin films devices (e.g. solar cells and X-ray detectors) for space application, where light-weight, large area, mechanical flexibility and radiation hardness are crucial features.

Revealing the Dynamics of Synthesis and Structure-Property Evolution of Hybrid Metal Halide Perovskites via Multi-Modal In Situ Probes Tze-Bin Song¹, Shambhavi Pratap², Nobumichi Tamura¹ and Carolin M. Sutter-Fella¹; ¹Lawrence Berkeley National Laboratory, United States; ²Technical University of Munich, Germany

The field of metal halide perovskites is moving towards more and more complex compositions enabling improved device performance and stability. Most of the improvements however, were achieved through empirical optimization of processing conditions. Fast and complex chemical reactions lead to significant variations in material properties. Precise control over device performance requires a better understanding and active control over synthetic parameters, thus in situ monitoring of evolving properties can help identify synthesis and structure-property relationships.

We study metal halide perovskite synthesis via multi-modal in situ characterization combining synchrotron diffraction, photoluminescence, infrared and optical imaging to shed light on evolving material properties. Using this approach, we are able to identify different formation paths determined by the nature of the chemical precursor, including the precursor phase transition to perovskite phase and direct perovskite formation from molecular building blocks. Moreover, we find that final film morphology is determined in the first seconds of annealing and can be related to crystalline precursor phases. This new multi-modal platform enables simultaneous optical as well as structural characterization already during spin coat deposition of multicomponent precursors and antisolvents, thus allows new insights into the complex dynamics related to perovskite formation.

Anharmonic Semiconductors—Lessons Learned from Halide Perovskites Omer Yaffe; Weizmann Institute, Israel

In semiconductor physics, the dielectric response, charge carrier mobility and other electronic material properties at finite temperatures, are always treated within the framework of the harmonic approximation. This approach is very
successful in capturing the properties of tetrahedrally bonded semiconductors such as silicon and GaAs.

In my talk, I will show that halide perovskites are fundamentally different due to their strongly anharmonic lattice dynamics. Large amplitude, local polar fluctuations induced by lattice anharmonicity localize the electronic states and enhance the screening of electric charge within the material. In other words, halide perovskites behave more like a liquid than a crystalline solid. I will also discuss the implications of these findings on other families of semiconductors such as organic and rock-salt semiconductors.

Investigations on Perovskite Materials and Solar Cells by Surface Science and Advanced Characterization
Yabing Qi; Okinawa Institute of Science and Technology, Japan

Metal halide perovskite solar cell research keep progressing on various fronts. My group at OIST uses surface science and advanced characterization to obtain fundamental understanding about perovskite materials and solar cells. The research focus in the field has been shifting from power conversion efficiencies to stability and upscalability. In this talk, I will present our research progress on degradation mechanisms of perovskite materials, development of strategies to improve stability of perovskite materials and devices, upscalable fabrication of perovskite solar cells and modules, and surface science understanding of perovskite materials and stability.

10:45 AM EN09.14.08
Energy Level Tuning of Perovskite Layers for Efficient Integrated Perovskite/Bulk Heterojunction Solar Cells
Matyas Daboczi¹, Jinhyun Kim¹, Jinho Lee¹,², Chieh-Ting Lin¹, Hongkyu Kang², Yi-Chun Chin¹, Gabseok Seo¹, Stoichko D. Dimitrov³, Martyn McLachlan¹, Kwanghee Lee³, James R. Durrant¹,³ and Ji-Seon Kim¹; ¹Imperial College London, United Kingdom; ²Gwangju Institute of Science and Technology, Korea (the Republic of); ³Swansea University, United Kingdom

Interfacial energy level alignment between the constituent layers of a solar cell is critical in order to avoid photogenerated charge carrier losses and hence to achieve high device efficiency¹. In this presentation we focus on the integrated perovskite/bulk heterojunction solar cell (referred to here as the integrated cell), which applies a small bandgap organic semiconductor based bulk heterojunction (BHJ) blend on top of a larger bandgap perovskite layer in order to harvest both the visible and near-infrared part of the solar spectrum²,³. We reach a high power conversion efficiency (PCE) of 17.7%, however this is lower than the 19.2% (calculated based on the increase in short circuit current), which is due to decreased fill factor in the integrated cell compared to the reference perovskite device. We show that the origin of such losses is the presence of a 250 meV energetic barrier at the perovskite/BHJ interface leading to undesired charge carrier accumulation and recombination. A possible strategy to overcome this limitation is to shift the energy levels of either the perovskite or the BHJ layer. We will demonstrate how this can be achieved by small compositional change of the perovskite layer. We will show two promising ways to tune the valence and conduction band edges of the widely used methylammonium lead iodide (MAPI) photoactive layer. First, by incorporating tin and bromide ions into MAPI, shifting the valence band edge between -5.4 and -5.0 eV and the conduction band edge between -3.8 and -3.5 eV is achieved. Applying only 15% tin and 30% bromide leads to a perovskite layer with the same bandgap (1.6 eV) as MAPI but with more than 200 meV shallower energy levels.

Second, we will show that that a similar shift (100-200 meV) towards shallower energy levels can also be achieved by the simple incorporation of only 12.5% bromide into MAPI. Despite the increased bandgap (1.65 eV) the best single-junction devices with such mixed halide system can reach PCE of 19.2% in single-junction devices. Surface photovoltage and energy level measurements show that the origin of such improvement is the shallower Fermi level in the developed mixed halide perovskite, which changes the interfacial band bending and by that helps hole extraction in the device. We will show that both of the developed perovskite layers with energy levels shifted shallower by around 200 meV compared to MAPI can be applied in the integrated perovskite/bulk heterojunction solar cell in order to improve on their efficiency.

Our results give an invaluable tool to increase the performance of perovskite based integrated devices through improved interfacial energy level alignment, which tool can also be applied in any perovskite multi-junction devices.

**New Deposition Route for Formamidinium Lead Iodide (FAPbI3) Perovskite Nanocrystals**

Dylan Amelot¹, Nadine Witkowski¹, Emmanuel Lhuillier¹, Alberto Calloni², Gianlorenzo Bussetti², Herve Cruguel¹ and Sebastien Royer¹; ¹Institut des nanosciences de Paris, France; ²Dipartimento di fisica, Politecnico Milano, Italy

Lead halide perovskite (LHP) have received a lot of attention over the past decade, notably due to the unprecedented evolution of LHP solar cells leading to efficiency up to more than 20% in only a few years. Recently, a new approach based on colloidal perovskite nanocrystals (PNC) of CsPbI₃ led to great improvements for nanocrystal-based solar cells[1]. A tremendous amount of work has been done over the past few years to better understand the electronic/excitonic structure, optoelectronic properties and degradation mechanisms and new surface chemistry tools are being developed[2-4]. However, there is still a lack of a clear, unified picture of the different mechanisms that limit the efficiency of the devices, whether at the material level or at the interfaces in device, or on how to address these limitations. There is also room for improvement of the transport properties of PNC films through more tailored surface chemistry treatments. A more standardized approach of film preparation and characterization could lead to better understanding the limitations of PNC devices and improving their overall efficiency.

At Institut des Nanosciences de Paris, we recently synthesized formamidinium (FA) lead iodide (FAPbI₃) nanocrystals, which have the smallest band gap of the LHP nanocrystal family (around 1.6 eV), ideal for photovoltaic applications and which show better stability than their Cesium-based counterparts. Characterizations using X-ray diffraction (XRD), Rutherford backscattering spectrometry (RBS), X-ray photoemission (XPS) and transport measurements on spin-coated films will be presented. These measurements allowed us to deduce the crystalline structure and inorganic stoichiometry of these nanocrystals, in agreement with literature. We also report on a ligand exchange procedure, using a process previously developed for CsPbI₃ [5], to enhance carrier transport in films. Valence band photoemission (UPS) combined with Inverse photoemission (IPES) measurements have been conducted in collaboration with a team at Politecnico Milano, suggesting that FAPI is a near intrinsic semiconductor with a weak n-type character. We are also developing a new route of film deposition that consists in spraying the nanocrystals in vacuum. We will present preliminary characterizations of the obtained films showing good agreement with spin-coated ones. This new deposition technique would allow for unprecedented in-situ measurements on these PNC as for instance studying the interfaces in devices or films under stresses such as radiation, temperature, oxygen or humidity.

**Peculiarities in the Emission and Absorption Properties of Cs₂AgBiBr₆ Double Perovskite Crystal**

Michal Baranowski¹,³, Szymon Zelewski³, Joanna Urban¹, Agnieszka Kuc¹, Laura Schade⁴, Roger Johnson⁴, Markus Dollmann⁴, Pabitra Nayak⁴, Henry J. Snaith¹, Paolo Radealli⁴, Robert Kudrawiec², Robin Nicholas⁴ and Paulina Plochocka¹; ¹Laboratoire National des Champs Magnétiques Intenses, UPR 3228, CNRS-UGA-UPS-INSA, France; ²Wroclaw University of Science and Technology, Poland; ³Helmholtz-Zentrum Dresden-Rossendorf, Germany; ⁴University of Oxford, Clarendon Laboratory, United Kingdom

Double perovskite crystals such as Cs₂AgBiBr₆ have appeared as a potential answer to inherent instability and toxicity of classic hybrid organics-inorganic led-halide perovskites. In their structure Pb²⁺ cation is substituted by pair of cations with formal oxidation states +1 and +3 forming so-called “double perovskite” with general formula
A\textsuperscript{+1}\textsubscript{2}B\textsuperscript{+1}\textsuperscript{2}X\textsubscript{6}. Band structure calculations show that many of the double perovskite compounds have a band gap in the range promising for solar cell applications and some of the possible compounds have already been synthesized corroborating theoretical predictions. So far Cs\textsubscript{2}AgBiBr\textsubscript{6} has been the most intensively studied representative of double perovskite family. Theoretical calculations predict that the fundamental band gap of Cs\textsubscript{2}AgBiBr\textsubscript{6} has an indirect nature but surprisingly the photoluminescence emission can be easily observed from this compound. In this work we show that overall picture of the emission form Cs\textsubscript{2}AgBiBr\textsubscript{6} might be far more complicated than indirect band to band emission. Using a combination of photoluminescence (PL), photoluminescence excitation (PLE) and absorption studies we show that the PL emission in Cs\textsubscript{2}AgBiBr\textsubscript{6} is dominated by a strong electron-phonon interaction. Our experimental results indicate that the emission from this material is related to a color center (or self-trapped exciton) rather than a band-to-band transition. The resonant excitation of this center results in a strong enhancement of PL emission demonstrating the competition between the nonradiative recombination paths related to the indirect bandgap and color center emission. Crucially, we show that the significant PL broadening together with the large Stokes shift between emission and PLE maximum can be well explained using Franck-Condon model indicating a strong electron-phonon coupling characterized by a relatively large Huang-Rhys factor ~12. In addition, the nontrivial nature of the PL emission in Cs\textsubscript{2}AgBiBr\textsubscript{6} is revealed by magnetic field studies. Surprisingly, the PL exhibits an unexpected red shift and decrease of its intensity with increasing magnetic field. Such behavior is extremely atypical for semiconductors, where usually a blue shift and increase of intensity of the emission line is observed at high magnetic fields as a consequence of the squeezing of the exciton wave function by magnetic field. Moreover, the PL shift in magnetic field depends on temperature and systematically decreases as the temperature increase from 4K to 100K. These results suggest that there remain many open questions concerning the exact nature of PL emission in these fascinating compounds.

11:30 AM EN09.14.11
Uncovering the Energy Level Alignment at a 2D/3D Perovskite Interface Scott Silver and Antoine Kahn; Princeton University, United States

Metal halide perovskite (MHP) solar cells have garnered significant attention over the past six years for their high efficiency and low processing costs. However, their relatively poor environmental stability remains as one of the preeminent challenges impeding their widespread proliferation. One increasingly popular method for improving the stability of these materials and devices is to cap the 3D MHP layer with a layer of a higher stability 2D Ruddlesden-Popper phase perovskite.\cite{1,2} These 2D-capped devices have demonstrated success in improving device lifetimes with minimal reduction in efficiency, yet the energy level alignment at these 2D/3D interfaces has not been measured directly and remains largely unknown. In this study, we fabricate an interface between the 3D methylammonium lead iodide (MAPbI\textsubscript{3}) and the 2D butylammonium lead iodide (BA\textsubscript{2}PbI\textsubscript{4}) using a butylamine post-treatment technique investigated in the literature\cite{3} and probe the ionization energy and electron affinity of the resulting film as well as the valence and conduction band offsets at the interface using ultraviolet and inverse photoelectron spectroscopy, respectively. The resulting energy diagram indicates a type I heterojunction with little if any charge transfer between the two layers. The BA\textsubscript{2}PbI\textsubscript{4}\cite{4} layer acts as a small barrier for the extraction of electrons and a larger barrier for holes. Design guidelines for optimizing the 2D/3D interface in future work will be discussed.

11:45 AM EN09.14.12
Band Alignment and Photoinduced Charge Transfer in CsPbBr\textsubscript{3}-CdSe Nanoplatelet Hybrids Coupled by Molecular Linkers Swayandipta Dey\textsuperscript{1}, Hagai Cohen\textsuperscript{1}, Iddo Pinkas\textsuperscript{1}, Hong Lin\textsuperscript{2}, Miri Kazes\textsuperscript{1} and Dan Oron\textsuperscript{1};\textsuperscript{1}Weizmann Institute of Science, Israel;\textsuperscript{2}Tsinghua University, China

Controllable interface characteristics are demonstrated at the nanoscale, using two types of semiconducting nanoparticles with nearly identical optical band gaps, CsPbBr\textsubscript{3} nanocrystals, and CdSe nanoplatelets, capped with
bifunctional molecular linkers. By exploiting chemical recognition of the capping molecules, the two types of nanoparticles are brought into mutual contact, thus initiating spontaneous charge transfer and the formation of a strong junction field. Depending on the choice of capping molecules, the magnitude of the latter field is shown to vary in a broad range, corresponding to an interface potential step as large as circa 1 eV. The band diagram of the system, as well as the emergence of photo-induced charge transfer processes across the interface, are studied here by means of optical and photoelectron based spectroscopies. Our results propose an interesting template for generating and harnessing internal built-in fields in heterogeneous nanocrystal solids where two disparate systems coupled by short molecular linkers form an analog of nano p-n junctions with the built-in field depending on the nature of the interface.

SESSION EN09.15: Structure and Morphology—Microscopic Imaging, Tomography and Grain Boundaries

Tomographic Atomic Force Microscopy Reveals 3D Interconnected Network of Efficient Charge Transfer Channels at Grain Boundaries in Polycrystalline MAPbI3 Thin Films Jingfeng Song,1 Yuanyuan Zhou,2 Michael Martin,1 Andrew Levin,1 Moishe Azoff-Slifstein,1 Nitin P. Padture2 and Bryan D. Huey1; 1University of Connecticut, United States; 2School of Engineering, United States

Hybrid perovskite solar cells based on methylammonium lead triiodide (MAPbI3) are of tremendous scientific and technological interest, with power conversion efficiencies already beyond 22%. Typically, the MAPbI3 thin films for planar solar cells are polycrystalline, with average grain sizes ranging from 100 nm to a few microns. Due to the correspondingly high interfacial area, it is thus imperative to characterize and understand the role of grain boundaries in the photo-generated carrier transport for MAPbI3 thin films. As with many photovoltaics, these interfaces may prove critical to the future design and optimization of high efficiency and reliability MAPbI3 devices. Accordingly, we demonstrate the first fully-3D photo-generated carrier mapping throughout polycrystalline MAPbI3 thin films via Tomographic Atomic Force Microscopy (TAFM). These results unambiguously identify for conventionally prepared polycrystalline MAPbI3 that the grain boundaries act as highly interconnected 2D conductive channels, including photoconductivities up to 4 times greater than the adjacent bulk. The conclusions are also supported by co-located I/V, I/intensity, surface potential, and topographic mapping.

2:00 PM EN09.15.02
Thermal Properties of Highly Oriented All-Inorganic CsPbX3 (X=Br, Cl) Perovskite Films—Dependence on Halide, Dimensionality and Crystal-Phase Tobias Haeger,1 Maximilian Wilmes,1 Johannes Bahre,1 Neda Pourdavoud, Stefan Zaeferrer, Ralf Heiderhoff and Thomas Riedl; 1University of Wuppertal, Germany; 2Max-Planck-Institut für Eisenforschung GmbH, Germany

Thermal management in hybrid and all-inorganic halide perovskite devices is expected to be of outstanding importance for the performance and reliability of solar cells, light-emitting diodes, and lasers, because both lifetime and performance are influenced by temperature or temperature gradients. Aside from hybrid halide perovskites, where the A-site cation is organic, the interest in all-inorganic perovskites is continuously increasing, as they provide a higher stability compared to their hybrid analogues. As thermal conductivities, thermal diffusivities, and heat capacities of these perovskites are typically low, their experimental assessment is extremely challenging [1-3].

Here, local thermal transport studies on all-inorganic cesium lead-halide based perovskite thin films, with Cl, Br as halides (X), will be presented. Re-crystallized CsPbX3 and CsPb2X5 layers were realized by the application of a planar hot pressing (PHP), previously developed by us [4,5]. Highly 100 oriented films are confirmed by X-ray diffraction (XRD) and electron backscattered diffraction (EBSD) analysis. Furthermore, we evidence a coexistence of grains consisting of the 3D phase (CsPbX3) and the 2D phase (CsPb2X5) depending on the preparation conditions of pristine layers [6]. Extended quantitative thermal conductivity measurements without the need of elaborate sample preparation are performed applying an advanced 3ω-technique in the frequency domain using our Scanning
Near-field Thermal Microscope [3]. We simultaneously map the topography, thermal conductivity (e.g. CsPbBr$_3$ and CsPb$_2$Br$_5$: 0.43 W/mK and 0.33 W/mK, respectively), thermal diffusivity (both 0.3 mm$^2$/s), and the volumetric thermal capacity (1.3 J/(cm$^3$K) and 1.1 J/(cm$^3$K)) with a high spatial resolution of typically 100 nm to understand the thermal properties in dependence of the dimensionality of the perovskite material. For comparison and as a reference, their single crystalline analogues, which are grown by anti-solvent vapour crystallisation, have been studied. In addition to heat transport analyses in dependence of the halide and dimensionality, the influence of temperature-dependent phase-transitions (e.g. 3D CsPbBr$_3$: orthorhombic - tetragonal - cubic) on the thermal properties are analysed the behaviour near the phase-transition is discussed in detail.

Our results demonstrate, that thermal management in all-inorganic halide perovskite devices will be a serious challenge and requires particular attention.

Enhanced Charge Transport by Incorporating Formamidinium and Cesium Cations for Two-Dimensional Perovskite Solar Cells Fei Zhang and Kai Zhu; National Renewable Energy Laboratory, United States

Organic-inorganic hybrid two-dimensional (2D) perovskites (n≤5) have recently attracted significant attention due to their promising stability and optoelectronic properties. Normally, 2D perovskites contain a mono cation (e.g., methylammonium (MA$^+$) or formamidinium (FA$^+$)). Here, we report for the first time on fabricating 2D perovskites (n=5) with mixed cations of MA$^+$, FA$^+$, and cesium (Cs$^+$). The use of these triple cations leads to the formation of a smooth, compact surface morphology with larger grain size and fewer grain boundaries compared to the conventional MA-based counterpart. The resulting perovskite also exhibits longer carrier lifetime and higher conductivity in triple-cation 2D perovskite solar cells (PSCs). The power conversion efficiency (PCE) of 2D PSCs with triple cations was enhanced by more than 80% (from 7.80% to 14.23%) compared to PSCs fabricated with a mono cation; the PCE is also higher than that of PSCs based on binary-cation (MA$^+$-FA$^+$ or MA$^+$-Cs$^+$) 2D structures.

Understanding Charge Separation and Recombination in your Own Perovskite Solar Cell with an Open-Access-Online Platform to Swiftly Compute Your Device Band Diagram Luca Bertoluzzi$^1$, Kevin A. Bush$^1$, Jixian Xu$^2$, Caleb C. Boyd$^{1,2}$, Rohit Prasanna$^{1,2}$, Brian O'Regan$^1$, Michael D. McGehee$^2$ and Nicholas Rolston$^1$; $^1$Stanford University, United States; $^2$National Renewable Energy Laboratory, United States; $^3$Sunlight Scientific, United States

Single junction perovskite solar cells have now achieved efficiencies exceeding 24% and silicon-perovskite tandem solar cells are outperforming single junction silicon devices. The path to achieve the last remaining efficiency percentiles to reach the Shockley-Queisser limit for single junction devices requires to understand the main limiting processes that hinder device performance.

One of the crucial parameters that control device performance is the photogenerated-carrier separation. Efficient charge separation can be achieved by understanding and controlling the electric potential distribution. In perovskite solar cells, the electric potential profile is controlled by mobile halide vacancies that migrate and accumulate at the contacts in response to an applied potential. The potential distribution is dependent on the vacancy concentration. Therefore, it is crucial to quantify the mobile vacancy concentration to understand the electric potential distribution in a perovskite device.

In this talk, we will first show how to measure and calculate the vacancy concentration and provide concentration values for a range of perovskite compositions and contacts. We will then briefly show how to easily simulate the band diagram of one’s own perovskite solar cell with an online-open-access platform we developed.$^1$ We will conclude this talk by discussing some important examples showing the role of the illumination side, the mobile ion
Metal halide perovskite materials exhibit exceptional performance characteristics for low-cost optoelectronic applications. Though widely considered defect tolerant materials, perovskites still exhibit a sizeable density of deep sub-gap non-radiative trap states, which create local variations in photoluminescence [1] that fundamentally limit device performance. These trap states have also been associated with light-induced halide segregation in mixed halide perovskite compositions [2] and local strain [3], both of which can detrimentally impact device stability [4]. Understanding the nature of these traps will be critical to ultimately eliminate losses and yield devices operating at their theoretical performance limits with optimal stability. We recently used local photoemission electron microscopy (PEEM) to directly visualize the deep trap sites, revealing spatially heterogeneous nanoscale clusters.

In this talk we detail a low-dose, high resolution and multi modal approach to determine 1) the physical origins of these deep trap states 2) their effect on the electronic properties of (Cs0.05FA0.78MA0.17)Pb(I0.83Br0.17)3 thin films and 3) their association with sub-grain crystallographic boundaries. By combining scanning electron and synchrotron X-Ray microscopy techniques with PEEM measurements we reveal that there are distinct structural and compositional fingerprints associated with the generation of these trap sites. In addition, our scanning electron diffraction measurements achieve a spatial resolution of 4nm with an accumulated electron dose of only ~6 e/Å² (over an order of magnitude lower than established tolerable dose limits for metal halide perovskites). We will also explore how this combination of high-resolution and low accumulated dose provides new insights into the pristine crystallography of these materials on the nanoscale; thus helping to answer ongoing open questions such as ‘what truly defines a grain?’ and ‘are grain boundaries beneficial or detrimental to performance’? Shifting the Thermodynamics of Polymorph Transitions in Metal-Halide Perovskites via Nanoconfinement
Xiaoqing Kong and Stephanie Lee; Stevens Institute of Technology, United States

Metal-halide perovskites undergo multiple temperature-dependent polymorph transitions, generally with the smallest bandgap phases thermodynamically favored only at elevated temperatures. We present nanoconfinement as a strategy to shift the thermodynamics of polymorph transitions in order to stabilize high-performance metal-halide perovskites against temperature-induced polymorph transitions and humidity-induced degradation. Specifically, when crystal sizes are reduced to the sub-micron length scale, the surface free energy contribution to the total Gibbs free energy of the crystals becomes increasingly important. By exploiting the dependence of the surface free energy on the symmetry of the crystal structure, it is possible to shift polymorph transitions to lower temperatures under nanoconfinement compared to the bulk. For methylammonium lead iodide (MAPbI₃) crystals confined in anodized surfaces.
aluminum oxide (AAO) templates with pore sizes ranging from 20 – 250 nm, the cubic polymorph was found to be stable at temperatures above 200 K, compared to 330 K for the bulk. Similarly, nanoconfined γ-CsPbI₃ formed at 370 K in AAO templates, compared to 448 K in the bulk phase and was stable to temperatures as low as 4 K once formed. Such stability afforded the extraction of phonon energies of CsPbI₃ from temperature-dependent photoluminescence spectra. Furthermore, these nanoconfined crystals exhibit excellent stability against humidity-induced degradation, with no change in their X-ray diffraction patterns over a period of at least two years upon storage in air.

Investigation of S-Donor Solvents for Processing Hybrid Organic-Inorganic Perovskites Joseph C. Hamill¹, Oluwaseun Romiluyi², Sara Thomas¹, Fengyu Zhang¹, Xiaoming Zhao¹, Michael F. Toney¹, Jeffrey Schwartz¹, Antoine Kahn¹, Paulette Clancy⁴ and Lynn Loo¹; ¹Princeton University, United States; ²Cornell University, United States; ³Stanford Synchrotron Radiation Lightsource, United States; ⁴Johns Hopkins University, United States

Lewis base solvents, such as dimethylsulfoxide (DMSO), that strongly coordinate with Pb²⁺ are commonly added to hybrid organic-inorganic perovskite (HOIP) precursor solutions to improve thin-film morphology and subsequent photovoltaic (PV) performance. Although nearly all previous studies of precursor solution chemistry have focused on oxygen-donor solvents as Lewis base additives, we expect “softer,” sulfur-donor solvents to coordinate more strongly with Pb²⁺, a borderline-soft Lewis acid. To confirm this hypothesis, we performed extended X-ray absorption fine structure (EXAFS) spectroscopy at the Pb L₃ absorption edge to probe the coordination environment of Pb²⁺ in solutions comprising mixtures of S- and O-donor solvents. Of the S- and O-donor solvent pairs examined, the S-donor solvent consistently outcompetes its O-donor structural analog for coordination sites around Pb²⁺. In the specific comparison between N-methyl-2-pyrrolidone thione (NMPT) and N-methylpyrrolidone (NMP), density-functional theory calculations indicate that NMPT coordination with Pb²⁺ is favored by 10 kcal/mol relative to NMP coordination with Pb²⁺. Similar to the addition of DMSO to precursor solutions, the incorporation of NMPT in fractional quantities provides morphological control of the perovskite film. Unlike DMSO, however, we found NMPT to be stable against undesired transmethylation or disproportionation reactions with methylammonium [1]. Consequentially, films processed with NMPT exhibit no sub-gap electronic states near the valence band edge, in contrast with films prepared using DMSO. We thus believe NMPT merits serious consideration as a solution additive for producing stable HOIP precursor solutions and high-quality HOIP thin films.

Advanced Photo-Hall Characterization to Unravel the Impact of PbI₂ Passivation in MAPbI₃ Julie Euvrard¹, Oki Gunawan² and David B. Mitzi¹; ¹Duke University, United States; ²IBM T. J. Watson Research Center, United States

Metal-Halide perovskite-based solar cells have shown a remarkable rise in performance in less than a decade with power conversion efficiencies now exceeding 23%. Recent literature provides a constant stream of new recipes and processing techniques, leading to improved power conversion efficiencies although often with limited detailed understanding of the mechanism for performance improvement. In particular, additive engineering and stoichiometric variations are widely studied to optimize the performances of the solar cells.[1,2] However, the underlying impact of additives and stoichiometry on transport and recombination properties are only little understood. In this study, we take advantage of a newly developed advanced characterization technique using a highly sensitive Hall-effect measurement performed at variable light intensity.[3,4] This new carrier-resolved photo-Hall technique gives access to both majority and minority carriers properties (n, p, µn and µp). In addition, carrier recombination lifetime τ and diffusion length Ld can be extracted with this technique using light intensities comparable to 1 sun. Importantly, all parameters can be extracted using the same sample and at the same light intensity level. We use the new technique to explore the impact of excess PbI₂ in MAPbI₃ precursor solution (MA: methylammonium), which has been suggested to improve solar cell efficiency through defect passivation at the grain boundaries.[5-7] Samples with similar grain sizes are compared to follow the evolution of transport and recombination properties of the perovskite film with and without the addition of excess PbI₂. We show that excess PbI₂ has a negligible impact on carrier density, conductivity and mobility, while it significantly improves the lifetime by one order of magnitude (from ~1 ns to ~20 ns). Combined with SEM images, these results suggest that
extra PbI₂ effectively passivates deep traps at the MAPbI₃ grain boundaries. Therefore, this study offers an in-depth analysis of the MAPbI₃ properties using an important new characterization technique and supports the passivation role of extra PbI₂.

4:15 PM EN09.15.09
The Role of Metal-Semiconductor Interface in Hybrid Perovskite Devices for High-Performance Solid-State Detector
Shreetu Shrestha1, Hsinhan Tsai1, Kasun Fernando1, Fangze Liu1, Yusheng Lei2, Michael Yoho1, Sheng Xu2, Kevin Baldwin1, Sergei Tretiak1, Duc Vo1 and Wanyi Nie1; 1Los Alamos National Laboratory, United States; 2University of California, San Diego, United States

Hybrid perovskites have emerged as excellent semiconductors enabling efficient opto-electronic devices such as solar cells, light emitting diodes, lasers as well as radiation detectors with performances approaching state-of-the-art. Apart from the intrinsic properties of the semiconductor, interfaces are critical to make a superior device. Hence, understanding the nature of the interface between metal contacts and perovskite is essential to further advance device performance, especially in low power detection applications (i.e. single photon detection mode) where a clean interface with minimized dark recombination is required.

Here, we use scanning photocurrent microscopy (SPCM) on lateral methylammonium lead triiodide (MAPbI) thin film device with commonly used high work function metal and low work function metal contacts to investigate perovskite-metal interfaces. By comparing the spatially resolved photocurrent maps of devices with Au (high work-function metal) to Ti (low work-function metal), we find that a Schottky barrier exists in both cases and the barrier is higher for the Ti/perovskite junction resulting in a lower photocurrent. Our results also suggest that the MAPbI thin films used in this study have a surface work function higher than Au indicating the presence of doping or band bending near the surface. From the decay of the photocurrent profile near the metal contacts, we estimate charge carrier diffusion length to be 9 ± 2 µm. Using this knowledge, we successfully demonstrate a single crystal MAPbI gamma ray detector from which sharp gamma-ray induced pulses are observed. This is benefitted from the clean interface built with high work function metal that blocks the dark current and extracts photo-generated carriers. Our study indicates that the interface plays a significant role especially in solid state detector operating at low flux photon counting mode.

Halide Perovskites with a Cesium Layer—Work Function Variation and a Model of Photo- and Thermal-Field Emission
Kevin L. Jensen1, Daniel Finkenstadt2, Andrew Shabaev1, Sam Lambrakos1, Matthew Critchley2, Sina Lewis1, Amanda Neukirch2, Nathan Moody3 and Sergei Tretiak4; 1U.S. Naval Research Laboratory, United States; 2U. S. Naval Academy, United States; 3The Ohio State University, United States; 4Los Alamos National Laboratory, United States

Halide perovskites have been extensively studied and show promise for a variety of optoelectronic application, e.g., satellites, energy conversion technologies, medical imaging, and in particular, photocathode materials for x-ray Free Electron Lasers (x-FEL’s) and photo-detectors. A thin layer of cesium (Cs) on pure inorganic perovskites, particularly CsPbBr₃ and CsPbI₃, has been shown to significantly improve their photocathode performance [1], primarily because the Cs coating significantly reduces the work function from ~4 eV to between 1.8 - 2.3 eV, depending on surface termination, crystal face, and degree of sub-monolayer coverage. In the present work, we shall: (i) combine findings from Density Functional Theory (DFT) with a phenomenological model developed by Gyftopoulos and Levine to predict the reduction in work function in relation to Cs coverage. (ii) describe the variation in work function Φ as a function of submonolayer coverage θ, (iii) explore the relationship between
emitted charge and work function variation using a thermal-field-photoemission model for which the transmission probability is evaluated using a novel approach to finding the Gamow tunneling factor for Schottky barriers, and (iv) demonstrate the performance of the new thermal-field and photoemission methods of evaluating current density compared to exact transfer matrix approaches (TMA) for the evaluation of transmission probability (methods which are applicable to photocathodes as well as thermal-field emitters in general).

Tuning the Transition Dipole Moment of CsPbBr3 Nanoplatelets for Improved Light Outcoupling of Blue Light-Emitting Diodes Tassilo Naujoks1, Thomas Morgenstern1, Carola Lampe2, Matthew Jurow2, Yi Liu2, Alexander S. Urban2 and Wolfgang Bruetting1; 1University of Augsburg, Germany; 2Ludwig-Maximilians-Universität München, Germany; 3Lawrence Berkeley National Laboratory, United States

The unique optical properties of lead halide perovskites have drawn significant attention towards their application in light emitting devices (LEDs) in recent years. While quantum yield, emission wavelength and stability are already in the focus of many research groups, the orientation of the emissive transition dipoles has rarely been investigated. As known from other thin film applications such as organic LEDs, this quantity can severely affect the light outcoupling of the device and thereby limit the external quantum efficiency.

In this work, we investigate CsPbBr3 nanoplatelets of variable thickness and determine the orientation of their transition dipole moments from thin film radiation pattern analysis. We then apply optical simulations to elucidate the performance limits of perovskite based blue LEDs in prototypical device architectures.

As was already shown, the transition dipole moment (TDM) of CsPbBr3 nanocrystals can be tuned from preferentially vertical in nanocubes to horizontal in ultra-thin nanoplatelets [1, 2]. At the same time, quantum
confinement renders the emission color from green to deep blue. Here, we use a systematic thickness variation from 2 to 6 monolayer thick nanoplatelets to study the tunability of the TDM orientation and the concomitant color shift. We find that with increasingly beneficial horizontal orientation, the outcoupling efficiency increases to values close to 30%. However, since the photoluminescence quantum efficiency degrades considerably for decreasing thickness [3], the overall maximum device efficiency does not significantly improve beyond 20%. Thus, for the currently available material sets we can conclude that while for nanocubes the non-ideal orientation limits device performance, devices with nanoplatelets are limited by non-optimal PLQYs. Nevertheless, our results reveal very promising new efficiency limits for solution-processed light emitting diodes: Solution-processed, highly efficient deep-blue LEDs, with strong horizontal TDM orientation made of CsPbBr3 nanoplatelets are in reach.

8:15 AM EN10.01.02
Interplay between Broadband and Narrow Photoluminescence in 2D Ruddlesden-Popper Perovskites Ido Hadar1, Ioannis Spanopoulos1, Peijun Guo2, Richard Schaller1,2 and Mercouri G. Kanatzidis1; 1Northwestern University, United States; 2Argonne National Laboratory, United States

2D Ruddlesden-Popper perovskites (2D R-P), are an emerging group of materials that derive from the rapidly growing family of organic-inorganic perovskites. The 2D R-P are formed by the addition of an organic cation to the 3D perovskite, which acts as a spacer and forces the perovskite layers to separate, offering an additional knob to tune the material’s properties. In general, the 2D R-P shows significantly improved stability in comparison to the 3D perovskites and the colloidal nano-perovskites, making these materials appealing for various optoelectronic applications, such as photovoltaic devices and light emitting diodes. An interesting aspect arises from 2D R-P’s versatile structure is the ability to control their photoluminescence properties (PL). Depending on the exact structure and composition, the 2D R-P may show narrow excitonic PL, tunable by quantum confinement effects, low energy emission related to edge states and for some specific structures broadband ‘white’ emission. The latter case is specifically desired as it shows fairly high PL quantum yield and offers a simple path toward devices. Yet, the exact physical origin for the wide emission and the materials’ criteria for obtaining it are still not fully resolved. Experimentally, it was found that perovskite structures exhibiting complex connectivity and strong distortion are more prone to show broadband emission, but there is no clear model of why. The current models explaining the wide emission are focused on study the kinetics between the excitonic states (leading to narrow emission) and the low energy states (leading to broadband PL).

In order to better understand the underlying structural and physical mechanism for the broadband emission, a material that shows a clear transition between the narrow and broadband emission will be beneficial. We found that the simple single layer 2D Ruddlesden-Popper perovskite – (CH3(CH2)3NH3)2PbI4 – can show such transition from narrow PL at room temperature to broadband PL at low temperature. This transition relates to a phase transition from the slightly distorted room temperature structure to a significantly distorted phase below 200 K. At lower temperatures the distortion becomes larger, leading to stronger broadband emission, and at even lower temperatures it becomes weaker in correlation with the previously published kinetic model. By studying additional single layer 2D R-P samples, with longer organic cations as the spacer groups, we further change the distortion and formulate a more general model for the narrow to broadband PL transition. This study enables us to gain a better understanding of how the octahedra distortion in perovskites activate the low energy emissive states and lead to broadband emission and give some simple design rules to rationally approach the synthesis of such materials.

8:30 AM EN10.01.03
Physical Dynamics in Soft Lattice Halide Perovskites Lina Quan1,2 and Peidong Yang1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Recently, lead halide perovskite materials have introduced a new paradigm for semiconducting materials. The controlled synthesis, detailed structural analysis, optical, and electronic properties are of great fundamental interest.
A high degree of ionic bonding character in perovskites gives rise to higher coordination environments, and significant structural disorder; the collective result is a family of “easy to make, easy to break” materials that are highly dynamic and readily reconfigurable. Particularly, highly ionic perovskite materials exhibit exceptional photophysical and optoelectronic properties even with significant electron-phonon coupling and structural disorder, motivating an investigation into the origins of these outstanding properties. This talk will focus on the research scope from simple ABX₃ inorganic halide perovskite towards other more complex halide perovskites and understand their structures and lattice dynamics. We develop the advanced synthetic methodology of perovskite nanostructures with desired size, composition, and optical properties, including colloidal, solution-phase and vapor-phase approaches. We anticipate rich phase transformation behaviors and rich electronic structures in such complex halide perovskites. Moreover, the phase transition and soft ionic lattice dynamics in such materials were demonstrated in detail using time- and spatially-resolved spectroscopy techniques.

9:00 AM *EN10.01.04
Luminescent Low Dimensional Metal Halide Perovskites and Hybrids Biwu Ma; Florida State University, United States

Organic-inorganic metal halide hybrids, including ABX₃ metal halide perovskites, are an emerging class of functional materials with exceptional structural and property tunability. During the last decade, remarkable progress has been made in using solution processable metal halide perovskites as active materials for optoelectronic devices, including photovoltaic cells (PVs), light emitting diodes (LEDs), photodetectors, and lasers, for their excellent optical and electronic properties. By controlling the morphological dimensionality, low dimensional metal halide perovskites, including 2D nanolealets, 1D nanowires, and 0D quantum dots, have been developed to exhibit distinct properties from their bulk counterparts, due to quantum size effects. For instance, the emission of CsPbBr₃ nanocrystals can be tuned from green for nanocrystals with sizes of larger than the exciton bohr radius (~ 7 nm), to blue for quantum dots, nanowires, nanolealets, and hollow nanocrystals with strong quantum confinement. Besides ABX₃ perovskites, organic metal halide hybrids, containing the same building blocks of metal halide octahedra (BX₆), can be assembled with low dimensional structures at the molecular level, i.e. single crystalline bulk assemblies of metal halides with 2D, quasi-2D, corrugated-2D, 1D, corrugated-1D, and 0D structures. Due to the strong quantum confinement and site isolation, these low dimensional metal halide hybrids at the molecular level exhibit remarkable and unique properties that are significantly different from those of ABX₃ perovskites. For instance, broadband white emissions have been achieved in single crystalline bulk assemblies of 1D metal halide wires and tubes; and near-unity photoluminescence quantum efficiency has been realized for a number of 0D organic metal halide hybrids containing various metal halide species or clusters. In this talk, I will discuss our recent efforts on the development and study of highly luminescent low dimensional metal halide perovskites and hybrids, from synthetic control to device integration.

9:30 AM BREAK

10:00 AM *EN10.01.05
Excitons, Phonons and Excited State Dynamics in Low-Dimensional Halide Perovskites William Tisdale; Massachusetts Institute of Technology, United States

Hybrid organic-inorganic halide perovskites are a newly rediscovered class of solution-processable semiconductor materials with surprisingly promising optoelectronic performance. When fabricated in a nanostructured form – either as layered 2D quantum wells or colloidal nanocrystals – hybrid perovskite nanomaterials exhibit a combination of interesting properties revealing both quantum mechanical and classical composite effects. In this talk, I will discuss the thermal, electronic, and excitonic properties of hybrid perovskite nanomaterials as a function of composition, structure, and temperature – and what these experimental observations tell us about the interactions between the organic and inorganic subphases of this interesting class of materials.

10:30 AM *EN10.01.06
Advances in Reduced-Dimensional Solution-Processed Light Emitters Edward H. Sargent; University of Toronto, Canada

I will discuss progress in the realization of electrically-driven optical sources (LEDs) based on reduced-dimensional materials. I will discuss perovskites, quantum dots, and hybrids of the two.
Multiexciton Interactions in Cesium Lead Halide Perovskite Nanocrystals
Katherine Shulenberger1, Matthew N. Ashner1, Seung Kyun Ha1, Franziska Krieg2,3, Nathan D. Klein1, Hendrik Utzat1, Maksym V. Kovalenko2,3, William Tisdale1 and Moungi G. Bawendi1; 1Massachusetts Institute of Technology, United States; 2ETH Zürich, Switzerland; 3Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Cesium lead halide perovskite nanocrystals have recently emerged as a promising material system for a number of lighting and lasing applications due to their extensive color tunability, high photoluminescence quantum yield, and relatively narrow emission linewidths. Furthermore, these materials exhibit relatively low-threshold optical gain. If perovskite nanomaterials are to meet this potential in light emission applications, it is crucial to have a comprehensive understanding of the properties – not just under low-flux excitation – but under high-flux, device relevant conditions as well. We have thoroughly investigated the properties of the doubly excited state (“biexciton”) in CsPbBr3 nanocrystals utilizing time- and spectrally-resolved ensemble photoluminescence, flux-dependent transient absorption spectroscopy, and single nanocrystal second- and third-order photon correlation measurements. Our results demonstrate that the biexciton state has a negligible and even slightly repulsive interaction energy. Furthermore, the dynamics of the biexciton state are much more rapid than what would be predicted by established statistical scaling models, providing insight into the processes which dominate multiexciton emission.

Exploiting the Moisture Assisted Passivation of Organo-Metal Hybrid Perovskite Nanocrystals
Huanyu Zhou, Jinwoo Park, Yeongjun Lee, Joo Sung Kim and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Organometal hybrid perovskites nanocrystals (PeNCs) with ABX3 structure (A=small organic cations, B=Pb and X=halides) have been widely adopted as the emitters owing to their superior optical properties, quantum efficiency and the tunable photoluminescence wavelength with high color purity. However, due to the dynamic electrostatic interaction between ligands and the quantum dots and the existence of surface defects, such PeNCs normally suffer from poor stability issues. In this study, PeNCs are dispersed in the polymer matrix and the stability of the PeNC is enhanced due to the compatibility of the polymer matrix with the ligand. In addition, we realize that with the controlled diffusion of moisture through the polymer matrix into PeNCs, the PL intensity increases by 125% after immersing in water for 2 months, which is induced by the surface passivation of PeNCs through the recrystallization process. Our work provides a fundamental approach to improve the stability of PeNCs against the environment with controlled diffusion of moisture and oxygen through the polymer matrix.

Recent Developments in Nanocrystal Quantum Dot Lasing—From Novel Concepts to Novel Devices
Victor I. Klimov; Los Alamos National Laboratory, United States

Colloidal semiconductor quantum dots (QDs) are attractive materials for realizing highly flexible, solution-processable optical gain media with readily tunable operational wavelengths [1,2]. However, QDs are difficult to use in lasing due to extremely short optical gain lifetimes limited by nonradiative Auger recombination [3,4]. This, in particular, is a serious obstacle for realizing cw optically and electrically pumped lasing devices. Recently, we have explored several approaches for mitigating the problem of Auger decay by taking advantage of a new generation of core/multi-shell QDs with a radially graded composition that allow for considerable (nearly complete) suppression of Auger recombination [5,6]. Using these specially engineered QDs, we have been able to realize optical gain with direct-current electrical pumping [7], which has been a long-standing goal in the field of colloidal nanostructures. Further, we applies these dots to practically demonstrated the viability of a ‘zero-threshold-optical-gain’ concept using not neutral but negatively charged particles wherein the pre-existing electrons block either partially or completely ground-state absorption [8]. Such charged QDs are optical-gain-ready without excitation, which allows us to reduce the lasing threshold to record-low values that are well below a fundamental single-exciton-per-dot limit. Most recently, we have developed QD devices that operate as both an electroluminescent (EL) structure and a low-
threshold, single-mode optically pumped laser. These devices feature a distributed feedback resonator integrated into a bottom electrode of a p-i-n multilayered stack. By carefully engineering a refractive-index profile across the device, we have been able to demonstrate excellent lasing behavior even with a very thin active region, which comprises only three monolayers of the QDs. These ultrathin devices can be pumped electrically and exhibit strong EL with good efficiency ‘roll-off’ characteristics. All of these recent developments demonstrate a considerable promise of colloidal QDs for implementing solution-processable optically and electrically pumped laser devices operating across a wide range of wavelengths.

SESSION EN10.02: Perovskite and QD Emitting Materials
Session Chairs: Maksym Kovalenko and Tae-Woo Lee
Monday Afternoon, December 2, 2019
Sheraton, 2nd Floor, Back Bay D

1:30 PM *EN10.02.01
Light-Induced Structural Transitions in Layered 2D Perovskites Aditya D. Mohite; Rice University, United States

Organic-inorganic (hybrid) perovskite have recently emerged as a new semiconductor platform for next generation optoelectronics devices. These perovskite solids feature weak bonds between their organic and inorganic building blocks, which results in an intrinsic softness and dynamics disorder of the lattice and an acute sensitivity to external stimuli. For example, our recent work demonstrated that continuous sunlight illumination leads to a uniform expansion of the perovskite lattice, which impact the optoelectronic properties of the three-dimensional (3D) perovskites. In particular, this effect is beneficial as it helps cure electronics impurities and lowers energetic barriers near the surface/interface. Here, we present comprehensive in-situ studies of light and electrical field induced structural dynamics of in layered two-dimensional (2D) hybrid perovskites. We correlate the changes in the structure of the 2D perovskite to modification of both the physical properties and the figures of merit in solar cells and light emitting devices. We propose a new microscopic model to explain the evolution of the structure and optoelectronic properties under external stimuli. These results demonstrate that structural characterization of hybrid perovskite under external perturbation is key in unraveling the fundamental physics of these materials.

2:00 PM *EN10.02.02
2D Heterostructures of Ruddlesden–Popper (RP) Layer Halide Perovskites and Their Optoelectronic Applications Song Jin; University of Wisconsin-Madison, United States

The remarkable solar performance of lead halide perovskites can be attributed to their excellent physical properties that present many mysteries, challenges, as well as opportunities. Better control over the crystal growth of these fascinating materials and fabrication of heterostructures using two-dimensional (2D) Ruddlesden–Popper layered metal halide perovskites with different bandgaps would open up opportunities for exploring new properties and
device applications. I will first briefly summarize our results on the solution and vapor-phase growth of single crystal halides and lead halides (APbX₃). Then I will focus my discussion on the growth of multi-layered multi-colored vertical heterostructures of 2D Ruddlesden–Popper (RP) layered lead iodide perovskites with defined n phases and atomically sharp interfaces, in which the long chain ammonium ligands serve as the barriers to prevent ion migration across the junctions. We have further developed the controlled growth of large area nanosheets of RP perovskite phases with varying n values and different anions and well defined vertical heterostructures of these phases. These heterostructures were used to study the carrier transfer mechanisms between different RP phases and as building blocks for optoelectronic devices. High performance room temperature lasing with broad tunability of emission was also demonstrated with single-crystal APbX₃ perovskite nanowires. The excellent properties of these single-crystal perovskite nanostructures of diverse families of perovskite materials with different cations, anions, and dimensionality make them ideal for fundamental physical studies of carrier transport and decay mechanisms, and for enabling high performance lasers, LEDs, and other optoelectronic applications.

Proton-Transfer-Induced 3D/2D Hybrid Perovskite for Stable Light-Emitting Diodes Joo Sung Kim¹, Hobeom Kim¹, Jung-Min Heo¹, Mingyuan Pei², In-Hyeok Park³, Zhun Liu⁴, Hyung Joong Yun⁵, Min-Ho Park¹, Su-Hun Jeong¹, Young-Hoon Kim¹, Jinwoo Park¹, Lijun Zhang², Hoichang Yang², Hyun-Myung Jang³, Kian Ping Loh⁶, Nam-Gyu Park⁶ and Tae-Woo Lee¹; ¹Seoul National University, Korea (the Republic of); ²Inha University, Korea (the Republic of); ³National University of Singapore, Singapore; ⁴Jilin University, China; ⁵Korea Basic Science Institute (KBSI), Korea (the Republic of); ⁶Sungkyunkwan University, Korea (the Republic of)

Metal halide perovskites (MHPs) has been considered as promising materials in the field of light-emitting diodes (LEDs), owing to their advantages on light emission such as extremely high color purity (full width at half maximum ≈ 20 nm at room temperature), high photoluminescence quantum efficiency > 90%, easily tunable bandgap and low material cost.¹ In addition, the efficiency of perovskite light-emitting diodes (PeLEDs) based on three-dimensional (3D) polycrystalline perovskites has been greatly increased despite the short period of research.²–⁴ However, the short lifetime during the operation has been a key challenge to be overcome for their practical applications.⁵ The most critical factor is the ion migration in perovskites, which can seriously degrade the crystal structure and luminescent efficiency during device operation, especially for PeLEDs because of the required high bias voltage for device operation.

Here, we demonstrate proton-transfer-induced 3D/2D hybrid perovskite that was obtained by adding a small amount of neutral amine instead of alkyl ammonium halide salt. Proton transfer from organic ammonium precursor to neutral amine in additive/perovskite composition enabled crystallization of 2D perovskite on the surfaces of 3D perovskite grains without destroying the 3D phase. In this study, we almost removed overshoot of luminance over time and highly extended the lifetime of PeLEDs by more than 20 times by developing a 3D/2D hybrid perovskite emitter; the 2D perovskite passivates the trap sites of 3D perovskite and blocks possible pathways of ion migration. We also identified the mechanism of remarkably suppressed luminance overshooting and significant lifetime extension by blocking ion migration in PeLEDs. Our work provides promising guidelines to improve the stability of PeLEDs with the exact explanation on degradation mechanism assisted by the ion migration in perovskite.

Inter-Triplet Coherences in Perovskite Nanocrystals Diogo B. Almeida1,2, Albert Liu2, Luiz G. Bonato1, Gabriel Nagamine1, Ana F. Nogueira1, Steven Cundiff2 and Lazaro Padilha1; 1Universidade Estadual de Campinas, Brazil; 2University of Michigan, United States

Currently, all inorganic CsPbX3 perovskite nanocrystals are among the most investigated semiconductor nanostructures due to their set of unique optical properties, which includes high emission quantum efficiency, tolerance to surface defects, and broadband tunability while maintaining narrow emission spectra. Fast emission lifetime (up to one order of magnitude faster than CdSe based nanomaterials at room temperature) is yet another relevant property of this class of nanomaterials, which is due to the fact that, different from other nanostructures, the band edge is defined by a bright triplet state. This triplet exciton fine structure is still not well explored and further understanding is necessary to turn these unique properties of perovskite NCs useful for optoelectronic application. However, accessing the ultrafast temporal evolution and the coherent dynamics of those states is difficult due to the inhomogeneous broadening. Here, we will show that we can get around this inhomogeneous broadening by using multi-dimensional coherent spectroscopy (MDCS), and access relevant information regarding the triplet fine structure.

In our experiment, we investigate, at cryogenics temperatures, an ensemble of CsPbI3 quantum dots with side lengths of 8.7 ± 2.6 nm. Using a sequence of three ultrafast laser pulses, with specified relative polarization, we resonantly excite different triplet coherences. For co-linearly polarized laser pulses, we observe a strong central emission peak, with a zero-phonon line of about 0.12 meV (FWHM), and two weaker ones positioned about 0.30 meV apart from the main peak, and nearly as broad as the center one. While the central peak is attributed to the absorption and emission from the ground level to same excited state \( \Psi_i \), the side band are related to the absorption and emission involving the ground state and \( \Psi_x \) and \( \Psi_y \), through coherent coupling. When we rotate the polarization of the second pulse to be perpendicular to the two others, the central peak disappears, while the side peaks at 0.30 meV becomes weaker and a broader peak, with linewidth of nearly 0.87 meV, and about 1.60 meV apart from the center, emerges becoming the most intense one. Those peaks are related to the absorption and emission involving the ground state and \( \Psi_i \) and \( \Psi_z \). We do not observe, in any configuration coherences between \( \Psi_x \) and \( \Psi_z \), which suggests that the dipole moment corresponding to \( \Psi_y \) is much stronger than for the other two. From the inter-triplet coherences we can infer that the coherence time for each one of the triplet levels is \( T_{2x} = 5.68 \) ps, \( T_{2y} = 5.32 \) ps, and \( T_{2z} = 0.76 \) ps. In addition to these, our data indicates that the triplet state splitting is size dependent and, by temperature dependence studies, we show that the inter-triplet coherence is only weakly dependent on the temperature up to about 50K.

Lead Halide Perovskite Quantum Dots: A Source of Quantum Light? Moungi G. Bawendi; Massachusetts Institute of Technology, United States

The development of practical optical quantum technologies requires the reproducible and scalable production of single quantum emitters with long optical coherence times that can be readily integrated with devices. We have recently demonstrated the potential for chemically-made, colloidal lead halide perovskite (CsPbX3, X=Cl, Br, I) quantum dots (PQDs), to be single emitters of quantum light. Using Photon-Correlation Fourier spectroscopy (PCFS) at low temperatures, we found that PQDs exhibit long optical coherence times and small exciton fine-structure splittings. The long coherence (80 ps) and short radiative emission lifetimes (210 ps) render the PQD emission linewidth near the Fourier transform limit. Moreover, we show that spectral diffusion is dramatically reduced compared to other colloidal quantum dots and that the majority (50-80%) of photons are emitted coherently. This fraction of coherent photons is already comparable to silicon vacancy centers in diamond, which are common emitters in quantum photonics. Our results suggest that, while all other colloidal quantum dot materials suffer from prohibitively incoherent emission, PQDs can be explored as sources of indistinguishable single photons that can be processed from solution onto virtually any substrate and coupled with hybrid nano-photonic components like waveguides or plasmonic gap cavities.

4:00 PM *EN10.02.06
Temperature Dependence of Radiative Decay Time in Perovskite Nanocrystals Alexander L. Efros; U.S. Naval Research Laboratory, United States
Single photon super-radiance is a way to move the radiative decay time into the sub-nanosecond time regime. Single photon super-radiance was introduced by Dicke, who demonstrated that single photon spontaneous emission of N coherently excited atoms occurs N times faster than the spontaneous emission rate of a single atom, \( t_0 \); in other words the single photon super-radiative decay time: \( t_{SR} = t_0 / N \). Single photon super-radiance has been observed recently in inorganic CsPbX₃ (X=Cl,Br,I) perovskite nanocrystals (NCs) at liquid hydrogen temperatures. Sub-nanosecond radiative decay time of weakly bound excitons can be also understood in terms of the phenomenon known as giant oscillator strength (GOS). GOS was introduced initially to explain the excitation spectra of shallow impurities. Despite relatively small concentration, these impurities are observed as narrow sharp lines with intensities comparable to the intensity of the exciton line in the band edge absorption spectrum. It was predicted theoretically that exciton weakly confined in a spherical NC, which radius \( a \) is much larger than the exciton radius \( a_{ex} \), is characterized by GOS which strength, \( f_{NC} = f_0 (a'/a_{ex})^3 \), where \( f_0 \) is the exciton oscillator strength. The single photon super-radiance connected with GOS of NCs observed generally at liquid helium temperatures shows unusual and counter-intuitive increase of the radiative decay time with temperature. We demonstrate that the unusual behavior of the radiative decay time observed in perovskite NCs is connected with the thermal population of upper optically forbidden exciton states and with phonon-induced admixture between these states and the ground exciton level, which reduces GOS of the ground exciton state. The latter mixing process is dominant at low temperatures and leads to formation of an exciton-phonon polaron.

**Environmentally Friendly Quantum Dots for Display Applications** Eunjoo Jang; SAIT, Korea (the Republic of)

Ever since the physics of quantum dot (QD) was discovered, much research effort has been carried out for more than 30 years, and lots of applications adopting QDs have been proposed. Especially, wide color gamut displays using QDs as active light emitting materials have drawn much attention. And, the QD-based consumer displays such as LED TVs, tablets, and special monitors are now on the market. They provide best color gamut, reasonable power efficiency, and affordable price showing superior competitive edge to OLED technology. However, there used to be issues and argues using Cadmium containing materials in practical consumer devices. In spite of the European RoHS Exemptions, we needed to be aware the environmental risk of producing large quantity of Cd-containing materials and using them in the consumer electronics. Samsung has dedicated to develop more environmentally friendly InP based QDs that showed considerably high efficiency and saturated color spectrum compared to the Cd-containing materials. The structure of Cd-free QD was specially tailored for display applications and the synthetic process was optimized to produce reliable materials in commercial scales. In order to improve the efficiency and stability of the QDs in the devices operating under severe atmosphere, specific composite materials were designed and the fabrication process was optimized. From 2015, Samsung has released Cd-free QD adopted UHD TV for major product line-up which show the best color gamut among the current displays. Now we are trying to expand this established Cd-free QD technology as a material platform and make additional breakthroughs in wider optoelectronic applications. Also, we are trying to understand the fundamental properties of defect states of InP QDs via density functional simulation and spectroscopic analyses.
Quantum dots are semiconductor nanocrystals whose size can be tuned to control their optical absorption and emission properties. When excited electrically or optically, a spatially confined electron-hole pair (exciton) is generated. The quantum dot’s emission wavelength can be changed through the confinement effect by tuning the quantum dot to be the size of the exciton’s Bohr radius or smaller. Due to their bulk bandgap, CdSe quantum dots are tunable across the entire visible spectrum. Quantum dots can also simultaneously sustain multiple excitations, which can result in two bound excitons (biexcitons), three bound excitons (triexcitons), or more. Multiexcitons have lower quantum yields than single excitons due to the addition of nonradiative Auger recombination and are typically generated under higher flux conditions, due to the Poissonian absorption statistics of quantum dots. The dynamics and recombination pathways of triexcitons specifically are not well understood and therefore their efficiency is not well optimized in quantum dot devices. Previous theoretical studies show that triexcitons in CdSe quantum dots occupy two angular momentum states of the band-edge 1S-like state (filling the 1S-like state) and one spin state of the higher-energy, 1P-like state. Furthermore, previous work in our group predicted that triexciton emission is dominated by band-edge S-like recombination rather than the P-like recombination, but not definitively proven. We utilize time-correlated single photon counting (TCSPC) with a four spectrally-filtered single-photon counting detectors to detect 1S-like and 1P-like emission from the triexciton state. We demonstrate that almost all triexciton emission occurs from band-edge S-like recombination, indicating that multiexciton interactions drastically reduce the emission rate from the P-like state. These results provide a crucial step to improving the efficiency of nanocrystal materials in device relevant conditions.
method to deposit perovskite films with good film morphology. What is more, the thickness of vacuum-evaporated films could be precisely controlled compared with that of solution-processed ones. Herein, we first demonstrated organic-inorganic hybridized 2D perovskite thin film as light emitting layer via evaporation method. Base on our characterization, we got 2D nanoflake structure perovskite crystals with small crystal size. The one-dimensional confined structure not only can significantly improve electron-hole injection, but also can enhance luminescence efficiency due to quantum confinement. The planar device EQE boost to 4.8% with luminance about 11000cd/m² after constructing the 2D structure. In addition, larger device size by 1.5cm*2cm were also demonstrated, which shows potential in large area display.

**EN10.03.04**

**Slot-Die Coating of Formamidinium Lead Bromide Nanocrystals for Large-Area Perovskite Light Emitting Diodes**

Alasdair A. Brown1,2,3, Xin Yu Chin3, Suan Hui Pu1, Ju Nie Tey2, Bahulayan Damodaran3, Liudi Jiang1, Subodh G. Mhaisalkar3,3 and Nripan Mathews3,3; 1University of Southampton, United Kingdom; 2Agency for Science, Technology and Research, Singapore; 3Nanyang Technological University, Singapore

Metal halide perovskites (MHPs) have recently demonstrated exceptional promise as emissive materials for light-emitting applications. They exhibit remarkable colour purity and high photoluminescence quantum yield (PLQY), tuneable across the visible spectrum. As a result, prototype small-area light-emitting diodes (LEDs) with external quantum efficiencies (EQE) exceeding 20 % have been achieved. A significant attraction of MHPs is their inherent compatibility with solution-processing. Considering also the low cost of the precursor materials, MHPs have the potential to facilitate cost-effective, high throughput roll-to-roll (R2R) LED fabrication on flexible substrates. Despite the potential, there have been very few reports of large-area perovskite LEDs realized through scalable deposition techniques; the vast majority still rely on spin-coating. Spin-coating places an inherent limitation on scalability; as each substrate must be coated separately it is unsuitable for desirable continuous processing. Slot-die coating provides an attractive alternative. It is a straight-forward continuous process, suitable for R2R deposition. Furthermore, the volume of excess solution required is fixed, thus material wastage for large-scale deposition processes would become almost negligible. This is in stark contrast with spin-coating, where most of the solution is ejected from the substrate.

The applicability of slot-die coating for light-emitting diode fabrication has been demonstrated extensively for organic light-emitting diodes, establishing the capability of the technique to reproducibly deposit films of around 40 nm. Recently, Prakasam et al. achieved the first slot-die coated LEDs by directing N₂ gas flow onto wet films to induce fast gas-assisted crystallization of MAPbBr₃. They obtained modest current efficiency (CE) of 2.6 cd A⁻¹ for 4.46 cm² active area devices, which were slot-die coated as a 230 cm² strip. Similar methods have been reported several times for slot-die coating of bulk perovskite films for solar cells, where crystallization control is also a challenging issue.[14]

MHP nanocrystals (NCs) provide a simpler alternative. As the perovskite phase has already been crystallized prior to film deposition, the NC ink can be slot-die coated without additional provisions. Thus, the development and optimization of a slot-die coating process for MHP NCs would provide a versatile large-area deposition method, demonstrating a significant advancement of perovskite LED scalability. Herein, we report the fabrication of slot-die coated LEDs from our FAPbBr₃ NCs. The slot-die coating parameters were optimised to obtain full surface coverage over an active area measuring 16 cm². Maximum external quantum efficiency (EQE) of 7.26 % (CE = 31.9 cd A⁻¹) and maximum luminance of 1428 cd m⁻² were achieved. To the best of our knowledge, both of these values are the highest reported for perovskite LEDs fabricated using a fully scalable deposition technique. These results represent a significant enhancement of the scalability of perovskite light-emitting diodes towards future commercial viability.

**Synthesis and Photophysical Properties of Diamine Intercalated Hybrid Layered Perovskites**

Rounak A. Naphade and Osman M. Bakr; King Abdullah University of Science and Technology, Saudi Arabia

Hybrid perovskite materials have expanded their scope of interest to a wide research community owing to their desirable photo-physical properties, which made them useful for opto-electronic applications. Low-dimensional hybrid perovskites, in particular, have been the subject of intensive research as of late due to the ease of tuning of
Here in this work, we present the case of the ethylene diammonium cation as an intercalating agent for forming a 1D layered lead halide perovskite framework. We show that the addition of mono-ammonium bromide salt (up to 20 mol %) during the crystal growth enables the manipulation of the crystal’s framework from 1D to 2D-stair-case like perovskite. The ethylene diammonium cation along with water molecules stabilize this stair-case like crystal framework. The ethylene diammonium cation acts simultaneously as an inter-layer cation as well as a cation filling the in between adjacent voids of octahedrons. This mono-ammonium bromide salt incorporation in the single crystals shows simultaneous broadband and narrow emission depending on the excitation source. With a combination of structural, spectroscopic, and Density functional theory (DFT) approaches we investigate the origin of dual emission from single crystals of this layered perovskite. Our findings suggest that self-trapped excitons and the presence of water molecules inside the crystal lattice control the dual emission from these crystal systems.

EN10.03.06
Increasing Photoluminescence Quantum Yield by Nano-Photonic Design of Quantum-Confined Halide Perovskite Nanowire Arrays Daquan Zhang, Qianpeng Zhang, Yu Fu, Leilei Gu and Zhiyong Fan; The Hong Kong University of Science and Technology, Hong Kong

High photoluminescence quantum yield (PLQY) is required to reach optimal performance in solar cells, lasers and light-emitting diodes (LEDs). Typically, PLQY can be increased by improving the material quality to reduce the non-radiative recombination rate. It is in principle equally effective to improve the optical design by nanostructuring a material to increase light out-coupling efficiency and introduce quantum confinement, both of which can increase the radiative recombination rate. However, increased surface recombination typically minimizes nanostructure gains in PLQY. Here a template guided vapor phase growth of perovskite nanowire (NW) arrays with unprecedented control of NW diameter from the bulk (250 nm) to the quantum-confined regime (5.7 nm) is demonstrated, while simultaneously providing a low surface recombination velocity of 18 cm s^{-1}. This enables an obvious PLQY enhancement from 0.33% up to 42.6% for MAPbI_{3} quantum wires, and up to ~90% for MAPbBr_{3} quantum wires, exclusively using nanophotonic design, which will be promising for LEDs applications with high external quantum efficiency (EQE). The simple extension of this technique to a wide variety of semiconductors and the ultra-high density of vertical QWs may also provide interesting opportunities in quantum transport, electronics and memory devices in the future.

EN10.03.07
Understanding the Trade Off Between Efficiency and Stability in Perovskite Light-Emitting Diodes with Bulky Ammonium Cations Jonathan Warby, Bernard Wenger, Olivia J. Ashton, Ashley Marshall and Henry J. Snaith; University of Oxford, United Kingdom

Recently metal halide perovskite light emitting diodes (LEDs) have been reported with high efficiencies, most often made by in situ generation of nanocrystals in a film or the formation of quantum well hetero-structures. In both cases, bulky ammonium cations are used which greatly improve the optoelectronic properties of the perovskite by direct chemical passivation, increased dielectric confinement and carrier funnelling, all which encourage efficient radiative bimolecular recombination.

However, the operational stability of these devices is poor with even the state of the art only able to function for a few hours. More often than not, this stability is overlooked in favour of achieving high efficiency, but this now needs to be urgently addressed.

In this work we investigate the influence of the bulky ammonium cation on the stability of CsPbBr_{3} based perovskite LEDs. Upon addition of these molecules into precursor solutions we observe an increase in external quantum efficiency of four orders of magnitude. Despite this excellent improvement in efficiency we also demonstrate that the optimised LEDs are far less stable than those made without the additive. Through optical and structural characterisation we elucidate the reason for this drop in stability and provide an insight into alternative strategies for obtaining both high efficiency and stable LEDs.

EN10.03.08
Dissected Mechanism of Elastic Mechnoluminescence in ZnS:Mn Microparticles Implies the Possibility of Nanoscale Stress Sensor Maria Mukhina1, Jason Tresback1, Justin Ondry2, Austin Akey1, Paul Alivisatos2 and Nancy Kleckner1; 1Harvard University, United States; 2University of California, Berkeley, United States
Elastic mechanoluminescent (ML) materials convert energy of reversible elastic mechanical deformation into optical emission. ZnS:Mn stands out among thousands of ML compounds due to one of the lowest reported thresholds for ML appearance in the range 0.6 - 1 MPa = 0.6 - 1 pN/nm² [1]. Material which is capable of reversible mechanoluminescence at such low pressure range is perfect candidate for nanoscale stress sensor demanded in many technological and biomedical applications. However, further development of ML-based technologies is stalled due to the limited understanding of mechanisms underlying appearance of elastic ML.

We use a new approach to study microscopic characteristics of low force elastic mechanoluminescence in single ZnS:Mn microparticles. It employs the combination of a micropositioner for force application and the Perfect Focus System (PFS) of a Nikon Ti2 widefield microscope to track pressure and ML from single microparticles which are 0.5 - 5 µm in size. We demonstrate that ML in ZnS:Mn is fully endogenous, non-destructive and reversible physical process. Furthermore, analysis of time-resolved microscopic images of ML patterns reveals striation, which does not overlap with analogous features seen in the photoexcited emission of the same particle. It implies that microparticle’s volume is heterogeneous in terms of ML, and certain microscopic structures within the volume are more effective ML emitters. We use Transmission Electron Microscopy (TEM), Focused Ion Beam (FIB) and Kelvin Probe Force Microscopy (KPFM) techniques to show that ZnS:Mn microparticles contain high concentration of zinc blende (ZB)/wurtzite (WZ) stacking faults with electrically charged interphase boundaries.

We propose a new mechanism of elastic mechanoluminescence in ZnS:Mn which relates its structural and mechanoluminescent properties and explains very low threshold for ML appearance. This mechanism relies on the presence of stacking faults and concomitant built-in electric fields which produce a saw-tooth like potential profile inside the crystal. In the faulted crystal, the electron density is shifted towards the positively charged interfaces of the stacking faults in order to compensate for the built-in fields. It leaves the negatively charged interfaces unscreened. Hence, the electrons and holes trapped at the oppositely charged interfaces serve as a source for ML photons. Application of mechanical stress induces an onset of piezoelectric field which is locally enhanced at the electron-depleted interfaces. The carriers trapped at the interfaces gain an excess energy and recombine either immediately or at the moment of the stress release. The local enhancement of the piezoelectric field provides the explanation for extremely low pressures (as low as 240 kPa) which are sufficient for ML excitation in ZnS:Mn. Based on the new model, the ML structural unit comprises two segments of one crystal phase separated by the inclusion of the other phase. Based on our TEM data, it can be scaled down to less than 30 nm what, along with the low threshold for ML appearance, makes ZnS:Mn a perfect candidate for nanoscale force sensor.

EN10.03.09
ZnO/Graphene Oxide Hybrid Quantum Dots-Based Deep-Blue Light-Emitting Diodes Won Kook Choi¹, Hong Hee Kim¹,² and Yeonju Lee¹,²; ¹Korea Institute of Science and Technology (KIST), Korea (the Republic of); ²Yonsei University, Korea (the Republic of)

Currently, much research interest related to achieving white emission has refocused on quantumdots (QD)-LEDs based on fluorescent semiconducting nanoparticles consisting of 10-100 atoms. QD-LEDs have a good color rendering index (CRI), high quantum efficiency, high purity, and narrow emission spectra due to the quantum confinement effect and the size-dependent tunability of the bandgap. Nevertheless, the development of Cd-free non-hazardous as well as In-free cost-effective QDs has become essential and is encouraging intensive research for future optoelectronic devices. Oxide semiconductors are appropriate as eco-friendly materials to produce white light if the visible light emission caused by the electron transition between the defect energy levels of interstitials or vacancies existing in the bandgap is effectively exploited. II-VI ZnO is one among such strong candidates. In general, the PL spectrum of ZnO is characterized by two features, near band edge (NBE) emission in the UV region and defect-related blue, green, yellow, and orange-red emissions in the visible region. Even though the origin of defect-related visible emission have not been manifestively revealed, Defects depending on the excitation wavelength (λex) related to the emissions of green, yellow, and orange-red from ZnO QDs are completely inhibited by removing oxygen vacancies via the hybridization of Zn interstitials with anti-bonding O-states of graphene oxide (GO) QDs. This also leadsto only λex independent violet-purple-blue (V-P-B) emissive ZnO-GO QDs with a high photoluminescence quantum yield (PLQY) of 92%. White-light emission with CIE (0.32, 0.34) from PL QD-LEDs
is realized using a mixture of ZnO and ZnO-GO QDs excited by a UV LEDs chip. ZnO-GO QD-based deep-blue LEDs with luminance of ca 2,000 cd/m², a luminous efficacy (LE) of more than 2.5 cd/A, and external quantum efficiency (EQE) of about 3% with CIE (0.16, 0.11) are also successfully achieved.

EN10.03.10
Tuning the Carriers Localization in CdS/CdSe/CdS Quantum Dots for an Efficient Amplified Spontaneous Emission Process
Gabriel Nagamine¹, Tomás Aguiar¹, Byeong Guk Jeong², Doh C. Lee², Wan Ki Bae³ and Lazaro Padilha¹; ¹Universidade Estadual de Campinas, Brazil; ²Korea Advanced Institute of Science and Technology, Korea (the Republic of); ³Sungkyunkwan University, Korea (the Republic of)

Quantum dots (QDs) have emerged as a promising material to be applied in the next generation of lasers. The possibility of controlling its emission color by size, added to its facile synthesis stimulated intense research in this field in the last years¹. However, there is still many challenges that need to be overcome to make this material competitive with current technologies. Among them, we can highlight the ones related to increase its output efficiency under long term optical or electrical pumping. An important strategy to reach this goal is to build heterostructures, such as core/shell or core/alloy/shell QDs². In this way, it is possible to increase both its absorption cross section and decrease losses due to, for example, non-radioactive Auger recombination. However, increased lattice mismatch in large shell structures drastically decreases their photoluminescence quantum yield (PLQY) due to the creation of interfacial defects. A novel class of heterostructured nanomaterial, called spherical quantum well (SQW), composed by an internal CdS seed, followed by an intermediary emissive layer of CdSe and an outer CdS shell can reduce the crystalline strain between the shell and the emissive layer, allowing for structures that combine high absorption cross section and near unity PL quantum yield³. Here, we investigate the performance of this new class of nanomaterial for lasing applications, by studying their multi-exciton dynamics and amplified spontaneous emission (ASE) threshold. From time resolved photoluminescence studies, we show that the multi-exciton Auger recombination rate is highly reduced in this nanostructure. Varying the shell and well sizes, we report Auger lifetimes from 0.3 to 1.4 ns across samples for positive trions, meanwhile for the negative ones, the lifetime varied from 1.5 to 8.0 ns. Inspired on these characteristics, the size dependence of the ASE properties on SQWs were studied. From that, we show that the ASE threshold decreases as the nanoparticle volume increases, because of the higher cross section, reaching 50 μJ/cm² for the biggest sample. However, considering the average of dots needed to generate ASE, this trend is inverse, going from 1.30 for the smallest particle to 2.35 for the biggest. To understand this phenomenon, the bi-exciton binding energy of the samples were investigated. From that, we show that the reason for this is a transition from an attractive bi-exciton interaction regime to a repulsive one, as the shell thickness increases. To conclude, the unique set of properties presented by SQW brings new insights to overcome current challenges on the application of QD in new laser technologies. Additionally, the ideas presented here can be expanded to other kinds of compositions, making this structure suitable to different kind of lightening emission applications, such as in LEDs and luminescent solar concentrators.

EN10.03.11
Investigation of the Spacer Effects on Emitting Properties of the Ruddlesden-Popper Phase Br-Based Perovskites
Ilgeum Lee¹, Omar Allam², Ju Won Lim¹,², Li Na Quan³,⁴, Seung Soon Jang², Edward H. Sargent⁴ and Dong Ha Kim³; ¹Ewha Womans University, Korea (the Republic of); ²Georgia Institute of Technology, United States; ³University of California, Berkeley, United States; ⁴University of Toronto, Canada

Recently, perovskite light emitting diodes (LEDs) has been attracting great attention as a next-generation LED that can replace existing OLED and QLED. However, methylammonium lead halide (MLH) perovskite is not applicable to LED devices due to its low moisture stability. Quasi-2D perovskites (PEA₂(MA₃₋₁PbBr₃₊₁ has been reported to enhance the photoluminescence (PL) and water-stability compared to conventional MLH 3D perovskite (MAPbBr₃). However, the development of conventional ruddlesden-popper phase perovskites has been only focused on red and
green emission region. In this regard, herein we tried to tailor the emission range of Br-based quasi-2D perovskite from green to blue region by integrating organic cation spacer. As the candidates for spacer, selected aromatic (phenylethylammonium (PEA), benzyltrimethylammonium (BTA)) and aliphatic cations (isopropylammonium (IPA), n-propylammonium (nPA)) were employed by controlling the relative concentration ratio. As a result, the PL intensities and the emission wavelength of the new class of quasi-2D perovskites, BTA and nPA-based perovskites, showed deep-blue emissions at 475 nm, with the uniform and well-structured surface coverage. In addition, The PL intensity of blue perovskite thin film was on par with that of green one ((PEA)2(MA)n-1PbnBr3n+1). By controlling the ratio of BTA and nPA, we could fine-tune the wavelength of the PL wavelength from 610 nm (green) to 475 nm (blue) systematically (with 7 nm intervals). Based on our dimensionality-controlled perovskites, the blue-emissive Q-2D perovskite LED showed low turn-on voltage (less than 4 V) with high-current density (42 mA/cm²). The protocol and strategy established in this study can be exploited to enhance high level electron quantum efficiency (EQE) and luminance.

EN10.03.12
Multi-Emissions from Calcined Oyster Shells Yu Ying Su; National Tsing Hua University, Taiwan

Calcined oyster shells contain an abundant number of color centers arising from Ca and O vacancies. Emissions occur at both 20K and 300K with intensity much greater than reported data on carbon supported ZnO nanocrystals. Optical transitions proceed through three-body mechanisms where nonradiative processes involve transverse acoustical and optical phonons. Oxides obtained from suppliers show a low profile of emission, attributed to water absorption that causes charge transfer and weakens spin-orbital coupling.

EN10.03.13
Photon Upconversion from Near Infrared to Blue Light with TIPS-Anthracene as an Efficient Triplet-Triplet Annihilator Naoyuki Nishimura1,2, Victor Gray1,3, Zhilong Zhang1 and Akshay Rao1; 1University of Cambridge, United Kingdom; 2Asahi Kasei Co, Japan; 3Uppsala University, Sweden

Photon upconversion (PUC) via triplet-triplet annihilation (TTA) is an attractive means for solar energy concentration, bio-imaging, and photochemical reaction, such as photoinduced drug delivery. In particular, generation of blue light (< 500 nm) via upconversion is important, because blue light is required for most photochemical reactions, as well as photocatalytic water splitting to produce hydrogen, since most materials with the efficient quantum yield for photocalytic water splitting can harvest only photons with energy above 500 nm. On the other hand, utilizing near infrared (NIR) photons is crucial for applications such as bio-imaging and drug delivery, as the window for high transparency of biological tissue lies in the NIR region (700 - 900 nm). Thus, PUC from NIR to blue would be beneficial to many emerging applications. As the difference in energy between blue and NIR photons is large (e.g., 470 nm: 2.64 eV and 800 nm: 1.55 eV), a reduction of energy loss in PUC process, leading to larger anti-Stokes shift (\( \text{PUC emission energy} - \text{excitation energy} \)), is also important. However, there has been no report, to the best of our knowledge, of a material with an anti-Stokes shift greater than 1.0 eV that also has a linear excitation intensity dependency (slope 1 for the PUC process). One of the keys to reduce loss in energy for PUC is to minimize the driving force of TTA process (difference in energy between 2T1 and S1 of TTA material). Reports of annihilators fluorophores which can accept low-energy triplets (< 1.55 eV) and generate blue light have so far mainly focused on 9,10-Bis(phenylethynyl)anthracene (BPEA) and perylene derivatives. However, these materials function with low efficiency of TTA and/or require large driving force for TTA. There is a clear need for PUC materials with a large anti-Stokes shift as well as efficient PUC from NIR to blue.

Here, we demonstrate efficient PUC converting from NIR energy to blue photons using the commercially available material 9,10-Bis[(triisopropylsilyl)ethynyl]anthracene (TIPS-Ac) as an efficient TTA material despite a low driving energy for the TTA process (< 0.32eV). When TIPS-Ac was sensitized with Pd(II) meso-Tetraphenyl Tetrabenzoporphine (PdTPBP), a generates triplets via intersystem crossing, the PUC photoluminescence quantum yield with excitation at 635 nm was 27 ± 0.5 % with a TTA efficiency of 77 ± 3 %. Combining TIPS-Ac with Pt(II) meso-Tetrphenyl Tetrabenzoporphine (PtTPBP), where we show directly generates triplet via NIR excitation at 785nm, the PUC achieved an anti-Stokes shift of 1.03 eV with a linear excitation intensity dependency. Therefore, there is a clear need for PUC materials with a large anti-Stokes shift as well as efficient PUC from NIR to blue.
EN10.03.14

Visualizing the Soft Ionic Lattice in Spatially Resolved Emissive Halide Perovskite Nanowire Heterojunctions

Minliang Lai1 and Peidong Yang1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Lead-halide perovskites are a family of semiconductor materials with excellent optoelectronic properties ideally suited for various light-emitting applications beyond solar cells. Particularly, inorganic perovskites CsPbX3 nanostructures are drawing increasing research interests because of their better stability and prior properties. Comparing to conventional semiconductors, these halide perovskites present a unique soft and dynamical ionic lattice. Owing to facile ion migration, anion exchange chemistry was demonstrated in CsPbX3 nanostructures with high PLQY throughout the exchange reaction process. Via developing a novel localized anion exchange method, we demonstrate spatially resolved multi-color CsPbX3 nanowire heterojunctions. These perovskite heterojunctions show tunable photoluminescence over the entire visible spectrum with high resolution down to about 500 nm, which can represent key building blocks for high-resolution displays. Moreover, the intrinsic solid-solid anion interdiffusion dynamics can be visualized in these perovskite heterojunction nanowires through photoluminescence techniques. Besides, there are rich structural phase transitions in the inorganic perovskites. The non-perovskite phase with a large bandgap and poor photoactivity can be thermally-driven transformed into a meta-stable perovskite phase with a decreasing bandgap and excellent optical properties. Using in situ nanoscale cathodoluminescence (CL) microscopy, we can directly visualize the transition dynamics from a non-perovskite to a perovskite phase in single-crystal CsPbX3 nanowires and resolve nanoscale nucleation and growth in the transient two-phase junctions. The reverse transition from perovskite phase to the non-perovskite phase can be further realized with moisture which introduces halide vacancy in the crystal lattice and lowers the kinetic barrier. These fundamental understandings can offer insightful guidelines for engineering the perovskite nanomaterials with novel functional devices.

EN10.03.15

Dynamic Control of Nanoparticle Deposition—Additive Manufacturing with Atmospheric Pressure Plasma

Alexander Ho and Rebecca Anthony; Michigan State University, United States

Additive manufacturing has become a well-established manufacturing style for a range of metals and polymers. An exciting new area is the extension of additive manufacturing to include nanoscale semiconductors, which exhibit interesting properties that can differ from their bulk counterparts. Plasmas have found considerable use in the synthesis of nanoparticles due to their wide operation range which effectively accommodates the tunable properties of nanoparticles. Atmospheric pressure plasmas allow for the miniaturization of reactors easing the integration of the reactors into additive manufacturing systems that rely on an aerosol jets for deposition. Presented here is our work on the additive manufacturing of silicon nanoparticle layers synthesized at atmospheric pressure with a nonthermal plasma. We generated a plasma with a 13.56 MHz RF power supply inside a glass capillary tube between two external ring electrodes. A silane precursor gas together with an argon background gas were flown to the reactor for the synthesis of silicon nanoparticles, with tunable size depending on gas flowrates. The plasma reactor was mounted to a programmable and motorized gantry responsible for driving the reactor through predetermined patterns in all three spatial dimensions. While we achieved sub-millimeter linewidths with aerodynamic focusing using a tapered capillary, we also seek to
exploit the innate nanoparticle charging properties of the plasma synthesis method to modify the deposition. Charge accumulation on the nanoparticles from the plasma and a high voltage power supply were used to control the linewidth of the deposition through electrostatic forces. Through this process we achieved even narrower linewidths, with thicknesses up to and exceeding 100µm as dictated by the dwell time of the reactor. Transmission electron microscopy (TEM) and x-ray diffraction (XRD) indicated that the particle crystallinity and size can be altered in-process via controlling the supplied power and gas flowrates, translating to a dynamic control over nanoparticle properties as we deposit the predetermined patterns. Fourier-transform infrared spectroscopy (FTIR) revealed a stable surface with oxygen-and nitrogen-containing compounds passivating the Si nanoparticle surfaces; this along with the amorphous region present at the edges of crystalline nanoparticles indicates the presence of an oxynitride shell. Photoluminescence of the nanoparticles was observed at a wavelength of 705 nm upon excitation with UV radiation. The ability to synthesize and deposit the nanoparticles with property tunability in-process points to the promise of this approach for additive manufacturing using plasmas.

EN10.03.16
Synthesized High Member of All Inorganic Two-Dimensional Ruddlesden-Popper Single Halogen Perovskite Nanocrystals Cheng-Chieh Lin¹, Shao-Ku Huang², Di-Yan Wang², Cheng-Yen Wen², Chia-Chun Chen³ and Chun-Wei Chen¹,²
¹Taiwan International Graduate Program, and National Taiwan University, Taiwan; ²National Taiwan University, Taiwan; ³Tunghai University, Taiwan; ⁴National Taiwan Normal University, Taiwan

A new model all-inorganic Ruddlesden-Popper phases perovskite (AIRPP) Csn⁺₁BnX3n⁺₁ (n = 1, 2, …) exhibits a more stable crystal structure in the ambient atmosphere and provides a unique quantum well structure separated by inorganic spacer (AX, A= Cs⁺ X= Cl⁻, Br⁻ and I⁻). However, a mixed halide AIRPP Cs₂PbI₂Cl₂ exhibited a large band gap and display strong UV-light response in photodetectors. Therefore, it is still very important topic developing single halide red (R), green (G) and blue (B) emissions with tunable optical properties in visible light range. In this study, we demonstrated phase stable quasi-2D all-inorganic Ruddlesden-Popper phases perovskite (AIRPP) Csn⁺₁PbₓBr3n⁺₁ nanosheets (n=3, 4) with single halide stabilized by additional stronger bounding surface ligand octadecanedioic acid (ODA). The pure phase of quasi-2D AIRPP nanosheets are confirmed by STEM, HR-TEM images and XRD measurements. The different n thickness and layer structure are also identified by density functional theory (DFT). From the optical characterization, the bandgap of Csn⁺₁PbₓBr3n⁺₁ nanosheets (n=3) was found to be ~2.7eV with photoluminescence quantum yield (PLQY) exceeding 40%. The film of Csn⁺₁PbₓBr3n⁺₁ nanosheets (n=3) also displays strong visible light response at a wavelength of 460nm. Moreover, these series of single halide AIRPP exhibited long-term stability over three months in ambient condition.

EN10.03.17
Properties of Ion Gel-Based Flexible Electro-Chemiluminescence Full-Color Display Do-kyun Kwon, Jong-Woo Kim and Jae-Min Myoung; Yonsei University, Korea (the Republic of)

Electro-chemiluminescence (ECL) displays using electrochemical reaction are attracting attention owing to their remarkable advantages, such as simple structure, ultra-thinning, and use of electrodes without work function limitations. However, despite these advantages of ECL displays, a significant limitation still exists, which is the simultaneous realization of red (R), green (G), and blue (B) emissions with excellent emission characteristics. Related studies reported so far have succeeded in improving the individual emission characteristics of R, G, and B ECL display, but have not implemented all colors simultaneously. In order to implement next-generation displays, it is necessary to improve the B emission characteristics and simultaneously realize emission of the three primary colors of R, G, and B.

In this study, ion gel-based flexible ECL full-color display has been successfully demonstrated by overcoming the limitations of simultaneous implementation of R, G, and B emissions. The ECL display was implemented using Ru(bpy)₃(PF₆)₂, [Ir(Fppy)₂(dmb)][PF₆] and FlrMepic corresponding to R, G, and B emissions, respectively. In particular, to achieve improved B ECL displays, the blended blue (BB) ECL display was designed using a mixed-metal chelate coreactant system with mixing of G and B luminophores. The BB ECL display shows significantly improved properties in terms of the operating voltage, luminance, and stability. Furthermore, even after dynamic bending tests of 5000 cycles at a radius of curvature of 10 mm, the flexible ECL display shows stable emission properties. The optical and electrochemical properties of ECL gels were measured using a PL measurement system and a cyclic voltamogram measurement. To confirm the emission of the ECL display, the AC voltage generated by the function/arbitrary waveform generator was used. The EL spectra, luminance, and color coordinates were observed using an EL measurement system and chroma meter.
Keywords: electro-chemiluminescence, ion gel, mixed-metal chelate system, multi-color implementation, flexible display.

EN10.03.18
Facile Room-Temperature Synthesis of Stable Lead Halide Perovskite Nanoplatelets by Ligand-Assisted Reprecipitation Seung Kyun Ha, Catherine M. Mauck and William Tisdale; Massachusetts Institute of Technology, United States

Colloidal lead halide perovskite nanocrystals, which are solution-processable, color-pure, tunable and highly luminescent, are newly arising semiconductor nanomaterials for light-emitting applications. And among nanocrystals with various geometries, quantum- and dielectric-confined two-dimensional colloidal lead halide perovskite nanoplatelet is one of the most favorable candidates for the next-generation light-emitting applications. In this work, we demonstrate a facile room-temperature synthesis of colloidal perovskite nanoplatelet (Chemical formula: \( \text{L}_2[\text{ABX}_3]_{n-1}\text{BX}_4 \), L: organic alkylammonium ligands, A: methylammonium or formamidinium, B: lead, X: bromide and iodide, \( n \): number of [BX\(_6\)]\(^4\)-octahedral layers in the direction of nanoplatelet thickness) via ligand-assisted reprecipitation. We also show that the band gap of the nanoplatelets can be continuously tuned throughout the visible range by halide composition engineering. Then it is further demonstrated that various organic species can be incorporated as surface-capping ligands without any major modifications in the synthetic protocols, opening up the possibility of optimizing the surface chemistry for various applications. Then we focus on the stability of deep-blue luminescent (\( \lambda_{\text{max}} = 437 \text{ nm} \)) nanoplatelet species, which is essential for achieving wide color gamut, and systematically investigate the factors that affect the photostability\(^1\). Photobleaching is found to be coming from intrinsic instability of the perovskite nanoplatelet lattice against UV irradiation, while moisture triggers the transformation of nanoplatelets into thicker, less-confined structures. It is further shown that the substitution of methylammonium for formamidinium and the addition of excess alkylammonium bromide ligands can effectively enhance both the photo- and ambient stability of the nanoplatelets. And lastly, we demonstrate stable color-pure deep-blue luminescence from the dropcasted film of methylammonium lead bromide nanoplatelets.

EN10.03.19
Colloidal Core/Shell Heterovalent Heterostructures for Highly Luminescent Cd-Free Nanocrystals Byeong Guk Jeong\(^1\), Jun Hyuk Chang\(^2\), Donghyo Hahn\(^2\), Hyeonjun Lee\(^3\), Doh C. Lee\(^3\) and Wan Ki Bae\(^1\); \(^1\)Sungkyunkwan University, Korea (the Republic of); \(^2\)Seoul National University, Korea (the Republic of); \(^3\)Korea Advanced Institute of Science and Technology, Korea (the Republic of)

We represent comparative study on core/shell heterostructure nanocrystals based on III-V/II-VI semiconductor with InP/Zinc chalcogenide geometry that show high photoluminescence quantum yield (>80\%) with narrow emission linewidth (~45 nm). We compared the optical properties of nanocrystals with different interfacial geometries before growth of zinc chalcogenide shell. The comparative studies based on spectroscopic analysis and elemental analysis by XPS and ICP-OES reveals that non-radiative traps in the InP nanocrystals are effectively suppressed by controlled interface and surface. Controlled interface of InP/zinc chalcogenide nanocrystal produce energetically favorable interface without net charge, which is called "neutral interface", to successfully confine the electron and hole wavefunction into the InP nanocrystals. Therefore, the III-V/II-VI heterovalent heterostructures show high PL QY of InP based core/shell heterostructures.

EN10.03.20
Properties of Phase-Stabilized Mixed-Cation Perovskite with Hydrophilic Polymer for Red Light-Emitting Diode Do Hoon Kim, Yun Cheol Kim and Jae-Min Myoung; Yonsei Univ, Korea (the Republic of)

The ionic crystals of perovskites have been widely investigated for application in light-emitting devices (LEDs) due to their adjustable optical bandgap by changing the composition of the halide anions. However, small ion size of Cs\(^+\) in inorganic perovskite causes poor crystallinity and small exciton binding energy owing to the inherent defects present in the bulk perovskite hinders the luminescence efficiency of perovskite LEDs (PeLEDs). Moreover, a cesium lead iodide (CsPbI\(_3\)) which is studied as an emitter of red PeLED is not only required to be heat-treated at a
high temperature of 200 °C for phase stabilization but also vulnerable to oxygen and moisture in the air. So, in order to improve the crystallinity and prevent the phase separation of perovskite, it is preferable to use mixture of Cs⁺ and methylammonium (MA) or formamidinium (FA) cation. Furthermore, by adding hydrophilic polymer into the perovskite precursor, the crystal size can be reduced. So, a flat and uniform perovskite film can be formed, leading to decrease of non-radiative defects and leakage current. The phase-stabilized mixed-cation perovskite with hydrophilic polymer not only improve the crystallinity of the perovskite structure but also prevent the phase separation of perovskite.

In this study, to improve the crystallinity and prevent the phase separation of perovskite, CsxMA1-xPbI3 films were fabricated as mixed-cation perovskite by adding methylammonium iodide (MAI) and poly(2-ethyl-2-oxazoline) (PEOXA) as a hydrophilic polymer into the CsPbI3 precursor. The optimized CsxMA1-xPbI3-PEOXA film deposited on poly-TPD showed a uniform surface coverage with a crystal size and thickness of 28.7 nm and 114.2 nm, respectively, and exhibited a strong electroluminescence peak centered at 662 nm. Furthermore, CsxMA1-xPbI3-PEOXA-based red PeLED showed stable device performance at 24 °C under 20.3% relative humidity for 3 days. Therefore, it is believed that the PeLED with a CsxMA1-xPbI3-PEOXA film can be a good candidate for red light-emitting PeLEDs.

EN10.03.21
**Efficient Iridium Phosphorescent Materials for Green Light Emitting Diodes**
Guodan Wei¹, Miao He², Wansi Li¹ and Meng Zhang¹; ¹Tsinghua-Berkeley Shenzhen Institute, China; ²East China Normal University, China

The design and exploration of high stable organic luminescent materials with high luminous efficiency has become an important research area in the frontier of chemistry and materials science. Iridium complexes are one of the best phosphorescent materials. This project aims to synthesize a new "3+2+1" dentate coordination type of luminescent iridium complex, allowing the introduction of a specific ligand in a controlled way, controlling the luminescence properties of iridium complex through appropriate selection of ligand. Finally, a green emissive iridium complex has been synthesized, and the photophysical studies reveals it display a structured emission bands at 474 and 500 nm. These complexes display structural stability at ambient temperatures and quantum yields greater than 30%. In addition to the study of physical properties, we cast this green phosphorescent material as phosphor powders on a 460 nm blue chip to form light-emitting diodes. It was found that the LED has realized pure green emitting and the Commission Internationale Ed l’Eclairage coordinate of the fabricated green LEDs was (0.3,0.6), Moreover, the green LEDs displayed luminous efficiency of 5 lm/W under an injection current of 30 mA.

EN10.03.22
**Improved Green Perovskite EL Performance through New Polymer HTL Based on Carbazole**
Seokwoo Kang, Sunwoo Park and Jongwook Park; Kyung Hee University, Korea (the Republic of)

In conventional organic light emitting diode (OLED) as well as perovskite light emitting diode (PeLED) device, polyvinyl carbazole (PVK) and Poly-TPD have been widely used as a hole transporting layer (HTL) in the past. However, PVK and Poly-TPD have disadvantage in terms of soluble property limitation during stacked-soluble process device preparation. So, more research is needed in terms of materials to apply these materials to perovskite devices. Therefore, we synthesized new polymer HTL material, PBCZCZ for PeLED device. It has non-soluble property to general solvent after thermal treatment and curing process. For the surface analysis of PBCZCZ and PVK, contact angle and AFM analysis were carried out. Contact angle of PBCZCZ is about 5 ° lower than that (76 °) of PVK, and AFM analysis shows similar surface roughness. Also, we found that PBCZCZ achieves much higher mobility than PVK. The structure of PBCZCZ is that two new functional groups are added to the carbazole group. The device configuration is ITO/PEDOT:PSS(40nm)/PBCZCZ(15nm)/CsPbBr3/TPBi(30nm)/LiF(1nm)/Al(100nm). When new polymer HTL material were used, it showed high luminance efficiency of 34.81 cd/A and EQE of 4.01%.

EN10.03.23
**Room Temperature Synthesis of Cesium and Formamidinium Lead Bromide Nanocrystals via Phosphine-Based Chemistry**
Filip Ambroz, Thomas J. Macdonald and Ivan P. Parkin; University College London, United Kingdom

Room temperature (RT) synthesis of perovskite nanocrystals (NCs) is typically achieved employing a ligand-assisted reprecipitation (LARP) method that is compared to the hot-injection (HI) approach cost effective and
industrially friendly. However, the method has many drawbacks that can hinder large scale production of NCs. In this work, we report an amine and an oleic acid free synthesis of lead bromide perovskite NCs using a combination of trioctylphosphine oxide (TOPO) and diisooctylphosphinic acid (TMPPA) ligands. The alternative combination of ligands allows us to synthesize NCs at room temperature (RT) and in air using industrially friendly solvents. We show how our approach can be used to synthesize fully inorganic, CsPbBr$_3$ NCs and hybrid organic-inorganic FAPbBr$_3$ (FA = formamidinium) NCs with the PL emission (fwhm ≈20 nm) between 530 – 535 nm which is in line with the Rec. 2020 color standards. Moreover, using spectroscopy techniques we investigated ligand interactions with the NC surfaces and find that the ligands used in this study are bond via a Pb-O-P bond. In addition, we show that compared to a typically used ligand combination of carboxylic acid and amines, phosphine ligands can be easier removed from the NC surfaces.

EN10.03.24
Anion Exchange Blue Perovskite Quantum Dots LED with Metal Halide

Jun Sato$^1$, Shota Ishikawa$^1$, Yoshihito Takahashi$^1$, Takayuki Chiba$^{1,2,1}$ and Junji Kido$^{1,2,1}$; $^1$Yamagata University, Japan; $^2$Yamaguchi University, Japan

Lead halide perovskite (CsPbX$_3$, X = Cl, Br, I) quantum dots (QDs) have great potential for light-emitting devices (LED) owing to their high color purity and ease of solution processability$^{[1-3]}$. The mix-halide perovskite QDs can be controlled their emission wavelength, CsPb(Cl/Br)$_3$ for blue region by adjustment halide composition. Here, we demonstrate anion-exchange blue perovskite QDs CsPb(Cl/Br)$_3$ from pristine CsPbBr$_3$ using metal chloride. CsPbBr$_3$ was synthesized by the general hot-injection method. The metal chloride was added into CsPbBr$_3$ solution. The anion-exchange CsPb(Br/Cl)$_3$ exhibit a strong blue-shift in their of photoluminescence (PL) spectrum and UV-vis absorption spectra. The PL peaks of the anion-exchange blue perovskite exhibited a blue-shift from 508 nm (pristine) to 470 nm owing to the replacement of Br$^-$ anions by Cl$^-$ anions in the perovskite QDs. Furthermore, the anion-exchange blue perovskite in toluene dispersion exhibited high PLQYs of about 90%. To investigate the reason for increase of PLQY, we performed X-ray photoelectron spectroscopy (XPS). We found the presence of anion defects causing non-radiative recombination in the pristine CsPbBr$_3$. On the other hand, anion defects were suppressed in the anion-exchange blue perovskite. Blue CsPb(Cl/Br)$_3$ LED with anion exchange showed external quantum efficiency (EQE) of over 1%.

SESSION EN10.04: Physics of Perovskite Light-Emitting Materials and Devices

Quantum-Confined Stark Effect of Lead Halide Perovskite Quantum Dots in a Mixed Dimensional van der Waals Heterostructure

Chitrareema Chakraborty$^{1,2}$, Hendrik Uitzat$^2$, Cheng Peng$^2$, Matthias Ginterseder$^2$, Mouni G. Bawendi$^2$ and Dirk Englund$^2$; $^1$Harvard University, United States; $^2$Massachusetts Institute of Technology, United States

The discovery of a myriad of two-dimensional (2D) materials has triggered enormous efforts to integrate distinct monolayers into van der Waals heterostructure for integrated nano-photronics and optoelectronics devices. Mixed dimensional (0D-2D) heterostructures have been previously studied only in relevance to interface charge transport, energy transfer, and photosensitization. In this work, we leverage on mixed dimensional van der Waals heterostructure and fabricate a vertical field-effect device using a combination of 2D and 3D materials to demonstrate quantum-confined Stark effect (QCSE) in highly luminescent perovskite-based (Cesium lead bromide, CsPbBr$_3$) colloidal quantum dots (QDs) with strong excitonic properties. Quantum-confined Stark effect (QCSE) is a basic feature of semiconductor nanostructures that characterizes the change in optical response on applying an electric field perpendicular to the structure.
In our device, few layers of h-BN (hexagonal boron nitride) and monolayer graphene serve as the dielectric and electrical contacts respectively. The QDs are deposited in the center of the heterostructure. We study the photoluminescence (PL) from the perovskite quantum dots embedded within the heterostructure at 4K. Application of a DC voltage in pre-determined step leads to a shift in the PL emission energy. This shift can be reversed by sweeping the voltage back to zero. The maximum observed energy shift is about 30 meV. The spectral shift is also accompanied by a change in intensity and linewidth of the QD which is the hallmark of the QCSE.

In conclusion, we have demonstrated QCSE in perovskite-based CsPbBr3 QDs by embedding them in a vertically stacked van der Waals heterostructure. Using 2D materials for QCSE based modulators makes it highly flexible and easy to integrate with any existing device. In future, such device concept can be used to resonantly tune the transition of a QD for strong coupling with another local emitter or a nano-cavity mode. Further, active feedback from such devices can also reduce slow spectral diffusion in QDs.

8:30 AM *EN10.04.02
Ferroelectric Polaron in Lead Halide Perovskites Xiaoyang Zhu; Columbia University, United States

Lead halide perovskites have been demonstrated as high performance materials in solar cells and light-emitting devices. These materials are characterized by coherent band transport expected from crystalline semiconductors, but dielectric responses and phonon dynamics typical of liquids. Here we explain the essential physics in this class of materials based on their dielectric functions and dynamic symmetry breaking on nano scales. We show that the dielectric function in the THz region may lead to dynamic and local ordering of polar nano domains by an extra electron or hole, resulting a quasiparticle which we call a ferroelectric large polaron, a concept similar to solvation in chemistry. The collective nature of polarization in a ferroelectric large polaron may give rise to order(s)-of-magnitude larger reduction in the Coulomb potential. We develop Fourier transform coherent phonon spectroscopy to directly probe the energetics and local phonon responses of ferroelectric polarons. The ferroelectric polaron may explain the defect tolerance and low recombination rates of charge carriers in lead halide perovskites, as well as providing a design principle of the “perfect” semiconductor for solar cells.

9:00 AM EN10.04.03
Coherent Single-Photon Emission from Colloidal Lead Halide Perovskite Quantum Dots Hendrik Utzat1, Weiwei Sun1, Alexander Kaplan1, Franziska Krieg2, Matthias Ginterseder1, Boris Spokoyny1, Nathan D. Klein1, Katherine Shulenberger1, Collin Perkinson1, Maksym V. Kovalenko2 and Moungi G. Bawendi1; 1Massachusetts Institute of Technology, United States; 2ETH Zürich, Switzerland

Chemically prepared colloidal semiconductor quantum dots have long been proposed as scalable and color-tunable single emitters in quantum optics, but they have typically suffered from prohibitively incoherent emission. We now demonstrate that individual colloidal lead halide perovskite quantum dots (PQDs) display highly efficient single photon emission with optical coherence times as long as 80 ps, an appreciable fraction of their 210 ps radiative lifetimes [1]. These measurements suggest that PQDs should be explored as building blocks in sources of indistinguishable single photons and entangled photon pairs. Our results present a starting point for the rational design of lead halide perovskite-based quantum emitters with fast emission, wide spectral-tunability, scalable production, and which benefit from the hybrid-integration with nano-photonic components that has been demonstrated for colloidal materials.

Rational Strategies to Obtain High Quantum Yields in Perovskite Materials for Light-Harnessing and Light-Emitting Application Neha Arora, M Ibrahim Dar and Richard H. Friend; University of Cambridge, United Kingdom

The extraordinary optoelectronic properties of metal halide perovskite semiconductors allowed the development of highly-efficient light-harnessing and light-emitting diodes based on this new generation of functional semiconductor materials. The outstanding power-conversion efficiencies shown by perovskite solar cells (PSCs) and remarkable external quantum efficiency displayed by perovskite-based light-emitting devices (PeLEDs) are realized, respectively, due to low photovoltage deficits and relatively high photoluminescence quantum yields. Therefore, it has become very important to investigate the causation of high photoluminescence quantum yields,
which translate into low-voltage losses in PSCs, and high external quantum efficiencies of PeLEDs. In my presentation, I will discuss the fabrication of high-performance mixed-cation perovskite-based LEDs and solar cells with an active layer based on a new composition. The improved external quantum efficiencies and photovoltages are obtained by improving the optoelectronic quality of the active layer, optimizing the charge extraction layers, and tuning the interfacial properties which in turn boosts the photoluminescence quantum efficiency, reducing the non-radiative recombination loss and thus enabling balance charge injection. The causation of high internal and external quantum efficiencies and photovoltage was investigated using various structural (Synchrotron-based x-ray scattering), morphological and spectroscopic (photothermal deflection absorption spectroscopy, photoluminescence quantum yield measurements, time-integrated and time-resolved photoluminescence) characterization techniques. The detailed insights gained through these various techniques will be discussed.

Mechanisms of Efficient Light Emission in Metal Halide Perovskites Yanfa Yan and Xiaoming Wang; University of Toledo, United States

Metal halide perovskites have been attracting great attention during the past few years as emerging optoelectronic materials in solar cells and light emitting devices (LEDs). Perovskite LEDs include both narrowband single color light emission and broadband white light emission. Recently, broadband white-light emission has been observed in one-dimensional (1D), two-dimensional (2D), and three-dimensional (3D) organic-inorganic lead halide perovskites. In addition to the broadband feature, the photoluminescence (PL) spectra of these materials show a massive Stokes shift compared to the corresponding absorption onset. The bandwidths of PL spectra are related to the strength of electron-phonon coupling. While it is weak in narrow band emission, it is strong in broadband emission forming self-trapped excitons (STEs). Interestingly, it has been observed in only certain three-dimensional and low-dimensional metal halide perovskites. In this talk, we will show by density-functional theory calculation that multiple STE structures exist in each perovskite exhibiting broadband emission. However, only the STE with Jahn-Teller like octahedral distortion is mainly responsible for the observed broadband emission, though it may not be the lowest energy structure. Both narrowband and broadband emission can be very efficient, which is attributed to the unique defect properties in metal halide perovskites, i.e., the dominant defects only create shallow levels in the bandgap.

10:30 AM *EN10.04.06
Cooling, Scattering and Recombination—The Role of the Material Quality for the Physics of Tin Halide Perovskites Maria Antonietta Loi; University of Groningen, Netherlands

Tin-based perovskites have long remained a side topic in current perovskite opto-electronic research. With the recent efficiency improvement in thin film solar cells [1] and the observation of a long hot carrier cooling time in formamidinium tin iodide (FASnI3) [2], a thorough understanding of the material's photophysics becomes a pressing matter. Since pronounced background doping can easily obscure the actual material properties, it is of paramount importance to understand how different processing conditions affect the observed behavior. Using photoluminescence spectroscopy, we therefore investigated thin films of FASnI3 fabricated through different protocols. We show that hot carrier relaxation occurs much faster in highly p-doped films due to carrier-carrier scattering. From high quality thin films, we extract the longitudinal optical phonon energy and the electron-phonon...
coupling constant, which are fundamental to understand carrier cooling. Importantly, high quality films allow for the observation of a previously unreported state of microsecond lifetime at lower energy in FASnI3, that has important consequences for the discussion of long-lived emission features in the field of metal halide perovskites.

11:00 AM EN10.04.07
Nanolaser Optimization through Statistical Optoelectronic Analysis Juan A. Alanis1, Patrick Parkinson1, Chennupati Jagadish2, and Hoe Tan2; 1The University of Manchester, United Kingdom; 2The Australian National University, Australia

Due to their characteristic elongated shape and reflective end-facets, semiconductor nanowires can be used as Fabry-Perot resonators to fabricate nanolasers. As a way of studying the key elements for lasing operation in these devices, we have developed and successfully employed a large scale optical technique to study interwire functional inhomogeneity. Taking advantage of this novel method we are able to locate and optically study a large number of nanolasers by Photoluminescence (Figure 1). Through a statistical comparison, different parameters such as nanowire length, material inhomogeneity, lasing wavelength etc. are correlated to identify which mechanisms contribute to low-power lasing. We discuss two applications of this approach; nanowires with multi-quantum-well GaAs/AlGaAs active region [1], and p-doped GaAs nanowires [2].

Taking advantage of a large scale optical technique, we have identified key parameters which would improve optoelectronic efficiency and potentially decrease the spread in performance of semiconductor nanowires. Also, we were able to find the best performing nanowire for single device applications. This approach is of industrial value, as well as providing identification of best operating nanolasers for the fabrication of devices for fundamental study.

Spin-Polarised Exciton Exchange Splitting and Luminescence Dynamics in Hybrid Metal-Halide Perovskites Ravichandran Shivanna1, Sean Bourelle1, Satyaprasad P. Senanayak1, Alexander Gillett1, Richard H. Friend1 and Felix Deschler2; 1University of Cambridge, United Kingdom; 2Technische Universität München, Germany

Excitons are the dominant photo-excited species in 2D layered perovskites and the early-time photoexcited species in 3D bulk metal-halide perovskites. Strong spin orbit coupling in these materials enables optical excitation of excitonic states with a defined total angular momentum and the generation of circularly-polarised emission from polarised spin-states. Here, we use circularly-polarised broadband transient absorption and luminescence spectroscopy to study spin-dependent exciton interactions and radiative recombination in the two-dimensional (2D) Ruddlesden-Popper perovskites (BA)3(MA/FA/Cs)2Pb3I11 and 3D bulk MAPbBr3. We spectrally resolve an ultrafast dynamic circular dichroism in the optical response that we discuss to arise from a photoinduced polarisation in the electronic state total angular momentum quantum number. We show that the optically-active states are split in energy via spin-dependent exchange interactions between excitons following photoexcitation, giving rise to shifts in the luminescence spectrum. We report that the room temperature exciton spin lifetimes in 2D metal-halide perovskites increases at low carrier densities, which we discuss as a spin scattering mechanism through Elliott-Yafet processes. Detailed analysis of the initial depolarisation kinetics indicate that the rate of carrier spin relaxation is reduced following the formation of ground state exciton from which luminescence occurs. Our results provide a fundamental picture of the role of exciton-exciton interactions in determining room temperature spin lifetimes and luminescence polarisation, highlighting the potential of hybrid perovskites for applications in spin-polarised light-emitting devices.

Manipulating Exciton Dynamics in Colloidal Cd$_{1-x}$Mn$_x$Se Quantum Dots via Tunable Spin-Exchange Interactions  
Ho Jin$^{1,2}$ and Victor I. Klimov$^1$; $^1$Los Alamos National Laboratory, United States; $^2$The University of New Mexico, United States

Strong quantum confinement unique to colloidal semiconductor quantum dots (QDs) significantly enhances spin exchange interactions between band carriers and Mn dopants. In this case, a single exciton can exert an effective exchange field of a few tesla on the embedded magnetic dopants, which leads to the formation of zero-dimensional magnetic polarons.$^{1,2}$ The strong spin exchange also enables extremely fast energy transfer between the excited Mn ion and the QD exciton which allows one to effectively manipulate nonequilibrium ‘hot’ carriers prior to their relaxation into the band-edge levels.$^3$ This process can also be utilized to generate hot electrons with weak cw optical excitation.$^4$

Mn-doped CdSe QDs represent attractive structures for studies of the effect of resonant versus off-resonant exchange interactions on photoexcited electronic dynamics in a coupled host-semiconductor/magnetic-ion system. However, a colloidal synthesis of high quality Cd$_{1-x}$Mn$_x$Se QDs is still challenging. Among existing synthetic methods, the diffusion doping yields simultaneously the highest Mn$^{2+}$ content and good size uniformity.$^5$ This methods exploits a gradient between Mn$^{2+}$ chemical potentials in the solution and the QD phases for making incorporation of magnetic ions into QDs thermodynamically favorable. In the present study, we aim to improve the Mn diffusion doping method by controlling the chemical potentials of Cd$^{2+}$ in solution. In particular, during the initial synthesis of CdSe QDs, we use secondary phosphines for increasing the nucleation rate and thereby improving the consumption of the Cd precursor. This helps form a pure MnSe shell on top of the CdSe cores upon introduction of a Mn source without producing a Cd$_{1-x}$Mn$_x$Se alloyed layer. This leads to the improved monodispersity of the resulting doped particles as indicated by the reduction of the absorption peak widening to less than 7 meV instead of >20 meV observed for the previous syntheses.$^5$ Further, the removal of excess Cd from the reaction mixture by post-treatment with oleic acid accelerates incorporation of Mn$^{2+}$ into the CdSe lattice by facilitating creation of Cd vacancies due to diffusion of Cd ions towards the QD surface. As a result of fast Mn incorporation, we can induce a 100-meV shift of the absorption edge in just 5 min of the reaction, which is ~50 times faster than for the previously reported procedures.$^5$ This new method allows us to tune the QD band gap by 600 meV, which is accompanied by the dramatic change in the strength of the sp-d exchange coupling between the magnetic dopants and the semiconductor host. By applying CdS shelling to the doped structures, we boost their room-temperature emission efficiencies to more than 60%. By varying the QD size and the level of Mn doping, we observe a strong effect of tunable exchange interactions on electronic dynamics on a wide range of time scales from hundreds of femtoseconds to hundreds of nanoseconds.

Time-Resolved Luminescence Spectroscopy of Light-Emitting Materials on Different Time Scales Combined with Spatial Resolution  
Eugeny Ermilov, Volker Bushmann, Christian Oelsner, Frank Birke, Felix Koberling, Matthias Patting, Marcus Sackrow, Michael Wahl and Rainer Erdmann; Picoquant GmbH, Germany

Luminescence properties of novel light-emitting materials are determined by the architecture and function of the respective devices and directly relate to the physical and chemical nature and quality of these materials. The understanding of photophysical processes as well as structure-property relationship of the new classes of light emitting materials are important steps toward the optimization of their properties to emit specific light for practical applications in different devices.

Time-resolved fluorescence spectroscopy is a modern and most valuable tool to investigate excited state dynamics in molecules, complexes, or semiconductors, which affect the light emitting properties of materials. This type of measurement technique became more and more popular in many scientific fields, including chemistry, biology, physics, as well as in life, materials or environmental sciences and is the ideal method for measuring also weak luminescence.
The combination of time-resolved luminescence spectroscopy with microscopic techniques is without doubt a highly modern and powerful kind of material investigation. Advantages of both techniques are combined in a variable, precise and powerful kind to investigate the photoinduced photophysical processes as well as structural properties of novel light-emitting materials.

Here we will demonstrate the performance of a spectrometer-microscope assembly for characterization and analysis of different light-emitting materials (e.g., halide perovskite, quantum dots and organic-inorganic nanomaterials) in terms of time resolution, ability to measure long decays (e.g., phosphorescence, delayed fluorescence) and record time-gated spectra using laser drivers with burst capabilities. Further more we present different kind of hardware as well as handling optimization for a combination of a state of the art photoluminescence spectrometer with a confocal upright microscope for steady-state, anisotropy, and time-resolved measurements. With this we give prove, that this multi-dimensional approach can be easily and successfully used to exploited investigations of e.g. photoinduced charge carrier dynamics in these materials and its correlation with the localized inhomogeneities and defect sites. Furthermore, surface effects, energy transfer transfer processes as well as the influence of dopants, impurities and defect sites on the luminescence properties of emitters will be discussed.

SESSION EN10.05: Synthesis of Perovskite Nanoparticles for Light-Emitting Devices

Synthesis of Lead-Free Perovskite Quantum Dots for Solar Cell and Lighting Applications
Zeying Chen1,2, Pravakar P. Rajbhandari1,2 and Tara P. Dhakal1,2; 1Center for Autonomous Solar Power, United States; 2Binghamton University, The State University of New York, United States
Metal halide perovskites have received remarkable attention as perovskite photovoltaic (PV) devices. These have already achieved unprecedented higher power conversion efficiency (PCE of 24%) approaching silicon-based PV (PCE of 27%). However, these outstanding optical efficiencies can only be realized by lead-based perovskites and the devices are chemically unstable in air and moisture. Therefore, the key to the large-scale production of perovskite-based solar cell will come down to address their “toxicity” and instability problems. In our research, we are taking up the challenge to replace lead with nontoxic or less toxic element, Sn, and partially or even completely substitute Sn with Ge. For stability, mostly inorganic elements will be chosen. In addition, synthesis of quantum dot (QD) of these materials with water-resistant shell encapsulation to further stabilize the perovskite material will be investigated. The QDs will be synthesized with varying size and compositions to cover the whole UV-VIS spectrum.

1:45 PM EN10.05.02
High-Efficiency Printed Metal Halide Perovskite Nanoparticle Light-Emitting Diodes
Jinwoo Park1, Young-Hoon Kim1, Hengxing Xu2, Yonghee Lee1, Joo Sung Kim1, Sungjin Kim1, Su-Hun Jeong1, Min-Ho Park1, Young-Woon Kim1, Bin Hu2 and Tae-Woo Lee1; 1Seoul National University, Korea (the Republic of); 2The University of Tennessee, Knoxville, United States
We demonstrated bar-coating followed by a fast solvent evaporation process to yield uniform, fully-covered and thickness-controllable films of metal halide perovskite (MHP) nanoparticles (NPs). Based on optimized device structure with uniformly printed MHP NPs, highly efficient perovskite light-emitting diodes (PeLEDs) were achieved. Large-area and active-matrix PeLEDs were also demonstrated. We also analyze the ion-migration and non-radiative recombination pathways in NP films by measuring capacitance, transient electroluminescence and magnetic-field dependent characteristics of NP based PeLEDs and NP films. This work provides a promising way to toward development of MHP emitters in large-scale industrial displays and solid-state lighting, and suggests analysis methods that can be useful for other perovskite optoelectronic devices.

2:00 PM EN10.05.03
Enhanced Stability of Colloidal Quantum Dots by Shell Encapsulation Enabled by Cross-Linkable Polymeric Ligands
Jaewan Ko and Joona Bang; Korea University, Korea (the Republic of)

Endowing quantum dots (QDs) with robustness and durability has been one of the most important areas of research in this field, since the major limitations of QDs in practical applications are their thermal and oxidative instabilities. In this work, we propose a facile and effective passivation method to enhance the photochemical stability of QDs by structurally designing polymeric double shell network of thiol-terminated poly(methyl methacrylate-\textit{b}-glycidyl methacrylate) (P(MMA-\textit{b}-GMA)-SH) block copolymers ligated to QDs. To achieve this, the cross-linking reaction of GMA epoxides in PGMA block was conducted using Lewis acid catalyst under an ambient environment in order not to affect the photophysical properties of pristine QDs, which provides QDs with robust double layers consisting of highly weatherable and transparent PMMA outer-shell and oxidation-protective crosslinked inner-shell. Consequently, the resulting QDs surrounded by crosslinked double shell layers exhibited exceptional tolerance to heat and oxidants when dispersed in organic solvents or QD-nanocomposite films, as evidently corroborated under various harsh conditions with respect to temperature and oxidant species. In addition, it was shown that the outer polymer brush can provide the miscibility of resulting QDs with host polymer matrix to fabricate a well-defined QD-nanocomposite films via cost-effective solution process. The present approach not only provides simple yet effective chemical means to enhance the thermochemical stability of QDs, but also offers a promising platform for the hybridization of QDs with polymeric materials for developing flexible light-emitting or light-harvesting devices.

2:15 PM EN10.05.04
Highlighting Challenges of Oleate-Capped Formamidinium Lead Bromide Perovskite Nanocrystals
Olivia J. Ashton, Ashley Marshall, Jonathan Warby, Bernard Wenger and Henry J. Snaith; University of Oxford, United Kingdom

Studies conducted on the stability of perovskite nanocrystals have begun to aid understanding of how to handle these emerging materials. Through extensive experimental and computational studies, a consensus has emerged in the community surrounding the crucial nature of the surface of the nanocrystals and the complex, dynamic ligand shell around them. Different ligands have been shown to both improve photoluminescence quantum yield to near unity, and bolster stability to washing and colloidal lifetimes. The binding groups of the ligands and their introduction in the synthesis or as a post-treatment have been highlighted time and again.

To date these impressive developments have mostly focused on cesium lead bromide, CsPbBr\textsubscript{3}. The perovskite family extends its compositional range in both the cation and anion sites, and the translation of successes is not straightforward. In this work, we investigate the fabrication of formamidinium lead bromide, FAPbBr\textsubscript{3}, via a phosphine oxide assisted synthesis and the challenges faced when applying lessons learnt from the all inorganic perovskite to this system. Through nuclear magnetic resonance spectroscopy coupled with optical characterisation we demonstrate the influence of the labile formamidinium protons on the surface chemistry of the nanocrystals and how this in turn changes their stability, structural integrity and affects the reaction pathway in the formation of these nanocrystals compared to their inorganic counterpart.

2:30 PM EN10.05.05
Light Emitting Diodes Based on Colloidal Quantum Dots with Ultrahigh Current Densities Exceeding 1,000 A per cm\textsuperscript{2}
Heeyoung Jung\textsuperscript{1}, Young-Shin Park\textsuperscript{1,2}, Jaehoon Lim\textsuperscript{1,3} and Victor I. Klimov\textsuperscript{1}; \textsuperscript{1}Los Alamos National Laboratory, United States; \textsuperscript{2}The University of New Mexico, United States; \textsuperscript{3}Ajou University, Korea (the Republic of)

Colloidal semiconductor quantum dots (QDs) have great potential as optical gain media for realizing solution processable lasers with readily tunable emission wavelengths. A present challenge in this area is the demonstration of electrically pumped lasing devices. Recent advances towards this goal include the realization of optical gain with direct current (d.c.) electrical pumping [1], the demonstration of high brightness QD light emission diodes (LEDs) [2], and the development of effective strategies for tackling the efficiency ‘droop’ problem [3]. Next tasks include pushing current densities to \textasciitilde100 A cm\textsuperscript{-2} (or above) levels and incorporation of an optical resonator into a QD-LED device. Here, we address the first of these challenges by practically demonstrating pulsed QD-LEDs that achieve ultrahigh current densities exceeding 1,000 A cm\textsuperscript{-2}. This allows us to inject more than 10 excitons per dot and thereby realize population inversion of both the ground-state (1S) and the excited-state (1P) transitions. This demonstration exploits continuously graded QDs (cg-QDs) embedded into a ‘current focusing’ \textit{p-i-n} LED [1].
actuated using short-pulse electrical bias. As we demonstrated previously, cg-QDs exhibit strong suppression of nonradiative Auger decay [1, 4], which is essential for achieving highly emissive multie exciton states. These dots are integrated into an inverted p-i-n LED with hybrid (inorganic/organic) charge transport layers. An interlayer of an insulating material with a narrow (~50 μm) gap is deposited on top of the QDs to limit the injection area and thereby increase current density (J). Using this approach, we achieve J of ~50 A cm⁻² with d.c. current excitation. We able to push current density to ~600 A cm⁻² using 5 μs voltage pulses, and increase it further to >1,000 A cm⁻² with 1 μs pulses. Using these ultrahigh current densities, we are able to realize an unusual electroluminescence (EL) regime when the intensity of the 1P band exceeds that of the 1S emission. Based on the quantitative analysis of the EL spectra and comparison with optically excited photoluminescence, we conclude that using electrical pumping we are able to excite at least 10 (and potentially >20) excitons per dots. Such excitation levels greatly exceed the thresholds for both 1S and 1P optical gain. Importantly, these extremely high current densities are realized using a fairly thick active medium comprising up to 4 QD monolayers. We further demonstrate that the layers of this thickness are capable of lasing if combined with optimized distributed feedback cavities. Not only these results prove the feasibility of electrically pumped lasing with colloidal QDs but they also suggest that the goal of practically realizing such devices is within close reach.

2:45 PM EN10.05.06
**Mechanistic Investigation of Alkanethiol Treatment of Colloidal CsPbX₃ Nanocrystals** Kenneth R. Graham, Md Aslam Uddin, Justin K. Mobley, Abdullah Masud, Tuo Liu, Rosemary Calabro, Doo Young Kim and Christopher I. Richards; University of Kentucky, United States

Metal halide perovskite nanocrystals (NCs) are promising materials for use in optoelectronics. However, further improvements in stability, reproducibility, and photoluminescence quantum yield (ΦPL) are essential for enabling commercial applications. Inadequate surface passivation is a major cause of instability, irreproducibility, and low ΦPL. We find that post-synthetic treatment with alkanethiols reproducibly yields stable NCs with near unity ΦPL for a range of synthetic conditions and varying initial ΦPL of the as-synthesized NCs. A mechanistic investigation shows that thiol addition leads to thioether formation via the thiol-ene reaction with octadecene, oleic acid, and oleylamine. Both thioliates and thioethers are suspected to bind to undercoordinated Pb atoms on the NC surfaces, and the surface binding and ΦPL increases can be rapidly accelerated through exposure to blue or UV light. Furthermore, we show that metallic Pb nanoparticles appear in many batches of synthesized CsPbBr₃ NCs and that dodecanethiol addition eliminates these metallic Pb particles. Applying similar alkanethiol treatment to thin films processed with varying Cs:Pb or methylammonium:Pb stoichiometry we find that alkanethiols only bind to the film surfaces when a significant excess of PbX₃ is included in the processing solution.

**Probing the Bias-Induced Interfacial Characteristics of MAPbBr₃ Perovskite LEDs** Tzung-Fang Guo, Aswaghosh Loganathan and Teng Lam Shen; National Cheng Kung University, Taiwan
The interfacial phenomenon in the case of MAPbBr$_3$-based organic-inorganic hybrid light-emitting diode (LEDs) depends upon the existence of vacant sites that enable electric-field driven ion migration which in turn causes detrimental effect on the device efficiency. A clear deeper knowledge of the fundamental interfacial mechanism in hybrid LEDs that is dependent on the material properties must be essentially brought in focus so as to improve the optoelectronic properties.

In this present study, we have attempted to bring out this interfacial phenomenal occurrences using Admittance Spectroscopy and demonstrate the fundamental mechanism in such perovskite LED and further establish a method to tune the interfacial kinetics by appropriate passivation of perovskite layer by additive engineering. Defect passivation via additive engineering improved the LED device performance incredibly evidenced by the lowering of built-in potential ($V_{bi}$) indicating faster light turn-on and reduced interface potential revealing better interfacial charge injection behavior. Moreover, the current-voltage (I-V) hysteresis behavior speculated to be arising due to ion migration is suppressed. Carrier dynamics is altered by enhancing the carrier injection due to improved interfacial conduction and noticeable change from inductive behavior to capacitive behavior due to increased carrier density. The DC bias dependences of characteristic times and carrier distribution are analyzed to understand the complex kinetic behavior of hybrid LED as it is composed of both organic and inorganic components. This clear understanding of the interfacial kinetics and carrier dynamics will enable materials scientists to establish strategic design to overcome the existing disadvantages in near future and improve the optoelectronic functionalities and properties.

4:00 PM EN10.06.02

Exciton Fine Structure of CsPbBr$_3$ Perovskite Quantum Dots—A First-Principles Study Oleksandr Voznyy$^{1,2}$ and Kamalpreet Singh$^{1,2}$; 1University of Toronto Scarborough, Canada; 2University of Toronto, Canada

Cesium lead halide perovskite nanocrystals are a highly attractive class of materials for coherent light emission, with implications for lasing, light-emitting diodes, and quantum computing. Fine-tuning their properties for the above applications requires an exact understanding of their exciton fine structure, in particular, spacing and polarization of their triplet and singlet states. Experimental reports have been controversial, implicating that the Rashba effect may be inducing an inversion in the order of bright and dark states.

To aid in the resolution of this debate, we performed an investigation of the fine structure of the triplet emission properties in these materials. Using the wave functions generated via DFT calculations including spin-orbit coupling for cubic, orthorhombic and tetragonal cesium lead halide perovskite nanocrystals of ~3 nm in diameter, we further augmented them with Coulomb coupling between the exciton configurations, to resolve the absorption and emission fine structure in a configuration interaction method.

We anticipate our work will aid in the resolution of the debated emission fine structure of CsPbBr$_3$ nanocrystals and thereafter allow for the development of bright materials for optoelectronics.

4:15 PM EN10.06.03

A New Tool to Probe Local Photophysical Properties in Passivated Perovskite Nanoplatelets for Light-Emitting Devices Miguel Anaya, Kyle Frohna, Javad Shamsi, Kangyu Ji, Krzysztof Galkowski and Samuel D. Stranks; University of Cambridge, United Kingdom

Confined versions of metal-halide perovskites have emerged over the past years as a versatile class of semiconductors for high-performance optoelectronic devices.[1] Despite their unique properties, this family of perovskites has however been observed to display photo-instability, especially when emitting in the blue region of the electromagnetic spectrum. Moreover, the use of ligands to mitigate agglomeration and the large density of surface defects in the material hamper charge carrier injection and radiative recombination and thus their definitive integration in real-world devices.[2,3]

In this talk, we will present a detailed photophysical characterisation of blue emitting CsPbBr$_3$ perovskite nanoplatelets (NPLs) in which a controlled Br- and light-based passivation strategy is employed to improve both their optical and electrical properties. In this regard, we will introduce a new powerful technique with which we can extract the Urbach energy, absorptance, quasi-Fermi level splitting and photoluminescence quantum efficiency (PLQE) values in the materials at the nanoscale by hyperspectral wide-field imaging. The observations reveal microscale heterogeneities in the pristine NPLs films that are remarkably suppressed in the treated samples. Furthermore, the optoelectronic quality of this blue emitters is boosted by means of a high PLQE surpassing 50%
and an important reduction of surface defects. Interestingly, our approach allows us to achieve fine control over the work function (as revealed by Kelvin Probe) of the systems. Finally, we fabricate LEDs based on the most efficient materials and obtain maps at the diffraction limit scale demonstrating homogeneous external quantum efficiencies close to 0.3% at 460nm, which match those at the macroscale.[4]

4:30 PM EN10.06.04
Real-Time Investigation of Colloidal Quantum Dot Self-Assembly During Blade-Coating Ahmad R. Kirmani1, James Z. Fan2, Edward H. Sargent2 and Lee Richter1; 1National Institute of Standards and Technology, United States; 2University of Toronto, Canada

Colloidal quantum dots (CQDs) have been intensely pursued for applications in flexible light-emitting displays and photovoltaics. Self-assembly of CQDs into long-range ordered 3D superlattices (SL) leads to emergence of new optical and electronic properties and offers to extend their benefits portfolio beyond those afforded by size-confinement. Technological viability of these structures requires their controlled fabrication using scalable coating methods. In this study, we explore lead sulfide (PbS) CQD self-assembly during blade-coating using time-resolved X-ray scattering and optical interferometry. Blade-coating is an established prototyping tool for slot-die coating. We monitor the nucleation and subsequent evolution of the CQD SLs during the ink-to-film transformation. A rich structural diversity is observed when tuning the CQD size, concentration, solvent and substrate temperature. SLs are found to nucleate very early in the coating stage from an FCC phase at the solvent-air interface during which the individual CQDs are randomly oriented. As the solvent nears complete evaporation, the system enters a transition stage where the FCC SL contracts and morphs into a final, dry BCC phase due to ligand packing frustration. This transition is marked by an orientational ordering of the CQDs that grows stronger with the CQD size. We also observe SL twinning during coating of the largest: 8 nm diameter CQDs. This study develops a fundamental understanding of and provides design rules for fabricating and tailoring self-assembled CQD solids via scalable coating.

4:45 PM EN10.06.05
High-Resolution Patterning and Tandem Processing Achievable for Quantum Dots Films Crosslinked with Photoinduced-Ligand Binding Agents Moon Sung Kang and Jeehye Yang; Sogang University, Korea (the Republic of)

To fully exploit the excellent luminescence characteristics of quantum dots (QDs), researches on EL displays based on QDs have been actively conducted. To achieve this, a multi-color QD patterning technology must be established. Processing and patterning of quantum dots involve a solution-based technique, unlike the organic light emitting materials which are typically deposited through evaporation-based technique. The applicability of QDs to various solution process allows one to carry out their deposition over a large-scale at low cost, but it also causes a problem of dissolving the bottom layer if the secondary layer is applied by solution process consecutively. To avoid this problem, several QD patterning techniques have been developed, such as inkjet printing and microcontact printing. Here we report a simple way to obtain high-resolution patterns of InP QDs using a chemical crosslinker (bis-perfluorophenyl azide) that can bind to ligands surrounding the QD surface to form a bridging network upon exposure to UV, which is referred to as the photoinduced-ligand binding agents (PiLBA). Due to the chemical durability of the cross-linked QDs, non-crosslinked portions can be etched chemically to form high resolution (<3 μm) patterns of QDs. Multi-color patterns can also be stacked laterally or vertically by repeating the same solution process (see images below). The EL characteristics of the cross-linked QDs varied systematically with the loading of the PiLBA. The simple strategy converting the QD films to be photo-resistive will make significant impact enabling the production of high-resolution, high-throughput, full-color EL displays based on QDs intensively explored in the community.
EN10.07.01
White Electroluminescence Devices with Double Emitting Layers Employing Red Quantum Dots and Blue Organic Phosphorescent Molecules
Jiwan Kim and Aram Moon; Kyonggi University, Korea (the Republic of)

Colloidal quantum dots (QDs) which are nano-sized semiconductors, have special properties such as easy emission tunability, high color purity and solution processability. With the commercial potential of QD-based displays being confirmed, quantum dot light-emitting diodes (QLEDs) have attracted attention as next generation display technology.

Over the past several decades, many groups have studied about the core / shell structure of QDs, charge transport layers and the charge balance to improve the efficiency and lifetime of QLEDs. The performance of QLEDs has dramatically improved through the studies, but it is only limited to monochromatic QLEDs. Therefore, for commercialization of full color QLEDs, studies on white emitting QLEDs should be conducted.

Herein, we fabricated white standard structured electroluminescence (EL) devices with double emitting layers (EMLs) using red QDs and blue organic phosphorescent molecules. The double EMLs were formed by stacking blue organic molecules EML directly on the red QDs EML.

Recently, organic light-emitting diodes (OLEDs) structure with the QD color filters has received huge attention in the display industry mainly applying QD to the color converting layer. This structure is different with our white QLEDs, but a blue OLEDs is commonly used between two structures. In this study, we used bis[2-(4,6-difluorophenyl)pyridinato-C2,N]iridium(III) (FIrpic) as the blue emitting organic materials. By using FIrpic, which has a broad emission spectrum, white emission with relatively high color rendering index (CRI) was obtained with less materials, only single QDs EML and organic EML.

When the applied voltage was more than 7 V, the red and blue peaks appeared simultaneously from the EMLs. Commission Internationale de l'Eclairage graph shows that the color coordinate shifts from the red region to the white region as the voltage increases. At an applied voltage of 12 V, the device exhibited a maximum luminance of 4,619 cd/m², a peak current efficiency of 2.17 cd/A and the high CRI of 66.

Our unique QLEDs with double EMLs shows the potential for white EL devices using less materials. Therefore, this result is expected to contribute to the development of practical full color display beyond OLEDs in the near future.

EN10.07.02
Mn-doped Lead Halide Perovskite Nanocrystals with High Luminescence and Application for Light-Emitting Diodes
Zhuo Chen, Lvming Dong, Hanchuan Tang and Jianfeng Zang; Huazhong University of Science and Technology, China

All-inorganic halide perovskites (CsPbX₃, X=Cl, Br and I) have emerged as one of the most prominent materials in the application of photoelectric devices due to remarkable properties such as high photoluminescence quantum yields and tunable emitting color, but toxic Pb is not environment-friendly. Therefore, the effort to develop lead-free all-inorganic perovskite QDs becomes inevitable. Herein, we report a simply, atmospheric synthesis approach for incorporating manganese (Mn) ions into cesium lead halide (CsPbX₃) perovskite quantum dots (QDs) with high luminescence and stability. Different Mn-to-Pb feed ratios are explored to study the influence on the intensity of two emission peaks, around 400 nm and 600 nm, respectively, and the optimum luminescence up to 65% is achieved.

The optical properties of as-prepared nanocrystals remain consistent even after several months. Besides, we obtain high luminescence Mn-doped blue perovskite nanocrystals and the stability has been greatly improved in comparison to those pure blue perovskite nanocrystals. Both the orange and white light-emitting diodes (LEDs) are obtained by directly employing the as-prepared CsPbₓMn₁₋ₓCl₃ QDs as color conversion materials on a commercially available 365 nm GaN LED chip and combining the orange nanocrystals with the Mn-doped blue perovskite nanocrystals on a UV LED. The excellent optical properties of the CsPbₓMn₁₋ₓCl₃ QDs offer great potential for the application of high
performance flexible displays on composite polymer substrates.

**Atomistic Defect States as Quantum Emitters in Monolayer MoS\(_2\)**

Michael Lorke\(^1\), Julian Klein\(^2\), Matthias Florian\(^1\), Florian Sigger\(^2\), Jakob Wierzbowski\(^2\), John Cerne\(^3\), Kai Mueller\(^2\), Takashi Taniguchi\(^4\), Kenji Watanabe\(^4\), Ursula Wurstbauer\(^2\), Michael Kaniber\(^1\), Florian Knap\(^2\), Richard Schmidt\(^5\), John Finley\(^2\) and Alexander Holleitner\(^2\);

\(^1\)University of Bremen, Germany; \(^2\)Technical University of Munich, Germany; \(^3\)University at Buffalo, The State University of New York, United States; \(^4\)National Institute for Materials Science, Japan; \(^5\)Max-Planck Institute for Quantum Optics, Germany

Quantum light sources in solid-state systems are of major interest as a basic ingredient for integrated quantum device technologies. The ability to tailor quantum emission through deterministic defect engineering is of growing importance for realizing scalable quantum architectures. However, a major difficulty is that defects need to be positioned site-selectively within the solid. In this work this is overcome by controllably irradiating single-layer MoS\(_2\) using a sub-nm focused helium ion beam to deterministically create defects. Subsequent encapsulation of the ion bombarded MoS\(_2\) flake with high-quality hBN reveals spectrally narrow emission lines that produce photons at optical wavelengths in an energy window of one to two hundred meV below the neutral 2D exciton of MoS\(_2\).

Based on ab-initio calculations we interpret these emission lines as stemming from the recombination of highly localized electron-hole complexes at defect states generated by the helium ion bombardment. Using a many-body approach for dephasing due to electron phonon emission, we quantify the spatial extension of the emission centers and compare them to the results of the ab-initio calculation. [1]

**EN10.07.04**

**Flexible Electrochromic Displays with Subpixelated Ion Gel-Based Viologens by Multiple Patterning**

Jong-Woo Kim, Do-kyun Kwon and Jae-Min Myoung; Yonsei University, Korea (the Republic of)

Electrochemical devices have attracted attention as display materials owing to their properties such as simple structure, low-power driving, and variety of electrodes irrespective of work function. Among the electrochemical materials, electrochromic materials which exhibit reversible color change by redox reactions have been used in the field of smart windows, mirrors, displays, and sensors. To utilize electrochromic materials for active-matrix display applications, an electrochromic display (ECD) requires simultaneous implementation of various colors and a fine-pixelation process.

In this study, flexible ECDs with simultaneously implementable subpixelated-EC gels by sequential multiple patterning were successfully demonstrated. Ionic liquid-based EC gels of monoheptyl-viologen, diheptyl-viologen (DHV), and diphenyl-viologen (DPV) were used to create the colors of ECDs: magenta, blue, and green, respectively. Especially, to realize an improved green color, DHV–DPV composite gels were synthesized. Three EC gels exhibited stable properties without degradation during repetitive operation. The subpixelation process for multicolored-flexible ECDs was designed to facilitate both easy fabrication and rapid operation with various patterns at low cost. The subpixelated EC gels using a film mask could be implemented to a minimum size of 200 \(\mu\)m. Furthermore, the subpixelated flexible ECDs exhibited high durability even after 1000 cycles of mechanical bending tests at a bending radius of 10 mm. The surface characteristics of the EC materials were confirmed by optical microscopy, and the optical characteristics were analyzed by using a UV-vis spectrometer. The redox potential of the EC gel was confirmed by cyclic voltammetry using a potentiostat. After fabrication of patterned-ECD on a flexible substrate, the analyses of optical properties and reliability test were conducted according to the applied voltage.

**Mapping Plasmon-Enhanced Upconversion Fluorescence Near Au nanodisks**

Lionel Aigouy\(^1\), Maria Ujue Gonzalez\(^2\), Hung-Ju Lin\(^1\), Mathilde Shoenauer-Sebag\(^1\), Laurent Billot\(^1\), Patrick Gredin\(^2\), Michel Mortier\(^2\), Zhuoying Chen\(^1\) and Antonio Garcia-Martin\(^2\);

\(^1\)ESPCI Paris, PSL Research University, CNRS, France; \(^2\)Inst. de Micro y Nanotecnologia - CSIC, Spain; \(^3\)Chimie ParisTech, PSL Research University, CNRS, France
Strategies for controlling and enhancing the fluorescence of molecules and nanocrystals have been the subject of intense research in the past decades [1-3]. This trend is motivated by the need to develop new highly sensitive biosensors, and by the possibility to improve optoelectronic devices like light emitting diodes and solar cells. Here, we present a study of upconversion fluorescence enhancement effects near Au nanodisks by scanning near-field optical microscopy. The enhancement and localization of light near the metallic structures are directly visualized by using a single Er/Yb-codoped fluorescent nanocrystal [4,5] glued at the end of a sharp scanning tip. Excitation was achieved in a transmission mode by a linearly polarized laser diode (\(\lambda = 975\) nm) focused in the tip-sample region. Fluorescence was detected in the visible range after the absorption of two photons by up-conversion. In general, the fluorescence enhancement pattern presents two lobes aligned in the direction of the incident polarization direction, but the intensity amount and the details of the enhancement distribution strongly depend on the nanodisk size. The observed patterns are in good agreement with the near-field maps calculated by finite-difference time-domain method, both in two and three dimensions above the structures. The relationship between the far-field optical response of the nanostructures and the achieved enhancement is also analyzed. [6]

Characteristics of Violet Light-Emitting Diodes Fabricated Using p-CuI Film/n-MgZnO Quantum Dot Heterojunction Sung-Doo Baek and Jae-Min Myoung; Yonsei University, Korea (the Republic of)

Solid-state lighting based on GaN and related compounds has been successfully developed and commercialized over the last few decades. Until recently, many researches have been attempted to discover new kinds of inorganic semiconductor candidates for next-generation light-emitting diodes (LEDs) that can replace GaN. Among those, ZnO has attracted much attention as a representative candidate due to its various advantages such as a wide direct transition band gap (~3.37 eV) with a large exciton binding energy (~60 meV), low-cost production, and harmlessness to the human body. However, it is challenging to obtain p-type ZnO due to native donor defect of oxygen vacancy in the ZnO lattice, thereby achieving ZnO p-n homojunction is a difficult task. To overcome this problem, many studies have been conducted on p-n heterojunction LEDs using n-type ZnO with other p-type semiconductors.

In this study, CuI possessing a direct transition band gap (~2.95 eV) with a large exciton binding energy (~58 eV) has been adopted as a p-type material for ZnO heterojunction LEDs. As an n-type material, MgZnO quantum dot (QD) which has much wider band gap than ZnO was used. Moreover, the size reduction of MgZnO QDs was observed, causing the band gap widening of MgZnO by the quantum confinement effect. The wider band gap of MgZnO can effectively suppress excess electron injection from cathode to the p-CuI layer, enhancing the electron-hole recombination efficiency by charge balance between electrons and holes. The CuI film was obtained by iodination process of Cu metal film deposited on ITO-coated glasses and the n-Mg\(_x\)Zn\(_{1-x}\)O QDs were separately synthesized by low-temperature solution process. The p-n heterojunction was formed by spin-coating of the synthesized n-MgZnO QDs on the CuI film. The morphology of the obtained p-CuI film and n-MgZnO QD were confirmed by scanning electron microscope and transmission electron microscope, respectively. Optical characteristics of each layer were evaluated by photoluminescence and UV-Vis-NIR spectroscopy. The Mg content of MgZnO QDs was examined by X-ray photoelectron spectra analysis. Finally, the electrical and optical characteristics of the fabricated LED were evaluated by current-voltage measurement, electroluminescence measurement with light emission images.

Wirelessly Operated Wearable Micro Light-Emitting Diodes on a Fabric Seung Hyung Lee, Han Eol Lee, Jung Ho Shin and Keon Jae Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In the era of hyper-connection, wearable displays are attracting attention as a two-way communication method. Although there have been several demonstrations of displays on clothes, the problem of high power consumption
still remained. In this work, we present wirelessly operated wearable micro light-emitting diodes (WμLEDs) fabricated on a fabric. The stability of the WμLEDs was investigated under harsh conditions like high temperature and humidity, mechanical deformation and sunlight, which means that the WμLEDs can be used for outdoor applications. Furthermore, a passive-matrix WμLEDs device was successfully demonstrated which emitted bright red light.

**EN10.07.08**

**Deep Red to Near Infrared Emitting Iridium Complex for Solution-Processable Phosphorescent OLEDs with Substituents Engineering** Sungjin Park, Seyeong Lim, Taehyun Kim and Taiho Park; POSTECH, Korea (the Republic of)

The emerging future engineering technology such as dark-vision displays and photobiomodulation light therapy has induced an enormous demand for the design of highly efficient, flexible, stable, and low-cost deep-red emitting luminophores. Herein, six new deep-red and near infra-red (650–800 nm) emissive iridium(III) complexes have been designed and synthesized, variation on cyclometalating (benzo[b]thiophen-2-yl)quinoline main ligand and picolinate, β-diketonate ancillary ligands. The structures and distorted octahedral coordination motifs of six iridium complexes were analyzed by single-crystal X-ray diffraction analysis. Herein, four iridium complexes were developed with electron donating or withdrawing substituents anchored on the quinoline moiety of (benzo[b]thiophen-2-yl)quinoline cyclometalating ligands. With single-crystal X-ray diffraction analysis, exact coordination geometry, intermolecular interactions were identified. In addition, deep study on the effect of the ancillary ligands on the excited-state process was carried out and the results were compared with reference compounds containing thenoyltrifluoroacetylacetone in place of the picolinate ancillary ligand. The picolinate ancillary ligand has rigid nature and high triplet energy level which induces a robust deep-red emission while the triplet spin density population and flexible deformation of β-diketonate ancillary ligand resulted an excited-state geometrical deformation, yielding unfavorable, nonradiative pathways. Therefore, iridium complexes which uses the picolinate as ancillary ligand show excellent emission efficiencies (Φ<sub>PL</sub> = 0.48 and 0.37, respectively) and were effectively employed as deep-red dopants in organic light-emitting diodes, constructed via a solution-processed approach. The unoptimized synthesized iridium complexes based devices with various doping ratios performed maximum external quantum efficiency values of 5.03% and 3.41%, respectively.

**EN10.07.09**

**Thiol Ligand Exchange—Enhanced UV-Visible Photostability of CsPbI<sub>3</sub> Perovskite Quantum Dots Synthesis and Polymer Film Application** Yongjin Kim, Seungmin Baek and Sang-Wook Kim; Ajou University, Korea (the Republic of)

PeQDs show high quantum yields (QYs) of 40–90% with a narrow full-width-at-half-maximum (FWHM) of 20–45 nm. The narrow FWHM results in a wide color gamut, making PeQDs attractive as promising materials for optoelectronic applications such as light emitting diodes (LEDs), photodetector and lasers. However, perovskite structures suffer from serious stability problems due to their ionic characteristics. Among the PeQDs, red-emitting CsPbI<sub>3</sub> QDs with the α-phase structure are particularly unstable and it is difficult to maintain the structural stability of these species under light, moisture, or heat conditions because iodine has a large ionic radius, weak ionic bonds, and low stability. synthesizing the perovskite quantum dots, oleic acid(OA) and oleylamine(OLA) are often used as capping ligands. However, it is difficult to stabilize the ionic perovskite due to weak surface binding, thus optical properties are easily degraded. Herein, we report highly photo-stable CsPbI<sub>3</sub> perovskite quantum dots after ligand exchange with thiol (-SH, X-type ligand). The success of ligand exchange from OA and OLA to thiol could be stabilize the structure. Because thiols can attach to the surface of CsPbI<sub>3</sub> due to their high affinity for Pb<sup>2+</sup>, thereby stabilizing CsPbI<sub>3</sub>. Also, the α-phase structure could be maintained and the photoluminescence (PL) could be persisted for an extended period. As a result, structure stability and optical properties (Quantum Yields) were improved. Furthermore, the synthesized CsPbI<sub>3</sub> PeQDs showed that the photo-stability was highly improved under UV(365nm) irradiation. The PL intensity of thiol-uncapped CsPbI<sub>3</sub> decreased sharply for 12 hours, while thiol-capped CsPbI<sub>3</sub> QDs maintained their PL for 120 hours. For LCD color filter application, perovskite film was prepared using PeQDs and cyclo olefin copolymer (COC). The thiol-treated PeQD films improved their stability compared with the untreated PeQD films under irradiation with a 15 volt back-light unit (BLU). Due to the reason, it is predicted that it will be suitable for use as a color filter for LCD.

Improving the Grain Growth for High-Performance Inorganic Perovskite Solar Cells

Dongliang Bai; Shaanxi Normal University, China

Perovskite have received extensive attention due to their unique crystal structure, high extinction coefficient, high carrier mobility, and long carrier migration distance. However, organic-inorganic hybrid perovskites are sensitive to light and heat, and are easily decomposed in the presence of light and heat. In view of the photosensitivity and heat sensitivity of organic-inorganic hybrid perovskite batteries, inorganic perovskites with excellent stability in light and heat have been favored. However, the efficiency of inorganic perovskite solar cells is low. In this paper, the quality of the film is improved by doping the inorganic perovskite, and the thickness of the perovskite layer is increased by appropriate temperature treatment of the inorganic perovskite solution to improve the efficiency of the inorganic perovskite solar cell and the stability. The following work:

The first part is that the manganese ions insert into the inorganic perovskite. Studies have shown that the incorporation of manganese ions significantly increases the crystallites and reduces the defects of the film. The efficiency of CsPbBrI$_2$ inorganic perovskite solar cells based on 2% MnCl$_2$ doping is 13.47%, and the average grain size is up to 1200 nm, which significantly reduces the defects of inorganic perovskite films, and the stability of device has been greatly improved. The device maintains an efficiency of over 90% for 30 days under low humidity conditions and exhibits excellent stability.

The second part increases the thickness of the inorganic perovskite film by heating the inorganic perovskite solution at a suitable temperature without adversely affecting the film quality. After heating the inorganic perovskite solution at 100 degrees for 5 minutes, the film thickness was thickened from 165 nm to 195 nm, and the current density was greatly improved. The efficiency of the CsPbBrI$_2$ inorganic perovskite solar cell was 14.81%, The device maintains an efficiency of over 90% for 30 days under low humidity conditions and exhibits excellent stability.

Highly Efficient Metal Halide Perovskite Light-Emitting Diodes Combining Plasmonic Nanomesh Electrodes and Nanophotonic Substrates

Liyang Chen$^1$, Jingxuan Cai$^1$, Siyi Min$^{1,2}$, Zhuofei Gan$^{1,2}$, Dehu Cui$^2$ and Wendi Li$^1$;
$^1$The University of Hong Kong, Hong Kong; $^2$Southern University of Science and Technology, China

Metal halide perovskites have emerged as promising materials for light-emitting diodes (LEDs), due to high color purity, tunable bandgap, high luminescence efficiency, and solution processability. The external quantum efficiency (EQE) of green perovskite LEDs has been boosted up to more than 20%, via strategies of compositional engineering, interfacial engineering, defect passivation, and crystal grain confinement, but the value is still far behind that of the commercial organic LEDs. A primary restriction of the EQE is the total internal reflection within the planar perovskite waveguide, due to the large refractive index contrast between the perovskite layer and the surrounding carrier transport layers; and the current efficiency is limited by non-radiative energy loss attributable to electrode quenching.

Here we propose an approach of embedding plasmonic nanomesh electrodes onto nanophotonic fused silica substrates to increase the device efficiency via their synergistic effect. On one hand, the current efficiency is improved when the plasmonic nanomesh electrode not only serve as transparent electrodes with small sheet resistance, but also offer localized surface plasmonic resonance to enhance spontaneous emission rate and realize electrode quenching control. On the other hand, 2D nanopillars of fused silica substrates confine the perovskite to the complementary nanostructure, and EQE is increased by light extraction enhancement through the perovskite “antenna”. FDTD Simulations are applied to optimize the 2D nanostructure (period, duty cycle, and depth) for the highest EQE with the adopted material system.

EN10.07.12

Nanophotonic Engineering for Perovskite Light-Emitting Diodes Performance Enhancement

Qianpeng Zhang, Daquan Zhang, Yu Fu and Zhiyong Fan; The Hong Kong University of Science and Technology, Hong Kong

Perovskite light-emitting diodes (LEDs) have developed very fast in the past five years, and the external quantum efficiency (EQE) higher than 20 percent has already been achieved. However, two issues remain. One is the light extraction issue; another is the stability issue. Perovskite LEDS with photoluminescent quantum yield (PLQY) higher than 80% have already been reported, but the planar structure device shows 20% closing to the limit. It means the light extraction is the next step to further enhance the EQEs of perovskite LEDs. In this work, we used nanophotonic substrate to improve the light extraction efficiency to 73% and achieved 17.5% EQE for
methylammonium lead bromide (MAPbBr₃) perovskite LED, which is enhanced twice compared to the planar device. The proposed nanophotonic substrate consists of two parts, namely nanodomes as couplers and photonic crystals as optical antennas. With a geometrical design, we found out the optimal geometry was one-micron pitch and 400 nm diameter for the photonic crystals. As for the stability issue, we fabricated LED devices with perovskite nanowires (NWs) embedded in anodic alumina membrane (AAM), and the AAM prevent the water molecule diffusion on the lateral direction. With the AAM protection of perovskite NWs, the T50 of our devices had been improved from 13 mins to 37 mins with the peak luminance more than 10,000 cd m⁻². Moreover, the NWs showed enhanced field emission and could achieve 16% EQE with the cesium lead bromide (CsPbBr₃) perovskite LED. Our work demonstrates the strength of nanophotonic engineering for perovskite performance enhancement in both efficiency and stability.

EN10.07.13
Polymer-Encapsulated Perovskite Nanocrystals—Fabrication and Optical Properties Carola Lampe, Verena A. Hintermayr, Maximilian Löw, Janina Römer, Willem Vanderlinden, Moritz Gramlich, Hyowon Jeong, Anton X. Böhm, Cornelia Sattler, Bert Nickel, Theobald Lohmüller and Alexander S. Urban; Ludwig-Maximilians-Universität München, Germany

Halide perovskite nanocrystals (NCs) have shown impressive advances, exhibiting optical properties that outpace conventional semiconductor NCs, such as near-unity quantum yields and ultrafast radiative decay rates. Herein, we present a block copolymer-templated synthesis for perovskite NCs providing a drastically enhanced stability. The polymer spontaneously forms micelles which act both as nanoreactors and as a protective shell. Encapsulated by this polymer shell, the NCs display strong stability against water degradation and ion migration. Heterostructures of encapsulated MAPI and MAPBr NC layers exhibiting efficient Förster resonance energy transfer (FRET), revealing a strategy for optoelectronic integration. Furthermore, we study the encapsulated NCs via single-particle spectroscopy and investigate the temperature dependence of the optoelectronic properties.

EN10.07.14
Colloidal Synthesis of Ni-Doped Cs₂AgInCl₆ Double Halide Perovskites Nabasindhu Das¹,²; ¹Indian Institute of Technology Roorkee, India; ²Indian Institute of Science, India

Over the last few years, there has been a steep growth in the study of lead halide perovskites, and due to their attractive optoelectronic properties, they have been incorporated into a number of devices like solar cells, lasers etc. However, due to the presence of lead as an environmentally unsustainable component and being toxic in nature, studies have been done to find alternative solutions to replace lead with other elements. Research has been done to partially dope these halide perovskites with Sn²⁺ and Ge²⁺, however these elements suffer from immediate oxidation to their respective +4 states. In the meanwhile, to obtain lead-free halide perovskites, recent studies have focussed on replacing two divalent ‘Pb²⁺’ cations with one monovalent and trivalent cation, generating quaternary A₂M⁺M³⁺X₆ compounds, which maintains the 3-D perovskite crystal structure as well as the charge neutrality. However, the problems in double perovskite structures are low photoluminescence (PL) emission and limited power efficiency (~ 2.2 %). This has further motivated the research groups around the world to search for direct-bandgap double perovskites, and a number of stable direct band gap perovskites have been computationally found to be stable. Bulk Cs₂AgInCl₆ has been synthesised by various groups having a direct band-gap of ~ 3.3 eV and a long carrier lifetime (~ 6 µs) and exhibit excellent stability to moisture, light and heat due to the presence of inorganic cation. Recently, L. Manna et. al. have doped nanocrystals of Cs₂AgInCl₆ with Mn²⁺ owing to the enhanced optical properties and observed a red-shift in the emission spectra.[1] Limited solubility of precursors in solvents causes a problem of solution processing in double perovskite synthesis. Herein, to solve the above problems we have undergone the synthesis of Cs₂AgInCl₆ nanocrystals by a simple colloidal hot-injection approach and further dope them with Ni to elevate their optical properties.

In this approach chloride salts of Ag and In were mixed in octadecene and size distribution control was done by injecting oleylamine and oleic acid as ligands. Nanocrystals were finally precipitated by injecting hot Cs oleate solution and the colloidal solution was re-dispersed in hexane post centrifugation and washing of the nanocrystals. 0.1 % and 0.3% Ni was doped by adding nickel chloride to the initial solution. The nanocrystals showed white photoluminescence under a UV lamp. STEM-EDS analysis was used to determine the Ni concentration in the doped nanocrystals. HRTEM micrographs of Ni-doped Cs₂AgInCl₆ nanocrystals that due to the inclusion of Ni ions, there was no disruption in the crystalline nature and no defects were formed. Optical properties were determined by UV-
vis spectrometry and PL spectrometry. There was a weak PL emission (PLQY ~ 1.6 %). Absorption onset of both doped and undoped nanocrystals was at ~ 350 nm with a strong increase in the absorbance at 272 nm. Undoped nanocrystals showed an emission peak at 560 nm that was consistent with earlier reported results of Cs2AgInCl6 NCs in the quantum confinement regime. In the Ni-doped nanocrystals, a blue shift in the emission spectra was observed with the emission peak at 490 - 470 nm, the extent of the blue shift depending on the Ni dopant concentration. Studies were done to determine the stability of as-synthesized nanocrystals and were found to be stable in air for at least a week with no change in the photoluminescence by the naked eye. Further studies to understand the behaviour of Ni2+ ions in the environment of the host matrix can be done by ESR spectroscopy which can shed light on the observed blue shift in the emission spectra of the doped samples. In conclusion, we have shown a colloidal route to synthesise Ni-doped Cs2AgInCl6 that gives phase-pure stable NCs in the air with increased bandgap.

**Inducing the Formation of Perovskite Nanoplatelets Using SnX4 Salts as Halide Precursors** Luiz G. Bonato, Raphael F. Moral, Gabriel Nagamine, José C. Germino, Arthur A. de Oliveira, Douglas S. da Silva, Fernando Galembeck, Lazaro Padilha and Ana F. Nogueira; State University of Campinas, Brazil

Lead halide perovskite nanocrystals (APbX3) are among the most exciting materials of the last 5 years due to their outstanding optoelectronic properties. These materials present narrow emission peaks and low trap state density. In cube-shaped perovskite nanocrystals, excitons are typically in weak quantum confinement regime, showing low size-dependence of the excitonic peak position as observed in the absorbance spectrum.1 Contrarily, the so-called 2D perovskite nanocrystals exhibit strong quantum confinement effects due to their limited thickness (just a few monolayers), resulting in absorption and photoluminescence (PL) excitonic transitions strongly dependent on the thickness of the nanocrystals,2 turning them promising materials for tunable optoelectronic applications.2 Therefore, the development of synthetic protocols to grow more stable and with higher control over the perovskite nanoplatelets (PNPL’s) thickness, is highly desirable. But to do this, it is crucial to gain insight into the mechanism that leads to the formation of PNPs.

In this work, we describe the formation of PNPs induced by the use of SnX4 (X = Cl, Br, and I) salts as the halide source through a new protocol, inspired by two distinct methods reported by Protesescu et al.3 and by our group.4 All spectral features corresponding to highly confined excitons (i.e., sharp excitonic absorption and emission) can be directly related to the 2D morphology of PNPs, which is confirmed by Transmission Electron Microscopy images. Besides that, the utilization of 1H-NMR and FTIR techniques helped to elucidate the nature of the disturbance in the acid-base equilibrium between oleic acid and oleylamine, caused by the Sn4+ cations. Our data suggest that the formation of Sn-oleylamine complexes is the cause of such disturbance, increasing the ratio [oleic acid]/[oleylamine], which was observed by the displacement in chemical shift of 1H-α to the amine group toward higher values. Such displacement can be assigned to a high concentration of oleylammonium species, increasing the ratio [oleylammonium]/[Cs+], favoring the formation of PNPs even at high temperatures, as supported by our results.

REFERENCES
Recently halide double perovskites have shown promise as phosphors for light emission applications such as white light phosphor converted LED applications. Here we report on halide double perovksite Cs2NaBiCl6 doped with Mn2+ ions resulting in an orange emitting compound under UV light. Optical measurements indicate an absorption profile comprised of localized Bi3+ 6s2 to 6s16p1 transitions. These isolated absorption processes lead to efficient energy transfer to Mn2+ sites leading to emission from the 4T1g to 6A1g transition. Unlike other reported Mn2+ double perovskite hosts, the zero dimensional electronic structure of Cs2NaBiCl6 surprisingly yields enhanced energy transfer to emissive sites. Compositions are analyzed via a variety of techniques such as XRD, UV-vis diffuse reflectance, photoluminescence, thermogravimetric analysis, and electron paramagnetic resonance. Through careful control of synthetic parameters single crystals with Br- partially substituting for Cl- are stabilized via hydrothermal methods. By relaxing the crystal field around absorbing Bi3+ sites, excitation peaks shifted to lower energies, closer to that of commercial blue LEDs. Tailoring of photoluminescent properties demonstrates the potential of double perovskite phosphors by tuning optical properties through chemical substitution. Routes to further improve this system as well as to extend these models to other double perovskite systems are discussed.

Exciton Properties in Individual Lead Halide Perovskite Nanocrystals

Brahim Lounis: University of Bordeaux, France

Lead halide perovskites have emerged as promising new semiconductor materials for high-efficiency photovoltaics, light-emitting applications and quantum optical technologies. Their luminescence properties are governed by the formation and radiative recombination of bound electron-hole pairs known as excitons, whose bright or dark character of the ground state remains unknown and debated [1, 2]. While symmetry analysis predicts a singlet non-emissive ground exciton topped with a bright exciton triplet, it has been predicted that the Rashba effect may reverse the bright and dark level ordering.

Spectroscopically resolved emission from single lead halide perovskite nanocrystals at cryogenic temperatures provides unique insight into physical processes that occur within these materials. At low temperatures the emission spectra collapse to narrow lines revealing a rich spectroscopic landscape and unexpected properties, completely hidden at the ensemble level and in bulk materials.

In this talk, I will discuss how magneto-photoluminescence spectroscopy provides a direct spectroscopic signature of the dark exciton emission of single lead halide perovskite nanocrystals [3]. The dark singlet is located several millielectronvolts below the bright triplet, in fair agreement with an estimation of the long-range electron hole exchange interaction. Nevertheless, these perovskites display an intense luminescence because of an extremely reduced bright-to-dark phonon-assisted relaxation [4]. Resonant photoluminescence excitation spectroscopy allows the determination of the optical coherence lifetimes in these nanocrystals and to assess their suitability as sources of indistinguishable single photons [5].

Charge-Carrier Recombination and Photon Recycling in Bulk and Quasi-2D Metal Halide Perovskites Laura Herz; University of Oxford, United Kingdom

Organic-inorganic metal halide perovskites have emerged as attractive materials for solar cells with power-conversion efficiencies now exceeding 23%. As these devices are approaching the Shockley-Queisser limit, bimolecular (band-to-band) recombination will dominate the charge-carrier losses, with trap-mediated charge recombination becoming less prominent.

We show that in methylammonium lead triiodide perovskite, bimolecular recombination can be fully explained as the inverse of absorption,[1] and exhibits a dynamic that is heavily influenced by photon reabsorption inside the material.[2,3] Such photon recycling is shown to slow charge losses from thin hybrid perovskite films, depending on light out-coupling.[2] Interestingly, for thin films comprising a quasi-two-dimensional (2D) perovskite region interfaced with a 3D MAPbI3 perovskite layer the blue-shifted emission originating from quasi-2D regions overlaps significantly with the absorption spectrum of the 3D perovskite, allowing for highly effective “heterogeneous photon recycling”. We show that this combination fully compensates for the adverse effects of electronic confinement, yielding quasi-2D perovskites with highly efficient charge transporting properties.[3]

In addition, we investigate optoelectronic properties of mixed tin-lead iodide and mixed iodide-bromide lead perovskites. We show how band-gap bowing in tin-lead perovskites is compatible with a mechanism arising from bond bending to accommodate the random placement of unevenly sized lead and tin ions.[4] While tin-rich compositions exhibit fast, mono-exponential recombination that is almost temperature-independent, in accordance with high levels of electrical doping,[4,5] lead-rich compositions show slower, stretched-exponential charge-carrier recombination that is strongly temperature-dependent, in accordance with a multiphonon assisted process. Finally, in the context of silicon-perovskite tandem cells, we discuss the mechanisms underlying detrimental halide segregation in mixed iodide-bromide lead perovskites with desirable electronic band gaps near 1.75eV.[6]

9:00 AM EN10.08.03/EN09.07.03
Photoluminescence Mechanisms in MAPbBr3 Films with Controlled Crystal Size Natalie Banerji; University of Bern, Switzerland

Organo-lead halide perovskites are excellent candidates for applications in light emitting diodes (LEDs). Methylammonium lead bromide (MAPbBr3) is the most investigated perovskite for visible perovskite LEDs, but its use is still limited by a low photoluminescence quantum yield (PLQY). Efforts to increase the PLQY of this material mainly consist in fine-tuning the morphology and reducing the grain size of the polycrystalline perovskite to the micro- and nanoscale. However, the origins of the increased PLQY with reduced crystal size remain unclear. Here we elucidate the physical processes underlying the light emission of MAPbBr3 thin films using time-resolved
A systematic correlation between the enhanced PL properties and the reduction of the crystal size, achieved by using different additives during solution-processing, is observed. The co-existence of free carriers and excitons at low excitation densities is shown in as-cast polycrystalline MAPbBr\(_3\) (crystal size of the order of few \(\mu\)m), while only excitons are present at high excitation densities. Using the Burstein-Moss and Saha models, important quantities such as the exciton binding energy, the reduced exciton effective mass and the trap density are estimated. We then explain the increased PLQY upon crystal size reduction by the presence of a bright exclusively exitonic population even at low excitation densities, together with reduced surface trapping thanks to passivation by the additives.

Ultrafast Electronic Sub-Gap State Dynamics and Exciton Coupling in Hybrid Metal-Halide Perovskites
Franco Camargo\(^1\), Tetsuhiko Nagahara\(^1\), Sascha Feldmann\(^2\), Richard H. Friend\(^2\), Giulio Cerrulo\(^1\) and Felix Deschler\(^1\); \(^1\)Politecnico di Milano, Italy; \(^2\)University of Cambridge, United Kingdom; \(^3\)Technische Universität München, Germany

Metal-halide perovskites show excellent properties for photovoltaic and optoelectronic applications, with power conversion efficiencies of solar cell and LEDs now exceeding 20%. This is unexpected, because these polycrystalline, solution-processed materials are likely to contain a significant density of defects compared to melt-grown semiconductors. Yet, typical effects from defects, such as strong absorption below the bandgap, low open circuit voltage in devices and dominant non-radiative recombination were not observed. In this contribution, we investigate thin films of metal-halide perovskites CH\(_3\)NH\(_3\)PbX\(_3\) (X = Br,I) with multidimensional optical spectroscopy to resolve the dynamics of band and defect states on ultrafast timescales. We report an unexpected coupling between the band transitions and a continuum of sub-bandgap states, which we report to extend at least 350 meV below the band edge. We explain the comparatively large bleach signal of these dark sub-bandgap states, compared to the levels detected in linear absorption, with oscillator strength borrowing from the band-edge transition. Our results imply that, upon valence to conduction band excitation, the sub-gap states are instantaneously bleached by the presence of charges in the band for the duration of the carrier lifetime and conversely, that almost dark sub-bandgap states can be populated by light excitation. Our findings provide fundamental insights into the photophysical origin of the exceptional defect tolerance of hybrid perovskites materials.

9:30 AM BREAK
and single crystalline organic-perovskite hybrid quantum wells (down to one mono-layer thick) and superlattices can be easily obtained via one-step solution-processing. Energy transfer and charge transfer between adjacent organic and inorganic layers are extremely fast and efficient, owing to the atomically-flat interface and ultra-small interlayer distance. The 2D hybrid perovskite superlattices are surprisingly stable, due to the protection of the bulky hydrophobic organic groups. The molecularly engineered 2D semiconductors are promising candidates for use in next-generation nanoelectronics, optoelectronics, and photonics.

10:15 AM *EN10.09/EN09.08.02
Nanoscale and Bulk Perovskite Single-Crystals—Surface Engineering for Efficient LEDs, Photodetectors and Solar Cells Osman M. Bakr; KAUST, Saudi Arabia

In colloidal nanocrystal form, lead halide perovskites possess high photoluminescence quantum yields, while in bulk single-crystal form they exhibit long charge-carrier diffusion lengths. However, without proper strategies to diminish crystal surface defects and manage surface quality, the desired characteristics of perovskites cannot be effectively exploited for photovoltaic and optoelectronic devices. Here I discuss novel strategies to passivate the surface defects and improve the surface quality of perovskite nanocrystals and bulk single-crystals, enabling the fabrication of efficient devices. We demonstrate the passivation of CsPbX$_3$-type nanocrystals with molecular ligands and metal dopants leading to stable near-unity quantum yield emitters, as well as efficient blue and red light-emitting diodes (LEDs). We also show the importance of designing crystal growth conditions, such as solvent, temperature, and substrate in order to grow bulk single-crystals with low-defect densities and good surface quality. Depending on the composition, MAPbX$_3$-type single crystals grown (tens of microns thick) under optimal conditions were used to realize: a) very sensitive visible-blind UV-photodetectors with nanosecond response time; and b) single-crystal solar cells with >21% power conversion efficiency. Unlike thin film polycrystalline solar cells, efficient cells with a grain-free single-crystal absorber are an ideal unobstructed system for investigating the device physics and chemistry of perovskites.

Teaching Halide Double Perovskites to Absorb Sunlight Adam Slavney$^1$, Bridget Connor$^1$, Kurt Lindquist$^1$, Stephanie Mack$^2$, Linn Leppert$^3$, Jeffrey Neaton$^4$ and Hemamala Karunadasa$^1$; $^1$Stanford University, United States; $^2$University of California, Berkeley, United States; $^3$University of Bayreuth, Germany; $^4$Lawrence Berkeley National Laboratory, United States

Halide perovskites exhibit remarkable properties as solar-cell absorbers, featuring both direct bandgaps suitable for sunlight absorption and long-lived charge carriers beneficial for charge extraction. However, the intrinsic instabilities and high toxicity of these water-soluble lead salts may impede the commercialization of this technology. Notably, even the origin of the materials' superior photophysical properties remains unclear, underscoring the importance of synthesizing and studying functional analogs of the lead perovskites. However, most stable materials studied as analogs have displayed weak sunlight absorption and short carrier lifetimes.

We recently introduced halide double perovskites, which can accommodate a much greater range of metals, as solar absorbers. Armed with this substitutional flexibility, we have explored alternative metals that can be incorporated into the perovskite lattice. Studying the electronic differences between the lead perovskites and lead-free double perovskites has shown us how to synthetically tune double perovskites to efficiently absorb sunlight. I will share our understanding of how to manipulate the symmetry and energy of the bandgap transition in these materials through i) dilute impurity alloying, ii) stoichiometric metal substitution, and iii) dimensional reduction. Our recent studies have led us to double perovskites with very similar properties to the lead perovskites, with small bandgaps and long-lived carriers. I will further present a pen-and-paper method for both understanding and predicting halide double perovskite band structures based on orbital symmetry arguments.

11:15 AM EN10.09/EN09.08.04
A-Site Cation Composition Effects in Organic-Inorganic Metal Halide Perovskite Quantum Dots—Crystallographic Phase and Particle Ordering Julian A. Vigil$^{1,2}$, Michael F. Toney$^2$ and Joseph Luther$^3$; $^1$Stanford University, United States; $^2$SLAC National Accelerator Laboratory, United States; $^3$National Renewable Energy Laboratory, United States
Hybrid organic-inorganic metal halide perovskites have demonstrated remarkable properties for thin-film solar absorbers and optoelectronics, including their ease of preparation, compositional tunability, defect tolerance and high charge-carrier mobilities. The promise of these materials has also motivated the development of modified bulk and nanoscale perovskites, including reduced-dimensional perovskites (2D, 1D) and quantum dots (QDs), with emergent optoelectronic properties. Perovskite QDs, in addition to a tunable band gap and high photoluminescence quantum yield, are of interest due to unique physical and structural phenomena such as the stabilization of metastable crystallographic phases. Luther et al. reported the stabilization of the high temperature, low-band gap cubic perovskite phase of CsPbI$_3$ at room temperature in small QD particles via colloidal synthesis (Swarmkar et al. Science 2016, 354, 6308, 92). In addition, alloying of these CsPbI$_3$ QDs with FAPbI$_3$ (yielding Cs$_{1-x}$FA$_x$PbI$_3$) by a simple cation exchange approach allows for access to the full compositional range (i.e. $x = 0–1$), unlike thin-film fabrication and direct synthesis of bulk Cs$_{1-x}$FA$_x$PbI$_3$ (Hazari et al. ACS Nano 2018, 12, 10327).

Herein, we report on structural studies of Cs$_{1-x}$FA$_x$PbI$_3$ QD films by synchrotron X-ray techniques. 15-nm Cs$_{1-x}$FA$_x$PbI$_3$ QDs ($x = 0, 0.5$) were deposited from colloidal solution, by both drop- and spin-casting methods, and investigated by grazing incidence small-angle and wide-angle X-ray scattering (GISAXS/GIWAXS). GIWAXS patterns indicate coherent particle ordering on the substrate for single-layer spin-coated films, while the subsequent ligand exchange and particle overcoating (2–5 layers) leads to reorganization and isotropic ordering of the particles. In addition, drop-casting and slow evaporation of the solvent from the colloidal solution also results in isotropic ordering. Interestingly, the diffraction patterns show evidence of distortion from the originally reported cubic perovskite phase, with significant tetragonal ($Cs_0.5FA_0.5PbI_3$) and orthorhombic ($CsPbI_3$) character. The distortion and phase contributions across the full range of alloyed Cs$_{1-x}$FA$_x$PbI$_3$ QDs will be reported and discussed.

Highly Efficient Hybrid Perovskite Nanoparticle Light-Emitting Diodes Using Mixed Cation Young-Hoon Kim¹, Sungjin Kim¹, Jinwoo Park¹, Seung-Hyun Jo¹, Hengxing Xu², Yonghee Lee¹, Laura Martinez-Sarti³, Henk J. Bolink³, Young-Woon Kim¹, Bin Hu¹ and Tae-Woo Lee¹; ¹Seoul National University, Korea (the Republic of); ²The University of Tennessee, Knoxville, United States; ³Universidad de Valencia, Spain

Hybrid perovskite nanoparticles (PeNPs) have significant potential to be used in perovskite light-emitting diodes (PeLEDs) because of their high photoluminescence quantum efficiency and, facile color tunability and synthesis. However, the highest electroluminescence efficiencies of PeLEDs based on hybrid PeNPs are still much lower than those of PeLEDs based on hybrid perovskite bulk films and all-inorganic PeNPs. Here, we suggest a strategy to improve the electroluminescence efficiency of PeLEDs based on hybrid PeNPs. We passivate the defect states of PeNPs by introducing large organic cation into the formamidinium lead bromide nanocrystals. Based on this high quality PeNPs, we were able to fabricate efficient PeLEDs. Our work provides a promising way to improve luminescence efficiency of the PeLEDs based on hybrid PeNPs.

11:45 AM EN10.09/EN09.08.06
Surface Chemistry of Colloidal Cesium Lead Halides Perovskite Nanocrystals and Its Impact on the Characteristics of Blue and Green Perovskite LEDs Maryna Bodnarchuk; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Colloidal organic/inorganic lead halide perovskite nanocrystals (NCs) are considered promising blue and green narrow-band emitters for the next-generation light-emitting diodes. High photoluminescence efficiencies are attained in these materials without epitaxial overcoating of the NC surfaces for electronic passivation of the surface states [1]. The major practical bottleneck of these materials relates to their labile surface chemistry. In particular, typically used ling chain capping ligands are problematic due to their dynamic and loose binding as well as their highly insulating nature. We have recently rationalized the typical observation of a degraded luminescence upon aging or the luminescence recovery upon post-synthesis surface treatments using a simple surface-structure model, supported by DFT calculations [2]. Healing of the surface trap states requires restoration of all damaged PbX$_6$ octahedra and establishing a stable outer ligand shell. Restoration of such a structure, seen as an increase in the luminescence quantum efficiency to 90-100% and improvement in the overall robustness of CsPbBr$_3$ NCs, was attained using a facile post-synthetic treatment with a PbBr$_2$+DDAB (didodecyldimethylammonium bromimde) mixture. In our most recent work [3], we have used DDAB as a sole ligand directly in the synthesis of perovskite NCs. We then used such NCs in LEDs and demonstrate high external quantum efficiencies of up to 3.6% in blue region (460nm) and 10% in the green region (520 nm).

High Performance Perovskite Light-Emitting Devices for Displays and Advanced Applications Zhi Kuang Tan; National University of Singapore, Singapore

The efficiency of electroluminescent perovskite devices have increased rapidly from 0.76% in earlier works to above 20% in recent reports. Such high performance, coupled with excellent spectral qualities and easy manufacturability have captured the attention of the academic and commercial communities. In this talk, we will discuss some physical principles behind device efficiency enhancement, and report our new strategies in improving the uniformity and robustness of perovskite light-emitting diodes. We will also report our recent activities in the deployment of luminescent perovskites in color-enhanced displays and other advanced consumer product applications.

2:00 PM EN10.10.02
Fabrication of High-Performance Perovskite Optoelectronic Devices Zhanhua Wei; Huaqiao University, China

Metal halide perovskite materials are an emerging class of solution-processed semiconductors with considerable potential for use in optoelectronic devices. For example, light-emitting diodes (LEDs) based on these materials could see application in flat-panel displays and solid-state lighting, owing to their potential to be made at low cost via facile solution processing, and could to provide tunable colors and narrow emission line widths at high photoluminescence quantum yields. However, the highest reported external quantum efficiencies of green- and red-light-emitting perovskite LEDs are around 14% and 12%, respectively—still well behind the performance of organic LEDs and inorganic quantum dot LEDs. Here we describe visible-light-emitting perovskite LEDs that surpass the quantum efficiency milestone of 20%. This achievement stems from a new strategy for managing the compositional distribution in the device—an approach that simultaneously provides high luminescence and balanced charge injection. Specifically, we mixed a presynthesized CsPbBr$_3$ perovskite with a MABr additive (where MA is CH$_3$NH$_3$), the differing solubilities of which yield sequential crystallization into a CsPbBr$_3$/MABr quasi-core/shell structure. The MABr shell passivates the nonradiative defects that would otherwise be present in CsPbBr$_3$ crystals, boosting the photoluminescence quantum efficiency, while the MABr capping layer enables balanced charge injection. The resulting 20.3% external quantum efficiency represents a substantial step towards the practical application of perovskite LEDs in lighting and display [1].

Moreover, we will show some research progress of perovskite LEDs with colorful emission, solar cells and other photonic applications in our lab.

High-Intensity CsPbBr$_3$ Perovskite LED using Poly(bis(4-phenyl)(2,4,6-trimethylphenyl)amine) as Hole Transport and Electron-Blocking Layer Gintautas Simkus1,2, Pascal Pfeiffer2, Simon Sanders2, Dominik Stümmler2, Aliénor Wagner1, Andrei Vescan1, Holger Kalisch1 and Michael Heuken1,2; 1AIXTRON SE, Germany; 2RWTH Aachen University, Germany
In the last years, metal halide perovskites have attracted great attention as promising materials for light-emitting diodes (LED), owing to their excellent optical and electronic properties such as high charge-carrier mobility, narrow emission spectra and easily tunable colors [1,2,3]. The highest external quantum efficiencies of CsPbBr$_3$ LED recently exceeded 20 % [4]. Efficiencies were enhanced mainly by suppressing non-radiative recombination and establishing improved charge balance. The most efficient LED utilize hole-transport layers (HTL) of either a hydrophilic organic co-polymer (PEDOT:PSS) or an inorganic oxide (NiO$_x$), ensuring beneficial wetting properties for perovskite formation [5]. Despite a huge variety of organic hole-transport materials, the polar solvents required for perovskite synthesis narrow their choice leaving PEDOT:PSS as one of the few remaining options. However, PEDOT:PSS is lacking sufficient electron-blocking properties in electron-rich CsPbBr$_3$-based LED structures. Consequently, an additional blocking layer is required to achieve optimum charge balance as a prerequisite for high luminous efficiency.

In this work, we employ the hydrophobic hole-transporting polymer poly(bis(4-phenyl)(2,4,6-trimethylphenyl)amine)) (PTAA) as HTL. PTAA exhibits a high LUMO value of 1.8 eV [6], ensuring the desired electron-blocking properties. Thus, the requirement for an additional blocking layer is eliminated, simplifying the LED fabrication process. This HTL was examined in LED structures with a configuration of glass/ ITO (100 nm)/PTAA (10 nm)/ CsPbBr$_3$ (60 nm)/(2,2',2''-(1,3,5-benzinetriyl)-tris(1-phenyl-1-H-benzimidazole)) (TPBi) (30 nm)/ LiF (1 nm)/Al (100 nm). In this stack, PTAA and CsPbBr$_3$ were deposited from solutions (PTAA – 3 mg/ml in toluene; CsPbBr$_3$ – 12 wt% of precursor solids PbBr$_2$ and CsBr with a molar ratio of 1:1.7 in dimethyl sulfoxide) by spin-coating in purified N$_2$ atmosphere (H$_2$O < 1 ppm, O$_2$ < 1 ppm). TPBi was selected as electron transport layer which also acts as a hole-blocking layer due to its deep HOMO level of 6.2 eV [7]. This combined with the PTAA electron blocking ability ensures superior carrier as well as exciton confinement in the emissive perovskite layer. The hydrophobicity of the PTAA surface was reduced by a short exposure to remote N$_2$ plasma, which allowed the formation of a dense CsPbBr$_3$ film from solution on top. The room temperature photoluminescence spectra of pure CsPbBr$_3$ layer (without any additives for grain passivation and trap density minimization) exhibited a saturated color ($\lambda_{\text{max}} = 520$ nm) with a FWHM of 18 nm indicating a low degree of energetic disorder. The fabricated LED yielded high current densities exceeding 200 mA/cm$^2$, a turn-on voltage of 2.9 V, bright emission of 10,000 cd/m$^2$ and stable EQE (external quantum efficiency) of 1.5 %. The LED performance could be improved considerably by employing molecular pinning to enhance the morphology of CsPbBr$_3$ layers which leads to suppressed non-radiative recombination at interfaces and perovskite grain boundaries [8].

SESSION EN10.11: Surface and Defect Passivation in Perovskite Light-Emitting Devices
Session Chairs: Tae-Woo Lee and Zhi Kuang Tan
Wednesday Afternoon, December 4, 2019
Sheraton, 2nd Floor, Back Bay D

3:30 PM *EN10.11.01
Defect Passivation of Perovskite Layers for Efficient Perovskite Light-Emitting Diodes Myoung Hoon Song$^1$, Seungjin Lee$^1$, Chung Hyeon Chang$^1$, Jong Hyun Park$^1$, Eui Dae Jung$^1$ and Han Young Woo$^2$; $^1$Ulsan National Institute of Science and Technology, Korea (the Republic of); $^2$Korea University, Korea (the Republic of)
The organic-inorganic hybrid perovskite materials have been studied extensively owing to their excellent optical and electrical characteristics that enable a remarkable enhancement of device efficiency in light-emitting diodes (LEDs) and solar cells. High film quality of perovskite is necessary to develop highly efficient and stable perovskite optoelectronic devices. However, defect sites such as voids, pinholes, grain boundaries and under-coordinated ions, creating a large number of undesired electronic trap sites can exist in solution-processed perovskite films. Here, we observe the significant beneficial effects on the efficiency and long-term stability of perovskite light-emitting diodes (PeLEDs) through passivating the defect sites of perovskite layers.

4:00 PM *EN10.11.02
Surface Passivation and Stability of Metal Halide Perovskite LEDs Barry P. Rand; Princeton University, United States

Hybrid organic-inorganic halide perovskite materials are of considerable interest for optoelectronics. We will discuss our approach to surface passivation using an excess solution stoichiometry of organoammonium so as to maintain an ammonium terminated surface in films that consist of nanoscale crystallites. Proper passivation allows for enhanced quantum yield and stable mixed halide stoichiometries. In another aspect, we have determined that metal halide perovskites not only feature ionic motion but are also considerably redox active and heat sensitive, and are looking to understand how redox chemistry, and ionic processes more generally, dictate material and device physics and degradation.

4:30 PM EN10.11.03
Dual Passivation of Both Lead and Halide Defects for Perovskite Light Emitting Diodes with External Quantum Efficiency Exceeding 20% Zhengguo Xiao, Zhibin Fang and Wenjing Chen; University of Science and Technology of China, China

Organic-inorganic hybrid perovskites are very promising for light emitting diodes (LEDs) due to their high color purity, tunable emission wavelength, and balanced electron and hole conduction etc. The optoelectronic properties of hybrid perovskite have shown to be very tolerant to defects, which has been demonstrated in solution processed perovskite photovoltaics. However, both lead and halide defects have been shown to be a big problem for solution processed perovskite LEDs (PeLEDs) with nanometer-sized crystallites. The defects cause obvious non-radiative recombination and short operation stability.

In this talk, we will report the molecular design of additives for dual passivation of both lead and halide defects in perovskites. We synthesized 4-fluoro-phenylmethylammonium-trifluoroacetate (FPMATFA) using a simple solution process. The C=O bond in TFA group can coordinate with lead and passivate the lead defects, while the organoammonium cations, FPMA+, can coordinate with halide and passivate halide defects. In addition, the bulky FPMA group can constrain the grain growth of 3D perovskite, which enhances electron-hole capture rates and radiative recombination rate. As a result, we achieved a decent external quantum efficiency of 20.9% for formamidinium/cesium based PeLEDs. What’s more, the operation lifetime of PeLEDs is also greatly improved due to the low trap density in the perovskite film.

4:45 PM EN10.11.04
A Room Temperature Synthesis of Highly Robust Phosphonate-Capped Cesium Lead Bromide Perovskite Nanocrystals with Near-Unity Photoluminescence Quantum Yield Alasdair A. Brown1,2,3, Thomas J. Hooper1, Xin Yu Chin1, Parth Vashishtha3,3, Suan Hui Pu1, Bahulayan Damodaran2, Ju Nie Tey1, Liudi Jiang1, Subodh G. Mhaisalkar3,3 and Nripan Mathews3,3; 1University of Southampton, United Kingdom; 2Agency for Science, Technology and Research, Singapore; 3Nanyang Technological University, Singapore

Over the last 5 years, the performance of perovskite nanocrystal-based light-emitting diodes (LEDs) has improved dramatically, achieving external quantum efficiencies (EQEs) which are comparable with their chalcogenide counterparts. Crucially, perovskite nanocrystals (NCs) can be synthesised with straightforward wet chemistry techniques under ambient conditions, in stark contrast to the high temperature, inert gas environment necessary for chalcogenide core-shell structures. All-inorganic cesium lead bromide (CsPbBr3) NCs are particularly promising, as they exhibit much better thermal and environmental stability than formamidinium (FA) or methylammonium (MA) based perovskites. However, the colloidal stability of CsPbBr3 NCs remains poor, which severely restricts any future application in optoelectronics.
The stability of perovskite nanocrystals is strongly reliant on surface chemistry. It is vital that the ligands bound to the nanocrystals can both passivate deleterious defects and form a robust attachment to the surface. Ligands that do not adhere strongly to the nanocrystals are prone to desorption, leading to agglomeration and rapid degradation of their initially exceptional luminescence. Until recently, labile carboxylic acid and alkylamine ligands were almost universally employed for CsPbBr$_3$ nanostructures. However, it has been shown that the dynamic binding equilibrium they establish limits both the colloidal and device stability. Phosphonic acids have since emerged as a promising alternative. A hot-injection synthesis of CsPbBr$_3$ NCs capped by octylphosphonic acid (OPA) ligands enabled LEDs with an EQE of 6.5 % and half-lifetime of over 30 mins. In contrast to the standard ligands, phosphonic acids have been shown to bind irreversibly to lead sites, thus indicating their high potential for stability enhancement. We sought to elucidate the underlying surface chemistry of phosphonic acid binding to CsPbBr$_3$ NCs. Through a ligand exchange approach, we revealed that OPA binds as the monoionic phosphonate, such that P=O and P−OH functionalities remain free. Most importantly, 2D $^1$H−$^{31}$P solid-state NMR demonstrated that these functionalities allow extensive inter-ligand hydrogen bonding, such that the nanocrystals are passivated by an interconnected octylphosphonate network. Based on the discovery of this phenomenon, we devised a direct room temperature, open-air synthesis of CsPbBr$_3$ NCs passivated by an octylphosphonate network. Trioctylphosphine oxide (TOPO) aided the dissolution of PbBr$_2$ and OPA in toluene, such that the injection of cesium octanoate immediately formed highly luminescent green-emitting nanocrystals. Post-synthetic treatment with didodecyldimethylammonium bromide (DDAB) provided DDA$^+$ ligands that bind to surface bromide, increasing the solubility, while the excess Br$^-$ filled any gaps in the octylphosphonate network. This approach proved exceptionally effective; even after 3 purification cycles with methyl acetate, a photoluminescent quantum yield (PLQY) of 95 % was retained. Thus we have successfully developed an ambient, room temperature synthesis of robust near-perfect CsPbBr$_3$ nanocrystals. We anticipate that this method will improve the viability of these nanocrystals for high performance optoelectronic applications.

EN10.12.03
Pulsed Laser Synthesis and Tuning Optical Properties of High Quantum Yield Nitrogen Doped Graphene Quantum Dots
Muhammad Shehzad Sultan$^1$, Vladimir I. Makarov$^1$, Muhammad Sajjad$^2$, Brad Weiner$^1$ and Gerardo Morell$^1$; $^1$University of Puerto Rico – Rio Piedras, United States; $^2$Austin Peay State University, United States; $^3$University of Puerto Rico - Rio Piedras, United States

The graphene quantum dots (GQDs), a zero-dimensional graphene quantum structure, have triggered an intense research worldwide. GQDs possess unique optical, chemical and physical properties as compared to conventional quantum dots (QDs), such as low toxicity, biocompatibility, optical stability, chemical inertness, high photostability and good water-solubility and therefore hold great application potential in biomedical, optoelectronics and energy storage devices. The doping of GQDs with heteroatoms is one of the most effective ways to tune their photoluminescence emission and to increase quantum yield. In this study, we developed a novel approach to synthesize high-quality Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. To observe optical properties of as synthesized N-GQDs, the UV-vis and
Photoluminescence measurements were carried out. The as-synthesized NGQDs exhibit high quality crystalline structure of graphene with an average size of about 3.7 nm. A high quantum yield was exhibited by the obtained N-GQDs as compare to the pristine GQDs. The obtained N-GQDs with oxygen-rich functional groups exhibit a strong emission. These outcomes result in an ample opportunity for the biomedical and optoelectronic applications.

EN10.12.04
Highly Processable and Thermally Stable Perovskite Nanocrystals Embedded in Ceramic Matrix by Aerosol Deposition
Chaeyeon Son, Sunghoon Kim and Sang-Wook Kim; Ajou University, Korea (the Republic of)

Inorganic perovskite structure has emerged as optoelectronic materials as possessing advantageous optical properties for display applications used in a polymer-encapsulated form. However, insulating polymers acting as a host matrix are generally vulnerable to thermal stresses, so that softening distortion or deterioration occurs in thermoplastic polymers (generally over 150 °C). So, we develop nanostructured CsPbBr3/Al2O3 composite film by aerosol deposition (AD). At first, CsPbBr3/Al2O3 composite powders are synthesized by the recrystallization of CsBr and PbBr2 ionic salts onto the surface of Al2O3 particles and have bright and saturated green emission. Next, the composite powder supported on submicron α-Al2O3 particles is effectively changed to a film-type by aerosol deposition (AD). AD, which is based on shock-loading solidification caused by countless collisions of fine ceramic particles, has many advantages for perovskite NCs, which operate at room temperature, in a vacuum system to minimize the exposure of oxygen and moisture and under an eco-friendly condition of the nonsolvent process. The ceramic composite film show high long-term stability at 150 °C for over 20 days, a pure green spectrum with a narrow full width at half maximum (522 nm and FWHM of 17 nm) and an absolute photoluminescence quantum yield of 8%–15%. General inorganic film have difficulty in flexibility and pattern. But, the films deposited by AD can be used as down-converting material for LCD backlight with a wide area of 89.2% in REC. Furthermore, it can be applied to a variety of display fields, such as high flexible chemical composite films, multilayer films, patterning of surfaces for an advanced color filter array, and deposition on protected substrates toward diverse display fields.

EN10.12.05
Core-Shell Perovskite Microcrystals
Sangyeon Cho1,2 and Seok-Hyun Yun1,2; 1Massachusetts Institute of Technology, United States; 2Harvard Medical School and Massachusetts General Hospital, United States

Lead halide perovskites (LHPs) are promising optoelectronic materials, but with ionic bonding characteristics, LHPs disassemble readily in any polar solvents. This structural instability, together with dynamic lattice disorder, has prohibited the crystalline coating of LHPs using polar precursors. Here, we report a sonochemistry-based technique to synthesize poly-norepinephrine (pNE)-coated CsPbBr3 microcrystals. The colloidal core-shell-type CsPbBr3 microcrystals were synthesized in a polar solvent without any surfactants. High-resolution X-ray photoelectric spectroscopy suggests that the electronegative catechol group of the pNE forms Lewis acid-base adducts with under-coordinated Pb atoms. This passivation reduces surface defects, decreases hysteresis, and increases optical gain. Density functional theory (DFT) supported these observations. Furthermore, the pNE coating serves as diffusion-blocking layers, increasing the lifetime of LHPs in water by 1000-fold. This allowed us to observe lasing from a single core-shell perovskite micro-particle in water. The pNE coating also enabled us to use conventional reactions to functionalize perovskite microcrystals, for example, with fluorescent proteins and plasmonic nanoparticles. This work may open a new avenue towards environment-stable and multifunctional perovskite laser particles.

EN10.12.06
Identifying and Reducing Interfacial Losses to Enhance Color-Pure Electroluminescence in Blue-Emitting Perovskite Nanoplatelet Light-Emitting Diodes
Robert Hoye1, May-Ling Lai1, Miguel Anaya1, Yu Tong2,3, Krzysztof Galkowski1,4, Tiaman A. Doherty1, Weiwei Li1, Tahmida N. Huq1, Sebastian Mackowski4, Lakshminarayana Polavarapu2,3, Jochen Feldmann2,3, Judith L. MacManus-Driscoll1, Richard H. Friend1, Alexander S. Urban2,3 and Samuel D. Stranks1; 1University of Cambridge, United Kingdom; 2Ludwig-Maximilian-Universitat Munchen, Germany; 3Nanosystems Initiative Munich (NIM) and Center for NanoScience (CeNS), Germany; 4Nicolaus Copernicus University, Poland

Perovskite nanoplatelets (NPLs) hold great promise for light-emitting applications, having achieved high photoluminescence quantum efficiencies (PLQEs) approaching unity in the blue wavelength range, where other metal-halide perovskites have typically been ineffective. However, the external quantum efficiencies (EQEs) of
blue-emitting NPl light-emitting diodes (LEDs) have typical values of 0.1% or below. In this work, we show that the performance of NPl LEDs is primarily hindered by a poor electronic interface between the emitter and hole-injector. Through Kelvin Probe and X-ray photoemission spectroscopy measurements, we reveal that the NPls have remarkably deep ionization potentials (≥6.5 eV), leading to large barriers for hole injection, as well as substantial non-radiative decay at the emitter/hole-injector interface. We find that an effective way to reduce these non-radiative losses is by using poly(triarylamine) interlayers, which lead to an increase in the EQE of the blue (464 nm emission wavelength) and sky-blue (489 nm emission wavelength) LEDs to 0.3% and 0.55% respectively. The EQEs of these devices are two orders of magnitude higher than the control devices without the poly(triarylamine) interlayer, and we elucidate the role of these interlayers through detailed spectroscopic and single-carrier device measurements. Our work also identifies the key challenges for further improvements in efficiency [1].

X-Ray and Neutron Scattering Studies of Colloidal Nanocrystal Quantum Dots and Their Ligands Michael P. Weir1, Daniel Toolan1, Neil C. Greenham2, Richard H. Friend2, Akshay Rao2, Anthony Ryan1 and Richard Jones1;
1The University of Sheffield, United Kingdom; 2The University of Cambridge, United Kingdom

Understanding the structure of the nanocrystal cores and stabilizing ligands in colloid quantum dots presents unique set of challenges that are ideally suited to study using X-ray and neutron scattering (SAXS and SANS) techniques. There is a large electron density difference between the metal chalcogenide (e.g. lead sulfide, PbS) nanocrystal core and most organic materials. This includes the native ligands present from synthesis (typically oleic acid, OA) and solvents or polymeric matrices where present. This provides an excellent contrast scenario for studying the shape, size, distribution and packing of QD cores using SAXS either in transmission or in grazing incidence (GISAXS) while dispersed or packed in various media. Similarly, with the potential for multiple isotopic contrasts (e.g. using deuterated solvents or ligands), SANS measurements are highly sensitive to the structure of ligands and other molecules adsorbed on the QD surface and to the correlations and packing of the QD cores.

In this presentation, we explore as a case study the characterisation of PbS-OA quantum dots and their functionalisation by exchange with ligands of varying chemistry, including a variety of carboxyl-terminated small molecules. For as-synthesized QD, SAXS allows a rough estimation of OA present in the given solution and an upper bound on the amount that is bound to the PbS cores, whilst some may remain in solution. Solution SANS measurements, utilising contrast variation, can then be used to determine the thickness and density of the OA shell. In combination, SAXS and SANS are therefore also well suited to the study of ligand exchange processes. Using SAXS as a pre-characterisation, SANS resolves the changes in ligand shell scattering length density, which are related back to changes in coverage and packing density and to the degree of native ligand, if any, that is still present. This presentation follows the structural changes that occur during various ligand exchange procedures and discusses some of the self-assembling structures that emerge.

EN10.12.08
Single-Step Production and Controlled Heteroatom Doping of Photoluminescent Graphene Quantum Dots through Laser Ablation in Liquid Rosemary L. Calabro, Dong-Sheng Yang and Doo Young Kim; University of Kentucky, United States

Graphene quantum dots (GQDs) are promising for a number of applications including catalysis, sensing, imaging, and photovoltaics. The advantages of GQDs over traditional inorganic quantum dots include (i) a cheap and large-scale synthesis with abundant carbon sources, (ii) excellent biocompatibility and environmental friendliness, and (iii) a high photodynamic index. One promising approach to tune the emission of GQDs and to enhance photoluminescence quantum yield (PLQY) is the incorporation of heteroatoms such as N, B, P, or S into the aromatic backbone of GQDs. Furthermore, the incorporation of heteroatoms into high-surface-area GQDs can develop highly active electrocatalysts and sensory materials. Traditional methods to produce GQDs require the use of harsh chemicals, long reaction times, and tedious purification steps and allows limited control over the functional groups in the produced GQDs. This presentation will report our recent progress in developing the synthetic technique of laser ablation in liquid (LAL) as a promising alternative method to prepare GQDs. LAL allows for fast production, use of fewer chemicals, simple purification, fewer byproducts, higher production yields, and improved
control of the product by precise tuning of laser ablation parameters. We have successfully developed LAL to produce N-doped GQDs from carbon nano-onions in aqueous solutions containing three nitrogen precursors (ammonia, ethylenediamine, and pyridine). The choice of nitrogen precursor molecule allowed for the tuning of both the overall nitrogen content as well as the distribution of nitrogen-related functional groups present in the produced GQDs. The variation of LAL parameters and nitrogen precursors enabled us to tailor photoluminescence (PL) spectral properties and PL lifetimes. We have found that high concentrations of amine groups tend to red shift the emission and exhibit shorter PL lifetimes whereas pyridinic groups caused a blue shift in the emission and exhibited longer PL lifetimes. Additionally, the PL properties of these GQDs was highly dependent on the nitrogen-related functional groups while band gap emission was mainly non-radiative. This presentation will also report the promising electrochemical features of these N-doped GQDs since they demonstrated high activity for the conversion of oxygen to hydrogen peroxide, an important chemical in many industrial applications. LAL was then employed to dope GQDs with other heteroatoms including B, P, and S that further tuned the PL properties and expanded potential applications.

EN10.12.09
Improving Color Purity in Thermally Activated Delayed Fluorescence Emitters Ramin Ansari, Wenhao Shao, Seong Jun Yoon, Jinsang Kim and John Kieffer; University of Michigan, United States

We explore the key factors that determine the emission bandwidth of thermally activated delayed fluorescence (TADF) emitters combining computational and experimental methods of investigation. TADF is one approach to achieve high internal quantum efficiencies (IQEs) in metal-free organic light emitting diode (OLED). In TADF the first triplet (T1) to first singlet (S1) reverse intersystem crossing (ISC) is promoted by configuring molecules in an electron donor-acceptor (D-A) alternation, so as to exhibit a small energy gap (DEST) between S1 and T1 levels. This allows for non-radiative triplet states to up-convert to radiative singlet states and fluoresce. However, the donor-acceptor strategy may result in molecular conformations that produce broad emission spectral bands (FWHM = 70-100 nm). Despite reports suggesting that suppressing D-A dihedral rotation can reduce the emission bandwidth, the actual reason behind the narrower-band emission is not well understood. Our results suggest that the intrinsic TADF emission bandwidth is mainly controlled by the charge transfer character, and that molecular space restriction or rotation have minimal effects. Our results can be used to design molecular organic alternatives with sharp emissions for LED applications.

EN10.12.10
Internal Contact Electrification Lights Up Electroluminescent Phosphors in ‘Phosphor–Polymer’ Elastic Composites—A New Strategy for Converting Mechanical Energy into Light Gyudong Lee, Seongkyu Song, Younghoon Kim, Soon Moon Jeong and Sung Jun Lim; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Mechanoluminescence (ML) is a light emission induced by mechanical action applied to a solid material. This phenomenon has been known for a long time and observed from numerous materials in our daily life. However, unlike photoluminescence or electroluminescence, ML had received little attention as a light-emitting technology because most of previously known ML processes are one-time momentary light emission events which require irreparable deformation of materials like breaking or tearing. Then, in 2013, Jeong et al. [1] reported a unique ML phenomenon that an elastic composite, which is phosphor micropowders (Cu or Mn doped ZnS) embedded in a stretchable polymer (PDMS), exhibits unprecedentedly bright and unwearying ML under repeated (~10^5 times) elastic stresses like stretching, bending, or pressing. This groundbreaking discovery has led to the development of many distinctive ML-based light-emitting technologies such as wind-driven full-color display, handwriting recognition, or magnetic-induced luminescence.

Despite the applications are being continuously expanded, the mechanism of this unique elastic ML process has remained unknown. Most of the previous models relied on a special piezoluminescent characteristic of doped ZnS phosphors called ‘self-recovery’ effect. However, none could fully explain the incomparably high brightness and durability of the new elastic ML. In this presentation, we will introduce a set of experimental evidences that this elastic ML is due to the characteristics of the phosphor alone but due to the interaction between the phosphor and the elastic polymer substrate. Especially, our findings claim that the interface between the phosphor and the elastic polymer plays the most essential role. We demonstrate that this elastic ML can be completely switched on and off depending on the combination between the compositions of phosphor’s surface coating layer and elastic polymer, and the combination that switches on the elastic ML is the one that maximizes the contact electrification at
their interface. We also show that such interface-driven ML is not working with common piezoluminescent materials but only working with high quality electroluminescent phosphors like doped ZnS. These findings strongly suggest that the elastic composite ML is in fact a lighting up process of electroluminescent phosphors by the internal microscale contact electrification at the phosphor–polymer interface. Moreover, our conclusion implies that this can be further developed as a general strategy for designing new composite materials using various nanoscale luminescent materials that can efficiently convert mechanical energy into lights.

Flexible and Stretchable LEDs with Silica Coated Cesium Lead Halide Perovskite Nanocrystals through APTES Treatment Sangyeop Lee, Sanghyun Jeon, Ho Kun Woo and Soong Ju Oh; Korea University, Korea (the Republic of)

Currently, cesium lead halide perovskite(CsPbX3 X = Cl, Br, I) nanocrystals (NCs) have been attracted enormous attention for optoelectronics materials due to their prominent optical properties such as excellent color reproducibility and high photoluminescence quantum yield (PLQY). Herein, we demonstrate a simple coating process of perovskite NCs by adding (3-Aminopropyl) triethoxysilane (APTES) with precursor to fabricate stretchable and flexible light emitting diode (LED). The chemical, optical, and structural properties of perovskite NCs without and with APTES treatments. It was demonstrated that APTES treatment successfully creates silica shell, which improves the stability of perovskite NCs by passivating their surface. As a result, silica coated perovskite can be embedded in polymer matrix without any degradation structure and luminescence efficiency. By embedding NC in PDMS, we fabricated stretchable color filters showing high color reproducibility and remaining high luminescence, stretchable LEDs with mixture of PDMS/Cu-doped ZnS and silica coated perovskite NCs, with improved durability and stability.

**EN10.12.12**

Inkjet Printed Metal Halide Perovskite for Light-Emitting Diodes—From Bulk Perovskite To Perovskite Nanoparticles Hyeon-Dong Lee1, Huanyu Zhou1, Hui Jae Choi2, Sungjin Kim1, Young-Hoon Kim1, Byung Doo Chin1 and Tae-Woo Lee1; 1Seoul National University, Korea (the Republic of); 2Dankook University, Korea (the Republic of); 3NREL, United States

Metal-halide perovskites (hereafter, perovskite) are promising materials for a light emitter of light-emitting diodes (LED) based on their narrow emission spectrum and the easy bandgap tunability. In the top-down approach using the perovskite dissolved in polar solvent such as dimethyl sulfoxide (DMSO), the growth mechanism can be easily controlled by using various additives and applying solvents, so small grain size with strong exciton confinement can be easily achieved. As the bottom-up approach, perovskite nanoparticles synthesized with passivating ligand have high photoluminescence quantum efficiency (PLQE) due to the strong exciton confinement. Both methods are promising way to develop the highly efficient PeLEDs, but these have been mainly studied by spin-coating process. Spin-coating process is a good process to easily control the morphology of perovskite film but is not suitable for fine patterned microarrays that meet criteria of high-definition display.

In this work, we induced an inkjet manipulated approach for fine patterned perovskite microarrays. Combining with a high viscosity co-solvent, the outward capillary flow as the cause of ring stains can be suppressed. Also, adding the additive into the perovskite ink, we modulated a crystal growth mechanism of perovskite ink, and finally obtained perovskite microarrays with perfect morphologies. With these results, we provide insight on how to fabricate perovskite microarrays for efficient PeLEDs.

**EN10.12.13**

Tailoring Size and Dimensionality (0D/1D/2D) of Cesium Lead Halide Perovskite Nanocrystals through Immiscible Polar Solvent Assisted Post Synthetic Oriented Attachment Sanghyun Jeon, Junhyuk Ahn, Ho Kun Woo and Soong Ju Oh; Korea University, Korea (the Republic of)

Herein, we demonstrate the post-synthesis engineering methods to precisely control size and dimensionality (0D/1D/2D) of as-synthesized all-inorganic cesium lead halide perovskite (CsPbBr3) nanocrystals (NCs). We investigate the chemical effects of polar solvents properties such as immiscibility, polarity, and boiling point on the surface of NCs as well as structural and optical properties. By appropriately utilizing the properties of solvent, the
effect of polar solvent could be indirectly and mildly conveyed to the NCs making them lose their ligands and attached with proximal NCs without destruction. Based on our observation, we developed “Immiscible solvent phase mixing” method to induce epitaxial growth of CsPbBr$_3$ NC. The size of NCs can be easily tailored by controlling the engineering time. Taking advantage of the minimal effect of mild solvent, we also developed liquid-air interface self-assembly method to systematically control the dimensionality. At the interface, NCs could be horizontally assembled and grown into large area, single crystalline nanowire (1D) and nanoplate (2D) via the oriented attachment process. Finally, we discussed the origin of non-destructive epitaxial growth phenomenon with suggested model system.

**Doped Two-Dimensional Perovskites for Light Emitting Applications** Daniele Cortecchia, Wojciech Mroz, Tetiana Borzda, Giulia Folpini, Rosaria Brescia, Luca Leoncino and Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Metal halide perovskites are gaining increasing interest for their light emitting properties and have become attractive for a wide range of optoelectronic devices such as light emitting diodes (LEDs), light emitting field-effect transistors (LE-FETs), lasers and scintillators. [1] While high efficiencies have been reached with 3D dimensional perovskites, the research community keeps exploring alternative structures to boost the luminescence yield and increase the material’s tunability. In particular, the increased structural flexibility has revived great interest in low dimensional perovskites. [2] Here, the possibility to increase the exciton binding energy by spatial and dielectric confinement is believed to be beneficial to improve the radiative recombination efficiency. However, with the exception of multidimensional perovskites of the Ruddlesden-Popper series where luminescence is strongly enhanced due to energy funneling effects, the quantum yield of single-layered 2D perovskite films remains low (<3%). This is likely due to detrimental trap-assisted recombination, and has so far hampered their effective integration into electroluminescent devices.

To overcome such issues and improve the emission properties of 2D perovskites, here we identify two synthetic and defect engineering strategies, [3] one involving the use of photoactive organic cations (such as 1-naphthylmetylammonium) and one based on metallic doping involving the use of transition metals (e.g. Mn$^{2+}$) and lanthanides (e.g. Eu$^{3+}$, Yb$^{3+}$). [4] While both strategies allow the tuning of perovskite luminescence from the visible down to the near infrared region (NIR), we find that highly efficient energy transfer from the perovskite to the metallic ion can be achieved in case of inorganic doping, provided that a suitable energy level alignment of the host-guest system is realized. In particular, by using temperature-dependent and time-resolved spectroscopy, we demonstrate that the presence of Mn$^{2+}$ ions allows to overcome the funneling of the photoexcited species in inefficient recombination pathways (e.g. permanent traps) thus improving the photoluminescence quantum yield beyond 20% in perovskite films. Finally, we provide a proof-of-concept demonstration of the electroluminescence properties of such doped-systems in light emitting diodes. [3]

Our work shows the potential of the doping strategy for the tuning and enhancement of the perovskite’s luminescence properties and further stimulates the investigation of a broader range of host/guest systems.

**Rational Design of Multicolor Lanthanide-Based Upconversion Nanocrystals** Sanyang Han and Akshay Rao; University of Cambridge, United Kingdom

Meeting the high demand for lanthanide-doped luminescent nanocrystals across a broad range of fields hinges upon the development of a robust synthetic protocol that provides rapid, just-in-time nanocrystal preparation. However, to date, almost all lanthanide-doped luminescent nanomaterials have relied on direct synthesis requiring stringent controls over crystal nucleation and growth at elevated temperatures. Here we demonstrate the use of a cation exchange strategy for expeditiously accessing large classes of such nanocrystals. By combining the process of cation exchange with energy migration, the luminescence properties of the nanocrystals can be easily tuned while preserving the size, morphology, and crystal phase of the initial nanocrystal template. This post-synthesis strategy
enables to achieve, for the first time, upconversion luminescence in Ce\(^{3+}\) and Mn\(^{2+}\)-activated hexagonal-phased nanocrystals, opening a gateway towards applications ranging from chemical sensing, biological imaging to anti-counterfeiting.

The stability of solution-processed semiconductors remains an important area for improvement on their path to wider deployment. Inorganic caesium lead halide perovskites have a bandgap well suited to tandem solar cells but suffer from an undesired phase transition near room temperature. Colloidal quantum dots (CQDs) are structurally robust materials prized for their size-tunable bandgap; however, they also require further advances in stability because they are prone to aggregation and surface oxidization at high temperatures as a consequence of incomplete surface passivation. Here we report 'lattice-anchored' hybrid materials that combine caesium lead halide perovskites with lead chalcogenide CQDs, in which lattice matching between the two materials contributes to a stability exceeding that of the constituents. We find that CQDs keep the perovskite in its desired cubic phase, suppressing the transition to the undesired lattice-mismatched phases. The stability of the CQD-anchored perovskite in air is enhanced by an order of magnitude compared with pristine perovskite, and the material remains stable for more than six months at ambient conditions (25 degrees Celsius and about 30 per cent humidity) and more than five hours at 200 degrees Celsius. The perovskite prevents oxidation of the CQD surfaces and reduces the agglomeration of the nanoparticles at 100 degrees Celsius by a factor of five compared with CQD controls. The matrix-protected CQDs show a photoluminescence quantum efficiency of 30 per cent for a CQD solid emitting at infrared wavelengths. The lattice-anchored CQD:perovskite solid exhibits a doubling in charge carrier mobility as a result of a reduced energy barrier for carrier hopping compared with the pure CQD solid. These benefits have potential uses in solution-processed optoelectronic devices.

**Direct Synthesis of CsPbBr\(_3\) Nanocrystal-Polymer Composite Films by UV Curable Prepolymer through Room Temperature Reprecipitation Method**

Sungho Woo

Wook Hyun Kim

Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Recently, all-inorganic metal halide perovskite nanocrystals (PeNCs) with a general formula CsPbX\(_3\) (X=Cl\(^-\), Br\(^-\), I\(^-\)) have been extensively studied for optoelectronic applications such as solar cells, light-emitting diodes (LEDs), photodetectors, and lasers due to their tunable bandgap, high photoluminescence (PL) quantum yield, long charge diffusion length, high absorption efficiency, and low-cost solution processability. The bandgap energies and PL spectra can be easily tuned over the entire visible spectral region of 410 ~ 700 nm through a halide anion exchange process. Additionally, PeNCs exhibited a narrow PL linewidths and high stability against heat and light, so they are widely studied as next-generation LED materials. [1,2] However, the instability of PeNCs to water or polar solvents due to their ionic bonding property is a major obstacle to their device applications. Several studies have been conducted on the encapsulation of PeNCs using silica or polymer materials such as polyhedral oligomeric silsesquioxane (POSS), mesoporous silica, tetramethylorthosilicat (TMOS), and polyvinylpyrrolidone (PVP). [3-5]

In this study, we describe the introduction of encapsulation by modified ligand-assisted reprecipitation (LARP) method in which the perovskite precursor salts solution is dropped directly into the UV curable prepolymers solution at room temperature. It is confirmed that PeNCs encapsulated by UV cured polymer have excellent moisture stability. We will present the data of UV-Vis absorption, PL, and XRD measurement of PeNCs-polymer composite films in detail. This work provides a simple and robust method for the preparation of stable and bright PeNC films that can applicable for water-stable and highly efficient wide color gamut LED displays or other optoelectronic devices.

Giant Modal Gain Coefficients in Colloidal Nanoplatelets

Burak Guzelturk, Matthew Pelton, Murat Olutas and Hilmi Volkan Demir; 1Stanford University, United States; 2University of Maryland Baltimore County, United States; 3Bolu Abant Izzet Baysal University, Turkey; 4Bilkent University, Turkey; 5Nanyang Technological University, Singapore

In recent years, colloidal II-VI nanoplatelets have become promising gain media for lasers offering properties superior than those of the conventional nanocrystals. Using the nanoplatelets, thresholds for amplified spontaneous emission were lowered to a few $\mu$J/cm$^2$ with gain lifetimes reaching up to 0.5 ns. In addition, early reports pointed out that modal gain coefficients in the nanoplatelets can be large. However, limits of the modal gain, which are important for practical laser applications, have not been understood nor elucidated to date. Here, we systematically investigate modal gain coefficients in CdSe nanoplatelets by performing variable stripe length measurements as a function of optical pump intensity. We find that modal gain coefficients in the CdSe nanoplatelets at room temperature reach a remarkable level of 6,600 cm$^{-1}$ with a material gain up to 15,300 cm$^{-1}$. The modal gain coefficient measured in the CdSe nanoplatelets is the largest among any other gain media at room temperature, and the material gain coefficient is on par with the best reports using epitaxially-grown quantum wells. We find that giant modal gain coefficients are ubiquitous to the CdSe nanoplatelet family as confirmed by samples having different vertical thicknesses and lateral sizes. The large gain coefficients of the nanoplatelets indicate that gain-active species, i.e., biexcitons, are highly persistent even under high pumping levels. Therefore, nonradiative processes including Auger recombination do not rapidly deplete biexcitons in the nanoplatelets as they do in typical quantum dots, overcoming an important bottleneck against achieving efficient lasing in colloidal semiconductors.

A Micro-Spherical Metal-Dielectric Plasmonic Platform for Strong Light Absorption and Emission

Seok Joon Kwon; Korea Institute of Science & Technology, Korea (the Republic of)

Micro-scale structured dielectric substrate have been widely employed for platforms for photonic devices such as photodetectors, photovoltaic devices, and light emitters. When the platforms are integrated with metallic nanostructures, they can also work as plasmonic platform supporting strong near-field in a form of surface plasmonic resonance (SPR) or gap plasmonic resonance (GPR). In the present study, we developed a plasmonic structure composed of dielectric micro-sphere which are coated with metallic nanoparticles. Due to the spherical shape, the structure exhibited strong absorption behavior in a wide range of visible (Vis) and near infrared (NIR) spectrum. The strong absorption was found to be due to strong resonance in the structure resulting from Fabry-Perot spherical cavity resonance and extended optical path length derived by metallic nanoparticles on the surface. As well as the strong absorption, the plasmonic structure also exhibited strong light emission properties in Vis spectrum. In particular, we observed whispering gallery mode (WGM) resonance-derived facilitated light emission, which was experimentally checked by upconversion nanoparticles (UCNPs) on the surface of the structure. When aligned in a form of micro lattice, the plasmonic micro-spheres also exhibited additional advantages in light emission such as wide viewing-angle and higher haze efficiency, which are promising in developing NIR-to-Vis light emission film.

Optical Gain Modulation of a Colloidal Quantum Dot Film in an Electrical Device

Junhong Yu, Sushant Shendre, Weon-kyu Koh, Baiquan Liu, Songyan Hou, Chathuranga Hettiarachchi, Savas Delikanli, Pedro H.
In view of optical gain application, colloidal quantum dots (CQDs) are suffering from band-edge state degeneracy which requires multiple-exciton to achieve population inversion. However, fast and efficient Auger process in the CQDs containing multiple-exciton increases the lasing threshold and limits the gain lifetime. Here, by applying the electric field to the quasi type-II CQDs (CdSe/CdS/ZnS core/shell/shell) embedded in the Sawyer−Tower circuit, we have demonstrated tunable amplified spontaneous emission (ASE) threshold in a long-sought practical device where the CQDs sandwiched between two dielectric layers retain their high quantum efficiency as in parent solution (quantum yield of > 70%). Singly-charged CQDs help building up population inversion due to pre-existing electrons while strongly enhanced Auger recombination in multiple-charged CQDs (i.e., doubly charged exciton) stymies the optical amplification. This approach allows us to fine-tune and achieve the optimal charging level to utilize the advantages of singly charged CQDs and reduce the adverse effect of doubly charged CQDs.

In addition to demonstrating tunable optical gain experimentally, we also developed a kinetic equation model to systematically analyze the electric field dependent light amplification behavior systematically. The kinetic model not only confirms our experimental results but also presents to be a reliable tool for accessing the requirements of the charging level to achieve nearly zero-threshold gain in CQDs. The implications, then, to potential applications of our robust and environment-undependable tuning method are broad, from controlling exciton recombination dynamics to continuous wave (CW) or possibly electrically pumped CQD lasers.

**Continuous-Wave Pumped Biexciton Emission in Copper-Doped Colloidal Quantum Wells** Junhong Yu¹, Manoj Sharma¹, Mingjie Li¹, Pedro H. Martinez¹, Savas Delikanli², Ashma Sharma¹, Yemliha Altintas², Chathuranga Hettiarachchi¹, Tze Chien Sum¹, Hilmi Volkan Demir¹,² and Cuong Dang¹; ¹Nanyang Technological University, Singapore; ²Bilkent University, Turkey

In atomically thin transition metal dichalcogenides (TMDs), biexcitons have sparked an unprecedented research enthusiasm since the first observation by Heinz and colleagues (Nature Phys. 11, 477–481, 2015). While TMDs are still suffering from synthesis cost, upscaling capability and quantum efficiency, colloidal nanomaterials can be an appealing complement to TMDs for biexciton sources. The specific hurdles and problems in demonstrating radiative, sustained biexcitons at room temperature in colloidal nanomaterials were earlier investigated by other groups: Klimov, Sargent, Moreels and others. Specific examples of major technical hurdles were manifested through: i) the efficient Auger recombination in multiple-carrier and quantum-confined environment, leading to ultrafast deactivation the high-order correlated excitonic states; ii) relatively small biexciton binding energy, which is comparable to the thermal energy at room temperature and much smaller than the inhomogeneous broadening of exciton emission, causing the biexciton emission only be resolved/observed at cryogenic condition.

Here, by doping the CdSe colloidal quantum wells with transition metal ions (copper) to create a new Coulomb interaction environment for band-edge excitonic resonance, we have reached and showed proof of sustained, well-resolved biexciton emission in a long-sought “all solution processable regime” enabling the easy integration of potential quantum emitters into almost any optoelectronic quantum architectures. Suppressed Auger loss in 1D quantum confinement and reduced Coulomb screening assisted by dopant-host interaction enables a biexciton binding energy of ~64 meV, a factor of 2 greater than the values reported in other colloidal nanomaterials and comparable to the value reported in TMDs. The biexcitons are robust, optically and mechanically in ways that have no parallel in the reported literature in terms of colloidal nanomaterials.

**EN10.12.23**

**Uniformly Dispersed Colloidal Quantum Dots in Conductive Polymer for High-Sensitivity and Ultra-Fast Infrared Photodetectors** Yifan Dong¹,²; ¹China University of Geosciences, China; ²The Chinese University of Hong Kong, Hong Kong

Near-to-mid-infrared (IR) photodetection technologies have the potential to revolutionize the infrastructures of surveillance and manufacturing by enabling military or civil night vision, environmental gas monitoring, and chemical spectroscopic analysis. However, current commercial IR photodetectors, particularly those with beyond 2000 nm spectral response, rely on expensive and size-limited epitaxial growth processes that are not compatible with silicon wafer technologies. Colloidal HgTe quantum dots (QDs), with a spectral response spanning almost the
entire near-to-mid-IR range, are a promising material candidate for the new generation photodetectors. However, at room temperature, the HgTe QD based photodetectors exhibit rather low specific detectivity of less than 109 Jones (or cm Hz1/2 W−1 in SI units); therefore, HgTe QD based photodetectors have to work at low temperatures to reduce dark currents and obtain better detecting performance. This requires the use of large cooling systems, which leads to a huge increase in the cost and limitation of the application, making it difficult to achieve miniaturized photodetection systems for portable imagers, spectrometers and sensor network applications. The limitations of HgTe QD based photodetectors intrinsically rise from the fact that HgTe QDs have low charge transfer properties and poor colloidal stability in ambient air condition. Combining HgTe QDs with a stable and highly conductive matrix, forming hybrid IR photodetectors is very promising to mitigate the limitations, as the conductive media can help with the facilitating charge transport mobility, providing great mechanical and chemical stabilities, and the HgTe QDs can act as the light absorber for sensing. P3HT, a well-established conjugated conductive polymer with excellent electronic properties, compatible band gaps and great mechanical and chemical stabilities, is an ideal candidate for the matrix material. However, achieving a controllable bicontinuous percolation network and a well-defined interface between QDs and the polymer matrix remains challenging, as it is very difficult to disperse high-density HgTe QDs uniform into P3HT matrix without aggregation, as it’s critical to tune the interface properties between HgTe and P3HT with efficient electron-hole separation and uniform phase distribution.

Here, we demonstrate for the first time a facile method to synthesize and control the nanoscale morphology and interfacial properties of poly(3-hexylthiophene) (P3HT) matrix and HgTe QDs hybrids using chemical grafting and ligand exchange methods. Solvent-assisted chemical grafting and ligand exchange were used to control the interface of P3HT/HgTe nanohybrids and the HgTe QD interparticle distance, respectively. It’s demonstrated that the formation of an interpenetrating and percolating P3HT/HgTe network gives rise to efficient charge separation and charge transport, significantly improving photovoltaic performance, which is promising for high-performance and low-cost IR photodetector applications.

EN10.12.24
Improved Stability and Performance of All Inorganic Perovskite Quantum Dots by Mixing Rubidium Cation and Fabrication of Their Full-Color Film with Wide Color Gamut
Seungmin Baek and Sang-Wook Kim; Ajou University, Korea (the Republic of)

In recent years, perovskite quantum dots (PeQDs) have received a lot of attention for many application. however, PeQDs were particularly unstable and the optical properties were readily degraded because of its structural instability. To overcomes these problems, We synthesized perovskite using new cations. Mixed-cation Cs0.4Rb0.6PbX3 (X = Cl, Br, I) perovskite quantum dots (PeQDs) are developed and show high quantum yields of 93% and 86% for green and blue wavelengths, respectively. The stability is significantly improved under heat, UV, and water aging conditions. We also fabricated the film by applying cyclic olefin copolymer to perovskite for the first time. The films have a wide color gamut covering up to 104.15% of the BT.2020-defined color space, with the white light color coordinates of (0.33, 0.32), luminance of 68.86 Cd/m2, and correlated color temperature of 5299 K at 20 mA

EN10.12.25
Efficient Light Emitting Diode Achieved by Using Mixed 2D/3D Perovskites and Manipulating Charge-Injection Balance
Weiming Qiu1,2, Azhar Fakharuddin1,3, Jielin Yan1,3, Guillaume Croes1,2, Robert Gehlhaar1, Andrey Kadashchuk4, Vidmantas Gulbinas5, Hongzheng Chen3 and Paul Heremans1,2; 1imec, Belgium; 2KU Leuven, Belgium; 3Zhejiang University, China; 4National Academy of Sciences of Ukraine, Ukraine; 5Center for Physical Sciences and Technology, Lithuania

Mixed 2D/3D perovskite films with self-assembled quantum wells have significantly improved the performance of perovskite light emitting diodes (PeLEDs). In this work, such films are fabricated through a two-step interdiffusion method that is widely employed in processing of perovskite solar cells, however, remains rarely explored for PeLEDs. Mixed 2D/3D perovskites based on FAPbBr3 and (MAPb(I/Br)3, with the incorporation of large-cation ligands, are fabricated for green and near-infrared emission, respectively. We systematically studied the processing condition on the morphology and optoelectronic properties of the resulting perovskite films. Moreover, with pumped-probe measurements, we also provide insight on how the charge dynamics change when tuning 3D perovskite to a mixed 2D/3D one, which significantly improves the radiative recombination. The PeLEDs based on two-step fabricated mixed 2D/3D perovskites show maximum external quantum efficiency (EQE) of 7.36% (green) and over 16% (near-infrared), which are significantly higher than PeLEDs using the corresponding 3D perovskites.
Finally, we present the importance of balanced charge injection on improving EQE roll-off as well as device stability. The electron injection is tuned systematically by doping the electron transport layer, reaching a balanced electron and hole injection at optimal condition. We achieve EQE > 10% beyond 100 mA/cm² and a remarkable half lifetime beyond 40 h at 10 mA/cm² for the optimized device with balanced injection.

**EN10.12.26**

**Uniformity Enhancement of Photo-Luminescent Quantum Dots Dispersed in Liquid Crystalline Matrix for Emissive Displays**

_Sujie Kang, Sin-Hyung Lee and Sin-Doo Lee; Seoul National Univ, Korea (the Republic of)

Quantum dots (QDs) have emerged as one of the most promising semiconducting nanoparticles (NPs) for high-performance information displays due to their tunability of the emission wavelength, narrow full width at half maximum (FWHM), and high quantum efficiency. In the QD-based displays, the uniform dispersion of the QDs is one of the critical issues to achieve the emission uniformity over the entire area of an individual pixel and to suppress the aggregation-induced quenching. In general, the QDs can be dispersed in a variety of host media such as organic semiconductor materials and cross-linkable polymers (hereafter referred to the QD hybridization). In the direct color conversion by the photo-luminescent (PL) QD hybridization, the color purity and the PL intensity of the QDs are limited due to the localized aggregation of the QDs in the host matrix. Thus, it remains a challenge to produce highly uniform dispersion of the QDs for the high color purity and the high PL intensity in well-defined patterns.

In this work, we developed a simple and effective method of achieving the uniform QD hybridization with the molecular field effect of the host matrix on the dispersion of the QDs. In order to utilize the molecular field effect, a reactive mesogen (RM), which exhibits the liquid crystal (LC) properties and can be photo-polymerized, was used as the host matrix. Two types of the QD hybrid films were prepared depending on whether the polymerized RM matrix was aligned or not. A solution of red QDs (with the peak wavelength of 620 nm), dissolved in the homogeneous RM solution, was spin-coated on a glass substrate with or without the homogeneous alignment and then photo-polymerized under the ultraviolet (UV) exposure. The RMs aligned along the homogeneous direction indeed suppressed the aggregation of the QDs due to the high degree of the molecular ordering of the RMs through the photo-polymerization. Based on the 3-dimensional emission profiles, probing using the confocal microscopy, in the ordered QD hybrid film, the mean peak-to-peak distance between two adjacent emission sites was found to be about 60 nm and the FWHM was comparable to the radius of an individual QD (about 40 nm). In contrast, in the non-ordered RM film, the FWHM was quite arbitrary and the distance between two emission sites was random due to the aggregation of the QDs. Note that the intensity of the emission spectrum of the ordered QD hybrid film increased with increasing the weight concentration of QDs. The aggregation of the QDs appeared at about 2 wt. % of the QDs.

We examined the electro-optical properties of the PL-based QD display consisted of the ordered QD hybrid patterns, a light modulator, and an excitation light source. A simple vertically aligned LC cell was fabricated as the light modulator. The blue LED with the peak wavelength of 455 nm was used as the excitation light. The QD hybrid film was patterned by the UV exposure through a photomask, followed by the removal of the un-polymerized region. The same process for red QDs was repeated for green QDs (the peak wavelength of 530 nm). For the blue patterns, the dummy regions containing blue absorbers were used for balancing the intensity. As the applied voltage increased, the intensity of the emission spectrum of the QDs increased according to the change in the phase retardation which converts the polarization state of the excitation light. This leads directly to the modulation of the emission spectra of the QDs with the color gamut extended to 82 % of the BT. 2020 standard. Our approach will provide a useful guideline to produce the QD hybridization for emissive displays with high color purity.

**Improving Thermal Stability of Core/Shell Quantum Dots Using Block Copolymer Protective Layer**

_Geon Yeong Kim, Eugene N. Cho and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Application of semiconductor nanocrystals increased over the years in fields such as solar cells, sensors, light-emitting diodes and electronics. Particularly, a form of nanocrystal known as quantum dots (QDs) has gained interest with the recent development in displays. With easy color tunability, high color purity, and high quantum yield, QDs has been selected as the candidate for next-generation displays. Because of use commercially, there is a
movement for shifting the materials composition from Cd-based to Cd-free core shell QDs such as InP/ZnS. However, these attractive initial properties are difficult to maintain when undergoing fabrication and long-term operation. This is especially the case for processing QDs at elevated temperatures. During thermal processing of QDs for display application, the quantum efficiency suffers a substantial loss. From the electronic process standpoint, the loss is due to carrier ejection to trap states or electron-hole pair ejection. In addition, the materials composition and structure can vary upon thermal processing due to phenomena such as particle sintering, Ostwald ripening, or surface composition change. Furthermore, oxidation of the shell can influence the quantum yield to decrease more than 50% as well as cause blue or red shift of the photoluminescence spectra.

In order to prevent degradation from thermal processing, we believe the key is to create a protective layer for the QD. Here, we utilize block copolymer (BCP) to act as a protective layer through micelle formation. The QDs were loaded into the core of the block copolymer micelles, using self-assembly property of block copolymer. The micelle core wraps around the QD expecting to hold ligands in place while the micelle corona gives additional protection of the QD from the surrounding environment. This will provide a two-way protective layer to the Cd-free core-shell QD preventing outer shell of the QD from ligand detachment and oxidation. The block copolymer protective layer is expected to improve the thermal stability and retain PL of 90% after post thermal treatment.

Room Temperature Optical Properties of Single Perovskite Quantum Dots Gabriele Raino1,2, Annelies Landuyt1,2, Franziska Krieg1,2, Caterina Bernasconi1,2, Stefan Ochsenbein1,2, Dmitry Dirin1,2, Maryna Bodnarchuk1,2 and Maksym V. Kovalenko1,2; 1ETH Zürich, Switzerland; 2Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Lead-halide perovskite APbX₃ (A=Cs or organic cation; X=Cl, Br, I) nanocrystals (NCs) are subject of intense research due to their exceptional properties as both classical¹ and quantum light sources.²⁻⁴ Many challenges often faced with this material class concern the long-term optical stability, a serious intrinsic issue connected with the labile and polar crystal structure of APbX₃ compounds. When conducting spectroscopy at a single particle level, due to the highly enhanced contaminants (e.g., water molecules, oxygen) over NC ratio, deterioration of NC optical properties occurs within tens of seconds, with typically used excitation power densities (1-100 W/cm²), and in ambient conditions.

Here,⁵ we demonstrate that choosing a suitable polymer matrix is of paramount importance for obtaining stable spectra from a single NC and for suppressing the dynamic photoluminescence (PL) blueshift. In particular, polystyrene (PS), the most hydrophobic amongst four tested polymers, leads to the best optical stability, one-to-two orders of magnitude higher than that obtained with poly-(methyl methacrylate) (PMMA), a common polymeric encapsulant containing polar ester groups. Molecular mechanics simulations based on a force-field approximation corroborate the hypothesis that PS affords for a denser molecular packing at the NC surface. These findings underscore the often-neglected role of the sample preparation methodologies for the assessment of the optical properties of perovskite NCs at a single particle level and guide the further design of robust single photon sources operating at room temperature.

References:
The best perovskite LEDs have external quantum efficiencies that approach or even exceed the limit expected from classical models of optical outcoupling with perfect internal quantum efficiency. I will discuss how light is transferred from trapped modes to outcoupled modes in these devices, presenting measurements of laterally resolved electroluminescence and photoluminescence that can distinguish between scattering and other mechanisms. We find an important contribution from photon recycling, where trapped photons are absorbed in the emissive layer and re-emitted, giving another chance to enter an outcoupled mode. I will discuss the effects of parasitic absorption in non-emissive electrode layers, and will present measurements on new geometries which further enhance optical outcoupling.

Low-Threshold Upconverting Microlasers via Controlled Assembly of lanthanide-Doped Nanoparticles

Energy looping Lanthanide-doped nanoparticles were introduced recently as an attractive gain medium for continuous-wave upconverted lasing. A useful architecture for constructing microlasers with these materials involves their adsorption onto dielectric microbeads that support stable whispering gallery mode (WGM) resonances. Despite recent advances in upconverting nanoparticle microlasers, improvement in resonators’ sizes, lasing threshold and reliable processability is needed for their utilization in different imaging, sensing and photonics applications. Our previously reported microsphere resonators exhibited a broad distribution of lasing thresholds and processing variability which limit their practical applications. In this work, a more complete understanding of the nanoparticles’ deposition process, and the structural factors that determine efficient lasing was achieved. We demonstrate using correlative microscopy that the quality of WGMs is significantly influenced by structural characteristics of the beads’ coating layer of nanoparticles, such as thickness and surface roughness. With this understanding, superior lasing was achieved following delicate control over the self-assembly of nanoparticles on the microcavity’s surface. We show that 5-µm microspheres with controlled sub-monolayer UCNP coatings exhibit 25-fold lower laser thresholds (1.7 kW/cm²) and 30-fold lower variability compared to the lowest threshold UCNP lasers. WGMs are observed in the upconversion spectra for microspheres as small as 3 µm, for which optical losses had previously prevented observation. These advances will enable the fabrication of more efficient upconverting lasers for imaging, sensing, and actuation in optically complex environments.

Widely Tunable Laser from Mixed-Halide Perovskites and Optical Amplification from Functional Perovskite Light-Emitting Diodes

Solution-processed perovskite semiconductors have emerged as efficient light emitters due to their bandgap tunability, high color purity, and favorable optical gain. Recently, optically pumped lasers from perovskite thin films have been demonstrated in various feedback configurations under either pulsed or continuous-wave excitation. However, unlike colloidal quantum dots or organic materials, the reports of lasing have been confined to either the green or near infrared spectral range, lacking red-emitting lasing due to undesirable halide phase separation. Through proper selection of self-assembled bulky ligand additives and the use of a cesium-mixed cation in the mixed-halide perovskite composition, we are able to suppress phase separation. In this study, we demonstrate widely tunable distributed feedback (DFB) lasers operating at room temperature. Our optimized mixed-halide perovskite films were prepared on quartz gratings and achieve single-mode lasing across the green and near infrared with a pump threshold of 4 µJ/cm² and full-width-half-maximum of 0.65 nm under pulsed optical excitation. The laser
devices were stable and robust so that the lasing emission lasted for more than 40 hours (~ $10^4$ laser pulses) under sustained excitation. Despite extensive research and progress on perovskite-based light-emitting diodes (LEDs) and lasers, realization of electrically driven solution-processed perovskite laser devices still remains elusive due to several barriers such as required high threshold current density, robust transport layers, and thermal management. Recently we have shown that hybrid perovskite LEDs can operate at the high current density regime (up to 620 A/cm$^2$) with no pronounced non-radiative Auger recombination. Further investigations enabled us to achieve amplified spontaneous emission from a typical perovskite LED structure, where the active layer is sandwiched by organic transport films. Methylammonium lead iodide perovskite with nanometer-sized crystallites have been optimized to provide high optical gain coefficient (~ 500 cm$^{-1}$), verified by a variable-stripe-length measurement. Then, second-order DFB Bragg gratings were patterned directly on indium tin oxide, acting as both transparent electrode and optical feedback structure. From this LED device architecture, we achieve single-mode DFB lasing with a threshold of 7 µJ/cm$^2$ and full-width-half-maximum of less than 1.0 nm through pulsed optical excitation. At the same time, this device was able to operate as an LED under direct current drive with a maximum external quantum efficiency (EQE) of 0.7%. In particular, the peak EQE occurred at a current density of 1.3 A/cm$^2$. Extrapolating from our previous work, these results suggest that operation at pulsed current densities of a few kA/cm$^2$ is achievable, putting the goal of electrically stimulated lasing within reach.

Controlling Orbit-Orbit Interaction in Hybrid Perovskites through Managing Grain Formation towards Amplified Spontaneous Emission

Bin Hu; University of Tennessee, United States

Organic-inorganic hybrid perovskites in polycrystalline films have demonstrated efficient amplified spontaneous emission (ASE). Essentially, amplified spontaneous emission can be enabled by initiating the cooperative interaction between light-emitting states. Here, we consider the orbit-orbit interaction that can occur through short-range and long-range interaction channels. Specifically, the short-range and long-range orbit-orbit interactions are occurred through magnetic dipole-dipole interaction and polarization-polarization interactions, fundamentally influencing the interaction between light-emitting states. In this study, we intentionally tuned the orbit-orbit interaction between short-range and long-range channels and simultaneously study the length scale of light-emitting states by using magneto-ASE measurements during ASE characterizations in polycrystalline perovskite (MAPbBr$_3$) films where the grain formation are effectively managed. Interestingly, by concurrently inducing fast and slow crystallization upon mixing two precursor solutions ( PbBr$_2$ + MABr and Pb(Ac)$_2$*3H$_2$O + MABr), the polycrystalline perovskite films can be prepared with large grains of micrometers attached with small grains of nanometers, leading to self-doping effects. In this situation, the small and large grains functions as doping agents and light-emitting centers, respectively. Especially, the self-doping realized by attaching small grains to the surfaces of large grains provides a unique method to tune the orbit-orbit interaction between short-range and long-range channels. As a consequently, cooperative spatially extended states can be formed, leading to low-threshold ASE. This presentation will discuss the tuning of orbit-orbit interaction towards generating cooperative spatially extended states by managing grain formation for generating ASE in organic-inorganic hybrid perovskites.

Spectral Linebroadening of CdSe Nanoplatelets and Quantum Dots for Light Emitting Devices
Johanna van der Bok, Bas Salzmann, Daphne Dekker, Matt Peerlings and Andries Meijerink; Utrecht University, Netherlands

There is need for efficient narrow band red and green luminescent materials for white light LEDs and LED-based display backlights to improve the energy efficiency and color gamut. Recently CdSe and InP semiconductor nanoparticles (known as quantum dots, QDs) were introduced in displays (e.g. Samsung QLED TV) because of their high efficiency and relatively narrow emission bands. A promising alternative for these QDs are CdSe nanoplatelets (2D NPLs) because of their narrower spectral linewidth compared to 0D and 1D confined nanostructures[1]. To enhance the quantum yield, stability and to tune the emission towards the red, a CdS or ZnS shell is grown around the NPLs. Unfortunately, core-shell NPLs do not exhibit the same narrow spectral linewidth. The difference in spectral width for core and core-shell NPLs has been explained by a difference in electron-phonon coupling after shell growth [2]. Here we aim to obtain insight in the origin of the difference in spectral width for core and core-shell NPLs. We investigated the temperature dependent line broadening of CdSe QDs, NPLs and core-shell NPLs.
Measurements were performed over a wide temperature range, between 4 and 423K and included measurements at elevated temperatures which are relevant for practical application in displays and white light LEDs but are usually neglected.

The line broadening studies reveal that homogeneous line broadening is similar for the various systems studied (core and core-shell NPLs and QDs). Homogeneous line broadening was found to be size dependent and small QDs (2.5nm diameter) showed a noticeably stronger homogenous broadening compared to the other systems. The significantly narrower band emission of core NPLs is explained by strongly reduced inhomogeneous broadening compared to core-shell NPLs and QDs. The larger spectral linewidth of CdSe core-shell NPLs is not due to an increase in homogeneous broadening caused by differences in electron-phonon coupling as previously suggested. Instead it is caused by an increased inhomogeneous linewidth after growth of the CdS or ZnS shell, probably related to inhomogeneities of the shell and exciton emission originating from different regions in the core-shell NPLs where the local electronic structure and bandgap are affected by variations in the shell thickness. This is supported by the recent improvements in synthesis procedures for core-shell NPLs which show less inhomogeneous broadening [3].

The present observations show that the spectral linewidth of NPL-heterostructure emission can be improved and is not caused by stronger exciton-phonon coupling due to the shell material. This makes green emitting core-crown NPLs and red emitting core-shell NPLs promising candidates for narrow band emitters in future displays and LEDs. Extending measurements to a regime that matches the operating temperature for the emitters in commercial applications (displays, white light LEDs) is rarely done but highly relevant. Our measurements up to 150 °C show a continuing increase in line width for both QD and NPL emission while the NPL emission line width remains narrower: ∼34 nm for green emitting QDs and ∼15 nm for green emitting NPLs at 150 °C. The significantly narrower emission bands for CdSe NPLs at device operating temperatures give the NPLs a clear advantage and make these emitters competitive with narrow band phosphors which have ∼20-30 nm spectral bandwidths in the green-red spectral region.

Design Rules for One-Step Seeded Growth of Nanocrystal Heterostructures Emory Chan¹, Haoran Yang², Leslie Hamachi³ and Iva Reza³; ¹Lawrence Berkeley National Laboratory, United States; ²Lawrence Berkeley National Lab, United States; ³Columbia University, United States

Quantum dot heterostructures such as core@shell nanocrystals are used as light-emitting materials for applications such as biological imaging, lasers, displays, and solid-state lighting. The inorganic shells of these materials, which confine excitons and chemically passivate these materials, are typically grown on seed nanocrystals through continuous or layer-by-layer methods, which are tedious and time-consuming. Here, we present design rules for more scalable reactions in which uniform shells are grown on CdSe quantum dots in a single step. We leverage high-throughput synthesis along with a custom library of precursors with tunable reactivity to develop a comprehensive understanding of the role of precursor reactivity, ligands, and temperature in these one-step seeded growth reactions. These experiments reveal a narrow region of experimental parameter space that promotes the uniform, purely heterogeneous growth of shell material on the seed particles. This “ideal growth” regime is sandwiched between opposing regimes that lead to secondary nucleation or ripening during growth. Coupled with kinetic simulations, these experiments reveal that precursor reaction rate and monomer solubility determine the balance between secondary nucleation and ripening. Therefore, accelerating the rate of shell growth through the use of more reactive precursors must be accompanied by a precise increase in ligand concentration in order to maintain uniform shell growth. These design rules will be critical for the predictable growth of complex, multi-shell architectures used to engineer band gaps and mediate multi-excitonic processes in high-efficiency quantum dot optoelectronic devices.

Single Exciton Gain and Stimulated Emission from Robust Doped PbS CQD Films at Room Temperature Sotirios Christodoulou¹, Iñigo Ramírez¹, Andreas Othonos², Alberto Figureira¹, Mariona Dalmases¹, Onur Ozdemir³, Santanu Pradhan¹, Grigorios Itskos² and Gerasimos Konstantatos¹; ¹ICFO - Institut de Ciencies Fotoniques, Spain; ²University of Cyprus, Cyprus
The last two decades CdSe-based colloidal quantum dots (CQDs) and most recently perovskite nanocrystals have been under the spotlight for lasing application as exhibit excellent optoelectronic properties such as high photoluminescence quantum yield (PLQY), optical stability and wide emission tunability. Already, CQD technology has delivered ultra-low lasing and stimulated emission thresholds even with continuous wave excitation (CW). Nevertheless, the research has centred in UV-Vis while very few examples has been shown in the low energy part of the electromagnetic spectrum.

On the other hand, light sources (lasers) in NIR is still the last piece missing for the realization of silicon Photonics (CMOS), while photodetectors and modulateors on Si have been already demonstrated. Apart from silicon photonics, the realization of low-cost, solution-processed materials with gain across the telecommunication window is of paramount importance for expanding the optical fiber data capacity beyond the limit of currently used Er-doped amplifiers. The realization of low-threshold and high gain amplified spontaneous emission (ASE) with high degree of tunability across the telecom band has not been achieved yet. The reason behind this challenge has been the high degeneracy of states in infrared CQDs over that of visible CQDs (twofold degeneracy of CdSe over eight-fold degeneracy for PbS-chalcogenides).

To tackle the high degeneracy of the PbS CQD we developed a doping scheme, which allow us heavily dope the PbS CQD filling with electron the conduction band. Both theoretical simulations (DFT) and experimental results (UPS) confirm that the Iodine substitution promotes the shift of the fermi energy (EF) over the conduction band (CB) while via size careful size selection of the CQD we can fine-tune the doping strength. Absorption spectra of the doped PbS CQD films shows a bleach of the band-edge transition according to the doping efficiency, while it is completely bleached when the CB is fully filled with 8 electrons. The doped PbS films are stable for months under ambient conditions while is the first demonstration permanent robust doping in conductive films.

Photothermal threshold quantum yield (PTQY) is a calorimetric technique, incorporating a photothermal deflection spectrometer and a photoluminescence spectrometer to simultaneously and precisely monitor the average amount of heat energy (non-radiative) and light energy (radiative) given off as a result of each incident pump photon. By
removing the need to directly quantify spectral radiance, with sufficient sampling, PTQY can achieve a theoretical precision of 0.02%, an improvement of multiple orders of magnitude in precision over conventional integrating sphere approaches. PTQY was previously applied by our groups to measure near unity CdSe:CdS quantum dots, measuring a peak PLQY of 99.6 ± 0.2% at an optimal CdS shell thickness. We will report on efforts to extend PTQY to study additional near unity nanoscale emitters, including halide perovskite nanoparticles, which can also achieve near unity PLQY, and have promising optoelectronic applications as single-photon sources or in optical refrigeration. Ultrahigh precision PLQY measurements are required to validate such utility. Furthermore, by validating that nanoscale emitters are operating near their thermodynamic limits, we will present how this technique can be applied to more directly quantify the impact of defects on photophysical properties.

Nanoscale Core-Shell Hyperbolic Structure—An Emerging Platform to Trigger Laser Action from Light-Emitting Materials
Hung-I Lin, Kanchan Yadav, Kun-Ching Shen, Chun-Che Wang, Ting-Jia Chang, Monika Kataria, Golam Haider, Pradip Kumar Roy, Yit-Tsong Chen and Yang-Fang Chen; National Taiwan University, Taiwan

Enhancing the light-matter interaction from low-dimensional nanoscale emitters has been attracted tremendous attentions for displays and optoelectronic devices. To achieve this goal, traditional methods have been used the plasmonic materials due to reshaping density of states (DOS) and tailing the light emission. However, the main drawbacks of the plasmonic materials are the propagation loss and narrowband resonance, which remains challenging to provide a broadband DOS to explore its functionality. Here, we develop a novel nanoscale core-shell hyperbolic structure with an extremely pronounced coupling effect inside the multishell (Au/SiO₂) nanoscale composite. Then, a giant localized electromagnetic wave of surface plasmon resonance is formed, causing a pronounced out-coupling effect than the plasmonic materials. To integrate the emerging light-emitting material, we mixed the nanoscale core-shell hyperbolic structure mixed with DCJTB dye molecules to measure the lasing spectra. DCJTB dye molecule, a kind of organic laser dye, has been used for solar-concentrator application. The lasing threshold is ultralow of ~42 μJ/cm², which was excited by a 374 nm pulsed diode laser. There is no laser action can be observed for the plasmonic-based Au nanoparticle at the low pumping power density.

Confirmed by simulation results, the nanoscale core-shell hyperbolic structure has achieved ~320 times higher scattering efficiency as compared with the plasmonic-based Au nanoparticle. Besides, the simulated mode volume is ~208 times smaller than the same components of multilayer structure, demonstrating that the nanoscale core-shell hyperbolic structure is able to strongly confine the energy, reduce propagation loss, then a tremendous feedback is formed to trigger the laser action. We believe that the nanoscale core-shell hyperbolic structure steps a great advance in lasing action from nanoscale materials, highly energy conversion efficiency for solar cells, and broadband absorption of optoelectronic devices applications.

Trion Dynamics in Perovskite Nanocrystals Yoshihiko Kanemitsu; Kyoto University, Japan

Metal halide perovskite nanocrystals (NCs) are a new class of semiconductor materials with excellent optical properties. These NCs are anticipated for use in light-emitting devices, because they exhibit high luminescence efficiencies at room temperature and their emission wavelengths can be easily controlled by the halogen composition and/or the NC size. In general, the trion, which is a stable state consisting of one electron–hole pair (exciton) and one excess charge, plays a crucial role in the optical responses of NCs. Trions usually cause photoluminescence intermittency, reduce the luminescence yield, and can also affect the threshold for optical gain. Thus, a deep understanding of the trion dynamics in NCs is important for development of NC-based light-emitting devices.

In this work, we analyze the dynamics of trions in perovskite NCs at room temperature. We studied their dynamics by means of single dot spectroscopy, femtosecond transient absorption spectroscopy, and Z-scan measurements [1-3]. Our results show that the biexciton Auger rate evaluated from femtosecond transient absorption spectroscopy can be expressed as the sum of the Auger rates of positive and negative trions obtained by single dot spectroscopy [4]. We further investigated the excitation fluence dependence of the trion generation. The trion generation in NCs under weak photoexcitation can be controlled by surface modification [5]. Under strong photoexcitation, the intrinsic nonradiative Auger recombination of biexcitons causes ionization of the perovskite NCs and trion generation. An important practical aspect is that the chemical modification of perovskites enables suppression of trion generation in light-emitting devices [6]. We discuss the trion dynamics in perovskite NCs and the mechanism of ionization of perovskite NCs.

Part of this work was supported by JST-CREST (JPMJCR16N3).

Carrier Dynamics in Halide Perovskite Nanocrystal Assemblies Jochen Feldmann; Ludwig-Maximilians-Universität (LMU), Germany

I will report on the optical properties of metal halide perovskite nano-platelets with controllable thickness down to one monolayer [1]. Pronounced quantum confinement effects, large excitonic binding energies and comparably high radiative recombination rates have been found, all depending on the number of monolayers present in the respective nano-platelets. Ultrafast optical experiments provide insight into characteristic charge carrier and spin relaxation scenarios in 2D perovskites [3]. Finally, the assembly of halide perovskite nanocrystals into ordered supercrystals [3,4] and the exchange of ligands lead to remarkable changes of their optical properties.

2:30 PM EN10.14.03
Improving Upconversion Performance of Colloidal Quantum Dot Nanostructures through Heterostructure Engineering Jill Cleveland, Tory Welsch, Eric Chen, Christopher Milleville, Kyle Lennon, Jing Zhang, James Bork,
Photon upconversion is a process in which two or more low-energy photons are sequentially absorbed in a material resulting in the emission of a higher-energy photon. Photon upconversion has a wide range of potential applications including optoelectronic devices, biotechnology, and solar energy harvesting. Semiconductor nanoparticles have recently emerged as a promising platform for upconversion due to the tunability of their absorption and emission wavelengths through control of particle shape, size, and composition. Additionally, semiconductors have inherently broadband absorption, capturing essentially all photons with energy above their bandgap, which is an important feature for solar energy harvesting applications. Previously our group developed a kinetic rate model and demonstrated upconversion could enhance solar cell performance beyond the Shockley-Queisser limit by providing additional above bandgap illumination from an upconversion layer located behind the cell. We have also demonstrated near-infrared (NIR)-to-visible upconversion photoluminescence in CdSe(Te)/CdS/CdSe core/rod/emitter colloidal quantum dot (QD) nanostructures under continuous wave illumination at solar relevant fluxes. While we and others have demonstrated the feasibility of using semiconductor nanostructures for upconversion, the reported efficiencies are rather low. We recently demonstrated that principles of semiconductor heterostructure engineering can be employed to achieve a factor of 100 improvement in upconversion efficiency. For example, by carefully controlling the core QD composition and introducing a gradient within the nanorod, we reduce nonradiative recombination rates and improve carrier transfer through the nanostructure, resulting in higher upconversion efficiency. We will report on the design, synthesis, and photophysical characterization via ultrafast and time-integrated optical spectroscopy of a range of such structures. We will describe further improvements in upconversion performance that could be realized by employing new colloidal synthesis techniques to optimize our current structures and introducing new particle shapes and elemental compositions.

The Room-Temperature Electrical Generation of a Single Exciton in a Single Colloidal Quantum Dot
Yunzhou Deng; Zhejiang University, China

The electrical generation of emissive excited states is at the heart of electroluminescent (EL) devices. The emissive excited state for colloidal quantum dots (QDs), a class of high-efficient and color-pure luminescent materials, is described as an exciton, i.e. a bound electron-hole pair. Recently, QD-based EL devices demonstrated distinctive performances at both single-dot and ensemble levels. However, the underlying mechanism associated with the electrical generation of excitons in QDs has yet to be clarified. Here we use the recently developed single-dot EL devices as a model system to identify the elementary steps responsible for the electrical generation of a single exciton confined in an isolated QD.

A new experimental technique, namely, optically probing a single emitter under electrical injection, was developed. We repetitively excited a single QD under constant electrical biases by a pulsed laser, enabling optically probing of all possible states associated with the single-dot EL. According to transient PL results, we identified the intermediate negatively-charged state (QD-) by the characteristic lifetime of the negatively-charged trion (X-). In addition, the occurrence of the intermediate QD- was verified by the red-shifted spectrum of the single QD measured under simultaneous optical and electrical excitation. The identification of the intermediate state suggested that the electrical generation of a single exciton in the single QD followed a deterministic pathway comprised of the prior electron injection and the succeeding hole injection. Quantitatively, the rate coefficient for hole-injection into a negatively-charged QD, which was substantially greater than that for hole-injection into a neutral QD, was determined to be comparable to that for electron-injection into QD.

This work provides a unique microscopic picture of the electrical generation of single excitons in single QDs at room-temperature. Our findings implicate the vital role of the long-lived intermediate QD- in boosting charge balance of single-photon EL devices and shall bring new insights into operation mechanisms of state-of-the-art QLEDs.

In Situ Fabricated Perovskite Quantum Dots for Display Applications

Haizheng Zhong; Beijing Inst of Technology, China

Perovskite quantum dots (QDs) are now emerging as low-cost alternative emitters for display applications. Very recently, we developed the in-situ fabrication of hybrid perovskite QDs embedded composite films (PQDCF) with high transparency, superior photoluminescence emission and additional processing benefits for down-shifting applications. The potential use of PQDCF as color converters in LCD backlights was successfully demonstrated, showing bright potential in display technology. Moreover, we further explored the electroluminescence devices based in-situ fabricated perovskite QDs. The enhancing role of ligand-assisted reprecipitation (LARP) process was illustrated, providing uniform FAPbX3 (X=Br, Cl, I) perovskite QDs films with photoluminescence quantum yield up to 78%. The electroluminescence devices with a maximum external quantum efficiency (EQE) of 16.3% and 15.8% were achieved, showing the promising to achieve high efficiency. In all, the in-situ fabrication strategy provides very convenient route for display technology.

III-V Colloidal Nanocrystals for Optoelectronic Applications

Sohee Jeong; Sungkyunkwan University (SKKU), Korea (the Republic of)

Recently, InP colloidal nanocrystals draw immense attention because of their successful debut in the display market and many researches in the field focus on improving the optical properties via various synthetic scheme. Still, understanding on synthetic mechanism, surface chemistry of III-V colloidal nanocrystals is limited which results in inferior optical properties with poorer stability when compared to Cd or Pb based colloidal nanocrystals. Here, I plan to discuss the chemical and physical properties of III-V nanocrystals based on their rather covalent bonding nature. Further, approaches to enhancing optical properties via chemically passivate deeper trap states from dangling bonds based on microscopic understanding on covalent surfaces will be shared.

4:30 PM *EN10.15.03

Unraveling the Origin of Operational Instability of Quantum Dot Based Light-Emitting Diodes

Jun Hyuk Chang1, Kookheon Char1 and Wan Ki Bae2; 1Seoul National University, Korea (the Republic of); 2Sungkyunkwan University, Korea (the Republic of)

Quantum dot (QD) based light-emitting diodes (QLEDs) are promising candidate for next generation display. For practical use of QLEDs, guaranteed operational stability at desired brightness is essential. Yet understanding the origin of operational instability of QLEDs is lagging behind. In this presentation, I explain the origins for the operational instability of QLEDs. The electrical characterization of QLEDs and spectroscopic analysis on the QD emissive layer within devices indicates two main mechanisms for the device degradation. The first is the luminance efficiency drop of the QD emissive layer in the running devices due to the accumulation of excess electrons in QDs, which escalates the possibility of non-radiative Auger recombination processes in QDs. The other is the electron leakage toward hole transport layers (HTLs) that accompanies irreversible physical damage to the HTL by creating non-radiative recombination centers. These processes are distinguishable in terms of the timescale and the reversibility, but both stem from a single origin, the disparity between electron versus hole injection rates into QDs. Ground on this experiment result, I offer rational guidelines that promise the realization of high performance QLEDs with proven operational stability.

Role of Cationic Ligands on Surface Passivation of Cesium Lead Bromide Nanocrystals

Lucy Yoon and Joshua Choi; University of Virginia, United States

A demand for more saturated color display, longer lifespan, improved economic viability, and optimal luminescence efficiency is rapidly growing in optoelectronic industries. Metal halide perovskite has been a rising candidate as our next generation semiconducting material due to the following: widely tunable bandgaps, exceptional efficiency, and
relatively facile and inexpensive fabrication processes. Inorganic cesium lead halide perovskite (CsPbX₃) nanocrystals, in particular, have emerged as an ideal option for practical application due to their high performance and intrinsic stability. Nanocrystals have challenges associated with major charge recombination sites on the surfaces. In order to overcome this problem, surface ligands can be employed to passivate charge traps. Ionic salts, given an advantage of ionic nature of perovskite, are effective at passivating either or both cationic and anionic defect sites. However, systematic understanding of the surface chemistry with the ionic salt ligands is still lacking. Here we present our study on the nature of cation and anion pairs on the efficacy of CsPbX₃ nanocrystal surface passivation. Based on a combination of optical spectroscopy, density functional theory calculations, device fabrication and testing, we show that the specific combinations of cations and anions result in superior charge trap passivation efficacy due to their different binding interactions and steric effects.

A New Approach to Fabricate Three-Dimensional GaN LEDs for Effective Light Energy Conversion
Youngshik Cho, Min Soo Jeon, Hanmin Jang, Heung Soo Lee and Dong Rip Kim; Hanyang University, Korea (the Republic of)

Herein, we experimentally demonstrate the successful fabrication of three-dimensional (3D) gallium nitride on silicon (GaN-on-Si) light-emitting diodes (LEDs) using 3D Si micro-scale structures on which multiple facets of {111} crystal planes are formed for effective light energy conversion. Hetero-epitaxial integration of GaN LED layers over 3D Si micro-scale structures by metal organic chemical vapor deposition not only forms continuous GaN layers on top of Si, but also achieves excellent crystal quality of GaN layer due to the effective release of the strain energy by the faceted structures of Si. Our GaN layers formed on 3D Si structures have threading dislocation densities (TDD) comparable to the GaN grown over the sapphire substrates. In addition, the formed GaN layers have unique 3D morphology favorable to the enhanced light emitting characteristics, while they exhibit broadband, multi-color emission characteristics due to the anisotropic formation of multiple quantum well (MQW) layers in the 3D structures, leading to realize full-color light emitters. While utilizing the advantages of 3D micro-scale structures, our approach to create GaN-on-Si LED with effective light energy conversion characteristics can be utilized to realize high performance optoelectronic devices for diverse applications.

Enhanced Electroluminescence Intensity Using Voltage Waveform Control in Alternative-Current Driven Organic Light-Emitting Diode
Byeong-gon Kim, Duck-Kyu Lim, Jun-Chan Choi and Hak-Rin Kim; Kyungpook National University, Korea (the Republic of)

In this work, we introduce an asymmetric voltage waveform to operate the AC-driven organic light emitting devices (OLEDs) for an increased amount of exciton generation. The device structure is the substrate/indium tin oxide electrode / polyimide / poly(9,9-di-n-octylfluorenyl-2,7-diyl) (PFO) with carbon nanotube (CNT) / aluminum (Al) electrode. In our proposed asymmetric structure, two types of charge carriers are injected from Al electrodes according to the electric field conditions. The energy barrier of hole injection from Al electrodes can be reduced by introducing CNT dispersion into the poly(9,9-di-n-octylfluorenyl-2,7-diyl) (PFO) layer. The holes injected through the CNT path accumulate on the PI/PFO interface and the excitons are created in the inverted field conditions. The hole injection barrier has lower CNT (0.7 eV) energy barrier than PFO's highest occupied molecular orbital energy
level injection barrier (1.5 eV). Therefore, the holes accumulate at the PFO/PI interface using the CNT paths. The electrons are injected into the lowest unoccupied molecular orbital energy level injection barrier (1.5 eV) of the PFO at the Al electrode. In this structure, the electrons have the mobility of PFO and the holes have the mobility of CNT. Holes are injected along the CNT channel during a positive cycle. At the same time, the charge carriers are generated in the CNT and the generated electrons generate weak light inside the PFO layer together with holes injected through the CNT. Weak light is generated due to the low density of electrons generated in the CNT during the positive cycle. The holes generated from the CNTs move to the PFO/PI interface and accumulate together with the holes injected through the electrodes. In the negative cycle, electrons can be injected and transported following the PFO paths. The injected electrons recombine with the holes generated by the electric field in the CNT, and the generated electrons and injected electrons move toward the PFO/PI interface. When the opposite polarity is applied, holes in the PFO/PI interface rapidly move toward the Al electrode. Since the hole mobility of CNT is much faster than the electron mobility of PFO, injected electrons and accumulated holes form excitons near the Al electrode. The hole mobility of CNTs is much faster than the electron mobility of PFOs of around 10^{-5} cm^2/Vs. Therefore, when a negative cycle is initiated, the holes at the PFO/PI interface recombine with the electrons injected near the Al electrode or rapidly escape through the electrode. More accumulated holes are needed to increase the amount of excitons that emit in combination with injected electrons. Therefore, if the positive cycle is longer than the negative cycle, the number of holes accumulated increases, and the probability of recombination the injected electrons and accumulated holes increases.

In our experiment, at the same operating voltage (40 V) and frequency (600 kHz) conditions, the electroluminescence (EL) intensities can be higher or lower according to the asymmetric waveform than that operated in conventional symmetric waveform, where the relative total EL intensities are 1.7:1:0.8 for samples operated at the waveforms having the relative polarity duration ratios.

3D Bromide Hybrid Perovskite–Based Microcavity for Large Surface and Low-Cost Polaritonic Applications
Paul Bouteyre1, Hai Son Nguyen2, Jean-Sébastien Lauret1, Gaëlle Trippé-Allard1, Géraud Delport1, Ferdinand Lédée1, Hiba Diab1, Ali Belarouci2, Christian Seassal2, Damien Garrot3, Fabien Bretenaker1 and Emmanuelle Deleporte1; 1Laboratoire Aimé Cotton, CNRS, ENS Paris-Saclay, Université Paris-Saclay, France; 2Université de Lyon, Institut des Nanotechnologies de Lyon - INL, UMR CNRS 5270, CNRS, France; 3Groupe d’Etude de la Matière Condensée, Université de Versailles Saint Quentin En Yvelines, Université Paris-Saclay, France

Since a couple of years, the hybrid organic-inorganic perovskites CH$_3$NH$_3$PbX$_3$, with X a halogen (I, Br, Cl), have emerged in the framework of photovoltaics and for light-emitting devices such as electroluminescent diodes and lasers. One of the main advantages of these materials is that they can be low-temperature and solution processed. Thus they can be deposited in large surface, which is suitable for wide-scale wafers and devices, with a low cost.

We consider here a one-dimensional planar microcavity containing a large-surface (1 cm$^2$) spin-coated CH$_3$NH$_3$PbBr$_3$ thin film as the optically active material. We choose this hybrid perovskite, emitting in the green range, to address the problem of the green gap for lasers and LEDs. We demonstrate the strong coupling regime between the photon mode of the Fabry-Perot cavity and the excitonic mode of the perovskite at room temperature even with a low-quality factor of the order of 100 [1]. This leads to the formation of the so-called polaritons, which are a linear and coherent superposition of the exciton and photon states.

Up to now, the strong coupling regime with 3D halide perovskites has been obtained for bromine or chlorine-based nano/micro-platelets or nano/micro-wires. The observation of polaritons in a spin-coated microcavity is particularly significant because it opens the route to new large surface and low-cost optoelectronic devices based on polaritonic effects, operating at room temperature and compatible with electrical injection. Indeed, all-optical logical devices on a single chip constitute the perspective of polaritons at room temperature: a large-area device is required to propagate the encoded information in the polaritonic flow across macroscopic distance.

From Photoluminescent Nanoparticle Powders to Ceramics—Process induced Barium Distribution between Particle Volume, Surfaces and Interfaces of MgO Nanocrystals Oliver Diwald, Thomas Schwab, Hasan Razouq, Gregor Zickler and Matthias Niedermaier; University of Salzburg, Austria

The rational design of nanoparticle based oxide ceramics is an important prerequisite for both, materials chemistry and physics and the manufacture of advanced materials with unprecedented optical properties.[1] Moreover, the search for suitable luminescent materials of sufficient availability, low cost and biocompatibility is of great scientific and economic interest. A possible approach to substitute currently used rare earth materials or heavy metals in optical applications, which feature luminescent properties in the visible range of light is the use of highly dispersed alkaline earth oxides (MgO, CaO, SrO and BaO). The emission properties of ionic surface dopants and segregated metal oxide clusters originate from surface exciton annihilation at low coordinated surface sites.[2]

In this study, a hybrid chemical vapour synthesis approach was used to incorporate impurity ions, such as Ba(2+), into the nanocrystalline MgO host lattice within the Mg-combustion flame.[3] Subsequent vacuum annealing promotes ion diffusion within the non-equilibrium solids, leads to particle reorganization and, ultimately, to the surface and interface decoration of the MgO nanocrystals with nanometer-sized photoluminescent BaO segregates. Structure characterization work performed with the help of X-ray diffraction and Transmission Electron Microscopy (TEM) revealed Ba-concentration dependent trends in nanoparticle growth. Moreover, annealing provides means to control impurity localization [3] and to trigger Ba-segregation within the MgO nanocrystals, as studied with Energy Dispersive X-ray Spectroscopy (EDX). The surface functionalization of the MgO nanoparticles leads to significant changes of the optical properties, showing BaO specific absorption bands (Ultraviolet-Visible-Spectroscopy) and both, a strong increase and a shift of the materials’ photoemission properties into the range of visible light (Photoluminescence).

After powder consolidation the controlled manipulation of impurity ions affects composition, energetics and, thus, the optical properties of constituent grains and grain boundaries. The here established understanding of impurity segregation including the important influence of surrounding atmospheres during processing was employed to functionalize the intergranular regions inside alkaline earth oxide nanoparticle derived ceramics. We tracked characteristic photoluminescence emission features that are specific to the surface excitonic properties of highly dispersed alkaline earth oxide ions and clusters as a diagnostic tool [2] and found that the properties could have been retained during consolidation and sintering.

EN10.16.05
Citric-Acid-Based Carbon Dots with Luminescence Quantum Yields > 50%—Spectral Tuning of the Luminescence by Ligand Exchange and pH Adjustment Florian Meierhofer1,1, Frank Dissinger2, Florian Weigert1, Siegfried Waldvogel2, Ute Resch-Genger1 and Tobias Voss1,1; 1Braunschweig University of Technology, Germany; 2Johannes Gutenberg University, Germany; 1Braunschweig University of Technology, Germany; 1Federal Institute for Materials Research and Testing, Germany

We report the synthesis and characterization of carbon nanodots (CDs) with high quantum yield (η>50%) and tailored optical absorption as well as emission properties. A well-described protocol with polyethyleneimine (PEI) as amine precursor is used as a reference to a new CD system which is stabilized by aromatic 2,3-diaminopyridine (DAP) molecules instead. The DAP stabilizer is installed in order to red-shift the absorption peak of the n-π* electron transition allowing efficient radiative recombination and light emission. Size, shape, and chemical composition of the samples are determined by (HR)TEM, EDX and FTIR-spectroscopy. Optical parameters are investigated using UV-VIS, PL and QY measurements. Several parameters such as concentration, excitation wavelength and pH are studied. Zeta-potential analysis indicate that pH-induced (de-)protonation processes of functional moieties directly affect the n-π* energy bands. This results in unique pH-dependent absorption and emission characteristics which are discussed on the specific chemical composition of each CD system.
Quantum Efficient Semiconducting Nanocrystal and Passivation Layer for Optimal Opto-Electronic Application

Taliya Gunawansa, Sangram K. Pradhan, Messaoud Bahoura, Jacob Strimaitis and Wagneci Hawley; Norfolk State University, United States

Photoluminescent colloidal quantum dots (QDs) have been enhancing a plethora opto-electronic devices including photodetectors, light-emitting diodes, displays, and solar cells. Incorporating quantum dots into the hetero-junction solar cell process has yielded significant increases in efficiency. A highly favored, cost and time efficient fabrication method of producing optimal tunable quantum dots is a one pot microwave irradiation technique. Water soluble cadmium telluride (CdTe) quantum dots are suitable for hetero-junction solar cells due to their high band-gap photoluminescence quantum efficiencies and mono-exponential exciton decays. Additionally, quantum dot enhanced photo-electrochemical (PEC) solar cells have yielded higher efficiency in charge generation amid the photoanode and electrolyte interface. Various characterization techniques were used to observe the opto-electronic properties of the CdTe QDs: photoluminescence spectroscopy (PL), ultraviolet-visible spectroscopy (UV-VIS), and transmission electron microscopy (TEM). Furthermore, the leakage current, capacitance, and frequency dispersion measurement show the stable performance of our CdTe QDs/Zn NPs hetero-junction solar cell.

Multi-Exciton Interactions and Size—An Interplay for Efficient Two-Photon Induced Gain in Perovskite Quantum Dots

Gabriel Nagamine, Jaqueline O. Rocha, Luiz G. Bonato, Ana F. Nogueira, Carlos H. Brito Cruz and Lazaro Padilha; Universidade Estadual de Campinas, Brazil

Lead bromide perovskite quantum dots (PQDs) have emerged recently as a promising material for lighting applications. Among its properties, we can highlight the defect tolerant structure, which allows for highly emissive nanoparticles, with photoluminescence quantum yield typically higher than 70%, for core only nanoparticles. Also, its facile synthesis opened the perspective for a scalable production for the application of future technologies. Additionally to that, two intriguing properties have been reported recently on the literature: ultra-low amplified spontaneous emission (ASE) threshold (typically in the order of 5-20 μJ/cm²)¹ and an extremely large two-photon absorption cross section (typically in the order of 10⁵ GM)². Although these properties are highly desirable for the application of PQDs in many optical systems, there is still no comprehensive study about the physical mechanism responsible for them. Here, we perform a systematic size dependence study of the two-photon absorption and threshold for two-photon induced ASE of PQDs to investigate the physical origin of these properties³. For the two-photon absorption studies, we analyzed PQDs nanoparticles with sizes ranging from 7.4 ± 0.8 to 12.5 ± 1.5 nm. From that, we report a 2PA cross section at 1.55 eV (transition at 3.1 eV) ranging from 2x10⁵ GM to 7x10⁵ GM. These values are almost one order of magnitude higher than for other visible emitting quantum dots such as CdSe and CdTe. However, by comparing the nanoparticles size, we show that this is just a matter of volume, and not due to any particular strong transition oscillator strength. We also performed size dependent two-photon excited ASE (2PA-ASE) studies on the PQDs. From that, we obtained that the 2PA-ASE threshold in terms of the fluence tends to be higher for the smallest samples, due to the reduced 2PA cross section. However, if we consider the threshold in terms of the average of excitons needed to generate ASE, the observed trend is the opposite, on which the biggest samples present the highest thresholds. In order to understand this unexpected behavior, the bi-exciton binding energies of the PQDs were investigated. From that, we observe a strong anti-correlation between the average of excitons needed to generate ASE and the bi-exciton binding energy, which goes from 41 to 61 meV. This indicates that the strong Coulombic interactions in PQDs are responsible for a red shift on the ASE energy, which causes a significant reduction on the reabsorption losses. This enables ASE with an average of excitons per dot of 0.73 for the smallest nanoparticles, which makes PQDs one of the most promising materials for future applications in the field of lasers.

EN10.16.08
First-Principles Study on the Fundamental Limit in the Homogeneous Linewidth of CdSe Quantum Dot
Sungwoo Kang\(^1\), Youngho Kang\(^2\) and Seungwu Han\(^1\); \(^1\)Seoul National University, Korea (the Republic of); \(^2\)Korea Institute of Materials Science, Korea (the Republic of)

For decades, the quantum dot has been studied as an important class of tunable light emitters with narrow emission linewidths. Although the development of synthetic method has reduced the linewidth contributed from the inhomogeneity in size and shape (inhomogeneous linewidth), the linewidth of single-particle (homogeneous linewidth) still exists because of exciton-phonon coupling, exciton fine structure, and spectral diffusion. It is widely accepted that the main contribution of the homogeneous linewidth is exciton-phonon coupling (~90%), followed by exciton fine structure (~10%). In this study, we develop a theoretical method to calculate the contribution of exciton-phonon coupling in the homogeneous linewidth of quantum dots. Ground-state electronic structure and phonon properties of the quantum dot are studied by density functional theory (DFT) calculations, and excited state is described by delta-DFT framework. Huang-Rhys factor is obtained by projecting structural distortion of exciton structure to phonon mode, and the luminescence spectra is calculated using the parallel approximation. As a model system, we investigate the luminescence linewidth of CdSe quantum dot with various size and structures such as tetrahedron, sphere, and spheroid. Our results are compared with recent experiments that identified the homogeneous linewidths by phonon-correlation Fourier spectroscopy and 2-dimensional electron spectroscopy.

EN10.16.09
Near Infrared Light Emitter of Single-Walled Carbon Nanotubes with Local Functionalization Using Bis-aryldiazonium Modifiers
Tomohiro Shiraki, Boda Yu, Naotoshi Nakashima and Tsuyohiko Fujigaya; Kyushu University, Japan

Single-walled carbon nanotubes (SWNTs) with semiconducting features emit photoluminescence (PL) in near infrared (NIR) regions. The NIR PL generates through a radiative relaxation process of exciton that is a bound electron-hole pair produced by photo-excitation of the tubes. Owing to their unique one dimensional nanostructures, the exciton is stable at room temperature and migrates through the one-dimensional structure.[1] As a new method to utilize the mobile excitons for PL enhancement, defect doping to SWNTs by local chemical functionalization is recently gathering great attention. The locally functionalized SWNTs (lf-SWNTs) show additional PL (\(E_{11}\)) with red-shifted wavelengths and enhanced quantum yields compared to original PL (\(E_{11}\)) of pristine SWNTs.[2-11] Therein, the local functionalization of the tubes creates emissive sites whose electronic structures are modified, giving narrower bandgap and exciton trapping features. Interestingly, the modifier molecules are found to be a key tool to modulate PL of lf-SWNTs. For example, we achieved largely red-shifted PL (\(E_{11}\)) generation over 100 nm-shifts than typical \(E_{11}\) PL by functionalization based on a proximal doping technique.[7] Here, we report chemical functionalization for such longer wavelength PL generation and wavelength tuning based on molecular structure design of the modifiers. Firstly, we synthesized bis-aryldiazonium modifiers (bAs) that have two reactive aryldiazonium groups connected with a methylene linker. In order to achieve wavelength tuning of \(E_{11}\) PL, the linker effects were examined by changing the connected positons on the aryl groups (para and \(m\)bAs for meta) and the length of methylene chains.[11] For local functionalization, SWNTs were solubilized in a D\(_2\)O solution containing sodium dodecyl sulfate (SDS), and then reacted with the synthesized bAs through diazonium chemistry. In PL spectra of the obtained lf-SWNTs (lf-SWNTs-pbA and lf-SWNTs-\(m\)bA), PL peaks appeared at 1245 nm and 1257 nm, respectively when the linker of five methylene units was used. Those were assigned to \(E_{11}\) PL that were observed in longer wavelength regions than \(E_{11}\) PL of mono-aryl functionalized lf-SWNTs (ca. 1140 nm). When the linker lengths of bAs were changed, it’s found that the shorter linkers induced longer wavelength PL. Namely, the methylene chain length is a factor for wavelength tuning of \(E_{11}\) PL. In addition, the lf-SWNTs-\(m\)bA showed larger spectral shifting behavior in the linker length-dependent \(E_{11}\) wavelength compared to the lf-SWNTs-pbA. Thus, the molecular design of the bis-aryldiazonium modifiers provides a wavelength modulation technique for \(E_{11}\) PL, which would develop new types of NIR PL nanomaterials applicable to bio-imaging/sensing and telecommunication devices. Details and other functionalization methods will be discussed at the meeting.

**Chemical Origin of Visible and Near-Infrared Photoluminescence from Graphite-Derived Carbon Dots**

Yoonsang Park¹ and Woosung Kwon²; ¹Pohang University of Science and Technology, Korea (the Republic of); ²Sookmyung Women’s University, Korea (the Republic of)

Carbon dots (CDs) have unique photoluminescence (PL) properties arising from their surface functional groups and carbon core. However, unclear microscopic origin of the visible and near-infrared PL from CDs hinders attempts toward energy modification and limits their practical use. Here, we investigate the chemical origin of the visible and near-infrared PL of graphite-derived CDs (gCDs) by manipulating their chemical structures via reduction and deprotonation. The relation between chemical and PL changes resulting from these modifications are thoroughly investigated. Using time-resolved spectroscopy, we establish the roles of functional groups and carbon cores in excitation of the energy states responsible for the visible and near-infrared PL. We find that oxidized sp³ carbon matrix and small sp² carbon clusters are responsible for resonantly excited and slightly tunable emission in the visible and the near-infrared, respectively.

**EN10.16.12**

**Highly Efficient AlGaN Deep Ultraviolet Light-Emitting Diodes with Localized Surface Plasmon Resonance by 40 nm Al Nanoparticles Array Using Block Copolymer Self-Assembly**

Gyeongwon Ha and Jin Kon Kim; Pohang University of Science and Technology, Korea (the Republic of)

AlGaN-based deep ultraviolet(DUV) light-emitting diodes(LED) have ability for sterilization, air/water purification, medical treatment and so on. However, most of DUV leds have low external quantum efficiency due to inherent problem such as low internal quantum efficiency and light extraction efficiency. These factors limit their practical applications. Here, We present a remarkable enhancement in AlGaN light-emitting diodes (LEDs) through the coupling of localized surface plasmon (LSP) mediated by a high density array of Al nanoparticle (NP). The array of Al NP with the optimum resonance diameter of ~ 40 nm for 285 nm DUV emission has been achieved by utilizing block copolymer self-assembly. The internal quantum efficiency is increased by 57.7% owing to the reduced radiative recombination lifetime mediated by LSP. As a consequence, the AlGaN DUV LEDs with the array of Al NP show the enhanced electroluminescence by 33.7% with comparable electrical properties to the reference devices.

**EN10.16.13**

**New Sulfide Precursor with Tunable Decomposition by Lewis Base for Controlled Shell Deposition on Quantum Dot Cores**

Joonhyuck Park and Hee-Sun Han; University of Illinois at Urbana Champaign, United States

Deposition of high quality, tailored shell is a key to achieve the optimal optical properties of quantum dots (QDs) such as high quantum yield, suppressed blinking and fluorescence stability. Commonly used sulfide precursors for shell deposition include bis(trimethylsilyl) sulfide (TMS₂S), thioureas and alkylthiols. Shell deposition is mostly achieved by slow injection of these precursors into a reaction pot containing QD cores at elevated temperature. For these precursors, the decomposition rate of precursors is only controlled by reaction temperature. As reaction temperature also governs the reactivity of the quantum dot surface, it is hard to independently tune the reactivity of precursors without affecting the instability of nanocrystals. Here, we present a new sulfide precursor whose decomposition rate depends on the structure and basicity of added Lewis base. We have studied the decomposition rate of the new precursors with various Lewis base molecules using variable temperature nuclear magnetic resonance spectroscopy and a dip probe that monitors absorption during shell growth. In this talk, I will introduce a new shell deposition method using this new precursor and Lewis base molecules that yields high quality shell.

**EN10.16.14**

**Enhanced Efficiency of InP Quantum Dot Light-Emitting Diodes by Metal Doped ZnO Electron Transport Layer**

Jaeyoul Kim¹, Byeong Guk Jeong², Wan Ki Bae² and Jeonghun Kwak¹; ¹Seoul National University, Korea
Quantum dot (QD) light-emitting diodes (QLEDs) have been gaining much attraction in the display and lighting industry due to their superb characteristics such as size-dependent bandgap tunability, narrow emission spectra, and low cost solution process. Although cadmium (Cd) QLEDs show excellent device performance, the toxicity is a serious concern for applications. Among eco-friendly QD materials, indium phosphide (InP) QDs are the most promising candidate for developing high-performance displays with a wide color gamut. However, the performance of InP QLEDs is still far behind compared to Cd QLEDs. In this work, we demonstrate that the efficiency of InP QLEDs are greatly improved by adopting metal-doped ZnO nanoparticle as an electron transport layer (ETL). By optimizing the Al doping concentration, we achieved a higher performance, in terms of the peak external quantum efficiency (EQE) of 3.62% compared to the device with an undoped ZnO nanoparticle of 1.81%. Systematic analysis on the optical and electrical properties of the metal-doped ZnO films was carried out to understand the underlying mechanism for the improved device performance. Compared to the undoped ZnO film, the Al doped ZnO film has enhanced electron mobility and reduced energy barrier for the electron injection into the InP QD emissive layer. We believe that the analysis based on the metal-doped ZnO will give further insight into improving and understanding InP QLEDs.

**EN10.16.15**

**Doping InP Quantum Dots with Cu⁺ Slows Down Hot Electron Cooling**

Paul T. Prins¹, Pieter Geiregat², Dirk A. Spruijt¹, Freddy T. Rabouw¹, Celso de Mello Donega¹ and Daniel Vannmaekelbergh¹; ¹Debye Institute for Nanomaterials Science, Netherlands; ²Physics and Chemistry of Nanostructures Group, Belgium

Nonresonant excitation of colloidal quantum dots (QDs) creates hot carriers that subsequently cool down to the band edges or are trapped in localized states. Carrier cooling and trapping typically happens on timescales from femtoseconds to picoseconds, orders of magnitude faster than the nanosecond to microsecond timescales of radiative recombination. Understanding cooling and trapping is relevant for (hot) carrier extraction in photovoltaics and to increase the luminescence output of QDs used as phosphor.

We investigate carrier cooling and trapping in InP QDs with a ZnSe₁₋ₓSₓ shell. Undoped QDs are compared to Cu⁺-doped QDs, where the Cu⁺ ion serves as a designed hole trap. Using pump probe transient absorption spectroscopy with femtosecond time resolution, we are able to monitor the population of electrons in the conduction band. Our comparative study shows that hot electron cooling is almost an order of magnitude slower in the Cu⁺-doped QDs than in the undoped QDs. We ascribe this to rapid hole trapping on the Cu⁺ ion. This confirms the model in which hot electron cooling goes via an Auger-like process, where the hot electron transfers its excess energy to the hole which subsequently relaxes by phonon coupling. In our Cu⁺-doped QDs the hole is trapped on a Cu⁺ ion on sub-picosecond timescales, so the Auger cooling pathway is unavailable to the hot electron. Instead it must cool down via another, slower, pathway, most likely by coupling to high-energy vibrations at the surface of the QDs. This must also mean that hole trapping on the Cu⁺ ion is faster than the Auger cooling timescale of the undoped QDs, which is of the order of 300 fs. Our results provide insight in the behaviour of hot electrons and holes in the short time period after excitation of both Cu⁺-doped and undoped InP QDs.

**EN10.16.16**

**Fast Electron Transfer from Colloidal PbS Nanosheets to TiO₂**

Shashini M. Premathilaka, Yiteng Tang, Tharaka M. Weeraddana and Liangfeng Sun; Bowling Green State University, United States

Colloidal PbS nanosheets are an emerging two-dimensional material for infrared applications. In contrast to the zero-dimensional quantum dot, the anisotropic structure of the nanosheet provides an additional parameter to tune its properties. In this structure, it is possible to independently tune the energy gap (through the thickness) and the other properties (through the lateral size). The other properties include the exciton oscillator strength, the exciton-exciton interaction, and the electronic coupling of the nanosheet with other materials. All of them are important in optoelectronic applications.

The strong coupling between the nanosheet and an electron-accepting material - TiO₂ - enables a fast electron transfer, favoring charge extraction for photovoltaic devices. Our time-resolved photoluminescence spectroscopy results show that it takes less than one nanosecond for the electron to transfer from PbS nanosheets to TiO₂ in a solution. It is about one thousand times faster than the electron transfer from PbS quantum dots to TiO₂ in the same
experimental condition.

**EN10.16.17**

**Synthesis and Photoluminescence Properties of Upconverting Nanomaterials Produced through Laser Ablation in Liquid**

Rosemary L. Calabro, Priya Karna, Dong-Sheng Yang and Doo Young Kim; University of Kentucky, United States

Upconverting nanomaterials are promising in several applications including bioimaging, sensing, photodynamic therapy, drug delivery, photovoltaics, and security. Specifically, NaYF₄ co-doped with Yb³⁺ as a photosensitizer and Er³⁺ as an activator is suitable for biological applications because Yb³⁺ can be excited by photons at 980 nm which have a long-penetration distance in biological tissues. Following the laser excitation of Yb³⁺, photoexcitation energy is transferred multiple times to Er³⁺ from Yb³⁺ before Er³⁺ emits both red and green photons. The overall upconversion efficiency of NaYF₄:Yb³⁺/Er³⁺ is highly affected by the phase with hexagonal (β) phase allowing for much better efficiency than cubic (α) phase. One major challenge in making upconverting nanomaterials feasible for biological applications is to synthesize highly performing β-phase upconverters with good solubility in water. Traditional methods, such as solvothermal synthesis, fall short with limitations including toxic side products, poor solubility in water, high reaction temperatures, long reaction times, and poor control of phase and morphology. Additionally, the conditions required to produce the preferred β-phase may cause damage to capping agents. This presentation will address our novel approach of laser ablation in liquid as a promising alternative for upconverting nanomaterial synthesis. The laser ablation in liquid allows a fast production, fewer chemicals, fewer byproducts, and control over the product by tuning the laser parameters. NaYF₄:Yb³⁺/Er³⁺ targets are prepared by coprecipitation, and then are pressed into a pellet and annealed to convert to β-phase. This is followed by 532 nm pulsed nanosecond laser irradiation of the pellet in either water or in aqueous solutions containing capping agents including citric acid, polyethylene glycol, ascorbic acid, or albumin. The laser irradiation induces formation of smaller particles that are stable in water. The size of the particles can be controlled by the laser fluence and the solubility can be tuned by the choice of capping agents in the liquid during laser ablation. Additionally, the samples produced through laser ablation show improved β-to-α ratios when compared to the annealed pellets. Laser ablation in liquid allows for direct capping of upconverting nanomaterials and the laser conditions can be tuned to prevent damage to the capping agent in solution. Finally, time correlated single photon counting analysis revealed that NaYF₄:Yb³⁺/Er³⁺ samples with capping agents showed longer photoluminescent lifetimes in both the green and red regions due to protection from surface quenching by the capping agent.

**EN10.16.18**

**Enhancing Phosphorescence in Metal-Free Organic Phosphors by Synergistically Combining Contributing Factors**

Ramin Ansari, Jinsang Kim and John Kieffer; University of Michigan, United States

In traditional metal containing phosphors, spin-orbit coupling (SOC) caused by a heavy atom effect of the metal, enhances the intersystem crossing between the first singlet (S₁) and triplet (T₁) states, which results in phosphorescence. Room-temperature phosphorescence (RTP) from metal-free organic phosphors is preferable for applications such as bio-imaging by eliminating toxicities of the standard metal complexes. However, the development of RTP from metal-free organic systems is challenging due to inefficient SOC for lack of heavy atoms. A common strategy to promote SOC for metal-free phosphors involves carbonyl groups that generate π* states. ISC from S₀ (ππ*) to T₁ (ππ*) is allowed according to the El Sayed rule. Furthermore, we have shown that intramolecular halogen effect can dramatically enhance RTP. Inspired by these results, we combine species exhibiting a heavy atom effect, molecular groups obeying El-Sayed rule, and intramolecular halogen bonding to synergistically enhance RTP. Our organic phosphors contain selenium, which is not toxic, bromine, and carbonyl groups. Our experimental and theoretical findings provide useful design guidelines for room-temperature organic phosphors with bio-imaging and sensing applications.

**EN10.16.19**

**Broadband White Emission in Cs₂AgIn₁₋ₓBiₓCl₆ Phosphors**

Matthew Gray and Patrick Woodward; The Ohio State University, United States

Here we report on the photoluminescent properties of the lead-free double perovskite solid solution Cs₂AgIn₁₋ₓBiₓCl₆. The In³⁺ end-member, Cs₂AgInCl₆, is a direct gap semiconductor that absorbs UV light (λ < 350 nm) and shows little to no photoluminescence. Incorporation of Bi³⁺ leads to a strong sub-band gap absorption that peaks in
the near UV (~360 nm) and extends into the visible (λ > 390 nm). This absorption, which is thought to originate from localized 6s2 → 6s1p1 transitions on Bi3+ ions, is split by a Jahn–Teller distortion of the excited state. In-rich samples (0.0 < x < 0.5) show strong photoluminescence that is attributed to radiative decay of self-trapped excitons, with a broad emission peak of significant intensity from 450 to 750 nm. The color of the emitted light is best described as white to yellow-white (CCT = 3119 K), due to the extreme breadth, FWHM ≈ 217(2) nm, of the emission peak. The excitation spectrum extends out to 450 nm for samples near x = 0.25, while the photoluminescent quantum yield (PLQY) reaches a maximum of 39 ± 3% in the x = 0.167 sample. The combination of highly efficient broadband photoluminescence that can be driven by visible photons (λ > 390 nm) emitted from a Ga1-xInxN LED is attractive for solid state lighting applications.

**EN10.16.20**

**High-Efficiency UV Light-Emitting Diodes Based on Catalyst-Free Gd-ZnO Nanotube Array Grown on p-GaN**

Norah Alwadai, Idris Ajia, Bilal Janjua, Boon Ooi and Iman S. Roqan; King Abdullah University of Science and Technology, Saudi Arabia

We report on the successful growth of a high-quality homogenous, hexagonal, well-defined, and vertical n-ZnO nanotube (NT) array on p-GaN films without catalyst or seeding, using pulsed laser deposition to fabricate high-efficiency ZnO NTs/GaN-based UV light emitting diodes (LEDs). The ZnO NTs were in-situ doped with gadolinium (Gd) (0.2 wt%) to increase the donor density and assisting in NT growth. Micro-photoluminescence (micro-PL) measurements reveal that our LEDs show an intense bandedge emission without a defect band. Our findings demonstrate for the first time a novel fabrication method for an electrically pumped Gd-doped ZnO NTs/GaN-based LED operating in the UV range, with a high internal quantum efficiency (> 65%). Scanning transmission electron microscope (STEM) reveal that Gd dopants in the PLD target create in-situ discrete Gd nanolayer (~ 1 nm). No efficiency droop effect is observed at high carrier injection rates, which can be due to the high binding energy of ZnO bound excitons and a negligible Auger recombination. PL measurements and time-resolved PL (TRPL) carrier dynamics investigations indicate that, at room temperature, the LED emission is dominated significantly by the radiative recombination process, confirming that a superior cost-effective UV LED structure can be obtained, with potential application in the large-scale device production.

**EN10.16.21**

**Dynamic Etching and Functionalization of Germanium Nanocrystals for Tunable Photoluminescence**

Shuang Cui, Robert Tenent, Gregory Pach, Nathan Neale and Lance Wheeler; National Renewable Energy Lab, United States

The narrow bulk band gap and large exciton Bohr radius of germanium (Ge) make it an attractive material as a low-toxicity replacement for II-VI and IV-VI semiconductor nanocrystals (NCs) in applications such as optoelectronics, biological imaging, and lithium-ion batteries. NC photoluminescence (PL) is dependent on precise control over the NC size and surface chemistry. NC size is experimentally varied using precursor chemistry and reaction times during Ge NCs synthesis. Here we report a post-synthetic method to simultaneously functionalize the Ge NCs surface and etch Ge NCs to a desired size. UV-Visible absorbance and PL spectroscopy showed quantum confinement effects and strong emission with no dependence on the excitation wavelength. At 7 nm, the PL emission of Ge NCs is blue-shifted from the bulk Ge value of 0.67 to 1.44 eV. Bandgap emission due to quantum confinement is shifted to higher energies of 1.68 and 1.85 eV as etching time is increased. Fine control over the size and surface passivation in one step renders ease fabrication of Ge NCs.

**EN10.16.22**

**The Effect of Molecular Conformations on The Photophysics of External Stimuli-Responsive Organic Emitters—Thermally Activated Delayed Fluorescence vs Room-Temperature Phosphorescence**

Youhei Takeda¹ and Przemyslaw Data²; ¹Osaka University, Japan; ²Silesian University of Technology, Poland

We have developed an organic emitter that displays external stimuli-responsive emission colors ranging from yellow to orange, based on the structure of twisted donor-acceptor-donor (D-A-D) triad comprising of dibenzo[a,j]phenazine as the acceptor and phenothiazine as the conformationally-flexible donors (Chemical Science, 2017, 8, 2677). The D-A-D triad also shows orange thermally activated delayed fluorescence (TADF) in CBP host matrix, and the OLED devices fabricated with the D-A-D emitter nicely shows a high external quantum yield up to ca.17%. More recently, we have revealed that the stimuli-responsive emission color-change is based on the
conformational change at the phenothiazine unit by time-resolved spectroscopy in the film (Journal of Materials Chemistry C, 2019, 7, 6616), where the thermally activated delayed fluorescence and room-temperature phosphorescence processes compete with each other. In this presentation, the effect of conformation of the molecule on emission properties will be discussed.

**EN10.16.23**
Integration of Uponconversion Nanoparticles and Core-Shell Meta-Structure—An Efficient Platform towards Efficient Uponconversion Efficiency

Yu Ting Huang, Ting-Jia Chang, Kanchan Yadav, Hung-I Lin, Monika Kataria, Chun-Che Wang, Yit-Tsong Chen and Yang-Fang Chen; National Taiwan University, Taiwan

Enhancing the quantum efficiency and tailoring the density of states (DOS) of upconversion nanoparticles (UCNPs) have been attracted tremendous attentions due to the applications range from bio-imaging to solar battery under the excitation of near-infrared light source. Plasmonic materials, such as noble nanoparticles or metal-like materials, have been widely used to achieve these goals. However, the intrinsic loss of plasmonic materials limit themselves play the dominant roles for broader applications. Previous results mainly focused on a relatively high pumping power density (MW/cm²) to excite the emission of UCNPs, which are too large for in-vivo imaging usage. Therefore, the demand of reducing pumping power density to achieve efficient quantum efficiency is urgently emerging.

Here, we provide a first integration of UCNPs and core-shell hyperbolic meta-structure, which allows us to drastically reduced the pumping power density (~0.1 kW/cm²) to achieve a giant emission from UCNPs for more than 20 times. This core-shell hyperbolic meta-structure is composed of the core material, SiO₂, with radius of 3 nm and alternative multishells, Au (5 nm)/SiO₂ (3 nm)/Au (5 nm). A continuous coupling effect in between the multishells is created, a pronounced energy is subsequently out-coupled to enhance the emission of UCNPs. As confirmed by the simulation results, the core-shell hyperbolic meta-structure increases the DOS, confines the energy with a higher ability, and transmits these energy to the decorated UCNPs rather than being annihilated. This unique characteristic makes the emission of UCNPs only require ultra-low power of excitation light with an extremely enlarged emission intensity. Our research provides an excellent alternative for the design of hyperbolic meta-structure and offers a new platform for the enhancement of upconversion efficiency, which is very useful for the realization of practical applications in many areas.

Pulsed Laser Synthesis and Superparamagnetic Properties of Metal-Free Nitrogen Doped Graphene Quantum Dots

Muhammad Shehzad Sultan¹, Vladimir I. Makarov¹, Muhammad Sajjad², Brad Weiner¹ and Gerardo Morell¹; ¹University of Puerto Rico - Rio Piedras, United States; ²Austin Peay State University, United States

In this study, we developed a novel approach to synthesize high-quality metal-free Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. Furthermore, for the first time, to our knowledge, their magnetic properties were investigated. The results indicate that N-GQDs exhibit superparamagnetic behavior. The specific size, shape and zigzag edge structure of N-GQDs were considered to explain the origin of the observed magnetism. The magnetization dependence led to estimating the N-GQD material magnetic permeability for different ambient temperatures. From the zero-field-cooled (ZFC) and field-cooled (FC) magnetization measurements, carried out at 50 Oe magnetic field strength, we estimated the blocking temperature $T_B$ to be around 300 K. Based on the experimental data analysis, the magnetic permeability, number of correlated spins per single N-GQD, and number density of superparamagnetic N-GQD per gram of material were estimated. The excellent superparamagnetic properties together with optical properties manifested by N-GQDs have the potential to lead to high performance biomedical applications.
Development of Solution-Processable Blue OLEDs Based on Thermally Activated Delayed Fluorescence (TADF) with Spiroacridine Donor

Chul Woong Joo, Nam Sung Cho, Jaehyun Moon, Seung-Youl Kang, Seong-Deok Ahn, Yun Hi Kim, Jonghee Lee and Hyunkoo Lee; ETRI, Korea (the Republic of); Gyeongsang National University, Korea (the Republic of); Hanbat National University, Korea (the Republic of)

Solution-processed Organic Light-Emitting Diodes (OLEDs) have attracted great attention as a device for application in large-size OLEDs because of simple fabrication process and easy scalability of the solution process. However, the device performances of the solution-processed OLEDs are still inferior to those of vacuum-deposited OLEDs and further improvement of the device performances of solution-processed OLEDs is required. In this work, high-efficiency solution-processed blue organic light-emitting diodes (OLEDs) were developed using two thermally activated delayed fluorescence (TADF) aromatic molecules, 10-(4-(4,6-diphenyl-1,3,5-triazin-2-yl)-2,5-dimethylphenyl)-10H-spiro[acridine-9,9'-fluorene] (TXSA) and 10-(4-(4,6-diphenyl-1,3,5-triazin-2-yl)-2-methylphenyl)-10H-spiro[acridine-9,9'-fluorene] (TTSA), composed of spiroacridine donor and triazine acceptor units. As a result, the blue OLEDs based on two novel TADF molecules exhibited remarkable electroluminescence with a high quantum efficiency of 14.9% and current efficiency of 29.3 cd/A. Our results demonstrate that TXSA and TTSA TADF molecules are prospective materials to fabricate high-performance solution-processed blue OLEDs with a simple device structure. Detailed device performances using TADF molecules will be presented in the presentation.

Current Transport Mechanism and Photodetection in Graphene Quantum Dot/GaN Schottky Contacts

Bhishma Pandit and Jaehee Cho; Chonbuk National Univ, Korea (the Republic of)

Graphene, as a typical 2-dimensional material, becomes a promising material due to its excellent electrical and thermal conductivity, flexibility, and high transparency. While the semi-metallic property of graphene limits the compatibility with the optoelectronic devices, graphene quantum dot (GQD) facilitates its implementation for various optoelectronic devices, enabling multifunctionality in sensing and emitting devices, because the quantum size effect provides the way to tune the energy bandgap of graphene. In this regard, understanding the current transport mechanism between GQD and semiconductor materials is obviously fundamental to explore.

In this study, we investigated the contacts of GQD formed on a n-type GaN semiconductor. Blue-luminescent GQDs (QD size < 15 nm) prepared by the hydrothermal method were sprayed on a GaN wafer and the electrical and optical properties of the fabricated contacts were measured. The GQD/GaN contacts showed rectifying behavior with a typical Schottky barrier height of 0.64 eV. The spectral photoresponse and temporal response of the GQD/GaN contact revealed that the responsivity shows a sharp increase for the wavelength shorter than 375 nm. Furthermore, the metal–semiconductor–metal (MSM) photodiode with interdigitated GQD contacts on n-type GaN was fabricated, which provides the lower dark current in comparison with the GQD/GaN Schottky diode. The responsivity of the MSM photodiode was remarkably improved with increasing the annealing temperature (up to 800 °C), showing good photoresponse in the ultraviolet (UV) region.

Three-Dimensional Whispering Gallery Mode Laser from AlInGaN-Based Rolled-Up Microcavity

Yufeng Li, Peng Hu, Xilin Su and Feng Yun; Shaanxi Provincial Key Laboratory of Photonics & Information Technology, Xi’an Jiaotong University, China; Solid-State Lighting Engineering Research Center, Xi’an Jiaotong University, China

Microcavities with whispering gallery modes (WGM), usually formed by two dimensional (2D) circular structures, are significant elements in integrated optics, quantum information and topological photonics. We report three-dimensional (3D) WGM from rolled-up microdisks and microtubes consisting of strain-released AlInGaN multiple quantum wells structure membranes. For the rolled-up microdisk, despite the ultrathin and deformed cavity laser, the
2D WGM shows a reasonably high quality factor (~1300) and exhibits single mode lasing in vertical direction due to the anisotropic feature of the rolled-up disk. For the microtube cavity, a highly polarized stimulated emission was achieved at a low threshold of 415 kW/cm². A high spontaneous emission factor $\beta$ of 0.46 was obtained due to large cavity confinement factor of 25.1% achieved by large refractive index contrast between the membrane and the ambient air. Our results suggest promising and practical pathways for achieving novel microcavities lasing with III-Nitride material system for on-chip application.

EN10.16.28

Intraband Mid- and Long-Wave Infrared PbS Colloidal Quantum Dots Photodetectors Enabled by Robust Heavy Doping

Onur Ozdemir1, Inigo Ramiro1, Sotirios Christodoulou1, Shuchi Gupta1, Mariona Dalmases1, Maria Pedrosa1 and Gerasimos Konstantatos1,2; 1ICFO - Institute of Photonic Sciences, Spain; 2ICREA, Spain

Photodetection in the mid and long-wave infrared (MWIR, LWIR) is of paramount importance for applications in night-vision, medical diagnosis, astronomy, environmental pollution monitoring, spectroscopy, and telecommunications. However, commercial infrared detectors are costly due to their epitaxial growth methods and complex non-monolithic integration with CMOS technology. Moreover, their performance is optimized upon cooling adding further complexity to their integration, power consumption, and miniaturization. The possibility of exploiting low-energy intraband transitions make colloidal quantum dots (CQD) an attractive low-cost alternative to expensive low bandgap materials for infrared applications. Unfortunately, fabrication of quantum dots exhibiting intraband absorption is technologically constrained by the requirement of controlled heavy doping, which has limited, so far, MWIR and LWIR CQD detectors to mercury-based materials. We have developed a robust doping strategy for PbS quantum dot solid-state films that allows harvesting of mid- and long-wave infrared radiation, well beyond the reach of PbS even in its bulk form. Our doping method leads to simultaneous interband bleach and an increase of intraband absorption. We show doping to be stable under ambient conditions for up to 2 months; therefore allowing, for the first time, to realize intraband PbS CQD photodetectors for energies below the bulk bandgap, in the 5-9 µm range. We also show that the doping is stable at low temperatures, which allows them to be used in sensitive photodetectors and other potential applications such as bolometers.

EN10.16.29

Broadband White-Light Emission from Supramolecular Piperazinium-Based Lead Halide Perovskites Linked by Hydrogen Bonds

Mi Hee Jung; Sejong University, Korea (the Republic of)

We demonstrate white-light emission using lead halide perovskites: (pip)$_2$PbBr$_6$ (pip = piperazine), (pip)$_2$Pb$_4$Cl$_{12}$, (1mpz)$_2$PbBr$_6$ (1mpz = 1-methylpiperazine), and (2,5-dmpz)$_0.5$PbBr$_3$ 2((CH$_3$)$_2$SO) (2,5-dmpz = trans 2,5-dimethylpiperazine, abbreviated as (2,5-dmpz)$_0.5$PbBr$_3$), in which the inorganic frameworks were connected by piperazinium dications through hydrogen bond, forming a three-dimensional supramolecular network. From single-crystal X-ray diffraction measurements and Raman spectroscopy, we identified the crystal structures and local environmental vibrational mode in the inorganic framework, finding that (pip)$_2$PbBr$_6$ crystallized in the centrosymmetric orthorhombic space group Pnnm, whereas (pip)$_2$Pb$_4$Cl$_{12}$ crystallized in the trigonal/rhombohedral space group R3. The zero-dimensional (1mpz)$_2$PbBr$_6$ structure crystallized in the centrosymmetric monoclinic space group P2/n, whereas the [PbBr$_6$]$^{4-}$ octahedral was separated by 1-methylpiperazine dication. The (2,5-dmpz)$_0.5$PbBr$_3$ 2((CH$_3$)$_2$SO) contained a half cation, which was completed by inversion symmetry, along with two dimethyl sulfoxide solvent molecules that crystallized in the monoclinic space group P2$_1$/c. Among the perovskites, (2,5-dmpz)$_0.5$PbBr$_3$ 2((CH$_3$)$_2$SO) exhibited the longest carrier lifetime (42 ns), the lowest band gap (2.34 eV), and the highest photoluminescence quantum yield (58.02%). This is because it is a 1D corner-sharing structure and has the localized electronic states near to the conduction band minimum, which contributes to high photoluminescence quantum yield and white-light emission.

EN10.16.30

General Synthetic Route to High-Quality Colloidal III–V Semiconductor Quantum Dots Based on Pnictogen Chlorides

Tianshuo Zhao1, Nuri Oh1,2, Davit Jishkariani1, Mingliang Zhang1, Han Wang1, Na Li3, Jennifer Lee1, Chenjie Zeng1, Manisha Muduli1, Hak-Jong Choi1, Dong Su3, Christopher B. Murray1 and Cherie R. Kagan1; 1University of Pennsylvania, United States; 2Hanyang University, Korea (the Democratic People's Republic of); 3Brookhaven National Laboratory, United States

The synthesis of colloidal III–V quantum dots (QDs), particularly of the arsenides and antimonides, has been limited...
by the lack of stable and available group V precursors. In this work, we exploit accessible InCl₃- and pnictogen 
chloride-oleylamine as precursors to synthesize III–V QDs. Through coreduction reactions of the precursors, we 
achieve size- and stoichiometry-tunable binary InAs and InSb as well as ternary alloy InAsₓSbx QDs. On the basis 
of structural, analytical, optical, and electrical characterization of the QDs and their thin-film assemblies, we study 
the effects of alloying on their particle formation and optoelectronic properties. We introduce a hydrazine-free 
hybrid ligand-exchange process to improve carrier transport in III–V QD thin films and realize InAs QD field-effect 
transistors with electron mobility > 5 cm²/(V s). We demonstrate that III–V QD thin films are promising candidate 
materials for infrared devices and show InAsₓSbx QD photoconductors with superior short-wavelength infrared 
(SWIR) photoresponse than those of the binary QD devices.

EN10.16.31
Decoding Fluorophore X—Characterization of a Novel, Non-Blinking, Single Photon Source Nicole Cogan¹, Zoran Ristanovic², Michel Orrit² and Todd Krauss¹; ¹University of Rochester, United States; ²Leiden University, Netherlands

Quantum light-matter interfaces are at the heart of quantum optics and solid-state approaches to quantum 
information science. In particular, single photon sources are highly desirable for photonic quantum sciences, such as 
quantum communication and quantum cryptography, in order to ensure physical security and protect information 
travelling over channels. Novel single photon sources are rare because they must satisfy a very strict set of criteria: 
the photons from such a source must be indistinguishable with an arbitrary high repetition rate, have near zero 
probability of multiple photon emission, and should operate at room temperature. An ideal single photon source 
should also emit photons deterministically at arbitrary times, or “on demand”.

We have discovered a potentially new single-photon source, denoted here as Fluorophore X. Single molecules of 
Fluorophore X exhibit a distinct three-peak photoluminescence (PL) spectrum centered at 610 nm, reminiscent of an 
organic dye. However, unlike a typical dye, the PL from Fluorophore X is extremely bright and robust, with a 
brightness comparable to small diameter CdSe nanocrystal quantum dots. PL from single molecules of Fluorophore 
X has a constant intensity (i.e. are nonblinking) with the ability to remain “on” for several minutes before turning 
“off”. This behavior is also quite different from traditional fluorophores, which typically photobleach quickly and/or 
exhibit fluorescence blinking. Notably, Fluorophore X exhibits photon antibunching at room temperature, with a 
g²(0) < 0.21. Interestingly, while Fluorophore X was originally observed over 20 years ago using single-molecule 
PL spectroscopy, in the intervening two decades it has been repeatedly misidentified as either an organic dye, a 
colloidal semiconductor or oxide nanoparticle, or as an “impurity” in various solvents, polymers, dyes, and 
substrates. In an important breakthrough, we have developed a simple method to synthesize and purify Fluorophore 
X in relatively large concentrations, which has enabled acquisition of the first ensemble PL, photoluminescence 
excitation (PLE), and absorption spectra of this molecule, at 300 K and at 10 K. While the PL spectrum and PL 
lifetime (few ns) are similar to a molecular dye, the unusually small Stokes shift of 10 nm (at ~ 600 nm) between 
absorption and PL spectra as well as the outstanding single molecule PL photostability suggest that Fluorophore X 
also has similarities to inorganic emitters. In fact, no small molecule is known to exhibit all these properties, making 
the structure and composition of this new and exciting single-photon source completely unknown. In that regard, in 
addition to the photophysical characterization of Fluorophore X, we will present NMR and mass spectrometry data 
that will shed important light on its molecular composition and structure.

EN10.16.32
Photoluminescence of High-Quality and Biocompatible Graphene Quantum Dots Synthesized by Hydrogen-Assisted Vacuum Pyrolysis of Silicon Carbide for Bioimaging Application Naeun Lee, Heonyong Jeong, Sang Yoon Lee, Jung Woo Kim, Hyung San Lim and Sung Oh Cho; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Graphene quantum dots (GQDs) which are composed of few layers graphene have superior characteristics such as 
large surface area, tunable photoluminescence. Using these characteristics, GQDs are used for bio-imaging, 
biosensing, and drug delivery. Various methods have been developed to synthesize GQDs, however conventional 
methods have some disadvantages such as using harmful chemicals and complicated process. Thus, a facile method 
to produce biocompatible GQDs with simple synthesis process is a major challenge. Herein, a facile route to high-
quality and luminescent GQDs based on hydrogen-assisted pyrolysis of silicon carbide (SiC) without use of harmful 
chemicals are developed. In pyrolysis of SiC, the morphologies of both graphene and SiC surface are significantly
affected by the annealing conditions, particularly the etching rate of Si and C atoms on the SiC surface. In this study, the GQDs were created on the bumpy structure of SiC by controlling the etching rate of Si and C atoms at high temperature. Annealing temperature in study was raised up to 1500°C and maintained for 30 minutes. Fabricated GQDs was detached from the substrate using ethanol and prepared GQD solutions were centrifuged to eliminate large particles detached from the substrates.

The average size of fabricated GQDs were measured to be 2.58 nm and GQDs were composed of few layers graphene. Synthesized GQDs are proven to have highly-ordered crystalline structure by HRTEM and Raman spectra. In Raman spectra, the D to G peak intensity ratio of the GQDs is 0.79 and this value means comparatively high crystallinity. Especially, sharp 2D band were observed in the Raman spectra. X-ray photoelectron spectra and Fourier transform infrared spectra support the high purity of GQDs and suggest the hydrogen termination of GQDs. Moreover, the size of the GQDs could be controlled by adjusting the annealing temperature. As the annealing temperature increases, average size of GQDs was reduced. Synthetic mechanism of GQDs are explained by removal rate of Si and C atoms. When SiC is heated at high temperature in a vacuum, the Si atoms on surface are rapidly removed. Therefore, the surface becomes bumpy and the remained C atoms rearranged to graphene. However, a small amounts of hydrogen in the furnace etch C atoms on surface, interfering with growth, resulting in nano-sized graphene domains are produced. Thus, the GQD are formed on a rough SiC surface.

UV-vis absorption spectra of the high-quality GQDs showed the 2 peaks located at 262 and 327nm. Absorption band at 262nm is originated from a π-π* transition of aromatic C=C bond and the other band at 327 nm are reported in other researches about GQDs. GQDs aqueous solution exhibited the strong PL signals and excitation-independent PL behavior. Furthermore, 3 emission peaks located at 360, 382 and 400 nm were observed in the spectra. The PL excitation (PLE) spectrum of the GQDs showed two broad peaks centered at 290 and 343 nm. The energy difference between these two PLE peaks is comparable to that between the two UV absorption peaks centered at 262 and 327 nm. It is assumed that the photoluminescence of GQDs are attributed to intrinsic emission.

High-quality GQDs exhibited an excellent biocompatibility in living cells. Cell viability test of high-quality GQDs were performed on hepatocytes. Treatments of cells with GQDs for 48 hours at various doses did not significantly affect cell viability in comparison to the control. The microscopic observation revealed that hepatocytes treated with GQDs retained normal cellular morphology. The low cytotoxicity of high-quality GQDs is attributed to the use of no any harmful chemicals in the synthetic process and high-purity. Collectively, these results strongly suggest that high-quality GQDs exhibited the clear PL spectra and excellent biocompatibility with low cytotoxicity. Therefore, high-quality GQDs synthesized by this method are more suitable in the bioimaging fields than existing.

**EN10.16.33**

**Efficient Upconversion Films for Si-Based Photodetectors**

Nidhi Dua, Sandeep Kumar and Madhusudan Singh; Indian Institute of Technology Delhi, India

Production of new materials for near-infrared (NIR) sensing and hyperspectral imaging based on Si-devices with a mature design and process technology is desirable. Efficient harvesting of unutilized infrared photons can also be used to enhance the sensitivity and efficiency of Si-based solar cells and detectors. Upconversion materials absorb multiple infrared (IR) photons and emit a single visible photon obeying energy conservation. Previous results have established the vital importance of obtaining hexagonal phase in the NaYF₄: Yb(18%), Er(2%) system. Doping with Gd(15%) results in a completely hexagonal phase with no minor cubic peaks observed in X-ray diffraction(Rigaku Miniflex benchtop X-ray diffractometer). It is important to establish minimal process conditions needed to achieve an annealed product with the highest photoluminescence efficiency. Fixing anneal time at 24 hours under ambient atmosphere, we find that after annealing at 400°C, a mixed-phase appears. Above 500°C, cubic phase dominates over the hexagonal phase, with a corresponding reduction in photoluminescence efficiency observed with 785 nm (intensity ~ 557 mW/cm²) excitation. A colorimetric change in upconverted emission from green (400°C, 539 nm), to red (500°C, 655 nm and 675 nm) is observed with a change in annealing temperature. This signifies that the mixed and cubic phase favors the red emission whereas the hexagonal phase favors the green emission. High-resolution transmission electron microscopy (HRTEM) (FEI TecnaiTF20, 200kV) scans reveal the formation of agglomerated particle clusters upon deposition from a suspension (in ethanol) at all annealing temperatures though spherical particles (~22 nm) can be observed for synthesized temperatures. Morphology of nanoparticles intrinsically changes from spherical to rod-shaped nanostructures in materials annealed at 500°C. Work is ongoing on the functionalization of these nanoparticles to reduce possible effects of concentration quenching, and to produce printable inks. These findings are expected to establish important composition and annealing process steps for the production of efficient upconversion materials and to develop a process for fabrication of low-cost near-infrared detectors.
EN10.16.34
Pressureless Sintering of $\text{M}_2\text{Si}_5\text{N}_8\text{Eu}^{2+}$ ($\text{M}=\text{Ba, Sr}$) Phosphor Ceramic Using MgO, CaO Additives Effect as Sintering Aids Jeong Woo Lee; Korea Polytechnic University, Korea (the Republic of)

$\text{M}_2\text{Si}_5\text{N}_8\text{Eu}^{2+}$ ($\text{M}=\text{Ba, Sr}$) phosphor shows excellent thermal quenching characteristic and a wide wavelength range of spectrum (580–620 nm) from yellow to amber according to Ba and Sr molar ratios, which is used for automotive amber LED light sources.

In this study, the phosphor with various Sr compositions were synthesized by heat-treatment at 1,600°C for 8 h. The fabrication of $\text{M}_2\text{Si}_5\text{N}_8\text{Eu}^{2+}$($\text{M}=\text{Ba, Sr}$) phosphor ceramic plate (PCP) was carried out by dry ball milling phosphor with MgO and CaO as sintering aid. The mixture was compressed into a pellet using uniaxially pressed with a 10 mm round pellet shaped and treated again through cold isostatic pressing (CIP) at 200 MPa for 10 min. These green bodies were pressureless sintered at 1550 – 1650 °C for 4 h under a mixed gas atmosphere of 95% N2+5% H2 to compare density and optical properties. The density of the sintered samples were measured by an Archimedes method and scanning electron microscope (SEM) image. Moreover, the microstructure of sample with EDS analysis of different grains and grain boundaries were observed using a transmission electron microscopy (TEM). The crystal structure was analyzed by an X-ray diffraction system (XRD) with CuKα radiation. When the molar concentration of Sr was 0.2 mol, the wavelength shows 600 nm optical characteristics suited to amber LED. As a result, when the ratio of MgO and CaO using the sintering preparation was 70: 30 ratio, the mixture add with 7 wt% shows the density of 4.318 g/cm3 to exhibit excellent sintering density. These sintered PCPs have excellent effect as adaptive optical characteristics for using an amber light for automotive LED applications.

EN10.16.35
InGaGaN Honeycomb Lattice Nanocolummun LEDs Gyo Imamura1, Keigo Yoshida2, Akihiro Ueno2, Keiji Takimoto1, Rie Togashi1, Ichirou Nomura1, Tomohiro Yamaguchi2, Tohrui Honda2 and Katsumi Kishino1; 1Sophia University, Japan; 2Kogakuin University, Japan

The emission efficiency InGaGaN-based visible LEDs dramatically deteriorates with increasing the wavelength from green to red, because of the lower radiative recombination rate as well as the worsening crystal quality as the InGaN content increases. On the other hand, bottom-up grown InGaGaN nanocolumns (NCs), which possess columnar nanocrystals with diameters ($D$) of typically 30-300nm, exhibit excellent nanocrystal effects such as dislocation-free, 1) lattice strain relaxation and no generation of misfit dislocations at the InGaN/GaN hetero-interfaces. The nanocrystal effects are advantageous for improving the red-emitting InGaGaN NC arrays, demonstrating a high internal quantum efficiency (IQE) of 20% at 600 nm. 2) At the same time, the enhanced photoluminescence intensity at 600 nm via surface plasmon and exciton coupling was observed improving the IQE. 3) The plasmonic effect is effectively introduced in NC LEDs, by depositing the plasmonic metals on the sidewall of the NC LEDs, close to the InGaN active layer, and do not conflicting with the current injection scheme. However, for InGaN NC triangle-lattice array, the spacing between NCs is ordinarily less than 50 nm, which makes the deposition of plasmonic metals on the sidewall difficult. In this study, we investigate novel InGaGaN NC honeycomb-lattice arrays, in which the NCs were arranged in the geometry of a honeycomb. The honeycomb-lattice arrays possess airspaces inside honeycomb structures, revealing the sidewalls of NCs. It is, therefore easy to deposit plasmonic metals on the NC sidewalls, which enables a fabrication of plasmonic NC LEDs. The period of the honeycomb-lattice array ($L'$) is defined by the distance between adjacent honeycomb structure centers. In the experiment, different InGaGaN honeycomb-lattice arrays with 150×150 μm² area were prepared on the same substrate changing $L'$ from 160 to 300 nm, employing the Ti-mask selective area growth (SAG) of RF plasma assisted molecular beam epitaxy. In the SAG, Si-doped n-type GaN were grown on Ti-mask patterned GaN template, preparing GaN NCs at the nanohole mask openings. On the GaN NCs, InGaN active layers were prepared, followed by the growth of Mg-doped p type GaN/AlGaN superlattice (SL) cladding layers. Finally, p-GaN contact layers were grown on the top of NCs. The height of NCs was approximately 800 nm. Beautifully arranged NC honeycomb-lattice arrays were obtained for $L'$ from 160 to 300 nm. The nanocolumn diameter increased with increasing $L'$, the corresponding $D$ were from 123 to 255 nm. Note that the InGaN honeycomb-lattice arrays without p-GaN/AlGaN SL cladding were evaluated by photoluminescence (PL) measurement, observing the PL peak wavelengths of 643 (red) and 577 nm (yellow) for $L'$ of 300 and 230 nm, respectively. Using the pn-junction NC honeycomb arrays (different sample), we made the process to form p and n type electrodes fabricating the InGaN
honeycomb-lattice NC LEDs. To suppress the leakage current, SOG was embedded at the spacing between NCs and the tops of NCs were exposed by a chemical etching. A thin Ni/Al contact layer was deposited on them, followed by the deposition thick ITO transparent electrode of 300 nm thickness. Finally, Ti/Al/Pt/Au metal electrodes of 30 nm diameter were prepared at the center of the 150×150 μm² NC top surface. The emission characteristics were evaluated under the direct current injection. When the injection current was 25 mA, a honeycomb-lattice NC LED with L'=300 nm exhibited the emission spectrum with the peak wavelength of 600 nm (orange emission). This is the first demonstration of InGaN-based honeycomb-lattice NC LEDs suitable for the plasmonic LED structure.

Stability and Doping of Lead-Free Double Perovskite Nanocrystals Yehonadav Bekenstein; Technion–Israel Institute of Technology, Israel

Replacing lead in halide perovskites is of great interest due to concerns about stability and toxicity. Recently, lead free double perovskites in which the unit cell is doubled, and two divalent lead cations are substituted by a combination of mono- and trivalent cations have been synthesized as bulk single crystals and as thin films. Here, we study stability and optical properties of all-inorganic cesium silver (I) bismuth (III) and silver (I) Indium (III) halide nanocrystals with the double perovskite crystal structure. The cube shaped nanocrystals are monodisperse in size with typical side lengths of 8 to 15 nm. The absorption spectrum of the nanocrystals presents a sharp peak, which we assign to a direct bismuth s-p transition and not to a quantum confined excitonic transition. In the case of indium nanocrystals Na+ doping increases the emission which is generally very brad and weak. Using spectroscopy combined with high resolution transmission electron microscopy (TEM) based elemental analysis, we conduct stoichiometric studies at the single nanocrystal level as well as decomposition assays in solution and observe that Ag⁺ diffusion and coalescence is one of the pathways by which this material degrades. Drying the nanocrystals leads to self-assembly into ordered nanocrystal solids, and these exhibit less degradation than nanocrystals in solution. Our results demonstrate that Cs₂AgBiX₆ (X = Cl, Br) nanocrystals are a useful model system to study structure-function relationships in the search for stable non-toxic halide perovskites.

EN10.16.37
Metal–Organic Frameworks as Environment-Friendly White Light Emitters Muhammad Usman, Maximillian Chibuike and Tatiana Timofeeva; New Mexico Highlands University, United States

Replacing the traditional lighting source with white light-emitting diodes (WLEDs) could take a significant bite out of global energy consumption. According to US department of energy, 29% reduction in energy consumption will be achieved by 2025 by replacing current lighting sources with LEDs. In order to resolve the energy crisis and to address the environmental concerns, designing WLED is highly desirable but isn't completely benign or budget friendly. To help reduce the environmental footprint and cost of these lights, we have designed a continuous broadband WLED based on metal-organic framework (MOF). Advantage of MOF-based LED is that alkaline earth metal is used in designing the luminescent material which is more environmental-friendly as compared with commonly used lanthanides. Its continuous emission spectrum resembles the spectrum of ordinary sun light and hence, emits a white light similar to natural light. In addition, the continuous broadband white light originates from a single component; hence the cost of production is much lower than the current technologies. The recent developments to use MOFs as white light emitter will be presented. Our design of this natural light emitter device with advantageous features will open new perspectives for developing environmentally friendly, human-friendly, and energy-saving solid-state lighting materials.

EN10.16.38
Methylammonium Lead Halide Nanocrystals for Efficient and Color Pure Red-LEDs Yasser H. Hassan¹, Jong Hyun Park², Aditya Sadhanala¹, Bo Ram Lee², Richard H. Friend³ and Henry J. Snaith¹; ¹University of Oxford, Canada; ²Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); ³University of Cambridge, United Kingdom

Recent advances in the synthesis of methylammonium lead halide perovskite nanocrystals (NCs) bringing them to
the forefront of promising candidates for light-emitting diodes, due to their potential for bandgap tunability through chemical composition, and high luminescence efficiency in the red emission window region. Nevertheless, achieving an effective red electroluminescence emission with bandgap stability is still an ongoing challenge for perovskites. Specifically, mixed halide (doping lead iodide perovskite with bromide ion) is a traditional approach to tune the bandgap to the effective red region; however, photoinduced ion segregation leads to bandgap instabilities. Here, we report highly efficient mixed halide perovskite NCs-based light-emitting devices (PeNCs-LEDs) with high color purity in the red emission window. We study the mechanism behind the instability in these NCs by using X-ray diffraction, in-situ photoluminescence, photothermal deflection spectroscopy, and femtosecond transient absorption measurements. Furthermore, we also present ways to stabilize the emission to obtain highly efficient perovskite NCs-based light-emitting devices. Our work represents a significant advance in augmenting mixed halide perovskites’ both bandgap instabilities and parasitic non-radiative losses in perovskites and thus alleviate the limits in red-perovskite-based light-emitting diodes.

Epitaxial Germanium-Tin Nanowires for Nanoscale mid-IR Emitters Michael Seifner¹, Alain Dijkstra², Jos Haverkort² and Sven Barth³,¹; ¹Vienna University of Technology, Austria; ²Eindhoven University of Technology, Netherlands; ³Goethe University Frankfurt, Germany

Germanium can be converted into a purely group IV-based direct bandgap material by alloying with >~9 at% Sn requiring to overcome the solubility limit of < 1 at%. Conventional approaches will not lead to the desired metastable compound and alternative synthesis strategies using kinetically controlled, low temperature growth conditions have to be established. To date, notable photoluminescence in Ge₁₋ₓSnₓ nanostructures is only observed in exceptional cases, mostly limited to the low temperature regime (~100 K) or in an energy range close to elemental Ge nanostructures and not in the IR-regime expected by the nominal composition. This contribution will demonstrate that metallic Sn can be used as both nucleation seed and source for the formation of single crystalline Ge₀.₈₁Sn₀.₁₉ nanowires via a CVD approach. These nanostructures are epitaxially grown on Ge (111) substrates in high yield. Moreover, a clear difference in composition and morphological structure evolution of micro- to nanoscale objects can be observed. STEM-EDX elemental mapping is used to determine the Sn content, while TEM confirms the single crystalline nature of the obtained products. The temperature and laser power dependent photoluminescence analyses verify the formation of a direct band gap material with emission in the mid-infrared region. The emission signal matches the expected energy for unstrained Ge₀.₈₁Sn₀.₁₉ material (e.g. band gap of 0.3 eV at room temperature) and illustrates excellent crystal quality of the nanowires samples. This is the first demonstration of room temperature photoluminescence in Ge₁₋ₓSnₓ nanowires and the optical properties are comparable to the best examples described for thin film samples of this metastable alloy. These materials with band gaps in the mid-IR hold promise in applications such as thermal imaging as well as photodetection and could be used as building blocks for group IV-based mid- to near-IR photonics.

Brighter Colloidal PbS Nanosheets as an Infrared Emitter Yiteng Tang, Shashini M. Premathilaka, Tharaka M. Weeraddana, Liangfeng Sun and Antara Antu; Bowling Green State University, United States

As the counterpart of colloidal two-dimensional visible-light emitters, colloidal lead-sulfide nanosheets are the
emerging efficient infrared light emitters with a tunable wavelength covering the whole fiber-optical communication band. Due to the lack of active surfaces such as \{111\} facets, the PbS nanosheets exhibit more efficient and stable optical properties than PbS quantum dots. Our experimental results show that colloidal PbS nanosheets dispersed in an organic solvent can achieve over 60% photoluminescence quantum yield at the wavelength around 1200 nm, exceeding the well-passivated colloidal PbS quantum dots emitting at the same wavelength.

In contrast to PbS quantum dots, the loss of the photoluminescence efficiency is greatly reduced when the PbS nanosheets are transferred from a solution phase to a solid film. The photoluminescence quantum yield of the PbS-nanosheet film reduces to 1/3 of the original nanosheets in solution, instead of around 1/10 as in the case of quantum dots. Thus a photoluminescence quantum yield \( \sim 20\% \) can still be achieved in a film of PbS-nanosheets. After coupling the PbS nanosheet film with a commercial green LED, we have fabricated an infrared LED with a down-conversion efficiency of about 13%.

The photophysics study of this infrared emitter demonstrates its excellent properties. A very narrow photoluminescence emission linewidth (~ 66 meV) has been achieved in the nanosheets even at room temperature. Meanwhile, we observed a sharp optical absorption peak near the band edge. This is the first demonstration of the exciton peak from colloidal PbS nanosheets, proving the existence of excitons in this extended two-dimensional material with a large dielectric constant.

(110)-Oriented 2D Halide (X = I, Br, Cl) Perovskites Templated by Small Cyclic Diammonium Cation with White-Light Emission Xiaotong Li\(^1\), Peijun Guo\(^2\), Mikael Kepenekian\(^3\), Ido Hader\(^1\), Claudine Katan\(^3\), Jacky Even\(^4\), Konstantinos Stoumpos\(^5\), Richard Schaller\(^2\) and Mercouri G. Kanatzidis\(^1\); \(^1\)Northwestern University, United States; \(^2\)Argonne National Laboratory, United States; \(^3\)Institut des Sciences Chimiques de Rennes, France; \(^4\)FOTON, France; \(^5\)University of Crete, Greece

Two-dimensional (2D) halide perovskites are emerging light-emitting materials because of their high tunability and outstanding physical properties. Besides the narrow-band emission that provide high color-purity, broad-band white-light emission that originates from self-trapped excitons (STE) in the highly distorted structures is also an intriguing field. The (110)-oriented 2D perovskites are generally distorted and believed to be good candidates for white-light emitting. Here, we report that 3-aminopyrrolidinium (3APr) is a cation which permits the formation of (110)-oriented 2D perovskites for all three halides, in the form of (3APr)\( \text{PbX}_4 \) (X = I, Br, Cl). Structural characterization by single-crystal X-ray diffraction reveals that the distortion of the inorganic part is influenced by the stereocchemical conformation of the cation between the perovskite layers. The high level of distortion results in the emergence of white-light emission, rarely seen in iodide perovskites, as well as the bromide and chloride isostructural analogues, which provides perfect platform to compare the broad emission mechanism for all three halides. The bromide and chloride perovskites show longer lifetimes and higher color rendering index (CRI) (83 and 85), relevant to solid-state lighting. The mechanism as studied by temperature-dependent PL suggests that a different STE mechanism is responsible for the observed broad-band emission for each halide. The detrapping energy is the highest for the chloride compound where the broad-band emission dominates even at low temperature. Comparative studies of white-light emission for all three isostructural halide perovskites as a set may advance the understanding of the mechanism for white-light emission in 2D perovskites.

Hybrid-Typed Perovskite Quantum Dots White LEDs for Wide Color Gamut Display Chieh-Yu Kang, Chih-Hao Lin, Chun-Lin Tsai, Chin-Wei Sher, Po-Tsung Lee and Hao-Chung Kuo; National Chiao Tung University, Taiwan

The main advantage of QDs-based WLEDs (quantum dots-based white light emitting diodes) over conventional WLED is high color purity with low cost production. Although there are several ways like QLEDs, QD film in LCD to apply QDs for next generation display, QDs-based WLEDs still have several superior potentials. Compared to QLEDs, they have higher efficiency and better reliability. This design requires fewer quantities of QDs to reach target color point which attributes to reduce cost hugely. Despite of great interest in QDs-based WLEDs, the major two issues that limits the practical applications are their instability and anion-exchange reaction when different QDs mixing together. It is important to develop a suitable packaging type to overcome the anion-exchange reaction in order to get long term stability.

Therefore, we proposed a hybrid-typed structure with blue LED pumping liquid green 518 nm PQD and red 630 nm PQD film. The liquid green PQD is on the top of red PQD film. Compared to the structure using green and red PQD
film (41 lm/W), this hybrid structure owned higher efficiency (51 lm/W) for PQD LEDs. It also showed outstanding color gamut that can be reached to 122 % of NTSC standard and 91 % of Rec. 2020 at a correlated color temperature (CCT) of 5516 K. The thermal resistance of hybrid-typed structure is better than the solid type structure. The device temperature vs current was measured. It shows that for hybrid-typed PQD WLED, the operating temperature will not increase too much with current increasing. The temperature gap between hybrid-typed and solid-typed PQD WLEDs is very big, which is about 15 Celsius degree. This characteristic resulted to better reliability performance at 200 hrs (12% decay).

However, the luminous efficiency and reliability performance is still not good enough to catch up conventional WLEDs' spec. We found that the drop of light intensity comes from the red QD. Thus, to improve this situation, we replaced the red QD to K$_2$SiF$_6$:Mn$^{4+}$ (KSF) for hybrid-typed structure in order to get higher efficiency and reliability without the decrease of color gamut. The light performances of hybrid type using liquid green PQD and 630 nm KSF mixed with silicone was measured. The luminous efficiency can reach to 85lm/W at 10 mA driving and wide color gamut can still be kept (122 % of NTSC and 91 % of Rec. 2020). The reliability results of this hybrid-typed PQD WLEDs have been tested. The light intensity only decays by 6 % at 1000 hours. In this study, we demonstrate that the hybrid-typed PQD WLED has the higher luminous efficiency (85 lm/W) compared to the solid-typed structure and good wide color gamut performance (123 % of NTSC and 92 % of Rec. 2020) and better reliability result show that hybrid-typed structure is one of the choice for next generation display.

Quantum Dot Based Flexible Full Color Micro-LED Display Lu Hing Hu, Jae Yong Choi, Sumin Hwangbo and Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Gallium Nitride (GaN) based blue light emitting diode (LED) is definitely an emerging technology which already grabbed attention from various fields, including indoor and outdoor lighting systems, displays, and medical devices because of its excellent quality of light illumination. GaN LEDs in micrometer scale can be driven at higher current densities and give promising energy efficiency in light emission. [1] The outstanding performance of micro-LEDs have attracted many researches that study the potential applications of micro-LEDs. [2, 3]

In this report, we have studied method to realize full color RGB micro-LED display by patterning quantum dots (QD) on GaN micro-LED, which will convert blue light into either red or green light. We developed QD-PR that can be photolithographically patterned in micro scale using conventional method. By mixing high refractive index nanoparticles, TiO$_2$ as scattering enhancers into the QD-PR, the light output intensity can be improved and standard RGB can be achieved. In addition, in order to realize flexible micro-LED display, micro-LED array is released from Si substrate by wet etching process and then transferred onto ultrathin plastic substrate. Finally, flexible RGB micro-LED display was demonstrated.

How Magic-Sized Clusters Grow—Insights from Experiments
Aniket Sandip Mule, Sergio Mazzotti, Aurelio Rossinelli, Simon F. Solari, Marianne Aellen and David J. Norris; Optical Materials Engineering Laboratory, Department of Mechanical and Process Engineering, ETH Zurich, Switzerland

Magic-sized clusters (MSCs) are semiconductor nanocrystals that have well-defined structural and optoelectronic properties. These clusters are believed to grow in discrete steps from one “magic” size to the next. However, even after decades of study, the nanocrystal community does not have a detailed understanding of why “magic” sizes exist and how they grow. This is due in part to the challenges in their experimental investigation, e.g. due to their small size they can be difficult to isolate and image via electron microscopy. Here, we work to overcome these issues by developing a synthetic protocol that yields MSCs up to larger length scales. These particles can be isolated and purified easily using size-selective precipitation. We then analyse a series of these MSCs using a combination of optical (absorption, photoluminescence, and photoluminescence excitation) and structural characterisation (XRD, NMR, and TEM). The comparison of these results with previous reports suggests that the particles exhibit tetrahedral shapes. Based on our observations, we propose an atomistic model that explains the growth of MSCs and rationalizes the existence of their precise structures. This work improves our understanding of nanocrystal growth and could help expand the library of available MSCs.

How Magic-Sized Clusters Grow—A Microscopic Theory
Sergio Mazzotti, Aniket Sandip Mule and David J. Norris; ETH Zurich, Switzerland

Magic-sized clusters (MSCs) are small semiconductor nanocrystals with well-defined structures and characteristic optoelectronic properties. Only a few “magic” sizes with superior thermodynamic stability are believed to exist. They have been shown to grow sequentially, meaning that one “magic” size transitions directly to the next. However, the origin of their stability and the mechanism that determines their growth remain puzzling. Our experiments, in line with previous reports, suggest that MSCs are tetrahedral in shape. Based on these findings, we present a microscopic model that rationalizes their stability and growth. By combining classical nucleation theory and the tetrahedral shape of MSCs, our model explains why MSCs correspond to local minima in a free-energy landscape and why they grow sequentially. Our model can help find other crystalline materials exhibiting the same “magic” growth behavior.

Halide Perovskites—Is it All about the Interfaces?
Philip Schulz; CNRS IPVF, France

The established paradigm, that functionality and performance of a semiconductor device is critically linked to the design of the interfaces in the device, has been a major working hypothesis to access the full potential of halide perovskite (HaP)-based optoelectronics, including photovoltaics and light-emitting diodes. As an example, the rapid improvements in the performance and stability of HaP solar cells mainly originates from careful interfacial design principles and a dedicated interface layout [1]. Despite these successes, many basic physical and chemical properties of HaP thin film and crystal surfaces and at the interface to adjacent layers, e.g. carrier injection layers in the case of perovskite emitters, have been difficult to access. These challenges arise as many key parameters, such as the energy level alignment between transport layer and emitter, are convoluted with the interface chemistry of the multi-component HaP semiconductor.

In my talk, I will present how we employ surface sensitive methods, with a focus on photoelectron (PES) and X-ray spectroscopies, to measure electronic properties, energetics and chemistry at the interface between perovskite films and transport or buffer layers. In particularly PES is used to determine the energy level alignment at the interface. Yet, we face severe challenges to generalize the trends from these observations as the complex chemistry between HaP layer and adjacent semiconductor often lies at the root of the observed interfacial alignment processes and band bending [2]. Furthermore, I will give examples for typical pitfalls that occur, when characterizing HaP surfaces and interfaces with PES methods. Most importantly, beam damages effects have been identified as the perovskite layers can exhibit distinct signs of degradation under vacuum conditions and concomitant irradiation with high-energy photons. However, while we generally intend to avoid these transient effects in our measurements, we can extract additional physical and chemical parameters from the evolution of energy level positions and stoichiometry during
the PES measurements with direct implications on the material stability and degradation pathways [3]. In the second half of my talk, I will discuss the use of these methods to access the effects of surface treatment and interfacial design routes for HaP quantum dot thin films. We demonstrated that treating the surface of CsPbI3 based quantum films with a formamidinium iodide solution led to improved device characteristics of perovskite quantum dot solar cells [4]. By using PES and X-ray absorption spectroscopy techniques, we were able to identify that the surface treatment can be employed for a targeted ligand exchange, opening up a broad application space of these treatments for perovskite quantum dot based light emitting devices [5].

1:45 PM EN10.19.02
Top-Emitting Quantum Dot Light-Emitting Diodes Based on InP Quantum Dots Taesoo Lee, Donghyo Hahm, Kyunghwan Kim and Jeonghun Kwak; Seoul National University, Korea (the Republic of) Cd-free quantum dot (QD) light-emitting diodes (QLEDs) such as InP QLEDs are now being actively researched for the substitute of environmentally toxic Cd-based QLEDs. We can classify the InP QLEDs based on the direction of emission, which are the bottom emission QLEDs (BQLEDs) emitting light through the substrate electrode and the top emission QLEDs (TQLEDs) emitting light through the top transparent electrode. The TQLEDs have several advantages for their use in display devices, such as high aperture ratios and efficient light extraction. In this work, we fabricated InP-based BQLEDs and TQLEDs and compared their optical and electrical characteristics. The TQLEDs showed better optical properties than BQLEDs because the outcoupling through the thin, top transparent silver anode in the TQLEDs was much higher than that through the indium tin oxide (ITO) in the BQLEDs. As a result, the maximum luminance of the TQLEDs was 29300 cd/m², which is 4 times higher than that of the BQLEDs (7400 cd/m²). The full width at half maximum of the electroluminescence (EL) spectrum was also narrowed down from 41 nm of the BQLEDs to 37 nm of the TQLEDs owing to the microcavity effect. The maximum current efficiency of the TQLEDs (9.7 cd/A) was increased by 1.4-fold compared to that of the BQLEDs (6.9 cd/A). Detailed performance and analysis on the TQLEDs and BQLEDs based on InP QDs will be presented.

2:00 PM EN10.19.03
Controlling Intermediates in the Two-Step Growth of PbS Nanocrystals Philippe B. Green, Philip Sohn, Christian J. Imperiale and Mark W. Wilson; University of Toronto, Canada
Advancing the synthesis of PbS nanocrystals for infrared optoelectronic applications requires improved mechanistic understanding of the growth process. Here we demonstrate that the nucleation of PbS nanocrystals is preceded by the formation of a distinct cluster intermediate. This intermediate is characterized by a reproducible red emission spectrum (λpeak: 740 nm) that exhibits a large Stokes shift (hv>300meV). Having revealed a two-step growth mechanism, we explore the manipulation of the cluster reaction lifetime to control nanocrystal growth kinetics. We demonstrate that the addition of diglyme (diethylene glycol dimethyl ether) gives straightforward control of PbS nanocrystal size. This occurs because diglyme accelerates cluster agglomeration, which reduces the number of nascent nanocrystals and results in a larger average size at completion. Further, the shortened cluster reaction lifetime minimizes the duration of the nucleation period, permitting the synthesis of nanocrystals with ensemble
linewidths comparable to leading literature reports at lower reaction temperatures. In sum, we report that the nucleation and growth of PbS nanocrystals proceeds via a two-step mechanism involving a cluster intermediate, and open the door to the use of process additives to tune reaction kinetics and tailor the synthesis of this critical infrared-active nanostructured material.

2:15 PM *EN10.19.04
Towards Ultra-Stable Indium Phosphide Quantum Dots David Wegner, Anass Benayad, Delphine Boutry, Marie Carriere and Peter Reiss; CEA, France

Colloidal semiconductor nanocrystals (quantum dots) possess unique optical properties, which make them attractive emitters for diverse applications in optoelectronic devices and biomedical imaging. During their life cycle, aging of quantum dots can lead to their dissolution and induce high toxicity due to the release of toxic chemical compounds. In this context, InP-based QDs have been proposed as less hazardous alternative to widely studied CdSe-based QDs. To enhance the photoluminescence quantum yield (PLQY) and (photo-)stability, InP QDs are generally capped with a Zn(Se,S) gradient shell. ZnSe acts as a “lattice adapter” due to its lower lattice mismatch with the InP core, while the external ZnS layer(s) are chemically more inert than ZnSe. We demonstrate that this type of shell alone does not provide sufficient stability, neither under controlled ageing conditions in a climatic chamber nor in biological environment. As shown by EXAFS, ageing led to dissociation of In-P and Zn-S/Zn-Se bonds, and to complexation of In and Zn ions with carboxylate and/or phosphate moieties. Moreover, these degradation products exhibited, in contrast to the pristine QDs, significant cytotoxic effects.

To improve the stability, further growth of additional shells on top of the gradient shell was performed, namely an intermediate ZnS shell and an outer alumina shell. In the case of this core / triple shell system continuous irradiation did not induce any chemical modifications detectable by means of XPS. To the contrary, in the case of the core / single shell system with the gradient shell degradation of the ZnS outer layer and oxidation of the In(Zn)P core occurred. These effects were also at the origin of a marked decrease of the PL intensity and a hypsochromic shift of the PL maximum. In summary, the overgrowth of InP-based core/shell QDs with an inert alumina shell leads to strongly enhanced chemical stability without impacting the PLQY. The formation of toxic degradation products under ageing conditions can thus be avoided.

2:45 PM EN10.19.05
Two-Colour Fluorescence Intermittency Spectroscopy—Shedding Light on Blinking in Nanocrystals Minhal Hasham and Mark W. Wilson; University of Toronto, Canada

Colloidal quantum dots (QDs) exhibit narrow emission across the visible and NIR spectrum, and reproducible wet-chemical syntheses produce QDs with size-tunable electronic properties. While already employed in LEDs, solar cells, and biomedical imaging, QDs suffer from photoluminescence intermittency (blinking)\(^1\), which is associated with irreversible photochemical damage\(^2\). The spectroscopic manifestation of blinking is clear—even under continuous above-bandgap excitation, emission from QDs will randomly switch between ON and OFF states, with both states lacking well-defined average lifetimes due to probability distributions that are power-law distributed over many orders of magnitude. However, it has remained challenging for spectroscopic evidence to distinguish between the variety of proposed mechanisms. Here, motivated by previous demonstrations of emission recovery from QD ensembles in the dark\(^3\), we employ a two-colour experiment to modulate the lifetime of the OFF states of QDs. By optically interacting with the OFF state, its lifetime was expected to be truncated at shorter timescales than the minutes/hours observed for thermal recovery at room temperature. However, we did not observe the expected light-driven recovery, even due to local heating. Thus, we consider that the optical cross-section of the dominant OFF state must be small compared to a control experiment using the excited-state absorption of Mn-doped ZnSe QDs\(^4\).

This result is surprising in light of previous thermal recovery kinetics, as the weak oscillator strength is consistent with an OFF state that is different than typical band-edge carriers. By shedding light on the spatial and energetic nature of the state(s) involved in blinking, we will guide modifications to synthetic procedures which produce non-blinking quantum dots, resulting in enhanced long-term photostability.

3:30 PM EN10.20.01
Recrystallized All-Inorganic Lead Halide Perovskite Thin-Films Show Low-Threshold Stimulated Emission and Lasing at Room Temperature
Neda Pourdavoud¹, Tobias Haeger¹, Andre Mayer¹, Manuel Runkel¹, Piotr Cegielski², Ivan Shutko¹, Anna Lena Giesecke², Ouacef Charfi³, Ralf Heiderhoff³, Stefan Zaefferer³, Max Lemme², David Becker-Koch⁵, Yana Vaynzof², Hella-Christin Scheer¹, Wolfgang Kowalsky³, Patrick Görrn¹ and Thomas Riedl¹; ¹Wuppertal University, Germany; ²AMO GmbH, Germany; ³Technical University of Braunschweig, Germany; ⁴Max Planck Institut für Eisenforschung, Germany; ⁵Heidelberg University, Germany

Aside from their remarkable success in photovoltaics, metal-halide perovskites are also highly promising as light emitters. For lasers, perovskites currently seed a new promise for the realization of electrically operated laser diodes that can be prepared from solution at low temperatures on virtually any substrate. The marriage of perovskite active materials with silicon (nitride) photonics holds promise to unlock substantial progress in the field of integrated optoelectronics.

As MA-based organic-inorganic halide perovskites lack intrinsic stability, all-inorganic perovskites, such as cesium lead halides, are particularly promising.

However, most attempts to use thin-films of CsPbX₃ for light emission only led to disappointing results with very low photoluminescence quantum yields (PL-QY) and amplified spontaneous emission (ASE) in CsPbX₃ thin-films has only been achieved at cryogenic temperatures. The poor performance at higher temperatures has been attributed to non-radiative recombination associated with a high number of defects. Unlike the case of thin films, CsPbX₃ nanoparticles (size < 10 nm) or nano-rods showed a high PL-QY and exhibited ASE at room temperature. These results nurtured the paradigm that for efficient light emission from lead halide perovskites at room temperature, one needs to confine the charge carriers/excitons on the nanometer scale to prevent their migration to non-radiative defects.

Here, we present results that challenge this paradigm. We demonstrate thin films of cesium lead bromide, which show a high photoluminescence quantum yield of 68% and ASE at room temperature with low threshold. The continuous films (~ 100% coverage of the substrate) are composed of large crystals with micrometer lateral extension. Our layers result from originally rough as-deposited layers, that were recrystallized by thermal imprint.[1,2] Using these layers, we demonstrate the first cesium-lead bromide thin-film distributed feedback (DFB) and vertical cavity surface emitting lasers (VCSELs) with ultra-low threshold at room-temperature. These results nurture the paradigm that for efficient light emission from lead halide perovskites at room temperature, one needs to confine the charge carriers/excitons on the nanometer scale to prevent their migration to non-radiative defects.

Environmentally Stable Room Temperature Continuous Wave Lasing in Two-Dimensional Photonic Crystal Polycarbonate Perovskite Composite
Jiyoung Moon¹, Masoud Alahbakhshi¹, Abouzar Gharajeh¹, Ross E. Haroldson¹, Sunah Kwon², Zhitong Li¹, Roberta Hawkins¹, Moon J. Kim¹, Walter Hu¹, Anvar Zakhidov¹,² and Qing Gu¹; ¹University of Texas at Dallas, United States; ²ITMO University, Russian Federation
Organic-inorganic perovskites have emerged as a promising laser gain medium due to its high quantum efficiency, balanced ambipolar charge transfer characteristics, strong light absorption, and long carrier lifetime. Various types of perovskite laser have been reported since the first demonstration of amplified spontaneous emission (ASE) from perovskite in 2014 [1]. Synthesis of nanowire or microdisk cavity, or spin-coating of perovskite thin film on pre-patterned structure have been the common method of making perovskite lasers. These devices are mostly tested under pulsed pumping and/or at cryogenic temperature due to their high lasing thresholds. Because of device self-heating at high pump power, their operation under continuous wave (CW) pumping at room temperature is hindered. One way to achieve CW room temperature operation is to reduce lasing threshold by directly patterning the perovskite into a high Q cavity with large mode confinement. However, perovskite’s sensitivity in polar solvents, high temperature and high-electron energy makes direct patterning using conventional lithography challenging. Previously, we showed that direct patterning of perovskite is possible with nanoimprint lithography (NIL), and demonstrated CW lasing with 13W/cm² threshold from a MAPbI₃ distributed feedback cavity at room temperature [2]. However, lasing only sustained for ~250s when operated around lasing threshold.

To achieve stable lasing behavior, in addition to designing for even higher Q cavities to further reduce operational power, we introduce multiplex strategies that include morphological, structural, and interfacial engineering of perovskite thin film. With these considerations, we demonstrate for the first time, over 90 minute-long green CW lasing with 9.4W/cm² threshold from polycarbonate MAPbBr₃ composite in a two-dimensional photonic crystal (2D PhC) cavity without any substrate cooling. This demonstration highlights (i) synergistic effect of high crystallinity of material, high Q cavity, and defect passivation (ii) facile, high output, and controllable fabrication method which can be applied to other types of perovskite and is closely aligned with what industry seeks for mass production (iii) ultra-low lasing threshold and long lasing stability at CW room temperature, making electrically pumped perovskite laser diode look promising.

Efficient Light Emitter by Scalable InGaN Nanowire Photonic Crystal Roksana Rashid¹ and Zetian Mi¹,²;
¹McGill University, Canada; ²University of Michigan–Ann Arbor, United States

To the urge for efficient semiconductor light emitters operating in the green gap, we’ve demonstrated InGaN nanowire photonic crystals, including dot-in-nanowires, nanotriangles, and nanorectangles with precisely controlled size, spacing, and morphology, and further establishes that bottom-up InGaN photonic crystals can exhibit highly efficient and stable emission. The formation of stable and scalable band edge modes in defect-free InGaN nanowire photonic crystals is directly measured by cathodoluminescence studies. The luminescence emission, in terms of both the peak position (λ ≈ 505 nm) and spectral linewidths (full-width-half-maximum ≈ 12 nm), remains virtually invariant in the temperature range of 5–300 K and under excitation densities of 29 W cm⁻² to 17.5 kW cm⁻². To the best of our knowledge, this is the first demonstration of the absence of Varshni and quantum-confined Stark effects in wurtzite InGaN light emitters—factors that contribute significantly to the efficiency droop and device instability under high-power operation. Such distinct emission properties of InGaN photonic crystals stem directly from the strong Purcell effect, due to efficient coupling of the spontaneous emission to the highly stable and scalable band-edge modes of InGaN photonic crystals, and are ideally suited for uncooled, high-efficiency light-emitting-diode operation.

Design of Novel Deep Ultra-Violet AC-Driven Electroluminescence Devices Based on Boron Nitride Nano-Materials Weiqiang Yuan, Thushan Wickramasinghe and Wojciech M. Jadwisienczak; Ohio University, United States
In this paper we study the prospect of using the hexagonal BN (h-BN) quantum dots and 2D nanosheets for generating deep ultraviolet (UV-C) emission by impact excitation and impact ionization. Our objective was to design and model alternating current driven thin electroluminescence devices (ACTEL) and alternating current driven powder electroluminescence devices (ACPEL) based on h-BN having different nano-morphologies. The recent efforts in developing dc-driven III-nitrides-based deep UV-photonic devices focused on band gap engineering of epitaxially grown heterostructures. Alternatively, one can consider developing UV-C light sources operating on principles of hot electrons impact excitation processes in h-BN material. We have shown by considering the lucky drift model and the Born Approximation (impact excitation cross section) for high field electronic transport in a single h-BN layer, when considering both ballistic and drift modes, that the electroluminescence (EL) efficiency of the ACTEL device is 0.04% when biased at 110 V. The low EL efficiency is primarily due to the long distance (~5 µm) secondary electrons need to pass between subsequent collisions in the h-BN matrix to gain sufficient energy required for electron-hole pair generation. This decreases the likelihood of an electron encountering a second collision after already being subjected to one collision within a single layer of the phosphor, significantly reducing the efficiency. To overcome this issue new ACPEL devices made of alternating h-BN phosphor-insulator layer pairs stacked together was considered. The focus was on selecting insulator material and optimizing the layers thicknesses to promote transport in ACPEL devices via ballistic mode primarily. In such a case primary electrons moving in the BN phosphor layer (ballistic mode) after encountering a collision, enter into a subsequent dielectric layer where they are reaccelerated before entering the next BN phosphor layer. The process is repeated through the ACPEL stack resulting in an efficiency enhancement as compared to a single h-BN layer ACTEL device. In the presentation we will demonstrate using COMSOL Multiphysics and analytical calculations that by taking into account the BN morphology (nano-poly-crystalline vs. single crystal) and the device structure (h-BN phosphor layer thickness, insulator layer parameters, number of layers pairs in the stack) the calculated ACPEL device emission efficiency can be as high as 20%.

**TUTORIAL: Silicon Photovoltaics—Device Concepts, Materials and Interfaces Engineering, Fabrication, Testing and Applications**
December 1 - December 1, 2019

* Invited Paper

**TUTORIAL**

Silicon Photovoltaics—Device Concepts, Materials and Interfaces Engineering, Fabrication, Testing and Applications

Sunday Afternoon, December 1, 2019
Hynes, Level 2, Room 205

Silicon and related thin films are applied widely in solar cells and other electronic devices. This comprehensive tutorial will introduce the processing methods, material properties, fundamental nature of interfaces and device engineering concepts. In Part 1 the design rules of solar cells will be discussed. In Part 2 the processing & properties of all materials and interfaces in a crystalline silicon solar cells will be reviewed. In part 3, the wide variety of high efficient crystalline silicon device architectures including their fundamental approaches to reduce the optical and
electrical losses will be presented. In part 4, the design schemes for modules, the characterization methods for performance and reliability, photovoltaic applications and its role in the energy transition will be discussed.

1:30 PM
**Device Physics of Solar Cells** Arno H. M. Smets; Delft University of Technology

The important optical, electrical and thermodynamic design rules that determine both the losses and performance of the photovoltaic devices will be discussed. A description based on balancing photo-generation with recombination gives simple insight into the operation of all modern solar cells.

2:15 PM
**Processing and Properties of Crystalline Silicon and Supporting Layers and the Nature of Their Interfaces** Arno H. M. Smets; Delft University of Technology

Processing of crystalline silicon and supporting layers like passivating materials (SiO2, Al2O3, SiNx, a-Si) are presented. The dependence of the material and interface properties on impurities, doping, crystal orientation, interstitials, defects, chemical and electrical passivation will be discussed.

3:00 PM BREAK

3:30 PM
**Device Architectures for High Efficient Crystalline Silicon Solar Cells** Arno H. M. Smets; Delft University of Technology

The wide variety of crystalline silicon device architectures including their fundamental approaches to reduce the optical and electrical losses will be surveyed. This overview will include Al Back Surface Field solar cells, Partial Back Contact (PERC) solar cells, heterojunction junction solar cells (HJ/HIT), interdigitated back contact (IBC), tunnel oxide passivated contact (TOPCon), bifacial solar cells and hybrid multi-junction PV concepts.

4:15 PM
**From Crystalline Silicon Cells to Reliable Modules: Characterization, Application and the Role of Photovoltaics in the Energy Transition** Arno H. M. Smets; Delft University of Technology

The different module interconnection and encapsulation schemes will be introduced. A short introduction on the important characterization tools for cells and modules will be given. Finally, residential up to large-scale utility applications and the role of crystalline silicon in the energy transition will be discussed.

Direct Observation of Dopants in Commercial Textured Silicon Heterojunction Solar Cells by Atom Probe Tomography

Yasuo Shimizu¹, Bin Han¹, Naoki Ebisawa¹, Yoshinari Ichihashi², Taiki Hashiguchi², Hirotaka Katayama², Mitsuhito Matsumoto², Akira Terakawa², Koji Inoue¹ and Yasuyoshi Nagai¹

¹Tohoku University, Japan; ²Panasonic Corporation, Japan

Silicon heterojunction (SHJ) solar cells [1], composed of a stack of thin intrinsic/doped amorphous layers, have been extensively developed towards high conversion efficiency photovoltaic property, which has been already employed in industrial production. Though a theoretical calculation demonstrates that the intrinsic limit of its efficiency reaches ~29% [2], the layer structures in actual SHJ devices still leave to be improved. The fabrication processing, such as doping methods, is considered for achieving ideal layer formation controlled with precise dopant concentration. In general, SIMS is used as a reliable analysis technique for obtaining the elemental profiles along the depth direction of the layers grown on flat substrates, which enables to determine an optimal doping condition. However, the elemental profiles on the pyramid surfaces in SHJ is unknown due to well-known dimensional limitation in the conventional analytical experiment. Therefore, it is a challenging issue to clarify how we effectively introduce the dopants in the pyramid surfaces determined by accurate characterization in commercial SHJ devices. Laser-assisted atom probe tomography (APT) has been proven useful for visualizing elemental distributions in Si-based device structures [3]. APT has a potential to directly detect the dopants and draw the concentration profiles perpendicular to the pyramid surface thanks to a site-specific lift-out by focused ion beam (FIB) technique. In this work, we established an experimental success in analyzing pyramid surface area less than 2×2 μm² dimension. In order to introduce B atoms into amorphous layers, we compared the elemental distributions of n-type layer doped by two kinds of doping molecules; (CH₃)₃B and B₂H₆.

After forming textured surface by alkali solution, intrinsic amorphous Si thin layer was grown by using plasma chemical vapor deposition, followed by B doped layer formation using (CH₃)₃B or B₂H₆. Finally, ~100 nm-thick of indium tin oxide as a transparent conducting layer was deposited on top. For APT specimen preparation, FIB apparatus equipped with SEM was used. A local electrode atom probe (LEAP4000XHR, CAMECA) equipped with a 355 nm wavelength pulsed laser was employed for APT analysis. Based on the atom maps including thin intrinsic/doped amorphous layers, we found that the amount of carbon, as a residual contaminant, doped by (CH₃)₃B is higher than that by B₂H₆. Furthermore, a large amount of hydrogen was directly observed in the amorphous layers, which may affect the photovoltaic property. The atom maps around the intrinsic/doped amorphous layers will also be presented.

This work was supported in part by NEDO (New Energy and Industrial Technology Development Organization) under METI (Ministry of Economy, Trade and Industry).

Ultrathin Silicon Oxide and p⁺-poly-Si Passivation for High-Efficiency c-Si Solar Cells

Ultrathin Silicon Oxide and p⁺-poly-Si Passivation for High-Efficiency c-Si Solar Cells

Xueqi Guo¹, Yuheng Zheng¹, Zhe Rui¹, Qing Yang¹, Zhixue Wang¹, Mingdun Liao¹, Chunhui Shou¹, Jie Yang¹, Xinyu Zhang², Qi Wang², Hao Jin², Baojie Yan² and Jichun Ye³

¹University of Shanghai for Science and Technology, China; ²Ningbo Institute of Materials Technologies and Engineering, China; ³Ningbo University, China
As an emerging technology, the surface passivation with an ultrathin silicon oxide and highly doped poly-Si stack has attracted a great attention because of the outstanding passivation quality. The carrier transport through the ultrathin SiOx was originally proposed through quantum tunneling, and therefore it was named as tunnel oxide passivated contact (TOPCon) [1] although the transport through pin-holes has been identified as the transport path in some cases [2]. The highest laboratory solar cell efficiencies of 25.7% and 24.4% were achieved with n-type and p-type FZ c-Si wafers, respectively [3,4], and a large-area cell efficiency of 22.8% was achieved with n-type CZ c-Si wafer using an industrial capable fabrication process [5], demonstrating the potential in the efficiency improvement of solar panels. However, most of the poly-Si passivation layers are doped with P to form an n-TOPCon structure for high quality passivation. From the industrial application point of view, p-type poly-Si as the passivation and contact layer (p-TOPCon) is highly desired in the solar cell manufacturing, especially for upgrading the current PERC lines. In this contribution, we report our recent progresses in the research and development of high quality p-TOPCon, where the ultrathin SiOx layer is made by chemical oxidization in high temperature HNO3, plasma assisted N2O oxidization, and thermal oxidization; and the p-poly-Si layer is made by PECVD with in-situ doping. We find that the SiOx made by the thermal oxidization performs better than those made by the other methods, with which a supper passivation using the p-TOPCon on n-type solar grade CZ c-Si wafers is achieved with iVoc of 729 mV, effective carrier lifetime (τeff) of 2.5 ms at 1×10^{15} cm^{-3} carrier density, and saturated recombination current density (J0) of 13 pA/cm^2. XPS analysis shows that the thermally oxidized film has a higher oxidization quality with a ratio of Si4+ chemical bonding configuration than those made by the other methods. In addition, the thermally oxidized SiOx layer reduces the B aggregation in the SiOx layer and the B diffusion into the c-Si wafer effectively as measured by ECV. We also investigated the PECVD a-Si:H deposition as well as various hydrogenation processes after the high temperature crystallization and their influences on the passivation quality. We find a wide PECVD process window for achieving high-quality passivation and an innovative hydrogenation method using water vapor annealing for improving the passivation quality effectively. We will also report the solar cell results with the p-TOPCon contact.

High Performance Semi-Transparent Si-Based Carrier-Selective Passivating Contacts for c-Si Solar Cells Manufactured at Different Thermal Budgets
Olindo Isabella; Delft University of Technology, Netherlands

Silicon solar cells based on PERC architecture [1][2] have become the new industrial standard beyond the Al-BSF architecture [3]. To aim at higher efficiencies, research is on innovative architectures based on carrier-selective passivating contacts (CSPCs) for quenching recombination mechanisms at contact interfaces. Focussing on Si-based CSPCs, low thermal budget heterojunction (HTJ) cells and high thermal budget TOPCon-like cells have achieved record efficiency values ~26% in both front/back-contacted (FBC) [4] [5] and interdigitated back-contacted (IBC) [6] [7] configurations. However, these architectures are challenging from upscaling stand point; thus, leaner and cost-effective processes that can enable efficiencies between 24% and 25% on large area are industrially appealing. In this contribution, we first review the opto-electrical properties and passivation quality of in-house developed semi-transparent CSPCs based on silicon alloyed with oxygen or carbon and manufactured at different thermal budgets. Then, starting from standard FBC cell configuration and recognizing the inherent parasitic optical losses due to Si-based CSPCs, we monitor the evolution of short-circuit current density in simple-process FBC and IBC devices endowed with our semi-transparent CSPCs.

In case of low thermal budget CSPCs compatible with HTJ architecture, we have developed and optimized n-type and p-type nc-SiOx:H layers, which concurrently exhibit wide band gap, optimal crystallinity fraction and low activation energy (E_{a-n} = 46.6 meV and E_{a-p} = 89.6 meV). These properties make our nc-SiOx:H layers excellent candidates for ideal carrier transport [8]. When employed in a double-side textured cell precursor based on 280-μm thick n-type FZ c-Si wafer, our nc-SiOx:H layers enable iVoc = 735 mV and iFF = 86.85% with τ_{eff} > 10 ms at also Δn < 10^{15} cm^{-3}. Rear junction devices based on such type of precursors, completed with sputtered ITO and Ag-based
screen-printed contacts, present efficiencies in excess of 21% with $J_{SC} = 39.1 \text{ mA/cm}^2$ for cell area of 7.84 cm$^2$ [9]. While further back-end optimization is needed to demonstrate higher efficiencies, this material system can boost the efficiency of FBC HTJ devices well beyond the current 25.1% efficiency record [4].

Passing to high thermal budget CSPCs, we have studied, as function of thickness, a wide range of poly-Si(Ox)(Cx) material systems by means of LPCVD (i.e. double-sided) or PECVD (i.e. single-sided) routes with ex-situ (implantation, diffusion) or in-situ doping and on flat or textured interfaces. Even though we have realized textured poly-Si CSPCs with thickness down to 6 nm (n-type poly-Si, $V_{OC} = 728$ mV, $J_0 = 6.5 \text{ fA/cm}^2$), our best n-type (p-type) CSPCs are flat 35-nm (20-nm) thick poly-SiO$_x$ layers, which exhibit $iV_{OC}$ up to 740 (716 mV) and $J_0$ down to 3 (11) fA/cm$^2$. These layers, similarly to poly-Si$_x$ layers [10], can be more transparent than poly-Si counterparts. As such, we have introduced polyO$_x$-polyO$_x$ FBC devices [11][12], which could yield 21.5% for cell area of 1 cm$^2$, by slightly improving the $V_{OC}$ of our poly-poly FBC standard devices ($V_{OC} = 691$ mV vs $V_{OC} = 682$ mV) and massively enhancing the $J_{SC}$ ($J_{SC} = 40.7 \text{ mA/cm}^2$ vs $J_{SC} = 38.1 \text{ mA/cm}^2$) without the use of any dual anti-reflective coating (DARC). To further augment the $J_{SC}$, we have devised a simple-process IBC poly-Si architecture, that exhibits $J_{SC:DARC} = 42.2 \text{ mA/cm}^2$ [13] with 23% for cell area of 2 cm$^2$ [14].

PO-SiOₓ on flat c-Si, an iVoc equal to 711 mV is obtained. By increasing the N₂O plasma treatment time, the iVoc increases to 723 mV. With the same process conditions, n-type poly-SiOₓ CSPC on textured c-Si gives 710 mV. The p-type poly-SiOₓ CSPC with PO-SiOₓ is also under development by optimizing the N₂O plasma condition and the high-temperature annealing process. In this case, preliminary results indicate an iVoc equal to 668 mV for flat layers.

Poly-SiOₓ – poly-SiOₓ FBC cell, featuring wet-chemical SiOₓ on both sides, textured n-type poly-SiOₓ at the front side and flat p-type poly-SiOₓ at the rear side, performs an efficiency of 21.5% with Voc = 691 mV, FF = 76.4%. The replacement of wet-chemical SiOₓ with PO-SiOₓ is ongoing, for which a higher FF and similar Voc at cell level are expected, leading to a cell efficiency well above 21.5%. Results will be presented at the conference.

11:00 AM EN11.01.05
Insights into the Gettering and Passivation Phenomena in Doped Poly-Silicon Passivating Contacts in Si-Photovoltaics by Atom Probe Tomography Apurv Yadav1, Di Yan2, Wenjie Yang2, Keita Nomoto1, Daniel Macdonald2 and Simon Ringer1; 1The University of Sydney, Australia; 2The Australian National University, Australia

We summarize our recent findings on the properties of doped poly-Si structures for solar cell applications in terms of their impurity gettering effects (iron); through analysis of 3D elemental distribution profiles of, phosphorus /and boron (diffused dopants), undoped poly-Si (control) and implanted iron (impurity). Doped poly-Si films with an underlying interfacial oxide layer have been shown to enable high efficiency silicon solar cells, due to their excellent electrical contact and surface passivating effects , and also because they possess very strong gettering properties (>99.9% metal (Fe- impurity) removal from the bulk) without compromising its passivating qualities.

Our study uses atom probe microscopy to determine the 3D distribution of elements to explore the phenomenon of gettering by poly-Si based layers. We investigate the role of dopants, oxygen, grain-boundaries and, interfaces, and observe if trends in the elemental distributions play a role in impurity gettering. This study is performed in conjunction with transmission electron microscopy (TEM) to facilitate atom probe reconstruction and support atom probe tomography (APT) analysis.

Our results indicated the gettering properties of poly-Si layers differ based on the dopants present (phosphorus vs boron) and are enhanced 1. in the presence of dopants (compared to undoped contacts), 2. at interfaces and 3. in the presence of oxygen.

The potential implications of these findings are in designing passivating contacts with enhanced gettering and passivating qualities. This will support the development of new solar cell processes for higher efficiency silicon solar cells at lower costs.

11:15 AM EN11.01.06
The Role of Defects for Charge Collection in c-Si HTJ Solar Cells Paul Procel, Aurora Saez-Armenteros, Carlos Ruiz-Tobon, Luana Mazzarella, Yifeng Zhao, Can Han, Guangtao Yang, Olindo Isabella and Miro Zeman; Technical University Delft, Netherlands

Defects in semiconductors are typically involved in performance degradation of photovoltaic devices in terms of recombination mechanisms and light instability [1-2]. Defects basically act as available energy states that can capture or emit charge inside the layer itself or to other materials/systems. In case of hydrogenated amorphous silicon (a-Si:H), these defects are related to non-periodic variations of the lattice potential, known as band tail energy states. These defects feature two state conditions: (i) neutral when empty or (ii) charged when occupied. Similarly, sub-gap electronic states close to mid-gap energy are defects in the form of dangling bond states [1]. The
latter defects are dominant for recombination mechanisms at room temperature and they show amphoteric nature, which means that they exhibit three different states of charge. Altogether, these energy states build a complex configuration for charge collection that is not fully understood yet.

By means of rigorous TCAD modelling [3], we hereby discuss the role of the energy states for charge collection in silicon heterojunction (HTJ) solar cells inside contact stacks, namely intrinsic a-Si:H/doped n-type or p-type a-Si:H / transparent conductive oxide (TCO). Specifically, we investigate the different nature and properties of defects which affect recombination mechanisms for charge transfer, also known as trap-assisted tunneling (TAT). Furthermore, we correlate these mechanisms to solar cell external parameters for pursuing more efficient device.

We observe that TAT processes are not dominant in case of energy alignment of occupied states and available states within contact stack system. In presence of a proper energy alignment, field/thermionic emission and band-to-band processes from and to hetero-interfaces are dominant. In fact, such events are more efficient, as they do not exhibit any energy loss in terms of elastic transitions between energy states. On the other hand, TAT transitions are evident in the absence of energy states alignment and imply energy variation. Accordingly, we analyze the individual material properties that evidence TAT processes. Interestingly, such conditions are fulfilled only for positive charge collection while TAT is not apparent for negative charge collection. The electronic properties, ruling the aforementioned energy alignment, are associated to the Fermi-energy of each individual layer forming the heterojunction contact: p-type a-Si:H activation energy ($E_{a,p}$) and TCO carrier concentration ($N_{TCO}$). Therefore, we performed numerical calculations to evaluate charge transport in terms of fill factor (FF) within reasonable ranges of $E_a$ and $N_{TCO}$ values. From our modelling results, we observed four different intervals featuring different charge collection processes:

a) $35 < E_{a,p} < 260 \text{meV}$ and $1 \times 10^{20} < N_{TCO} < 1 \times 10^{21} \text{cm}^{-3}$: Elastichange transitions (FF>85%)

b) $260 < E_{a,p} < 430 \text{meV}$ and $1 \times 10^{20} < N_{TCO} < 1 \times 10^{21} \text{cm}^{-3}$: TAT based on dangling bond states (80%<FF<85%)

c) $35 < E_{a,p} < 260 \text{meV}$ and $1 \times 10^{19} < N_{TCO} < 1 \times 10^{20} \text{cm}^{-3}$: TAT based on valence band tail states (55%<FF<80%)

d) $260 < E_{a,p} < 430 \text{meV}$ and $1 \times 10^{19} < N_{TCO} < 1 \times 10^{20} \text{cm}^{-3}$: TAT based on dangling bond states (60%<FF<80%). Note that here the energy variation within TAT intervals is larger than b).

We identified that defects featuring energy close to Fermi-energy (i) work more effectively on TAT processes and (ii) are closer than 10nm to the p-type a-Si:H/TCO interface (tunneling distance). In particular, TAT based on dangling bond states is more efficient than TAT based on tail states. Such a difference is ascribed to the initial dynamics (from neutral state) of recombination based on amphoteric states, that is able to capture positive charge from c-Si or negative charge from TCO, whereas tail states only allow to capture positive charge from c-Si.

11:30 AM EN11.01.07
Investigations of and Solutions for Contamination Mechanisms of Intrinsic poly-Si Gap Contamination in SiOx. Passivated Interdigitated Back Contact Silicon Solar Cells Matthew B. Hartenstein1,2, William Nemeth2, Vincenzo LaSalvia2, Steven Harvey2, Matthew Page2, David L. Young2, Paul Stradins2 and Sumit Agarwal1;
1Colorado School of Mines, United States; 2National Renewable Energy Laboratory, United States

We demonstrate a new, purely mechanical mask alignment technique for dopant patterning of interdigitated back contact solar cells (IBC's) monocrystalline silicon (c-Si) solar cells. This technique uses ceramic pins to hold the mask and substrate tightly together for dopant deposition using plasma- enhanced chemical vapor deposition (PECVD). Problems associated with this dopant patterning step are investigated and solutions are developed for each. IBC silicon solar cells are the current record holders for silicon photovoltaic efficiencies based on various contacting structures [1]. Additionally, passivated contact schemes involving heavily doped polycrystalline silicon on silicon oxide (poly-Si/SiOx) have been demonstrated on both two-sided architectures [2][3] and IBC architectures [4][5][6], achieving efficiencies over 25%. These poly-Si/SiOx IBCs have been demonstrated with oxides of ~2.2 nm thickness to great success. Many groups have achieved high efficiencies on IBCs with these 2.2 nm passivating oxides by patterning the back-side dopants using photolithographic techniques, ion implantation, or laser doping, but these processes are undesirable due to their complexity, potential damage to the cell or cost. However, IBC solar cells have not yet been demonstrated using the ~1.5 nm tunneling oxide passivated contact structure fully contacted with doped polycrystalline silicon (poly-Si) fingers separated by intrinsic poly-Si. We investigate factors that are critical for the performance of IBC solar cells based on these tunneling oxide poly-Si passivated contacts. Because many of the above-mentioned dopant patterning techniques have led to fabrication complications, we have chosen to pattern the back side using masked PECVD of doped hydrogenated amorphous silicon (a-Si:H). Although this is a
simpler process, there are a few troubles which can occur. During patterning of doped lines using direct deposition through a shadow mask, we show using time-of-flight secondary ion mass spectrometry (TOF-SIMS) that the intrinsic polyc-Si gap becomes contaminated with dopants, leading to shunting. Two possible contamination mechanisms during high-temperature crystallization annealing are investigated. Using controlled experiments in a crystallization tube furnace, it is shown that dopants can desorb from the surface of the doped a-Si:H and transfer through the gas phase to be adsorbed onto the intrinsic gap and diffuse inward to contaminate the intrinsic gap. Mitigation strategies are developed for each of these contamination mechanisms to minimize shunt losses, confirmed using conductivity measurements. Dopant migration during PECVD is mitigated through a partial etch back of the a-Si:H surface to clear the intrinsic gap of dopants before crystallization. Gas phase transfer is mitigated by addition of a barrier between the doped a-Si:H and the gas phase, either with a capping layer or by annealing in an oxygen ambient which forms a surface layer of SiOx, etched away by further processing. Complete IBC cells fabricated using these processing strategies will be presented at the conference. Improved IBC manufacture techniques will reduce the cost of such high efficiency cells and modules, promoting the expanded use of solar energy.

Investigating the Practical Efficiency Limits of Solar Cells by Using Thin CZ-Quality Substrates André Augusto, Pradeep Balaji, Joseph Karas, Richard King and Stuart Bowden; Arizona State University, United States

Different silicon solar cells technologies have surpassed or are close to surpassing 26% efficiency. Dielectric oxides and amorphous silicon-based layers combined with minimal metal/silicon contact areas were responsible for reducing the surface saturation current density below 3 fAcm⁻². At open circuit, for passivating contact solar cells, the recombination is mostly fundamental (Auger and radiative), representing near 80% of the total recombination. At the maximum power injection, the fundamental recombination fraction drops to less than 50% as the surface recombination and SRH bulk step in. As a result, to further increase the performance is paramount to reduce the bulk dependence and secure proper surface passivation. Bulk dependence can be mitigated either by improving the bulk quality or by reducing the wafer thickness. We demonstrate for commercial relevant high-quality CZ wafers, thinner wafers and surface saturation current densities 10 times lower than the present state-of-the-art, are required to further increase the efficiency and narrow the gap towards the fundamental limit. For an n-type SRH bulk lifetime of 10 ms and a resistivity of 3 Ohm.cm, the optimum substrate thickness range is between 40 to 60 μm. By optimizing the thin layer of a-Si:H (<7nm) we have accomplished surface saturation currents below 1 fAcm⁻² across multiple substrates thicknesses, reaching effective minority carrier lifetimes over 2.2 ms and implied open-circuit voltages of 765 mV on 40 μm-thin n-type CZ substrates after ip/in a-Si:H stack deposition. We use thinner wafers as testbed to optimize the thin intrinsic a-Si:H layer, as the effective minority carrier lifetime response to surface passivation increases inversely with the substrate thickness, and bulk recombination becomes less predominant in the final make-up of the lifetime, particularly at maximum power injection. We manufactured screen-printed silicon heterojunction solar cells on free-standing 40 μm-thin CZ-wafers with efficiencies close to 21%. In these cells the screen-printing layout needs to be optimized, and further gains in current and fill factor are expected in the coming months. These results were a direct consequence of an extreme good surface passivation and improved generation current provided by an antireflective bi-layer thin-ITO/SiO₂. The antireflective bi-layer increased the current density in 1.2 mAcm⁻² from our baseline antireflecting coating, mostly by mitigating the parasitic absorption via thinner ITO front layer.

Performance of Silicon Solar Cells Using Very High Resistivity Substrates André Augusto, Apoorva Srinivasa, Richard King and Stuart Bowden; Arizona State University, United States

Today’s highest-efficiency solar cells typically operate near the threshold between low-level and high-level injection. It is not well understood if pushing further into a regime in which the cell operating point is solidly in high level injection at all times of the day has further benefits for initial solar cell performance, for reducing degradation rates, or for controlling the charge state and diffusivity of impurities that determine recombination in the bulk. In this work we explore the potential advantages of using very high resistivity n- and p-type, to manufacture high performance solar cells. Analytical modeling indicates that high resistivity substrates (10 Ωcm - >10k Ωcm) are required to have bulk Shockley-Read-Hall lifetimes in the millisecond range to outperform wafers with standard resistivities (< 10 Ωcm). Additionally, for resistivities over 10 Ω.cm, efficiencies show to be weakly dependent of the bulk resistivity. These results if experimental verified, can lead to more affordable ingot manufacturing, by lessening the requirements of dopants homogeneity along the ingot. We successfully passivated both n- and p-type substrates using i-a-Si:H, obtaining surface saturation current densities comfortable below 10 fAcm⁻² and effective minority-carrier lifetimes over 2 ms at maximum power injection over the entire range of bulk resistivities (3 Ωcm - >10k Ωcm). For very high resistivity wafers (15k Ωcm) effective minority-carrier lifetimes over 10 ms were measured for both n- and p-type substrates. At moment we are manufacturing and characterizing solar cells and passivated samples, both p- and n-type over a wide range of temperatures (up to 80 °C) and injections. Preliminary results on silicon heterojunction solar cells indicate similar performance behavior for different light intensities regardless the base resistivity of the substrate.

Progress in the Fabrication of Liquid Phase Crystallized Silicon Solar Cells Hassan Ali¹, Frank Pennartz¹, Nelli Hambach¹, Friedhelm Finger¹, Wolfhard Beyer¹, Daniel Amkreutz², Maurice Nuys³ and Stefan Haas¹;¹Forschungszentrum Jülich, Germany; ²Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany
Liquid phase crystallization (LPC) technology offers an alternative solution to the established wafer-based solar cells. It is a kerfless fabrication method that promises high efficiency solar cells on large-sized glass substrates. Recently, a conversion efficiency of 14.2% for back contacted 13 µm thick silicon on glass was demonstrated [1]. In this technology, amorphous or nano-crystalline silicon films prepared by various fabrication methods are used. In our work, we focus on films deposited by plasma-enhanced chemical vapor deposition (PECVD) due to its industrial relevance and easy integration into large-scale manufacturing. The standard layer stack for PECVD-based LPC solar cell consists of a multifunctional SiOx/SiN/SiOx (ONO) interlayer directly deposited on the glass followed by a 5-10 µm thick amorphous silicon (a-Si:H) precursor layer and finally a SiOx capping layer to promote the wettability of the film during crystallization. To drive out the hydrogen from the standard a-Si:H layer, the whole stack goes through a 2-day oven annealing (RT to 550 °C) process before crystallization by an 808 nm line-shaped continuous wave (CW) laser source. Without this hydrogen removal, the material delaminates during crystallization [2]. Unfortunately, this slow annealing process increases the manufacturing time.

In our contribution, we sum up our recent progress in the fabrication of the LPC layer stack and present an alternative solution to further reduce the manufacturing time of LPC cells. To reduce the annealing time, a porous material with interconnected voids was realized [3]. This allowed to rapidly anneal the a-Si:H precursor layer within 30 minutes (under ambient or nitrogen atmosphere) up to 550°C and drive out the hydrogen without material delamination, thus decreasing the manufacturing time and heating cost drastically. We examined this hypothesis by introducing artificial vents into dense films for the H effusion, which usually delaminate during the 30-minute rapid annealing process. With these vents, the film stabilizes depending on the distance between the vents. Furthermore, the LPC process induces strong thermal-induced stress which may lead to glass cracking. Profilometry was implemented to evaluate the radius of surface curvature and Stoney's equation was used to quantify the mechanical stress before and after laser crystallization. To lower the thermal-induced stress, laser scan speed was optimized to decrease the thermal gradient between layers of mismatching thermal expansion coefficients [4]. As a result, we were able to achieve (using porous precursor material) crack-free crystallized poly-crystalline silicon with grain diameters of several µm and grain lengths of several mm. Also, the crystallization was made possible without the need for a capping layer.

In conclusion, we were able to get rid of the capping layer fabrication step and significantly decrease the annealing time. Hence, we present a high-throughput approach for future up-scaling of liquid phase crystallization technology.

**Smart Stack Technology for Si-Based Tandem Solar Cells**

Hidenori Mizuno, Kikuo Makita, Hitoshi Sai, Takuya Matsui, Tetsuhiko Miyadera, Takeshi Tayagaki, Toshimitsu Mochizuki, Ryuji Oshima, Takeyoshi Sugaya and Hidetaka Takato; National Institute of Advanced Industrial Science and Technology (AIST), Japan

Developing strategies towards Si-based tandem solar cells has gained considerable attention in the photovoltaic research community to prepare for the future demand of higher-efficiency solar cells. In this respect, we have proposed “smart stack” technology, an approach using metal nanoparticle arrays to bond dissimilar semiconductor materials both electrically and optically. Such functional metal nanoparticle arrays can be readily available by a method known as block copolymer nanolithography. Using Pd or Cu nanoparticle arrays, for example, we have fabricated triple-junction tandem cells comprising of InGaP/GaAs top cells and crystalline Si (c-Si) bottom cells. Through the fine tuning of the InGaP/GaAs cells as well as the introduction of advanced c-Si cell technologies (such as tunneling oxide passivated contact or heterojunction), efficiencies of over 30% have been recently realized. Other than InGaP/GaAs top cells, lead halide perovskites are of great interest, and efforts to demonstrate perovskite/c-Si
tandem by the smart stack technology is also actively ongoing. This presentation overviews the concept, process, and device performances of the smart stack technology, including some of recent attempts.

Efficiency Potential and Application of Singlet Fission Enhanced Silicon Solar Cells Benjamin Daiber1, Koen v.d. Hoven1, Moritz H. Futscher1, Joris Bodin1, Alyssa v.d. Boom2, Sidharam Pujari2 and Bruno Ehrler1; 1AMOLF, Netherlands; 2Wageningen University, Netherlands

Silicon is the dominating solar cell material, therefore add-ons on the silicon solar cell that can improve the power conversion efficiency are urgently needed. In certain organic materials singlet fission generates two triplet (spin 1) excitons from one singlet (spin 0) exciton. If the triplet excitons are harvested in the silicon solar cell the efficiency could be dramatically increased, as we show. There are different transfer pathways between the organic singlet fission material and silicon. We have simulated the achievable efficiency for each transfer path with realistic assumptions such as a singlet fission quantum efficiency of 1.7 (1.7 e-h pairs per high energy photon), a transmission loss of 5%, and different entropy gains of the Singlet Fission process.

Even with these realistic assumptions, the efficiency of a silicon/singlet fission solar cell can be as high as 34% when combined with the current record silicon solar cell of 27%. We found that dissociating the triplet excitons at the interface leads to a large potential efficiency gain because a triplet energy lower than the silicon bandgap still leads to charge generation, and allows for high current generation. We also find that current singlet fission materials do not absorb light strongly enough, motivating sensitization schemes. A direct triplet exciton transfer shows lower overall efficiencies because the energy level requirements are more strict, however the solar cell architecture is more elegant since there are no additional contacts needed. Finally, we compare the singlet fission/silicon solar cells to the efficiency potential of perovskite/silicon tandem solar cells. We find that tandem cells are particularly beneficial for a silicon base cell with low efficiency, while a highly efficient silicon solar cells benefits less from the perovskite top cell. In contrast, the efficiency gain from the singlet fission layer is almost constant for all silicon base cells, and for highly efficient silicon cells would clearly outperform a high-efficiency perovskite top cell.

We also fabricated Silicon solar cells with a top layer of tetracene. The silicon base cell are back-contacted, so we can HF-etch the silicon solar cell from one side to have direct access to the Silicon <111> sides of pyramidal textured silicon. Through measuring the photocurrent under a magnetic field we can differentiate between the photocurrent contribution of singlet and triplet excitons. A newly improved magnetic field dependent photocurrent setup allows us to measure current changes in the order of 0.01% and is a vital tool for a precise attribution of the origin of the photocurrent. We find that after deposition of the tetracene layer we see an injection of singlets or photons into silicon, but after aging the solar cell we see evidence for triplet transfer. The characteristic Merrifield curve (photocurrent as function of applied magnetic field ) inverts, which suggest the injection of triplet excitons from tetracene into silicon. This behavior can be observed for and tetracene-silicon solar cells that have been aged for five days in air or six weeks encapsulated in nitrogen atmosphere. We discuss a changing orientation of the tetracene molecules over time and a thin layer of silicon dioxide growing between tetracene and silicon. A better understanding of the energy transfer processes at the interface will be important for future device applications.

Electron Paramagnetic Resonance Study of Sodium Guests in Silicon Clathrate—A Cage-Like Crystalline Silicon Allotrope Yinan Liu1, William K. Schenken1, Ahmad A. Majid1, Lakshmi Krishna1, Timothy A. Strobel2, Reuben T. Collins1, P C. Taylor1 and Carolyn A. Koh1; 1Colorado School of Mines, United States; 2Carnegie Institute of Washington, United States

Si clathrates are cage-like, crystalline Si allotropes with potentially exciting optoelectronic properties. Room temperature and atmospheric pressure metastable clathrates are synthesized in the presence of alkali guest atoms, such as Na, which occupy the interstitial sites in the cages. Na guests, however, degenerately dope the crystals. Realizing the potential of these materials as new, crystalline Si-based, earth abundant electronic materials requires fundamental understanding of guest properties and how to control their occupancy and diffusion in the cage-like host crystal structure. Elucidation of these properties is complicated by complex interactions among the Na donors. For this reason, a detailed understanding of isolated, or nearly isolated, Na donors is critical to eventually realizing the potential of these semiconductors for electronic and opto-electronic devices.

Here, we present an EPR study of Na guests in type II Si clathrate as a function of temperature and Na concentration. Since at low temperatures a Na donor is paramagnetic, EPR hyperfine interactions allow low concentrations of Na ions to be detected while probing the interaction between ions and the Si cages. In low
temperature measurements, the EPR spectrum with ≤1 at. % of Na exhibits four hyperfine lines due to the interaction of the Na valence electron with the nuclear spin \( I=3/2 \) of Na\(^{23} \). The hyperfine coupling constant \( 13.3 \text{ mT} \) together with the atomic coupling constant for an isolated Na atom \( 31.6 \text{ mT} \) indicates that about 42% of the wave function of the paramagnetic electron resides on the Na atom and the rest resides on the surrounding Si sublattice. The type II crystal structure includes both small and large cages. At this low Na concentration, the Na is almost entirely in the large cages and a small anisotropy in the four hyperfine lines indicates it is slightly off center in the cage, as suggested by other measurements. We also identify an EPR contribution at \( g=2.005 \) which is consistent with the presence of Si dangling bonds in a highly disordered or amorphous Si phase. Identifying this line as due to dangling bonds allows a clearer identification of the other features in the clathrate spectrum.

The observation of structure from "super hyperfine" interactions of the Na valence electron with more than one magnetic nucleus provides additional insight into the properties Na as a donor in type II clathrate. Doublets surrounding each of the four Na hyperfine lines are identified, using EasySpin spectral simulations, as arising from naturally occurring Si\(^{29} \) nuclei in the surrounding Si cage. Based on the magnitude of the Si\(^{29} \) interaction, it is estimated that about half of the spin density on the Si sub-lattice extends past the confining cage. Additional fine structure is observed halfway between the strong hyperfine lines. Simulations suggest they arise from the interaction of either one or two electrons on Na\(^{23} \) nuclei \( I=3 \) in adjacent cages. This spectrum consists of 7 lines, four of which are hidden by the four strong hyperfine lines for isolated Na\(^{23} \) atom cages, with the others positioned between the hyperfine lines as observed. Interactions of electrons associated with Na\(^{23} \) atoms in adjacent cages is consistent with spin density extending beyond the confining cage. In addition to probing the nature of the Na donor in the clathrate structure, EPR provides other useful information. For example, using the integrated intensity of the Na hyperfine lines we estimate the concentration of isolated Na in samples specifically prepared to have low Na content to be \( \sim 3 \times 10^{17}/\text{cm}^3 \) which is approaching a regime where the doping is not degenerate. Dopant Profile Engineering to Improve Charge Carrier Lifetime in Gold-Hyperdoped Silicon Sashini S. Dissanayake\(^1\), Philippe K. Chow\(^2\), Nikki O. Pallat\(^1\), Rhoen Fiutak\(^1\), Jeffrey M. Warrender\(^2\) and Meng-Ju Sher\(^1\);
\(^1\)Wesleyan University, United States; \(^2\)U.S. Army Combat Capabilities Development Command - Armament Center, United States

Intermediate band photovoltaics have been proposed to better utilize the solar spectrum and ‘hyperdoping’ of silicon is an effective method to realize such a material [1]. We investigate various hyperdoping methods and dopant concentration profile tailoring, to increase the charge carrier lifetime in intermediate band semiconductor materials. Hyperdoping is a well-established technique to introduce large concentrations of deep-level dopants such as heavy chalcogens and transition metals for intermediate band formation [1,2]. Various hyperdoping and annealing methods — namely, dopant ion implantation followed by pulsed laser melting (PLM) [3], or dopant ion implantation followed by flash lamp annealing (FLA)[4], or dopant thin film deposition followed by PLM [5] can produce impurity-supersaturated, single crystalline layers, which absorb sub-bandgap light. A drawback of the non-equilibrium PLM technique is inherent dopant segregation to the silicon surface [6], which leads to short charge carrier lifetimes without contributing to device performance. In this study, we investigate the extent of the surface segregation on the photocarrier lifetime using controlled etching methods as a way of removing the surface-segregated silicon surface.

We investigate the influence of the etch processing on charge carrier lifetime using terahertz (THz) spectroscopy. Optical pump THz probe spectroscopy is a non-contact photoconductivity measurement for measuring carrier lifetime with picosecond temporal resolution [7]. We focus our study of the recombination dynamics on the gold-hyperdoped silicon (Si:Au) system, prepared via thin film deposition and PLM. We find that whereas unprocessed Si:Au layers exhibit rapid recombination with a lifetime of 16 ps, CF\(_4\)-based reactive ion etching (RIE) increases the lifetime by a factor of 2, contrary to the widely-known role of RIE for increasing surface recombination. We also characterize the structural and absorption properties of the material. Additionally, we simulate the lifetime dependence on dopant concentration profile. We use these THz lifetime measurements to verify results of dopant profile engineering, to optimize materials for intermediate band photovoltaics. This study provides a material processing-based approach towards overcoming the historically-low external quantum efficiencies reported for hyperdoped Si optoelectronic devices.

Monolithic Thin-Film Chalcogenide-Silicon Tandem Solar Cells Enabled by a Diffusion Barrier
Alireza Hajijafarassar, Filipe Martinho, Andrea Crovetto, Jorgen Schou and Ole Hansen; Technical University of Denmark, Denmark

Following the recent success of monolithically integrated Perovskite/Si tandem solar cells, there has been a surge of interest in alternative wide bandgap top-cell materials with prospects of a fully earth-abundant, stable and efficient tandem solar cell. Thin film chalcogenides such as Cu2ZnSnS4 (CZTS, 1.6 eV band gap) or Cu2BaSnS4 (CBTS, 2.0 eV band gap) could be suitable candidates. However, this class of materials has the disadvantage that generally at least one high temperature step (> 500 C) is needed during the synthesis, which could contaminate the Si bottom cell. Here, we systematically investigate the monolithic integration of CZTS and CBTS on a Si bottom solar cell. A simple double-sided Tunnel Oxide Passivated Contact (TOPCon) structure is used as bottom cell, and a thin TiN layer is selected as both a diffusion barrier and a recombination layer between the two sub-cells. We show that TiN successfully mitigates in-diffusion of CZTS elements into the c-Si bulk during the high temperature sulfurization process, and no evidence of electrically active deep Si bulk defects in samples protected by just 10 nm TiN. Post-process minority carrier lifetime in Si exceeded 1.5 ms, i.e., a promising implied open-circuit voltage (i-Voc) of 715 mV after the high temperature sulfurization. Based on these results, we demonstrate the first proof-of-concept two-terminal CZTS/Si and CBTS/Si tandem devices with a efficiencies up to 3.3%. A general implication of this study is that the growth of complex semiconductors on Si using high temperature steps is technically feasible, and can potentially lead to efficient monolithically integrated two-terminal tandem solar cells.

Hyperdoped Si Photodetectors with High Efficiency and Extended Infrared Response
Yining Liu1, Wenjie Yang2, Jeffrey M. Warrender3, Quentin Hudspeth1, Peter Hadchiti1, Jim Williams2, Imad Agha1 and Jay Mathews1;
1University of Dayton, United States; 2Australian National University, Australia; 3Benet Lab, United States

Supersaturated solutions of transition metal impurities in Si have been shown to create intermediate bands (IBs) between the valence and conduction bands in Si. This new IB induces sub-band gap absorption, thereby increasing the range of optical absorption in silicon further in the infrared. The extended response of this hyperdoped Si make it a promising material for photovoltaic devices. Ion implantation followed by pulsed laser melting has been demonstrated as a method to produce concentrations of impurities in Si that are well above the solid solubility limit. Recently, photodetectors fabricated from Si hyperdoped with Au or Ti have been shown to have sub bandgap responsivity, demonstrating the material’s promise for increasing the efficiency of Si solar cells beyond conventional limits.

To achieve devices that could be commercialized for PV cells or other demanding applications, hyperdoped Si must show significant optical absorption, and high quality Ohmic contacts for carrier extraction must be achieved. In this work, we fabricated Si layers hyperdoped with Au or Ti at varying thickness, measured the optical absorption enhancement relative to Si, and attempted to form Ohmic contacts to the layers. The results show significant enhancement of optical absorption by increasing the implant energy. For making Ohmic contacts to hyperdoped materials, we tried several treatments, including boron or phosphorus shallow doping, rapid thermal annealing (RTA) of contact, etching off the top metallic layer, and modifying the PLM process to suppress dopant segregation. Recipes for Ohmic contacts to each layer were demonstrated. And the low ohmic contact resistivity around 0.1 ohmcm2 can be achieved.

Prototype photodetectors were fabricated out of Au or Ti hyperdoped Si materials produced using the II-PLM
method. The devices were fabricated using the optimized Ohmic contact process to maximize the carrier extraction. The IV characterization shows a rectifying effect for the Si based junction. The detection range is extended to 2μm, well beyond the limit of typical Si photodetectors. More importantly, the external quantum efficiency in the sub-band gap region was increased by nearly two orders of magnitude over previously published work. These results represent a significant improvement in the development of a hyperdoped Si solar cell. The enhancement in optical absorption and carrier extraction should translate to a significant increase in solar cell efficiency.

ZnS,Se<sub>1-x</sub> Photovoltaic Carrier-Selective Contacts to Si—Band Offsets and Simulation-Driven Design Rebecca D. Glaudell and Harry A. Atwater; California Institute of Technology, United States

ZnS,Se<sub>1-x</sub> films are promising materials for front carrier-selective contacts in silicon photovoltaics given their wide bandgaps and low resistivities compared to amorphous silicon, with the potential to capture more photo-generated current than a traditional heterojunction with intrinsic thin layer (HIT) solar cell. We have synthesized ZnS,Se<sub>1-x</sub> films (x ranging from 0 to 1) grown on Si by molecular beam epitaxy and employed X-ray photoelectron spectroscopy and spectroscopic ellipsometry to measure band offsets of ZnS,Se<sub>1-x</sub> with respect to Si and have compared the results to Sentaurus optoelectronic simulations of photovoltaic devices incorporating ZnS,Se<sub>1-x</sub> carrier-selective contacts. Further experimentally-determined parameters, including complex refractive index and resistivity, were also included in simulations of a HIT-style cell to determine the ZnS,Se<sub>1-x</sub> top contact mole fraction x, doping level, and thickness for optimal device performance. In simulations, the highest performance ZnS,Se<sub>1-x</sub> contact is found to outperform the simulated and experimental performance of a comparable HIT cell with a- Si/ITO front contact. Experimental transport measurements for ZnS,Se<sub>1-x</sub> top contacts will be discussed.

This material is based upon work supported by the NSF and the DOE under NSF CA No. EEC-1041895, by the DOE under Award Nos. DE-EE0006335 and DE-EE0004946, and by the NSF Graduate Research Fellowship under Grant No. 1144469.

EN11.03.02
PEDOT:PSS Hole Transport Layers Deposited by Spray Coating for Silicon Solar Cells Deniz Türkay<sup>1,2</sup>, Naser Beyraghi<sup>1,2</sup>, Milad Ghasemi<sup>1,2</sup>, Konstantin Tsoi<sup>1,2</sup>, Kerem Artuk<sup>1,2</sup>, Elif Cuce<sup>1,2</sup> and Selcuk Yerci<sup>1,2,2</sup>; 1Center for Solar Energy and Applications (GÜNAM), Turkey; 2Middle East Technical University, Turkey

The low temperature budget, availability of various deposition techniques, and wide range of adjustability in physical and electrical properties makes poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) a promising candidate as an hole-transport layer (HTL) for low-cost silicon based heterojunction solar cells. However, majority of works utilizing a PEDOT:PSS layer for silicon solar cells incorporate a spin-coating process for the deposition, which in fact is not a suitable technique for mass production as it inherently requires batch processing and a large portion of the dispensed solution is wasted in the process. In this work, we spray coat PEDOT:PSS layers on silicon surfaces as an alternative and use two different equipment: an in-house built airbrush system and a commercial ultrasonic coating system. For both systems, we investigate the coating quality on mirror-polished and random pyramid textured monocrystalline wafers. We analyze the effect of sample temperature and sample-to-nozzle distance on morphological properties and on electrical performance (contact resistivity, surface saturation current density) of the deposited films. Since the optimal deposition parameters and chemical content of the PEDOT:PSS films are heavily influenced by the hydrophobicity of the silicon surface, we perform the depositions on (1) surfaces having an ultra-thin chemical oxide, and (2) surfaces that are subjected to an HF dip prior to the deposition for oxide removal. Under optimized conditions, we achieve surface saturation current densities below 30 fA/cm<sup>2</sup> and contact resistivities below 100 mΩ.cm<sup>2</sup>. Finally, to demonstrate the performance on a device level, the
films are used as HTLs at the rear side of silicon solar cells where an n-type amorphous silicon layer serves as the electron transport layer at the front side of the cell.

EN11.03.03
On the Origin of Photoresponse of Au- and Ti-Hyperdoped Si Photodiodes

Shao Qi Lim¹, Christopher Lew², Philippe K. Chow³, Brett Johnson², Jeffrey M. Warrender¹ and Jim Williams¹; ¹Australian National University, Australia; ²The University of Melbourne, Australia; ³US Army ARDEC, United States

Si-based near-and mid-infrared photodetectors have been demonstrated through the introduction of an intermediate band in the bandgap of Si by hyperdoping with deep level impurities. The potential CMOS compatibility of such materials makes it attractive to the ICT and military sectors, and could advance the realization of cheap and high-resolution infrared imaging. These materials are typically fabricated by ion implantation followed by pulsed laser melting (PLM) to achieve hyperdoping concentrations beyond the Mott limit (~10²⁰ cm⁻³).

Studies involving Te-, Se-, and S-hyperdoped Si have demonstrated optical activity up to the mid-infrared [1-2]. However, at the highest doping concentrations the material undergoes an insulator-to-metal transition, making it unfavourable for a near-infrared photodetector. On the other hand, detectors made from Si hyperdoped with transition metals that introduce deep level states closer to mid-gap of Si, such as Ti and Au, exhibit a near-infrared photoresponse with an activation energy between 0.72—0.78 eV [3-4]. However, these diodes have very low quantum efficiencies, and the reason for this is currently unclear.

In a recent study of Au-hyperdoped Si diodes [5], we observed a deep level defect at Ec-0.35 eV originating from the interaction between implantation and PLM-induced defects at concentrations as high as 10¹⁴ cm⁻³ within the device depletion layer. In this presentation we present photocurrent data from these diodes and show that the Ec-0.35 eV defect and the Au-related deep level give comparable contributions to photocurrent. Hence, our experiments suggest that the near-infrared spectral kink previously observed in both Au- and Ti-hyperdoped Si diodes is almost certainly related to the Ec-0.35 eV defect and not hyperdoping, indicating that there is an underlying problem with present photodiode structures for hyperdoped materials. In a further series of experiments, we show that the hyperdoping of Ti in Si (required for optical activity) cannot be achieved by PLM in the nanosecond regime, providing further evidence for the contribution of processing defects to the observed near-infrared absorption and photoresponse in the Si(Ti) system.

EN11.03.04
Controlling the Spacing of Silicon MW Arrays for Radial Junction Solar Cells via Microsphere Lithography

Namwoo Kim, Inchan Hwang and Kwanyong Seo; UNIST, Korea (the Republic of)

Silicon microwires (MWs) have been widely investigated for realizing the high-efficiency silicon solar cells thanks to the outstanding light absorption property and ease of the formation of the radial junction. To achieve the high-efficiency MW based radial junction solar cells, it is necessary to control the structure of MW arrays such as diameter and length of the MWs and spacing between MWs. The structure of MW arrays is generally determined by the process conditions of the optical lithography, which is the method of forming the pattern. However, the patterning process based on optical lithography reaches the fundamental diffraction limit of about 200 nm. Also, the optical lithography process uses photoresist that is harmful to the human body and requires expensive equipment and a specific place, such as a clean room.

In this presentation, we introduced a novel fabrication process of MW arrays through microsphere lithography. In general, the microsphere lithography is the technique to form hexagonally packed ordered arrays of micrometer-sized latex or silica spheres as lithography masks. The spacing between the spheres can be controlled simply by etching the uniformly arranged the microsphere arrays. Also, microsphere lithography has the advantages of low cost, large scale fabrication, and high throughput performance.

We formed a monolayer of polystyrene beads using microsphere lithography on a silicon wafer and controlled the
spacing between the beads through the oxygen plasma etching up to 100 nm. As a result, we successfully fabricated MW arrays with a dense spacing of 100 nm using polystyrene beads monolayer as an etching mask. The fabricated MWs via the microsphere lithography process exhibited an excellent light absorption of 97% at the entire wavelength region (300-1100 nm) even without anti-reflection film layer. The MW arrays with dense spacing enable the use of MWs that are shorter than that of MWs with micro-scale spacing due to the reducing of a reflective surface. Also, the reduction of the MW length has the effect of reducing the surface recombination of the carriers separated by the radial junction of the MW. Therefore, we expect the proposed microsphere lithography would be the essential process for the formation of optimized MW arrays for the high-efficiency radial junction solar cells.

EN11.03.05
Facile Annealing Strategy to Improve Surface Uniformity of Sputtered BaSi2 Films
Yilei Tian1, Ana B. Montes1,2, Olindo Isabella1 and Miro Zeman1; 1Delft University of Technology, Netherlands; 2University of Lisbon, Portugal

BaSi2 is regarded as a promising absorber material in thin-film solar cell applications, due to its excellent optical and electrical properties, including a suitable band gap (~1.3 eV), a high light absorption coefficient reaching 10⁵ cm⁻¹ for photon energy > 1.5 eV, a long minority carrier lifetime τ (~10-27 μs), and essentially elemental abundance and nontoxicity [1]. Besides molecular beam epitaxy and thermal evaporation, sputtering is an industrially applicable technique to fabricate BaSi2 thin films. However, structure transformation and property degradation due to thermal annealing process have become major concerns for obtaining high-quality BaSi2 films [2]. Herein, we present a facile annealing method to suppress the surface oxidation of sputtered BaSi2 process by employing a capping BaSi2 film, which further improves surface uniformity of BaSi2 films.

Depositions of BaSi2 thin films were done in a radio-frequency magnetron sputtering setup. Detailed deposition parameter can be found in our previous research [2]. Glass substrates were used. After the sputtering process, deposited BaSi2 films were subsequently annealed at 600 °C for 30 min in vacuo. During the annealing process, the sample was covered by the other BaSi2 film on the glass substrate, with a film facing film configuration. Raman spectra were recorded on a Renishaw InVia Raman microscope with a 633-nm laser. Raman mapping was done with a scan area of 40 × 40 μm².

Three distinct regions can be observed from the Raman mapping of the BaSi2 sample, which was partially covered by the other BaSi2 film during the annealing, including (i) a uniform region (covered by BaSi2), (ii) a transition region and (iii) a non-uniform region (exposed to the annealing environment). Five Raman peaks of BaSi2 (bands at 276 cm⁻¹, 293 cm⁻¹, 355 cm⁻¹, 376 cm⁻¹, and 486 cm⁻¹) can be found in all these three regions [3]. In addition to those peaks, a peak at 245 cm⁻¹, which might be related to the surface oxidation, and a peak at 519 cm⁻¹, which indicates the formation of Si nanocrystals (NCs), can be observed in the transition and non-uniform regions. Raman intensity maps of peak 245 cm⁻¹ show that surface oxidation mainly occurred in the exposed (non-uniform) region, and more Si NCs are also detected in this region due to the oxidation. Contrarily, the covered region presents nearly no Si NCs and oxide peaks. This suggests that surface oxidation could be effectively suppressed by covering BaSi2 films during annealing. Also, BaSi2 distributes more uniformly in the covered region according to the Raman maps of peak intensity of 486 cm⁻¹ (BaSi2). In the exposed region, a smaller width of peak at 486 cm⁻¹ can be observed, uncovering a better BaSi2 crystalline quality in the exposed region compared to the covered region. Because of the existence of capping BaSi2 layer, less heat can reach to the covered BaSi2, thus leading to a less effective crystallization.

In this annealing method, the capping BaSi2 layer might function in effect as an oxygen-eliminating agent, so that less oxygen exists between those two BaSi2 films. In our configuration, the capping BaSi2 layer is closer to the heater, which heats to a higher temperature the capping BaSi2 compared to the covered BaSi2. Hence, the residual oxygen in the annealing environment is inclined to react with the capping BaSi2 film and this suppresses the oxidation of the covered BaSi2. However, the lower temperature of covered BaSi2 in turn slightly slows down the crystallization of BaSi2. Currently, we are working on the optimization of annealing condition to improve the crystalline quality, such as increasing the temperature, prolonging the duration and adjusting the annealing atmosphere. Further characterizations are being conducted as well.

Enhancement in Efficiency of Solar Cells by Controlling Layers Thickness and Interfacial Layer of Directly Grown Graphene
Malik A. Rehman; Sejong, Korea (the Republic of)

Although semiconductors pn junctions and metal semiconductor Schottky junctions are considered to be constituent elements of photovoltaic and electronic devices. But after the discovery of graphene, immense interest has been developed to make graphene silicon Schottky junction solar cells. The ultrathin 0.33 nm layer of graphene has capability to absorb 2.3% of visible light. These ultrathin layers are not just used as an absorbance material, but due to its essential properties such as tunable work function it increases the Schottky barrier height and built in potential for efficient transport of charge carriers in photovoltaic devices. Recently, graphene/Si Schottky junction solar cells are extensively used to harvest solar energy but high efficiency is limited due to huge surface recombination at the interface. Moreover, during the wet transfer process; wrinkles, surface defects and impurities deteriorate the performance of device. Thus, we propose an ideal approach to directly grow the graphene on planar and textured silicon by using plasma-enhanced CVD, compatible with industrial level applications. Thus, by controlling the thickness of interfacial layer Al₂O₃ and graphene, we achieved highest efficiency. The high-k dielectric layer of Al₂O₃ blocks the electron and eventually reduces the surface recombination at the interface. However, with the optimization of graphene thickness layer, there was an improvement in the work function of graphene, likewise an enhancement in open circuit voltage. Resultantly significantly improving overall device efficiency. Additionally, with control of thickness of graphene on bare silicon, efficiency was increased from 3.6% to 5.51%. Thus, so far with interfacial layer optimized thickness, we achieved highest efficiency of 8.4%. Interestingly, with doping of nitric acid and anti-reflection polymer layer coating of PMMA efficiency is remarkably improved from 5.51% to 9.18%. However, with doping and polymer layer coating the cell stability for longer time was compromised, while, with Al₂O₃ interfacial layer solar cells have excellent stability for more than one year.

Interdigitated Back-Contact c-Si Solar Cells with Non-Conventional Selective Contacts
Benjamin Andres Pusay, Rosa Estefania Almache, Gerard Masmitja, Eloi Ros, Joaquim Puigdollers, Isidro Martin, Cristobal Voz and Pablo Rafael Ortega; University of Politecnica-Catalunya, Spain

The photovoltaic industry is mainly dominated by crystalline silicon (c-Si) based solar cells where, the contact selectivity is usually achieved by doping the wafer surfaces with phosphorus and boron atoms. Several alternatives are used in order to avoid the high temperature, furnace-based, diffusion process. Examples include silicon heterojunction using both intrinsic and doped amorphous silicon films, or the formation of p⁺ and n⁺ regions by laser-firing of doped dielectric films. Nevertheless, in both cases the use of toxic and flammable gases is required. Recently, the use of dopant-free materials based on transition metal oxides like MoOₓ and V₂Oₓ have shown excellent hole and electron selectivity. The use of TiO₂ is an attractive option to form electron-selective contacts, due to its small conduction- and large valence-band offsets (ΔEₓ ~0.05 eV, ΔEᵥ ~2.0 eV), allowing an easy electrons transport through the c-Si/TiO₂ interface while blocking the holes. The introduction of a SiO₂ interlayer at the c-Si/TiO₂ interface improves the quality of the selective contact reaching efficiencies up to 21.6%. The replacement of this high temperature (700 C) SiO₂ layer by other dielectric films deposited a low temperatures is an interesting objective. [1]

In this work we study the properties of Al₂O₃/TiO₂ stacks deposited by Atomic Layer Deposition at low temperature (125 C) as electron transport layers. The goal is to use the optimized Al₂O₃/TiO₂ stacks as selective contacts in interdigitated back-contacted (IBC) c-Si(n) solar cells. Results have confirmed surface recombination velocities below 40 cm/s with implied open circuit voltage values of 675 mV in symmetrical Al₂O₃/TiO₂ test samples. Specific contact resistance values below 3 mΩcm² are also measured. These excellent results pave the way to use these stacks as electron selective contacts on IBC solar cells, in combination with V₂Oₓ hole selective contacts. Experimental and technological details as well as first IBC solar cell results will be presented. [1] X. Yang, et al., Advanced Materials 2016, 28, 5891.

Neural Network to Determine Appropriate Thermocouple Positions in Crystal Growth Furnace

Neural Network to Determine Appropriate Thermocouple Positions in Crystal Growth Furnace
Abderahmane Boucetta1, Kentaro Kutsukake2, Hiroaki Kudo1, Tetsuya Matsumoto1, Takuto Kojima1 and Noritaka Usami1;
1Nagoya University, Japan; 2AIP, RIKEN, Japan
To produce high-quality silicon ingots for solar cells, good control of growth conditions such as the gas flow and the temperature distribution is required. This last has a direct effect on the growth rate, the shape of solid/liquid interface, and thermal stresses. For this concern, it is important to measure the temperatures inside the furnace and around the crucible. However, it is difficult to implement infrared thermometers in directional solidification (DS) furnaces nor installing many thermocouples (TCs) because of the limited space and the movement during the growth. The current study focuses on finding the appropriate positions to install TCs around the crucible that allow us to get the temperature distribution. Due to the presence of abundant variables such as the crucible movement and the temperature of multiple heaters, we decided to solve this issue by a combination of crystal growth simulation and machine learning. Crystal growth experiments with typical conditions were simulated using CGSim software, and the results were used as training data for machine learning. To predict temperature distribution from the limited number of TCs, we have made $2^1C_4 \times 5985$ neural network (NN) models by picking 4 TC positions out of 21 candidate positions on the crucible wall. The NN models consist of 8 inputs (3 heater temperatures: upper, middle and bottom, 4 measured TC temperatures: TC1, TC2, TC3 and TC4, and crucible position) and 21 outputs that correspond to the temperatures distribution on the crucible wall. The minimum loss was obtained at the NN model with the TC positions at 0, 1, 2 and 9 cm from the bottom of the crucible to its top. All the NN models with the ten lowest losses have the TC positions 0, 1 and 2 cm from the bottom of the crucible. This suggests the importance of measuring the temperature around the bottom of the crucible to obtain the precise temperature distribution.

**Boosting Silicon Solar Cell Efficiency through Upconversion-Assisted Enhanced Absorption in Near Infrared**

Nidhi Dua, Rajinder S. Deol, Mohammed S. Reza and Madhusudan Singh; Indian Institute of Technology Delhi, India

Mono- and multi-crystalline silicon-based solar cells form the bulk of global installed photovoltaic capacity (~403 GW in 2018) for commercial power generation, with a 27% cumulative annual growth rate achieved in 2018, with grid parity being achieved in an increasing number of countries. The industry has matured over the last 15 years, going from silicon shortage to solar overcapacity, which has resulted in anti-dumping duties being imposed in several countries. Power conversion efficiencies in silicon are impacted by bulk defects, contacts, solar spectrum mismatch, etc. Specifically, the absorption coefficient in silicon starts declining below $10^3$ cm$^{-1}$ above around 800nm, declining to one-tenth that value near 1000nm. Such material limitations also manifest themselves in a peak in the responsivity of silicon-based detectors. In this work, we report on the development of an upconversion-based absorber (NaYF$_4$: Yb(18%), Er(2%), Gd(15%)) operating near 980 nm used for increasing the efficiency of a commercial solar cell. The absorber was synthesized using thermal decomposition, followed by powder X-ray diffraction (PXRD) measurements which reveal a mostly hexagonal phase closely associated with high upconversion photoluminescence (PL) efficiencies. An ink composed of the product with polystyrene (PS) was formed with a loading ratio of 23% w/w in chloroform. Micro glass slides were cleaned using stepwise solvent clean, followed by a plasma ashing step, prior to spin coating with the ink to deposit a thin film. Scanning electron microscopy (SEM) scans of the deposited reveal a thickness of ~158±33 nm. Atomic force microscopy (AFM) scans reveal that the roughness of the films is approximately 31 nm. When excited with 785 nm laser light (intensity ~560 W/cm$^2$), upconversion emission at green (539 nm) and red (665 nm) is observed using a Horiba/Labram spectrometer. Upon excitation with 980 nm, however, green emission is observed with the naked eye. To test the viability of the idea, we used the coated glass slide in two measurement setups with a low-cost commercial solar cell (the slide placed on top of the solar cell): a) a 980 nm laser diode (Thorlabs, intensity ~ 450 mW/cm$^2$), b) under AM1.5G conditions with a solar simulator (Newport LCS-100). Under direct irradiance of 980 nm laser diode, we observed an enhancement of the short-circuit current ($J_{sc}$) of ~ 25% . The control device in each case was a blank uncoated glass slide placed on top of the solar cell. As expected, the enhancements were found to be somewhat lower with the solar simulator (~7.2% in $J_{sc}$). These increases are preliminary results with unoptimized films in a measurement geometry that is unlike one we envisage for deployed solar cells. We are currently engaged in verifying these initial measurements, and tuning the precise loading ratio with these upconversion absorbers to obtain higher increases in short-circuit currents, and developing films that can be deposited directly on top of the commercial solar cell to minimize incoupling losses.

**Theoretical Study of Tandem Solar Cell Configuration Based on Different Si Allotropes**

Rodion Belosludov and Haruhiko Morito; Institute for Materials Research, Tohoku University, Japan
The growing energy supply demanded by modern society poses challenges to scientists and engineers in that many of the currently used technologies and prospective innovations must be directed in a more sustainable way. The reduction in the use of fossil fuels and replacement with new environmentally friendly energy sources, especially renewable energy resources represents one of the present grand energy challenges. Sunlight is the most abundant free renewable energy source and crystalline silicon photovoltaics are among the leading technologies for solar power conversion. The efficiency of the solar cell mainly depends on the band gap and is limited to a maximum theoretical power conversion of ~ 31% [1]. One possible strategy to improve efficiency is to optimize the response of the photoactive materials at shorter wavelengths. The combination of high-efficiency solar cells in a tandem configuration on a Si platform using thin film III–V materials as well as perovskites has recently attracted great attention [2]. Silicon clathrates are inclusion compounds that consist of a Si cage-like framework with a direct 1.9 eV band gap and can be considered for photovoltaic applications including thin-film single-junction devices such as Si clathrate on c-Si for all-Si tandem cells.

The structural optimization and electronic properties of Si clathrates with cubic structures I (CS-I) and II (CS-II), silicon surface and Si clathrates on silicon surface have been performed using first-principles calculations within the framework of density functional theory (DFT).

The atomic optimization of Si clathrates with and without Na atoms as well as Si (001) surface were carried out. The obtained results showed that the band gap of pure Si clathrate is larger in comparison of band gap of Si surface. The present of sodium shifts the Fermi level to conduction band which indicates the importance of guest removing from clathrate framework. The reconstruction Si clathrate on c-Si surface was performed using ab-initio molecular dynamic simulations during 5 ps at 300 K. The clathrate structure remains cage-like framework after deposition of Si surface and the electronic structure of tandem configuration is changed due to removing dangling bonds on the surface. Thus, the present study revealed the possibilities for modifying the electronic and optical properties of crystalline silicon photovoltaics by deposition of thin-film Si clathrate.

Effect of Buffer Layer Changing on Characteristics of the Tandem Solar Cell of Dye-Sensitized Solar Cell and Silicon Solar Cell Masaya Ando, Shinya Kato, Naoki Kishi and Tetsuo Soga; Nagoya Institute of Technology, Japan

Since the conversion efficiency of single junction silicon (Si) solar cells is close to the theoretical limit, the application of tandem solar cells with stacking order in different band gap energy (E_g) has attracted the attention. It is expected that the solar cell performance can reach around 40% efficiency by combining the silicon solar cell (E_g=1.12 eV) as the bottom layer and dye-sensitized solar cell (DSSC) based on the N719 dye (E_g=1.7 eV) as the top layer for tandem solar cell structure. In that cell, poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)/PEDOT:PSS can be used as the buffer layer between the top cell and bottom cell which involved the silver (Ag) grid and passivation layer component. Although the DSSC/Si tandem solar cells have been investigated so far, there is no detailed information near the PEDOT:PSS of this tandem solar cell. Therefore, here, we studied the effect of changing in property of buffer layer containing PEDOT:PSS on the solar cell characteristics.

To make the solar cell device, firstly, we prepared the electron transport layer by depositing titaniumdioxide(acetylacetonate)/TiO_2 via spin-coating which was followed by nanoporous TiO_2 (P25) deposition via doctor blade method onto FTO glass substrate. Then, this layer was annealed at 450°C for 30 minutes and soaked in N719 dye for 18 hours to fabricate the DSSC electrode. Secondly, for Si solar cell preparation, the 80nm-thick ITO was sputtered on a pn junction Si wafer. Thereafter, Al electrode was deposited on the back surface of Si wafer by thermal evaporation method. Also, PEDOT:PSS (PH1000) layer with dimethylsulfoxide (DMSO) addition was coated on ITO by spin-coating. Finally, the performance of DSSC/Si tandem solar cell was measured by AM 1.5 solar simulator after an iodine electrolyte injection.

As a Si solar cell, a pn junction Si wafer (pn-Si) and a pn junction Si wafer with Ag grid and a passivation layer (Ag-pn-Si) were prepared. When the only PEDOT:PSS layer was deposited between the top cell and the pn-Si bottom cell, the open-circuit voltage (V_op) of tandem cell was more than 1 V, whereas the V_op of DSSC and Si solar cell before stacking were 0.6-0.7 V and 0.5 V, respectively. On the other hand, if Ag-pn-Si is introduced as a bottom cell, the device stability became poor since it is difficult to protect the electrode corrosion due to the iodine electrolyte usage. Although the only deposited ITO layer in-between the top cell and bottom cell could greatly
reduce the $V_{oc}$ up to 0.2 V, interestingly, the introduction of ITO layer under PEDOT:PSS has succeeded in electrode protection from corrosion which has improved the photovoltaic properties. Based on these results, it is noted that the improvement of buffer layer in the DSSC/Si tandem solar cell can increase the conversion efficiency of photovoltaic device. Furthermore, PEDOT:PSS film conditions on the photovoltaic properties of DSSC/Si tandem solar cell will be discussed later.

**A Study on Circuit Modeling for Shadowing Loss Analysis of Shingled Photovoltaic Modules**  
Jisu Park, WonJe Oh and Jaehyeong Lee; Sungkyunkwan University, Korea (the Democratic People's Republic of)

In the case of the shingled solar module, the power decrease according to the shading is large because of the reduction of the cell area due to the division. Therefore, it is necessary to develop a simulation method with high accuracy according to shading ratio and type to analyze the power loss and to design a module structure that shows stable power even when shading.

Based on the measured photo I-V data, the cell strips circuit is modeled using a double diode model, and the shingled string circuit is modeled by serial connection of the electrical equivalent circuits of the cell strips according to the number of interconnection. Since the cell strips are bonded by a conductive adhesive, the cell strip circuits are connected in series via the RECA corresponding to the ECA resistance component. Next, circuit modeling for shading loss analysis of shingled strings is performed. Finally, the accuracy of shading loss analysis circuit modeling is verified by comparing simulation results with actual measured values.

Based on the accurate shading loss analysis method, the shading loss according to the module structure is analyzed by applying the bypass diode according to the serial, parallel, and parallel / parallel arrangement of the string. We then design the module structure with low shading loss by calculating the power rate in shading.

EN11.03.13  
**A Study on the Design of Solar Cell Electrode Structure for High Power Photovoltaic Module Fabrication**  
WonJe Oh, Jisu Park and Jaehyeong Lee; Sungkyunkwan University, Korea (the Republic of)

New technologies for fabricating high-power modules include a cell dividing and bonding technique. This technique divides and joins cells into a string arranged in series and parallel to produce a module. Since the bus bar structure is not visible, the effective area for absorbing light increases, and since there is no space between cells, modules with high density can be manufactured. Therefore, modules with higher output than existing modules can be manufactured in the same area. The module manufactured by the dividing and bonding technique is called a shingled PV module, and this module requires a new electrode structure for dividing and bonding. Therefore, we designed the front electrode structure suitable for the shingled PV module by calculating the power loss according to the number of cell divisions and the number of fingers. Simulation results show that the number of fingers at maximum efficiency decreases as the number of divisions increases. This is because as the number of divisions increases, the distance between the busbars becomes narrow, so that the current collection of one finger between the bus bars becomes smaller. Therefore, in order to collect the same amount of current, the interval between the fingers must be widened, which means a decrease in the number of fingers. Therefore, as the number of divisions increases, the maximum efficiency is obtained in the case where the number of fingers is small. In addition, the actual solar cell of the electrode pattern having the optimum number of fingers for each type of divided cell is manufactured and analyzed. In order to investigate the applicability of the solar cell with the designed electrode structure to the shingled PV module, we investigated the characteristics change after bonding the cells divided by the laser with the conductive adhesive.

**Investigation of Silicon Carbide Schottky Barrier Diodes with Silicon Nitride Interface Layer**  
Hasan H. Gullu¹, Ozge Bayrakli Surucu², Makbule Terlemezoglu³,³,⁴, Seda Kayra Gullu³,⁵ and Dilber Esra Yildiz⁶; ¹Atilim University, Turkey; ²Kirsehir Ahi Evran University, Turkey; ³Middle East Technical University, Turkey; ⁴Tekirdag Namik Kemal University, Turkey; ⁵Tubitak Space Technologies Research Institute, Turkey; ⁶Hitit University, Turkey

Silicon carbide (SiC) has attracted considerable attention for photonic and electronic device applications due to inherent electrical and high thermal conductivity, indirect wide band gap, large critical breakdown electric field, high saturation electron drift velocity and high chemical stability in the use of metal-semiconductor (MS) Schottky barrier diodes (SBDs) with and without interfacial layer. It has also superior characteristics that present alternatives
to the inherent problems in the use of oxide and carbon based catalysts. In this study, a novel metal-insulator-semiconductor (MIS) diode including a silicon nitride (Si$_3$N$_4$) layer was investigated to improve SiC based MS diode. Although there are many reported work on the electrical characteristics of this kind of wide band gap semiconductor diodes under the effect of insulator layer, it is still an open research area to develop a complete understanding on contribution to the electronic characteristics. Recently, high dielectric constant materials have attracted considerable attention as an alternative interfacial layers for their photonic and electronic device applications at metal/semiconductor interface. Under this aim, the current-voltage, capacitance-voltage and conductance-voltage characteristics of MIS 4H-SiC diodes were analyzed and compared to the MS diodes. The MS heterojunction diode was fabricated by thermal evaporation of Au metal onto the n-4H SiC wafer substrate and Si$_3$N$_4$ layer was deposited into the metal/semiconductor interface by magnetron sputtering method. Forward and reverse biasing behavior of diodes were discussed according to thermionic emission with Gaussian distribution of barrier height and Schottky emission models, respectively. Device parameters as, barrier height, ideality factor, interface states, and series resistance were also calculated comparatively among these two diodes. The capacitance values for MS diode was found in decreasing behavior from ideality with crossing the certain forward bias voltage point whereas rapid increase in conductance values with the increasing voltage was observed for all fabricated diodes. Under all these works, high device performance was considerably observed from the Au/n-4H SiC diodes with Si$_3$N$_4$ interfacial insulator layer.

EN11.03.15

Defects in a-Si for Electronically-Coupled Upconverters in Silicon Solar Cells Wenjie Yang and Daniel Macdonald; Australian National University, Australia

The electronically-coupled upconverter (ECUC) is a novel concept for harvesting sub-band gap photons in silicon solar cells through the impurity photovoltaic effect [1]. Unlike conventional intermediate band approaches [2] in which mid-gap defects/impurities are introduced to the bulk of the device, this approach utilises a wider-band gap upconverter layer (e.g. a-Si) situated at the rear of a conventional Si solar cell in which the defects are contained. The band offset between the upconverter and the Si-bulk sweeps sub-band gap photocarriers generated in the upconverter into the base whilst isolating carriers generated in the base from entering the upconverter, allowing a net gain in carriers.

While a-Si ECUC layers containing ion-implantation-induced defects have been shown to absorb at sub-band gap wavelengths [3], it remains to be seen whether sub-band gap photocarriers can indeed be generated. In this work, we use a range of different implantation and post-implantation annealing conditions to control the type and concentration of defects in the a-Si. We investigate the generation of carriers in a-Si ECUC layers by measuring the band-to-band photoluminescence from both the Si substrate and the a-Si layer itself, under sub-band gap laser excitation of a few kW/cm$^2$. We also use time-resolved photoluminescence to study the recombination dynamics within the a-Si layer. Finally, we explore the possibility of incorporating other impurities into the ECUC layer to enhance its sub-band gap photoresponse.

Fabrication of poly-Si Membranes Using Water-Soluble Sacrificial Sr$_3$Al$_2$O$_6$ Oxide Layers Jungkwu Kwon, Changhoon Jeong, Jungi Min and Sangwoo Ryu; Kyonggi University, Korea (the Republic of)

Recently facrication of heterostructure membranes using sacrificial layers has been widely investigated as it can be used to understand the effect of interfacial strain inside the bottom-up heterostructures. In addition, similar to 2D materials like graphene, a transfer method of a thin heterostructure membrane into other devices is simulating industrial interest. However, most of the previous works report only limited size of the membranes. In this study, we show a cost-effective way to fabricate large scale poly-Si membranes grown ona water-soluble Sr$_3$Al$_2$O$_6$ (SAO) sacrificial buffer layer. SrCO$_3$ and α-Al$_2$O$_3$ are mixed at a molar ratio of 3:1 and calcined at 1200°C to synthesize
SAO. The SAO slurry is prepared by mixing the synthesized SAO powder with PVB and ethanol, and a 10 μm-thick SAO layer is deposited on a Si wafer with a micrometer film applicator and then sintered 650°C. After the deposition of Si on top of Si on top of the SAO layer using various deposition method, the dissolution of SAO into water. XRD analysis reveals that poly-Si membranes are obtained. In order to explore the possible application to solar cells, photovoltaic properties of the poly-Si membranes such as light absorption, current density, open circuit voltage and minority carrier were examined.

EN11.03.17
Organic/Inorganic Hybrid Coatings of Silicon Solar Cell Back Sheet to Reduce Moisture Permeability
Dongwook Jung, Jungi Min, Eunjin Jang and Sangwoo Ryu; Kyonggi University, Korea (the Republic of)

Al₂O₃ is one of the widely investigated materials for preventing moisture permeation of electronic devices. However, a phase transition occurs when it is exposed to a harsh environment making a channel inside through which water can permeate. In this work, a silane-based polymer (Silamer) layer is introduced to solve this problem as Al₂O₃ is deposited on a back sheet (BS) of silicon solar cells. Al₂O₃ was deposited at 70 °C by atomic layer deposition (ALD) and Silamer was spin-coated followed by curing in low vaccum at the same temperature. During this process, the Silamer layer forms a three-dimensional SiO₂-embedded organic layer and planarizes the BS covering pin-hole defects, which reduces the moisture permeation. By adjusting the thickness and the structure of the deposited layers, Silamer (400 nm) / Al₂O₃ (40 nm) / BS is found to be the most effective for waterproofing with the lowest WVTR value through Ca tests. As it is applied to silicon solar cells, this organic/inorganic hybrid coating shows to reduce potential-induced degradation effectively which is mostly caused by ion migration through the channels formed by the moisture permeation. In addition, alternative deposition methods of Al₂O₃ other than ALD for scaling up will be discussed.

EN11.03.18
First-Principles Study in Search for Stable Dopants in Hyperdoped Silicon for Infrared Photoresponse
Naheed Ferdous and Elif Ertekin; University of Illinois at Urbana-Champaign, United States

Silicon (Si) based solar energy conversion systems have a large variety of applications, including photovoltaics, photodiodes and photodetectors. The conversion efficiency depends on the absorption of incoming solar energy. Unfortunately, photoresponse of Si is limited by its band gap (1.12 eV) that does not allow absorption below visible wavelength of sunlight. For effective solar energy conversion to electrical signal, enhanced photoresponse has been achieved by doping silicon beyond its solid solubility limit. The highly non-equilibrium supersaturation process is known as hyperdoping that includes ion implantation followed by pulsed laser melting and rapid resolidification. The high concentration of dopants modifies the optoelectronic properties of Si by forming defect levels within the forbidden band gap, but it comes with a price of metastability. Most recently gold (Au) has gained renewed interest as an impurity in Si that is intentionally introduced to extend optical absorption towards infrared region. However, experimental evidence showed that upon thermal relaxation, the absorption suddenly drops down. This suggests that the solubility and stability of dopants in Si are equally important as infrared absorption. Therefore, a systematic study is essential to identify possible dopants that have either high solubility or low diffusivity so that it becomes kinetically trapped during thermal relaxation and preserves the high optical absorption. In this work, we use first-principles density functional theory (DFT) to obtain the possible defect configurations of candidate dopants in Si. Primarily late 3d transition metals are chosen as they provide defect levels in the middle of the band gap of Si and are promised to provide infrared absorption. Among them, manganese (Mn), cobalt (Co) and silver (Ag) are chosen from optical point of view. On the other hand, from the solubility point of view, nickel (Ni) and copper (Cu) shows better solubility (1 and 2 orders of magnitude higher) than Au, which are group IB materials. Further, we analyze the optical absorption of possible equilibrium defect configurations in conjunction with their solubility. Finally, we discuss how diffusivity can play a role during thermal relaxation and consequently on optical absorption.
High-Volume Production of Ultra-Low-Cost Silicon Absorber Materials Manufactured via Kerfless Direct Wafer® Process

Adam Lorenz, Jasmin Hofstetter, Ralf Jonczyk, Ray Fraser, John Linton and Ali Ersen; 1366 Technologies Inc., United States

As the PV industry strives toward terawatt scale, addressing the last remaining cost centers of the crystalline silicon value chain is essential to achieving the extremely low levelized cost of electricity (LCOE) required to drive solar's adoption. To date, improvements within the value chain have focused primarily on cost reduction, with most technical contributions happening on the surface of the material, at the cell level. New fabrication methods have emerged that change this dynamic and allow for significant strides in both cost reduction and technical advancements with the absorber materials themselves.

Alternative absorber fabrication methods such as the Direct Wafer process are synergistic with lower cost and higher absorption, as well as more efficient energy usage. In Direct Wafer manufacturing, which has reached high-volume production, wafers are grown one-by-one directly from a small reservoir of molten silicon in a high-purity growth environment. Direct access to the wafer-forming surface and the molten silicon reservoir allow modifications of individual wafer properties, customized for a given cell architecture. Efficiency parity with high-performance cast multi-crystalline wafers has been demonstrated on a PERC production line at 20.5% average efficiency. This discussion will also demonstrate that Direct Wafer technology is synergistic for use with future cell architectures such as TOPCon that are insensitive to bulk resistivity and require high minority carrier lifetime or device architectures such as tandem which necessitate a low-cost base material with bandgap suited for long wavelength absorption.

The high-purity growth environment of the Direct Wafer process limits the introduction of dopant impurities into the feedstock and allows high bulk resistivity beyond 100 Ω-cm. Since wafers are also grown one-by-one, bulk resistivity can also be easily tuned and targeted around virtually any resistivity. This allows for a much tighter distribution than what is possible in ingot-based wafers where resistivity distribution is governed by solid-liquid segregation leading to a wide range of resistivities along the ingot height.

The low impurity concentration in Direct Wafer product is also reflected in the high effective lifetime that can be achieved. Electron lifetime in Direct Wafer product increases with increasing resistivity and effective lifetime >1 ms have been validated. Advanced cell architectures like PERT and TOPCon cells require lifetimes of milliseconds to achieve their efficiency entitlement and leverage potential LCOE advantages despite increased cell production cost. Currently, mostly high-cost n-type mono-crystalline wafers are used for advanced cell architectures because of higher lifetime in n-type silicon. With Direct Wafer product, there is considerable potential to accelerate the adoption of higher efficiency device architectures as low-cost, high-resistivity Direct Wafer product replaces the more expensive n-type mono wafer.

Advanced, low-cost wafer manufacturing also provides a course to cost effective tandem cell fabrication. The technical roadmap for the Direct Wafer process provides for a cost of just $0.12 per wafer through a combination of ~1.5g/W silicon utilization and lower non-silicon conversion costs than current ingot-sawn wafers. This base, combined with low-cost cell processing tailored for long wavelength absorption at lower current, makes an economically favorable candidate for realizing commercial tandem modules that exceeds the performance of today’s best single-junction silicon modules at a lower total cost/watt.

An inherent high-purity growth environment and unique features distinguish Direct Wafer technology from standard sawn wafers. The benefits of a more efficient approach to fabrication coupled with the ability to access the raw material at the melt level present an opportunity to leverage low-cost wafer technology with numerous future advanced cell architectures.

Investigation of the Role of Hydrogen in Light- and Elevated Temperature-Induced Degradation in p-Type Silicon through Intentionally Inducing Defects with Tabula Rasa

Abigail R. Meyer1,2, Vincenzo LaSalvia2, William Nemeth2, Matthew Page2, David L. Young2, Paul Stradins2 and Sumit Agarwal1; 1Colorado School of...
Currently, the photovoltaic (PV) market is dominated by boron-doped, or $p$-type, silicon (Si) solar cells. More specifically, the Si PV market is moving from a more traditional architecture, the aluminum back surface field (Al-BSF) solar cell to a more advance structure, the passivated emitter rear contact (PERC) solar cell. The PERC cell features exceptional surface passivation and therefore, higher efficiencies compared to the Al-BSF. However, with the surface no longer limiting the PERC cell, bulk lifetime becomes increasingly more important to raise efficiencies. One source of recombination within the PERC Si bulk is light and elevated temperature induced degradation (LeTID) where cells and modules experience a decline in minority carrier lifetime when exposed to illumination at elevated temperatures. LeTID was discovered only ~5 years ago and therefore, the degradation and regeneration mechanism, along with the defect structure, are unknown. A preliminary solution to LeTID has been discovered [1] but requires intense illumination and high temperatures and can take ~15 hours to complete. In order for $p$-PERC cells to continue to dominate the PV market, we must ensure their efficiencies rise and remain stable throughout their time in the field.

LeTID can result in a ~10% relative efficiency loss of $p$-PERC solar modules over their lifetime in the field [2]. The defect which causes LeTID is thought to be hydrogen, and more specifically, related to the over hydrogenation of cells during the firing process to create contacts. Many empirical studies have been conducted to link hydrogen to LeTID, but no atomistic studies have been brought forward to solidify this hypothesis. In this work, we aim to study the role of hydrogen in LeTID by intentionally inducing defects in boron-doped float zone ($p$-FZ) silicon (Si) and therefore, manipulating the amount of hydrogen that is held in the Si bulk after fast firing. We hypothesize that by allowing the Si bulk to hold more hydrogen, samples will experience increased degradation caused by LeTID compared to samples without intentionally induced defects.

References
stability. Furthermore, they have shown specific colors owing to the colors of polymers or dyes. To address this issue, some researchers have been developed near infrared (NIR)-absorbing STSCs to fabricate neutral-color STSCs like that of glass. However, NIR-absorbing STSCs have been shown very low PCE under 1% until now. Accordingly, a different approach is required to develop STSCs with neutral color, high PCE, and long-term stability.

As a method to develop new-concept neutral-color STSCs with high PCE and stability, crystalline silicon (c-Si) based STSCs can be considered. c-Si would be one of the best candidates to develop STSCs because conventional c-Si solar cells are known to exhibit high PCE and long-term stability compared to other solar cells. However, the development of c-Si based STSCs is extremely challenging due to the opaque characteristic of c-Si wafers with thicknesses of 200 µm. To fabricate STSCs using c-Si, thinning of c-Si has been considered as a method to increase transparency. However, as the absorption of long-wavelength light is extremely limited in thin films, their application to solar cells is not suitable. In addition, a thin c-Si film has a particular color because of absorption spectrum cutoffs in the visible light wavelength range.

In this presentation, we show a novel approach to develop neutral-color transparent c-Si solar cells. First of all, we have developed a neutral-color transparent c-Si substrate using a 200-µm thick c-Si wafer, which is known to be opaque. Transparent c-Si substrates were fabricated by placing hole-shaped light transmission windows on a bare c-Si wafer. These windows were designed to enable the transmission of all incident visible light through the substrate, resulting in a colorless substrate. In addition, the spacing between the holes was appropriately selected by considering the minimum angle of resolution for humans to ensure that the individual transmission windows are not visible to the human eye. A light absorption area was also designed on the substrate to efficiently absorb incident light of the spectral range between 300 nm and 1100 nm. The transmittance of the transparent c-Si substrate was systematically tuned from 20% to 50% under the full solar spectrum. The STSCs fabricated with the substrate exhibit a PCE of up to 12.2%, with $J_{sc} = 29.2$ mA/cm²; $V_{oc} = 588$ mV; and $FF = 71.1\%$ with a transmittance of 20%. The cell performance of the transparent c-Si solar cells is higher than those of other neutral-color semi-transparent solar cells reported thus far. Hence, our novel c-Si STSCs presents a unique opportunity to develop next-generation neutral-color STSCs which would satisfy high efficiency as well as high stability. Furthermore, we believe that this study makes a significant contribution to not only photovoltaics fields but also various transparent optoelectronics.
etch process is the protection of the passivation layer during the patterning, which eliminates a wet cleaning step and an additional deposition of the intrinsic a-Si:H layer. We report for this simplified process flow the best device with 22.7% efficiency (22.4% average efficiency and area of 2x2 cm²) and a $V_{OC}$ of 728 mV demonstrating high-quality passivation.

Second, we discuss the challenges of interconnecting IBC cells, notably connecting opposite cell polarities in the same plane with selective isolation and the necessity to use low-temperature processing. To develop an industrially relevant technology, low-cost and simplicity are essential but unmet requirements by current solutions. To overcome this challenge, we introduce the 3D woven interconnection concept based on standard module materials. Polymer encapsulant is interwoven with low-temperature solder-coated metal ribbons to form a three-dimensional woven fabric. The encapsulant provides the electrical insulation between ribbons of opposite polarity. Part of the ribbons electrically interconnect neighboring cells while ribbons in a perpendicular direction connect the cell metallization to the cell-to-cell ribbon, hence creating a two-level metallization. Additionally, the co-development of the materials and the lamination process enables a combined soldering and module lamination in one process step and within the limits of industrial laminators. We will demonstrate the adaptation of this technology to bifacial IBC cells as well as to busbarless cell design. We report on the properties of the interconnect in single-cell and mini-modules demonstrating < rel. 2% FF loss, Rsh> 7MΩ in isolation tests and showcase its stability in over 400 thermal cycles.

Third, we present our latest development in perovskite device stacks focusing on $\text{Cs}_{0.15} \text{(CH}_3\text{N}_2)_{0.85} \text{Pb(I}_{0.71} \text{Br}_{0.29})_3$ (CsFAPbIBr) as a photo-stable mixed-halide with a wide bandgap (1.72 eV). We show that the key to achieving high $V_{OC}$ is the careful control of perovskite-hole transport layer interface. Through effective interface passivation, we fabricate 1.72 eV mixed-halide perovskite solar cells with a $V_{OC}$ deficit as low as 0.5 V. We demonstrate in single junction semi-transparent perovskite devices with efficiencies of 11.7% without passivation and 13.8% with Al$_2$O$_3$ passivation layer in small area devices. This device also maintains an average transmittance of 90% in the wavelength range of 700 – 1200 nm making it an ideal top cell in 2 or 4-terminal tandem devices, which consequently contributes to a record 27.1% efficient perovskite/IBC c-Si tandem cell (area: 0.13 cm²), and 25.3% efficiency for 4 cm² perovskite minimodule on 4 cm² c-Si IBC cell. In the end, we will also report on upscaling of perovskite modules up to 30x30 cm² area.

Investigating the Contact Mechanism for Screen-Printable Ag/Cu Paste in the Si Solar Cell Using Microstructural, Optical and Electrical Analyses Keming Ren, Ye Tang, Yong Zhang and Abasifreke Ebong; University North Carolina at Charlotte, United States

The cost of photovoltaic electricity hinges on the metallization of the Si solar cells, which dominate today’s commercial cells. In a bid to further reduce the cost of the metallization, one of the feasible methods is to use cheaper metals to replace the dominant screen-printed Ag metal contacts, which account for the most cost of the metallization. Among all the metals, Cu is considered as an excellent potential alternative due to its similar conductivity (1.7 μΩ-cm for copper, 1.6 μΩ-cm for silver) but ~90 times less cost. However, Cu is known to diffuse into Si at high temperature, leading to shunt the junction and reduce the minority carrier lifetime in the cell. Thus, researchers have used plated Ni/Cu in which Ni acts as a barrier through NiSi formation to block Cu from diffusing into Si. But, because of the involving processing steps and reliability issues, this technology is not adopted. Since screen-printing technology is high-throughput and simple to manufacture solar cells, the most cost-effective method is, therefore, replacing the Ag or part of the Ag in the paste by Cu. But this method puts a strict requirement to the nature of the paste, in particular, that prevents the Cu from diffusing into Si during the high-temperature sintering of the contacts. Thus, it is important to investigate the microstructural (SEM, TEM), optical (Raman Spectroscopy) and electrical (conducting AFM) properties of the Ag/Cu/Si interface through one-step atmospherical firing process and thus to understand the contact mechanism of the Ag/Cu paste. This work, therefore, reports on the microstructural analyses (SEM, TEM) of the Ag/Cu/Si interface, supported by the Raman Spectroscopy and the conductive AFM. The preliminary studies showed that there was no evidence of Cu diffusion into the Si and Cu was found only in the reformed glass after high-temperature sintering. The conductive AFM revealed the contact mechanism was through the Ag crystallites grown in the Si. The electrical output parameters of the solar cell corroborated the microstructural, optical and electrical analyses.

Performance and Stability of Monofacial and Bifacial PERC Silicon Cells, with Comparison to Al-BSF
Jennifer Braid, Eric Schneller, Menghong Wang, Alan Curran, Jiqi Liu, Nick Bosco, Jennifer L. Carter, Raymond Weiser, Laura Bruckman, Bryan D. Huey, Kristopher Davis, Jean-Nicolas Jaubert and Roger H. French; 1Case Western Reserve University, United States; 2University of Central Florida, United States; 3National Renewable Energy Laboratory, United States; 4University of Connecticut, United States; 5Canadian Solar, Inc., China

Passivated emitter and rear contact (PERC) silicon photovoltaic cells comprise over 50% of all solar cells manufactured in 2019, and are expected to completely replace traditional aluminum back surface field (Al-BSF) cells by 2023. In addition to higher power yield due to reduced recombination at the rear contact, PERC cells can easily be manufactured with monofacial or bifacial architectures. However, the additional passivating dielectric layer in PERC cells, as well as the reduced rear-side metallization in bifacial cells, calls into question the long-term durability of this technology versus the established Al-BSF cell.

Here we compare the performance of monofacial and bifacial PERC cells, benchmarking against Al-BSF, both as bare cells, and in minimodules through damp heat exposure. Cells are characterized with illuminated I-V curve tracing, Suns-Voc, and electroluminescence, as well as photoluminescence and spatially resolved external quantum efficiency. Cell fragments are also investigated with photoconductive atomic force microscopy.

In this work, we show that PERC cells have greater stability through damp heat exposure than Al-BSF. Bifacial PERC cells also show surprisingly high mechanical durability compared with full rear side aluminized cells. Al-BSF cells show greater corrosion and resulting resistive losses than PERC cells when encapsulated with EVA. Performance loss due to additional degradation modes are also quantified. Comparison of electroluminescence and photoluminescence images of mini-modules, as well as external quantum efficiency measurements, reveal the underlying degradation mechanisms for each cell type. These results are confirmed with photoconductive atomic force microscopy, with which electrical properties of the cell including Voc and Isc are mapped cross-sectionally to study operational changes of the degraded cell.

Modified Laser-Fired Contact Process for Efficient PERC Solar Cells Inho Kim, Jae Myeong Choi and Beomsic Jung; Korea Institute of Science and Technology, Korea (the Republic of)

A laser-fired contact (LFC) process is one of the techniques for making local electrical contacts at the rear side of PERC (passivated emitter and rear cell) solar cells. In the LFC process, opening of the passivated dielectric layers and alloying of Si and Al need to be made in a single step laser process. For this reason, the LFC process is accompanied by the loss of Al and the laser damage to the Si wafer. In this study, we present a novel multi-step LFC process combining the conventional LFC and laser induced forward transfer (LIFT) processes. The modified LFC scheme we proposed consists of three steps: (1) opening of the passivation layers and partial alloying of Al-Si, (2) additional deposition of Al on the local contact holes, (3) post laser firing of the transferred Al. Applying the modified LFC process to the PERC cells, we demonstrate the effective recombination velocity of the laser processed wafers can be remarkably reduced while maintaining the low contact resistance. The best of the PERC solar cell with the modified LFC process exhibited 20.5% of an efficiency while the conventional LFC cell showed 18.6%. The efficiency gains of the modified LFC PERC cells was largely contributed by the enhanced open circuit voltage (Voc) and fill factor (FF).

Metallization Pastes for n-Type Solar Cell Mass Production toward >23% Efficiency Qijie Guo, Guangyao Jin, Mia Li, Fangqing Guo, Bingfei Cao, Youyong Xu and Paul D. VerNooy; DuPont, United States

Significant growth of n-type solar cell with passivated contact technology is expected in the coming few years. However, whether it will become the mainstream technology to replace the dominant position of p-type in the market will be subject to the total cost of ownership improvement throughout the whole value chain engagement. Today p-PERC cell efficiency is approaching 22.5%; n-type needs to demonstrate >23% efficiency with good yield and cost to be competitive. Passivated contact is a key technology for n-type in the drive for higher efficiency, however, metallization pastes specially developed for passivated contact is needed to achieve performance and cost competitiveness in mass production. DuPontTM, a leading innovator in metallization technology for Si solar cells, is developing a total package metallization solution for n-type passivated contact structure to help our customers stay ahead in this next wave of high efficiency technology upgrade after PERC. A new generation Solamet® PV3Nx with improved performance on contacting ultra-lightly doped boron emitter and an upgraded PVD2x busbar paste
were developed to be suitable for both double printing and dual printing applications. In addition, an innovative formulation was developed to minimize the recombination loss on thin polycrystalline silicon film for rear side metallization. Overall, we believe innovations in metallization technology will lead to a potential efficiency of >23% for n-type in mass production.

Solar Fuel Production Using Combined Silicon-Based Photovoltaic-Electrochemical Systems—Challenges for Efficiency, Stability and Up-Scaling Friedhelm Finger, Vladimir Smirnov and Katharina Welter; Forschungszentrum Juelich, Germany

Preparing chemical fuels from natural resources by using renewable energies and thereby replacing the fossil fuel exploitation with all its detrimental consequences is and will be a major research activity and challenge now and in the near future.

One approach which already receives considerable attention is the generation of hydrogen from water via electrolysis using solar cells as a power source. We have been concerned with this concept: an integrated photovoltaic (PV) - electrochemical (EC) device feasible for stand-alone operation under sunlight illumination, yielding high solar-to-hydrogen (STH) conversion efficiencies, using preferably natural abundant and non-toxic materials and having an up-scalable technology.

As solar cell material we have chosen thin film silicon (hydrogenated amorphous and microcrystalline silicon). The thin film silicon approach has the unique features of i) an easy vertical and lateral integration of multi-junction cells which allows for tuning of the required output voltage while making very efficient use of the solar spectrum, ii) an already established scalable production technology, and iii) earth-abundant and non-toxic photovoltaic base materials.

Alternatively, we have investigated series connected crystalline silicon wafer based solar cells.

We will show and compare the performance of PV-EC coupled systems with STH conversion efficiencies of close to 10% and 14% for thin film and crystalline silicon solar cells, respectively, and demonstrate the development and up-scaling of related PV-EC cassette systems including the preparation of earth abundant based catalyst materials.

The results can be used to discuss the concept of a closely coupled PV-EC system vs. “wired” systems where a photovoltaic module is connected to a possibly locally remote electrolyzer, and to estimate annual hydrogen production for typical outdoor illumination conditions.

2:00 PM EN11.06.02
Overview of Si Tandem Solar Cells and Approaches to PV-Powered Vehicle Applications Masafumi Yamaguchi1, Kan-Hua Lee1, Kenji Araki1, Nobuaki Kojima1, Yoshiho Ohshita1, Taizo Masuda2 and Akinori Satou2; 1Toyota Technological Institute, Japan; 2Toyota Motor Co., Japan

Development of high-efficiency solar cell modules and new application fields are significant for further development of PV (photovoltaics) and the creation of new clean energy infrastructure based on PV. Especially, Si tandem solar cells such as III-V/Si, chalcogenide/Si, and perovskite/Si tandem cells are desirable for high-efficiency and low-cost cells. We surveyed the progress of heterogeneous Si tandem solar cells and analyzed the prospects of their conversion efficiencies by estimating ERE (external radiative efficiency) as a measure of non-radiative recombination loss. Although 35.9% efficiency under 1-sun has been demonstrated with InGaP/GaAs/Si 3-junction tandem cell, 41% efficiency will be realized with the 3-junction Si tandem solar cells by improving ERE from 3% to
Regarding 2-junction Si tandem cells, 32.8% and 28% have been achieved with GaAs/Si and perovskite/Si tandem cells, respectively. The 2-junction Si tandem cells have an efficiency potential of 35% by realizing 20% ERE. The authors have demonstrated 28.2% with mechanically stacked InGaP/GaAs/Si tandem solar cell. Most recently, Sharp has also achieved 33.0% efficiency with 3.604cm² InGaP/GaAs/Si 3-junction solar cells by using the mechanical stack.

High-efficiency and low-cost solar cells such as Si tandem cells have great potential for PV as a vital energy source in mobility application where the installation area is limited. The NEDO established a “PV-Powered Vehicle Strategy Committee” for investigating the potential for contributing to reducing CO₂ emissions in the transport sector by installing high-efficiency solar cells on automobiles. According to the IRENA’s and NEDO’s reports, new broader PV market with more than 10GW and 50GW in 2030 and 2050, respectively are expected to be established. Cumulative PV capacity for PV-powered vehicles will be 50GW and 0.4TW in 2030 and 2050, respectively. According to statistics by the Ministry of Japan, 2/3 of the family car runs less than 30 km per day in Japan. Namely, the average annual energy that is needed to the light-weight family car powered by sunlight will be 642 kWh/year. 642 kWh/year is not an incredible value as well as a promising because the use of more than 30 % of high-efficiency PV enables the society that majority of the family cars run by the sun and without supplying fuel. Thus, we are developing high-efficiency and low-cost solar cells and modules for automobile applications.

Approaches on automobile application by using III-V/Si tandem, partial concentration, and static low concentration and so forth are also presented. Because of the space limitation, it should be a high-efficiency panel. III-V/Si tandem cells are one candidate. The CPV (concentrator PV) is very attractive for saving the cost of the cell. Cars move quickly, and appearance is essential. Trackers were thought to challenge to implement. One of our choices is a static concentrator customized to the automobile. In addition to high-efficiency, low-cost, 3-dimensional curved surface, color variation and so forth are needed and thus further R&D of solar cells, and modules for automobile applications are necessary.

Although III-V cells have an extremely high conversion efficiency of up to 46.0%, which is suitable for this application, cost reduction is necessary to realize the concept. The Si tandem solar cells by combining Si and other materials such as III-V compound, II-VI compound, chalcopyrite, perovskite, and so forth are desirable for realizing super high-efficiency and low cost. Recently, Si tandem solar cells have paid considerable attention because of high-efficiency and low-cost potential.

New static low concentrators were proposed for the vehicle application. Besides, a III–V/Si partial CPV module with high diffuse sunlight transmission is studied and low concentration static III-V/Si partial CPV module with 27.3% annual efficiency for car-roof application has been developed.

Impedance Spectroscopy as a Tool to Characterize PID and CID in Bifacial and Standard PERC
Photovoltaics Kevin Musselman¹, Travis Yeow¹, Jing Sun², Zheng Yao² and Jean-Nicolas Jaubert²; ¹University of Waterloo, Canada; ²Canadian Solar Inc., Canada

Advancements in photovoltaic technologies are hindered by degradation mechanisms such as potential induced degradation (PID) and current-induced degradation (CID). In this work, impedance spectroscopy is used to examine passivated emitter and rear cell (PERC) silicon modules with PID and CID. A comparison between control and degraded modules is done to identify key differences in the impedance spectra and determine the extent of the degradation. CID was also examined at the cell level, where reductions in minority carrier lifetimes could be more accurately measured. The PID and CID mechanisms studied are found to induce unique changes in the impedance spectroscopy results, making them distinguishable and quantifiable. Finally, the ability to mitigate CID through the use of different silicon wafers and a current induced regeneration process was characterized by impedance spectroscopy.

Atomistic Structure of Si/GaAs Heterointerfaces Fabricated by Surface Activated Bonding Revealed by STEM Combined with Low-Temperature FIB
Yutaka Ohno¹, Yasuo Shimizu¹, Yasuyoshi Nagai¹, Ryotaro Aso², Naoto Kamiuchi³, Hideto Yoshida³, Jianbo Liang³ and Naoteru Shigekawa³; ¹Tohoku University, Japan; ²Osaka City University, Japan; ³Osaka University, Japan

Tandem solar cells consisting of Si and III-V compounds are one of the promising candidates for next-generation
terrestrial photovoltaic systems. Surface-activated bonding (SAB) at room temperature (RT), in which surfaces of substrates are activated before bonding by creating dangling bonds under an energetic particle bombardment in a high vacuum, is applied to form Si/GaAs heterointerfaces with a low interface electrical resistance [1], and high-efficiency InGaP/GaAs/Si triple-junction cells are demonstrated [2]. Even though the interface electrical resistance (~10^{-1} \Omega cm^2) is low enough for solar cells, it is still higher than the ideal one at defect-free heterointerfaces (~10^{-4} \Omega cm^2), presumably due to the defects introduced during SAB processes. The interface resistance varies depending on SAB conditions including energetic atom irradiation and post-bonding annealing [1]. In order to understand the origin of the resistance, atomistic structure of the hetero-interface, depending on SAB conditions, have been examined by cross-sectional transmission electron microscopy (X-TEM).

In general, X-TEM specimens with heterointerfaces, in which the bonding materials are different in etching rate, are fabricated with milling techniques using energetic ions such as focused ion beam (FIB). We have clarified that the structural and compositional properties of semiconductor homointerfaces fabricated by SAB are modified during FIB processes operated at RT, especially for wide-gap materials, and such a modification can be suppressed by FIB processes operated at -150 °C [3]. In the present work, we have therefore examined the atomic arrangement and composition at Si/GaAs heterointerfaces fabricated by SAB using X-TEM specimens fabricated by FIB milling operated at -150 °C.

Si/GaAs heterointerfaces were fabricated at RT under a SAB condition [4], with the substrates of B-doped (100) p-Si (with a carrier concentration of 2x10^{14} cm^{-3}) and Si-doped (100) n-GaAs (2x10^{16} cm^{-3}). X-TEM specimens with an as-bonded heterointerface were prepared at -150 °C by using a FIB system (FEI, Helios NanoLab600i) with a cold stage customized for the FIB system (IZUMI-TECH, IZU-TSCS004) [3]. The specimens were examined by high-angle annular dark-field (HAADF) and energy dispersive x-ray spectroscopy (EDX) analyses under scanning TEM (STEM) with a JEOL JEM-ARM200F analytical microscope.

HAADF-STEM-EDX revealed that, an amorphous layer, about 4 nm in thickness, is introduced along the as-bonded heterointerface. Most of the amorphous layer are composed of Si, and no amorphous GaAs is apparently observed, as proposed [4]. Atomic intermixing across the heterointerface, within a range of a few nm, is observed. Both Ga and As atoms penetrate into the amorphous Si layer, and the amount of Ga atoms in the layer is about two times larger in comparison with As atoms. Those excess Ga atoms, acting as p-type dopant, can improve the electrical property of the amorphous p-Si layer, that is damaged during the SAB processes. Similarly, the electrical property of the n-GaAs bonding surface can be improved via the penetration of Si atoms. Those self-restoration processes may assist the formation of low-resistance Si/GaAs heterointerfaces by SAB. We will also discuss the effect of post-bonding annealing.

Novel IWO and IWO:h Deposited by DC Mode Sputtering for Silicon Heterojunction Solar Cells Annabel Mikosch, Weiyuan Duan, Andreas Lambertz, Friedhelm Finger and Kaining Ding; Forschungszentrum Jülich GmbH, Germany

The silicon heterojunction (SHJ) solar cell is promising for mass production of high efficiency solar cells. To date, the average SHJ solar cell conversion efficiency in mass production is well above 23%. The improvement of transparent conducting oxide (TCO) in SHJ solar cells in terms of transparency and conductivity is one of the key issues to achieve higher conversion efficiencies. The most commonly used TCO is Sn-doped indium oxide (ITO), due to its high transparency and low resistivity. Compared with ITO, W-doped indium oxide (IWO) shows higher charge carrier mobility resulting in high transparency in the near infrared (NIR) spectral range while maintaining low resistivity.\(^1\) The carrier mobility can be further increased when hydrogen is introduced during the deposition leading to hydrogenated IWO:H\(^2\). Therefore, IWO and IWO:H could be advantageous candidates for a high-efficiency SHJ solar cells.

Until now, the application of IWO and IWO:H in SHJ solar cells has been studied using soft deposition methods such as reactive plasma deposition (RPD)\(^3\) or radio-frequency (rf) mode sputtering.\(^2\) But for the mass production of
SHJ solar cells, direct current (DC) mode sputtering is commonly used as it offers high throughputs and is an established deposition technology in the optoelectronic industry. To successfully introduce the novel, high mobility TCOs into a SHJ solar cell production line the DC sputtering of IWO and IWO:H needs to be developed and investigated with respect to possible sputtering damages on the thin silicon layers of SHJ solar cells.

Here, we present our most recent work on DC sputtered IWO on SHJ solar cells. In preliminary experiments to this study we have optimized the deposition process for single layers of IWO on glass from Corning type Eagle. The resulting films exhibited high transparency (average absorption of < 2% from 400 - 1100 nm), low sheet resistance (105 Ω/sq), and carrier mobility of up to 55 cm²/Vs. The IWO films were also applied to 19 × 19 mm² SHJ solar cells increasing the short circuit current density $J_{sc}$ from 38.65 mA/cm² to 39.09 mA/cm² compared to ITO without introducing sputtering damage to the underlying solar cell. In this contribution, we extend the study of DC sputtered IWO further by introducing hydrogen to fabricate IWO:H and also apply the TCOs on full size M2 solar cells. The novel TCO layers deposited by DC sputtering will be compared to ITO with respect to contact resistance and sputtering damage to the underlying silicon layers. To our knowledge, this is the first study of DC sputtered IWO and IWO:H using an industrially relevant technique for SHJ solar cells.

3:30 PM EN11.06.06
**The Value of Efficiency**
Ian Marius Peters¹, Carlos David Rodriguez Gallegos², Sarah Sofia¹, Tonio Buonassisi¹ and Erin Looney¹; ¹Massachusetts Institute of Technology, United States; ²Solar Energy Research Institute of Singapore, Singapore

What is the value of improving the efficiency of a solar cell? In this contribution we introduce a tool to assess the value of efficiency (VOE) by analyzing the dynamic co-dependence of levelized cost of electricity (LCOE) on manufacturing cost and efficiency. Looking at historic trends we find that the allowable cost for innovation has dropped rapidly in the past and is projected to further decline in the future, but at a slower pace. This is good news for researchers, as it will ease the difficulties of hitting a moving cost target. Additionally, we find that VOE values for residential- and utility scale systems converge at different levels, indicating a stronger future diversification of these PV market segments. Similarly, we find local differences for VOE suggesting a further possible market diversification based on region. Efficiency is a much stronger driver for LCOE reductions in a handful of highly industrialized countries like the U.S., Germany, Australia or Japan than in the rest of the world. Advanced solar cell concepts like $n$-type monocrystalline PERC silicon solar cells could, hence, be economically preferable to multicrystalline silicon solar cells in these regions, but may not be the better choice in countries like China or India. Extending the analysis to more advanced concepts including tandem solar cells, we confirm previous finding that these concepts have great potential to improve LCOE for residential applications, but will likely struggle to compete on the utility market. Finally, we explore the detrimental impact of degradation, and show that competing on the basis of LCOE necessitates matching the stability of established technologies.

3:45 PM EN11.06.07
**Optimizing the Absorbing Layer Thickness of the Top Cell in 4-Terminal Gallium Arsenide-on-Silicon Tandem Solar Cells**
Riley Whitehead¹, Kaitlyn VanSan², Michael Rienäcker¹, Henning Schulte-Huxel², Robby Peibst², John Geisz¹ and Adele Tamboli¹,²; ¹National Renewable Energy Laboratory, United States; ²Colorado School of Mines, United States; ³Institute for Solar Energy Research in Hamelin, Germany

One method to improve silicon solar cell efficiency is to stack a silicon cell beneath a wide-bandgap top cell. To improve the overall tandem cell efficiency from that of silicon alone, the top cell material should have a higher spectral efficiency than silicon for the wavelengths of light within the top cell’s bandgap. GaAs is currently the material with the highest recorded cell efficiency for a single junction cell, at 29.1% efficiency. GaAs also has a theoretical and realized spectral efficiency higher than that of silicon between the wavelengths of 360-860 nm. Our team was able to exploit these GaAs attributes to obtain a record efficiency of 32.8% for a mechanically-stacked rear heterojunction (RHJ) GaAs-on-Si (GaAs/Si) tandem cell designed to operate in the 4-terminal (4T) (i.e. optically coupled but electrically independent) configuration.

The purpose of this study is to further optimize the GaAs emitter layer thickness to maximize the efficiency of the
4T GaAs//Si tandem cells. Our record 4T GaAs//Si tandem solar cell was achieved using a 2 µm GaAs emitter layer but subsequent optical modeling of the 4T GaAs//Si tandem solar cells suggests that a slightly thicker emitter could potentially lead to even better top cell efficiencies. In addition, NREL began a collaboration with ISFH that provides high-efficiency interdigitated back contact (IBC) solar cells that could further improve the tandem cell efficiencies, when used as the Si bottom cell in the 4T GaAs//Si cell.

Our un-certified current-voltage (I-V) results show an efficiency increase of 0.43% (absolute) by increasing the emitter thickness from 2.0 µm to 2.8 µm. The tandem cells are currently pending cell certification but the results for the GaAs//Si tandem cell with an emitter thickness of 2.8 µm is expected to be >32% and could potentially exceed the existing record efficiency. We will present the results of modeling the GaAs emitter thickness using modified Hovell equations that estimates the Jsc, based upon light absorption and carrier recombination. We will compare these modeled predictions to the NREL-certified I-V and external quantum efficiency (EQE) results obtained from 4T GaAs//Si tandem cells fabricated with absorber layer thicknesses varying from 1.5 to 3.5 µm. We will also compare the performance of our 4T GaAs//Si tandem cells to the record 4T GaAs//Si tandem cell efficiency of 32.8%.

Role of the Interlayer in Improving Passivating Contact with Atomic Layer Deposited TiOx on Crystalline Si
Takeya Mochizuki1, Kazuhiro Gotoh1, Yasuyoshi Kurokawa1, Takahisa Yamamoto1, Tomohiko Hojo2, Eiji Akiyama2 and Noritaka Usami1; 1Nagoya University, Japan; 2Tohoku University, Japan

High efficiency crystalline Si (c-Si) solar cells can be realized by employing carrier selective contacts to efficiently collect one type of photogenerated carriers by providing excellent passivation performance and low contact resistance at the heterointerface. Atomic layer deposited TiOx (ALD-TiOx) is known as one of the promising candidates for electron selective contacts owing to the small conduction band offset (<0.05 eV) and large valence band offset (>2.0 eV), which can selectively transport photogenerated electrons in c-Si while repelling holes. Passivation performance could be modified by both surface treatment of the c-Si substrate prior to deposition and post-deposition process. Therefore, it is important to understand underlying physics during the process to establish the guideline how to improve passivating contacts.

In this contribution, we report on the role of the interlayer in improving passivating contact with ALD-TiOx/c-Si, and show that formation of low-density SiOx prior to depositing TiOx is of crucial importance to improve passivation performance.

All experiments were carried out on double-side mirror-polished float-zone (Fz) grown c-Si(100) substrates. After degreasing and removing a native oxide layer, various chemical treatments were done to form SiOx interlayer with different densities. TiOx layers were deposited at 150 °C by a thermal ALD (GEMStar-6, Arradiance). The forming gas annealing were carried out in a mixed gas (3% H2 and 97% Ar) to activate the surface passivation performance. The effective minority carrier lifetime of the samples was measured by a WCT-120 lifetime tester (Sinton Instruments). For a part of samples, EEL spectra were obtained using an EEL spectrometer attached to a Cs-corrected STEM (JEM-ARM200FC, JEOL Ltd.), which was operated at 200 kV. The desorption of hydrogens was characterized by thermal desorption spectroscopy (TDS) using a quadrupole mass spectrometer with different heating rates to analyze Si-H2 bonding energies.

The effective carrier lifetime of about 1.4 ms was achieved by inserting ultra-thin SiOx interlayer formed by nitric acid at room temperature. The TEM images and EEL spectra revealed that non-stoichiometric SiOx existed for as-deposited samples and Ti contained, near-stoichiometric SiO2 was formed after post deposition annealing. This suggests that diffusion of Ti and O atoms took place during the post deposition annealing. To enhance this process, we considered that introduction of SiOx interlayer with lower density is effective. As a result, employment of so-called SC-2 solution (HCl:H2O2:H2O=1:1:5) prior to deposition of TiOx led realization of the effective lifetime of 1.7 ms. The enhanced diffusion of O from TiOx would also contribute to the reduction of the contact resistance by increasing O vacancies in the ALD-TiOx layer. Furthermore, higher Si-H2 bonding energy was confirmed by TDS, suggesting that hydrogens also play a role in improving passivation performance.

First Principles Modeling of Water-Induced Polymer Encapsulant Degradation in Silicon Modules
Arun Kumar Mannodi Kanakkithodi1, Rishi Kumar2, David P. Fenning2 and Maria K. Chan1; 1Argonne National Laboratory, United States; 2University of California San Diego, United States
An outstanding issue in photovoltaic modules is the accelerated degradation caused by the presence of moisture, which leads to interfacial instability, encapsulant decomposition and corrosion at contacts. Currently, experimental observation and characterization of moisture in PV modules is not trivial, which presents a major obstacle to designing high-reliability modules. First principles calculations provide a suitable way to study the ingress of water and its detrimental effect on the polymer encapsulant and on the interface between the semiconductor and the polymer. In this work, we use density functional theory (DFT) computations to model the structure, degradation mechanisms, and adhesive strength on metal surfaces of ethylene vinyl acetate (EVA), the most common polymer encapsulant used in Si PV modules. The molecular structure of EVA is modeled both as an isolated single chain and in a crystalline arrangement with closely packed chains, using a structure prediction algorithm that includes Van der Waals corrections applied to the standard DFT functional. Infrared active modes computed for the low energy EVA structures using density functional perturbation theory match well with reported experiments. The Nudged Elastic Band (NEB) method is applied to model the decomposition mechanism of EVA, with and without the presence of water, following the Norrish I and Norrish II mechanisms, leading to the formation of acetaldehyde and acetic acid, respectively. Computed energy barriers show a preference for acetic acid formation, are lower in the presence of a water solvent than in vacuum, and match well with reported experimental activation energies. The NEB computed energy barrier is further seen to be dependent on the percentage of deacetylation and the presence or absence of a catalyst, such as a proton or a hydroxyl ion. This systematic study leads to a clear picture of the hydrolysys-driven decomposition of EVA in terms of energetically favorable mechanisms, possible intermediate structures, and IR signatures of reaction products. We further model the adhesion of EVA and related polymers (including decomposition products) on surfaces of metals such as Cu and Ag, in order to determine the sticking power of the polymer encapsulant and thus the strength of the interface with and without the presence of water.

Influence of the Dopant Gas Precursor in p-Type Nanocrystalline Silicon Layers for High Efficiency Heterojunction Solar Cells  Luca Antognini, Vincent Paratte, Jan Haschke, Christophe Ballif and Mathieu Boccard; Ecole Polytechnique Federale de Lausanne, Switzerland

While standard design of Silicon heterojunction (SHJ) uses amorphous silicon (a-Si) doped layer, switching to nanocrystalline silicon (nc-Si) is a promising route to improve efficiency [1]. One challenge to ensure a good contact is the fast nucleation of the nc-Si on the underneath intrinsic a-Si passivating layer. To promote the crystallization without damaging the passivation, a short SiH4/H2/CO2 plasma treatment was introduced prior to the p-layer deposition [2], [3] which enabled efficiencies up to 23.45% [4]. As shown by the results of p-i-n solar cells [5], clarifying the role of the boron source in SHJ is crucial for further improvement.

In this work, we compare the use of BF3 and TMB for nc-Si hole contacts. Efficiency values over 23% are obtained for both gases for the same deposition parameters, however cells using TMB-based layers yield a better FF (81.7% vs. 80.8%), whereas BF3 cells exhibit a better Jsc (40.0 mA/cm2 vs. 39.2 mA/cm2).

Symmetric stacks of c-Si(n) / a-Si(i) / nc-Si(p) / ITO address the question of the stability of the passivation along the process. We see that the implied open-circuit voltage (iVoc) is strongly reduced by the p-layer deposition for BF3, while it is not systematically changed for TMB. The ITO deposition reduces also more strongly the passivation when deposited on BF3 p-layer, reducing iVoc by ~ 30mV while it is not the case for the samples with TMB p-layer. However, annealing enables full recovery of the sputtering damage with even slight improvement (~735 mV) compared to the value before ITO deposition.

Using Spectroscopic ellipsometry, similar thicknesses were found for both dopant gases, yet with a smaller refractive index for BF3-based layers (n=2.6 vs. n=3.5 at 600 nm) and a higher optical bandgap for BF3 (E04=2.23 eV vs. 1.79 eV), which suggests a more porous layer. UV-Raman spectroscopy yields a higher crystallinity for BF3 layers than TMB (Xc = 60% v.s. Xc = 40%), confirming the structural difference of both materials. Both results are consistent with the difference in short-circuit current when used in a solar cell.

The marked difference between these materials indicates distinct optimization path that need to be unraveled. We plan to further investigate the nucleation and the doping efficiency differences by varying the dopant gas flux and
the surface pretreatment and relate them to the past results obtain from p-i-n solar cells. We will also investigate the 
contribution of carbon and fluorine via Secondary Ion Mass Spectroscopy (SIMS) to understand the effect of the 
dopant gas on the device performance to enable further efficiency improvement.

Highthroughput Fabrication of Efficient Perovskite Solar Modules and Tandem Solar Cells Jiinsong Huang;
University of North Carolina at Chapel Hill, United States

The efficiencies of small-pixel perovskite photovoltaics have increased to well above 20%, while the question is 
whether fabrication methods can be transferred to scalable manufacturing process. Here we report a method of fast 
blading large area perovskite films at an unprecedented speed of 99 millimeter-per-second or higher in ambient 
condition by tailoring solvent coordination capability. Combing volatile non-coordinating solvents to Pb2+ and low-
volatile, coordinating solvents achieves both fast drying and large perovskite grains at room temperature. The 
reproducible fabrication yields a record certified module efficiency with aperture area of 63.7 cm2. The perovskite 
modules also show a small temperature coefficient of -0.13%/°C and nearly fully recoverable efficiency after 58 
cycles of shading, much better than commercial silicon and thin film solar modules. The application of the coating 
method to perovskite/silicon tandem cells and will also be presented. We will answer the question whether the 
perovskite layers can be fabricated at the speed of silicon cells are produced in the regular production lines.

Crystalline Si (c-Si) solar cells are driving the progression of renewable electricity generation technologies thanks to 
lowering costs and increasing efficiencies. One solution to maintain this cost-competitiveness on the long-term involves increasing efficiencies beyond the limit of c-Si by stacking a perovskite solar cell on a commercial c-Si one to form a photovoltaic tandem device. The tunable bandgap, soft processing conditions and high single-junction performance of perovskites indicate that this approach could upgrade c-Si solar cells to efficiencies >30% through a few extra process steps with low additional process costs.

For maximum photocurrent and compatibility with existing c-Si process flows, the perovskite solar cell should be deposited directly on the textured front side of the c-Si solar cell, a texture that improves light management in the c-
Si. But this pyramidal texture imposes several microfabrication challenges as the perovskite absorber is typically deposited via solution processing, and is about one order of magnitude thinner than the height of the pyramids it needs to cover. Achieving a conformal deposition of all the layers of the top cell on this pyramidal texture and hence maximum performance requires a fine control over the layer formation to avoid pinhole formation.
In that regard, electron microscopy techniques, notably analytical transmission electron microscopy (TEM), can shed some light on the device nanostructure and its dependence on processing/operation conditions, guiding the development of devices. However, the fragile nature of perovskite solar cells complicates their preparation into thin cross-sections necessary for TEM observations and their analysis with high-energy electrons. This presentation will review artifacts that may occur during TEM sample preparation and observation, elaborate several strategies to identify and mitigate them, before discussing several topics correlating nanostructure and performance of perovskite single-junction and tandem solar cells. This contribution will present how electron microscopy data coupled with other techniques provide valuable inputs to guide the development of high-efficiency (>25%) tandems featuring textured n- and p-type c-Si solar cells, notably by i) identifying optimal bottom cell contact nanostructures, ii) isolating crystallographic and chemical features enabling the recombination junction to quench shunts, iii) guiding the removal of shunts running through the perovskite absorber on textured c-Si by adapting process conditions and iv) visualizing the dewetting of charge-selective layers during the crystallization of the perovskite solar cell on certain recombination junctions. In addition, degradation pathways triggered by reverse voltages (also investigated through TEM in situ biasing experiments), during long-term operation at maximum power point at various temperatures, or during damp heat tests (85°C/85% relative humidity) will be examined. These results highlight the dynamic nature of the perovskite nanostructure (ionic migration within the absorber and into the contacts, volatilization of species, crystallographic phase change/decomposition) depending on the external stimuli and its influence on the solar cell performance.

References:
Wide-bandgap (~1.7-1.8 eV) perovskite solar cells have attracted substantial research interest in recent years due to their great potential to fabricate efficient tandem solar cells via combining with a lower bandgap (1.1-1.3 eV) absorber (e.g., Si, copper indium gallium diselenide, or low-bandgap perovskite). However, wide-bandgap perovskite solar cells usually suffer from large open circuit voltage ($V_{oc}$) deficits caused by small grain sizes and photoinduced phase segregation. We show that in addition to large grain sizes and passivated grain boundaries, controlling interface properties is critical for achieving high $V_{oc}$'s in the inverted wide-bandgap perovskite solar cells. We adopt guanidinium bromide solution to tune the effective doping and electronic properties of the surface layer of perovskite thin films, leading to the formation of a graded perovskite homojunction. The enhanced electric field at the perovskite homojunction is revealed by Kelvin probe force microscopy measurements. This advance enables an increase in the $V_{oc}$ of the inverted perovskite solar cells from an initial 1.12 V to 1.24 V. With the optimization of the device fabrication process, the champion inverted wide-bandgap cell delivers a power conversion efficiency of ~19% and sustains more than 72% of its initial efficiency after continuous illumination for 70 h without encapsulation. The improvement on performance of wide-bandgap perovskite subcells enables us to fabricate efficient and stable perovskite tandem solar cells.

The record power conversion efficiency is 28 % for perovskite-silicon tandems and 23.2 % for perovskite-perovskite tandems. One of the challenges that must be overcome to achieve efficiency greater than 30% is to reduce the voltage loss in high bandgap perovskite cells and prevent light-induced phase separation. We have found that treating the surface of perovskites can dramatically reduce the extent of light -induced phase separation, which has interesting implications for how the process occurs. We have also developed new strategies for increasing the bandgap in perovskite compounds that have modest amounts of bromine. We have been able to make semitransparent high bandgap solar cells with greater than 20% power conversion efficiency that do not suffer from light-induced phase separation. These advances in combination with improvements in the atomic layer deposition of highly impermeable metal oxide contacts enable the fabrication of highly efficient and stable tandems.
conditions but does not require lateral current extraction between the cells, which becomes challenging when scaling devices to large areas.

In this talk I will give an overview of the history of three terminal devices and discuss the wide range of possibilities to create high efficiency tandem devices from combining various top cells with Si bottom cells. I will show how TCAD models agree with simple physical models and experimental results to explain the trends in the behavior of 3T tandems.

2:00 PM EN11.08.02
Performance Comparison of III-V//Si Tandem Solar Cells in the Three-Terminal Configuration Kaitlyn VanSant1, Emily Warren2, Michael Rienäcker3, Henning Schulte-Huxel1, Robby Peibst1, John Geisz2, Paul Stradins2 and Adele Tamboli2,1; 1Colorado School of Mines, United States; 2National Renewable Energy Laboratory, United States; 3Institute for Solar Energy Research in Hamelin, United States

Multi-junction solar cells are a key pathway towards achieving higher photovoltaic efficiencies. The theoretical efficiency limit of a single-junction (1J) Si solar cell is 29.6%, whereas efficiencies >32% have already been achieved for 1J III-V top cells stacked on Si bottom cells in both the two terminal (2T) and four terminal (4T) configurations.2,3 We will present a third path towards achieving efficiencies >32% with mechanically-stacked III-V-on-Si (III-V//Si) tandem solar cells using a three terminal (3T) configuration.

The typical tandem device architectures either connect the sub-cells in series in a 2T configuration, or operate the stacked sub-cells independently, which requires four terminals (4T). Both configurations, however, have considerable drawbacks. The 2T configuration requires that the sub-cells are current matched to operate efficiently and so this narrowly constrains the choice of the sub-cell materials. The 4T configuration does not require sub-cell current matching but this design prohibits the possibility of monolithic growth and necessitates the inclusion of gridlines or a lateral conduction layer at the back of the top cell which reduces the transmission of light to the bottom cell.4

The 3T configuration is a hybrid approach devised to address the constraints of the other two. The additional contact associated with the interdigitated back contact (IBC) Si bottom cell enables extraction or injection of current which circumvents the need for current matching between the sub-cells. The 3T design does not require an intermediate grid and is potentially compatible with both mechanical stacking, if a transparent conductive adhesive (TCA) is used, or monolithic growth. Moreover, simulations predict that 3T tandem cells could achieve efficiencies over 32%, comparable to record 4T tandem cell efficiencies.3,4

We have fabricated and measured 3T mechanically-stacked III-V-on-Si (III-V//Si) tandem solar cells and will present an overview of how a 3T tandem solar cell operates. We will compare the JV and QE characteristics of a GaInP//Si tandem cell to a GaAs//Si tandem cell and analyze how the performance between these two 3T tandem solar cells differ, depending on which sub-cell is current limiting.

2:15 PM EN11.08.03
An Ambipolar Poly(Vinylidene Fluoride-co-Trifluoroethylene) Passivated Back Surface Field Layer for High Efficient Organic/Si Hybrid Solar Cells Sung Bum Kang, Myeong Hoon Jeong and Kyoung Jin Choi; Ulsan National Institute of Science and Technology, Korea (the Republic of)
The interfacial layer between semiconductor and metal cathodes in photovoltaics play a critical role in enhancing the transport of charges carriers or preventing the recombination at the interface. Here, high crystalline and self-assembled poly(vinylidene fluoride-co-trifluoroethylene) (P(VDF-TrFE)) thin films are shown to function as a passivation layer and also acts as back surface field layer for photovoltaic devices, simultaneously. The P(VDF-TrFE) thin films are spincoated on the bottom of n-Si surface by modified breath figure methods. After that, poly(3,4-ethylene dioxy thiophene):poly(styrene sulfonate) are formed on the top of nano-textured Si as the junction. Comparing previously reported organic / Si hybrid solar cells with this study, such devices demonstrate record-breaking photovoltaic conversion efficiency of 18.1% with electrostatic passivation and reflection of minority carriers by the induced built-in electric field. Furthermore, due to its switchable ferroelectric property, the P(VDF-TrFE) thin films can be utilized to the p-Si solar cells as passivated back surface field layers. Finite-difference time-domain simulation reveals that the electric field due to the below spontaneous polarization causes band bending of Si, reflecting minority carriers and reducing the surface recombinations of the devices.

Insights into the Intrinsic Recombination Limit of Silicon Devices Mariana I. Bertoni; Arizona State University, United States

High-efficiency solar cell devices characterized by extremely high open-circuit voltage ($V_{OC}$) values have shown that the traditional constraints imposed by extrinsic recombination processes will be eventually surpassed at some time in the foreseeable future. The accurate evaluation of Auger lifetime and its temperature-dependence are thus fundamental not only for the correct interpretation of effective carrier lifetime data, but also for the simulation of device performance, especially when these are deployed in the field, where the operating conditions can greatly vary from the standard testing conditions. In this work, we present the Auger lifetime across a range of temperatures from 300 to 500 K and a range of injection level from $5 \times 10^{14}$ to $1 \times 10^{16}$ cm$^{-3}$ showing that, in stark opposition with what generally accepted, a strong increment of the lifetime values happens at high temperatures. Based on these results, we discuss the ambipolar Auger coefficient in the high injection range and propose a parameterization for its temperature dependence in agreement with a model previously presented in literature. Finally, we evaluate the intrinsic-limited implied voltage ($iV$) within the same range of injection level and temperature, and show that the evaluated strong increment of Auger lifetime counteracts the typical drop of high-efficiency solar cells performance with high temperature.

4:00 PM EN11.09.02
Microparticle-Assisted Texturing (MPAT) Process on As-Cut Crystalline Silicon—Controllable Texture Size, Low Optical Reflectivity, Quick Formation, Extremely Low Material Loss and Toward Mass-Production Cong T. Nguyen, Keisuke Ohdaira and Hideki Matsumura; Japan Advanced Institute of Science and Technology (JAIST), Japan

Heterojunction back-contact (HBC) crystalline silicon (c-Si) solar cells with energy conversion efficiency > 26%, which reaches nearly the theoretical limit of ~30%, have been achieved, hence reducing fabrication cost becomes more and more valuable. The decreasing thickness of c-Si to < 100 µm is one of the keys since c-Si typically takes half of the total cell cost. Usually, the surface of c-Si is textured to improve sunlight confinement or efficiency. For such thin c-Si, small texture size and low amount of Si etching loss are strictly required to maintain its mechanical strength during fabrication processes. In mass-production, wet processes are preferable for lowering the cost. We have already reported a novel method, so-called microparticle-assisted texturing (MPAT) process, in which glass microparticles were mixed with conventional alkaline-based texturing chemical solutions to reduce the texture size, etching duration, and etched c-Si thickness by almost one order of magnitude. The MPAT process was applicable to
c-Si with a thickness down to 50 µm. The superiorities were attributed to that the glass microparticles with certain kinetic energy can sweep out reaction-generated hydrogen bubbles from the c-Si surface to speed up the texture formation. However, the previous work focused on only mirror-polished c-Si wafers. In this work, we studied the MPAT process on as-cut c-Si used for actual solar cell mass-production. The similar superiorities such as small texture size (< 3 µm), low optical reflectivity (R~7%) quick formation (3–5 min), and extremely low c-Si loss [< 2 µm, even smaller than the depth of the saw-damaged layer (SDL) ~ 6 µm] were revealed. In addition, we also developed a suitable wet chemical cleaning prior to surface passivation using catalytic chemical vapor deposition (Cat-CVD) silicon nitride (SiN_x)/amorphous silicon (a-Si) stacked layers. A world-record low surface recombination velocity (SRV) ~ 0.38 cm/s was achieved. Owing to the high-quality surface passivation, both SDL removal and texturing can be done by only the MPAT process within a few minutes. After coating SiN_x/a-Si, the reflectivity reaches ~ 0.4 % at minimum, and < 2% in wide wavelength 450–950 nm. Toward mass-production using the MPAT process, etching of multiple c-Si full-size wafers with a pitch of 5 mm was proved to be possible to obtain uniform textures with a yield almost 100%. Therefore, the MPAT process is almost close to the mass-production of low-cost and high-performance thin c-Si-based solar cells.

Polycrystalline silicon (poly-Si) has proven to be a game-changing material in the field of high thermal budget carrier-selective passivating contacts (CSPCs) for c-Si solar cells beyond PERC architecture. However, doped poly-Si exhibits a very high free carrier absorption (FCA), which has turned the attention of researchers towards wide bandgap materials, such as poly-SiO_x and poly-SiC_x. In these materials, the opto-electronic properties depend on oxygen and carbon alloying, respectively. To properly model the generation profile in solar cells based on poly-Si, poly-SiO_x or poly-SiC_x, CSPCs, a thorough understanding of their optical properties, especially the absorption coefficient, is essential.

As weak FCA at long wavelengths is difficult to detect using ellipsometry, we have used in this work two techniques, the absolute photothermal deflection spectroscopy (PDS) and the reflection / transmission (RT), that are sensitive enough to measure absorption values below 1%. In this way, we could obtain the absorption coefficient of n- and p-type doped poly-SiO_x and poly-SiC_x, CSPCs on quartz and on crystalline silicon (c-Si) wafer substrates, respectively, in the wavelength range between 300 nm to 2000 nm. The absorption coefficients of doped CSPCs obtained from these measurement techniques are in the same order to magnitude, albeit we observed small differences owing to the different substrates and/or the measurement techniques.

By changing the oxygen-to-silane gas ratio, \( R_{CO2} = \frac{[CO2]}{([CO2] + [SiH4])} \), and carbon-to-silane gas ratio, \( R_{CH4} = \frac{[CH4]}{([CH4] + [SiH4])} \), the optical properties of our in-house developed poly-SiO_x and poly-SiC_x layers can be obviously altered. We note a decrease in the FCA for n- and p-type doped poly-SiO_x layers in the infrared region with respect to the reference poly-Si (\( R_{CO2} = 0 \)). Among n- and p-type doped poly-SiO_x and poly-SiC_x layers, n-type doped poly-SiO_x (\( R_{CO2} = 0.83 \)) layer with a doping concentration of 1e20 cm^{-3} has the least FCA in the wavelength range between 800 nm and 1200 nm. In this respect, for the same thickness, it would be better to use n-type doped poly-SiO_x rather than n-type doped poly-SiC_x, at the back side of front/back-contacted or interdigitated back-contacted c-Si solar cell architectures.

The obtained absorption coefficient values can now be used as input to study the optical behaviour of single- and multi-junction solar cells endowed with such CSPCs. Simulations of two, three and four terminal perovskite / c-Si solar cells are ongoing and will be presented at the conference.

Elimination of Shadowing Losses Using Light Trapping Metallic Electrodes Mengdi Sun and Pieter G. Kik; University of Central Florida, United States
Transparent electrodes are used in many optoelectronic devices, such as solar cells, high speed photodetectors, imaging arrays, and displays. Common materials used for transparent electrodes include conductive oxides, carbon nanotubes, graphene, and metal nanowire networks. In all current approaches a balance needs to be struck between good electrical conductivity and high optical transmission: thinner films lead to higher transmission, but lower electrical conductivity. Among the many approaches, metal nanowire electrodes provide extremely high conductivity, but introduce significant shadowing losses due to reflection and absorption.

In this presentation we numerically investigate the optical and electrical performance of silver nanowire electrodes that can virtually eliminate all shadowing losses by the metallic contacts. This is achieved through light trapping via total internal reflection at the surface of a thin dielectric cover layer. Two kinds of interdigitated electrodes are considered, using either cylindrical silver wires or triangular silver wires. It is shown that both designs can simultaneously provide high optical transparency and high electrical conductivity when using micron sized silver wires. The relative contribution of radiative and non-radiative loss is evaluated as a function of wire size, including the effect of surface plasmon polariton mediated dissipation. The performance is analyzed at high metal coverage to highlight the importance of light trapping. It is shown that 2 μm wide triangular silver wires with 25% metal coverage, embedded in a Si₃N₄ cover layer can provide a peak transparency of 98% and an average optical transmission of 93% across a broad wavelength range spanning from 400nm to 1.1μm, while offering sheet resistivity as low as 0.35Ω/sq. Reducing the wire width to 300nm reduces the light trapping efficiency of triangular electrodes by ~40%, which is quantitatively explained in terms of the angular distribution of the reflected light from isolated wires. A new figure of merit is proposed to evaluate the overall performance of light trapping transparent metallic electrodes, and it is shown that triangular electrodes progressively outperform cylindrical electrodes as the wire size increases. Methods for producing large area light trapping electrodes will be discussed.

4:45 PM EN11.09.05
Zr-Doped Indium Oxide (IZRO) Transparent Electrodes for Perovskite-Based Tandem Solar Cells Erkan Aydin¹, Michele De Bastiani¹, Xinbo Yang¹, Muhammad Sajjad¹, Faisal Aljamaan¹, Yury Smirnov², Mohamed N. Hedhili¹, Wenzhu Liu¹, Thomas G. Allen¹, Lujia Xu¹, Emmanuel Van Kerschaver¹, Monica Morales-Masis², Udo Schwingenschlögl¹ and Stefaan De Wolf¹; ¹King Abdullah University of Science and Technology, Saudi Arabia; ²University of Twente, Netherlands

Parasitic absorption in transparent electrodes is one of the main roadblocks to enable power conversion efficiencies (PCEs) for perovskite-based tandem solar cells beyond 30%. To reduce such losses and maximize light coupling, the broadband transparency of such electrodes should be improved, especially at the front of the device. Here, we show the excellent properties of Zr-doped indium oxide (IZRO) transparent electrodes for such applications, with improved near-infrared (NIR) response, compared to conventional In-doped tin oxide (ITO) electrodes. Optimized IZRO films feature a very high electron mobility (up to ~77 cm²/V.s), enabling highly infrared transparent films with very low sheet resistance (~18 Ω/sq for annealed 100 nm films). For devices, this translates in a parasitic absorption of only ~5% for IZRO within the solar spectrum (250-2500 nm range), to be compared with ~10% for commercial ITO. Fundamentally, we find that the high conductivity of annealed IZRO films is directly linked to promoted crystallinity of the indium oxide (In₂O₃) films due to Zr-doping. Overall, on four-terminal perovskite/silicon tandem device level, we obtained an absolute 3.5 mA/cm² short-circuit current improvement in silicon bottom cells by replacing commercial ITO electrodes with IZRO, resulting in improving the PCE from 23.3 to 26.2%. [1]

Atomic Layer Deposited Nanolayers for Silicon Photovoltaics

Bart Macco, Jimmy Melskens and Erwin Kessels; Eindhoven University of Technology, Netherlands

Thin films are ubiquitous in the preparation of crystalline silicon solar cells. With the introduction of the PERC technology also the method of atomic layer deposition (ALD) has been introduced in high volume manufacturing in photovoltaics. Currently, the technique is quickly gaining market share for the deposition of ultrathin Al₂O₃ nanolayers for rear side surface passivation. The advantages of ALD are that it is scalable, that it is well suited to prepare high quality and uniform nanolayers, and that it is a "soft" deposition technique preventing interface damage. In this presentation the state of the art of ALD for silicon photovoltaics will be discussed as well as some ongoing developments and potential new applications. This includes new materials for surface passivation, nanolayers for passivating contacts, transparent conductive oxides as well as applications of ALD for polysilicon passivating contact solar cells.

Thermally Stable Passivating Hole-Selective Contacts Using Atomic Layer Deposited Molybdenum Oxide with Thin Aluminum Oxide

Geoffrey Gregory, Zhengning Gao, Titel Jurca, Parag Banerjee and Kristopher Davis; University of Central Florida, United States

One high efficiency crystalline silicon (c-Si) solar cell that has potential to be cost-competitive with Al-BSF devices while maintaining the passivation quality of PERC structures is the silicon heterojunction. Most notably is the Heterojunction with Intrinsic Thin-layers (HIT) solar cell, which chemically passivates the surface of the c-Si with intrinsic hydrogenated amorphous silicon (a-Si:H) while allowing charge carriers to conduct through the contact. Doped a-Si:H layers then create the potential gradient necessary for carrier diffusion and charge collection to occur.

Even with its high performance and simplified fabrication process, the HIT solar cell has potential to be improved upon. The a-Si:H layers produce parasitic absorption of high energy light. Many groups have also found the a-Si:H contacts to be sensitive to annealing treatments above 200°C. This limits the processing space for the metallization step, which typically occurs at much higher temperatures.

In this work we use Atomic-Layer-Deposited (ALD) MoOₓ as a hole-selective contact to c-Si in combination with thin SiOₓ and Al₂O₃ passivation layers to study the solar cell parameters of carrier selective contacts without the use of a-Si:H. While the optical properties of MoOₓ present a significant reduction in parasitic absorption compared to a-Si:H, the temperature stability of the material is still in question. Many groups have been unable to anneal MoOₓ based contacts above 120°C without degrading the electrical properties of the contact. We show that by using a thin Ni capping layer before Al metallization, the contact remains stable up to 300°C with contact resistivities below 10 mΩ-cm². This presents significant improvements on the thermal budget of the MoOₓ processing sequence and will allow for more appropriate contact formation steps.

Using Ultraviolet Photoelectron Spectroscopy we measure a work function of 6.2 eV in our 5nm MoOₓ contact. We simulate the band-bending and hole concentration at the c-Si surface as a function of the MoOₓ contact work function and show that our films exhibit sufficient hole-selective properties. Additionally, High Resolution Transmission Electron Microscopy images show that when a thin Ni capping layer is not used prior to Al metallization, a 2-3 nm Al₂O₃ layer forms at the Al/MoOₓ interface. This insulating interlayer contributes to a large barrier to hole transport, making the Al/MoOₓ contact incompatible with high efficiency heterojunction solar cells. The Al/Ni/MoOₓ contact, however, exhibits no such interlayer. This suggests that Ni may act as a diffusion barrier to O species during solar cell fabrication.

Finally, we show that by using a thin (~1 nm) Al₂O₃ passivation layer at the MoOₓ/c-Si interface, we are able to achieve a minority carrier lifetime of over 1 ms on n-type c-Si.

TiOₓ Thin Layer as an Efficient Passivating Hole Selective Contact

Takuya Matsui¹, Martin Bivour², Martin Hermle² and Hitoshi Sai¹; ¹National Institute of Advanced Industrial Science and Technology (AIST), Japan; ²Fraunhofer Institut für Solare Energiesysteme ISE, Germany

Using Ultraviolet Photoelectron Spectroscopy we measure a work function of 6.2 eV in our 5nm MoOₓ contact. We simulate the band-bending and hole concentration at the c-Si surface as a function of the MoOₓ contact work function and show that our films exhibit sufficient hole-selective properties. Additionally, High Resolution Transmission Electron Microscopy images show that when a thin Ni capping layer is not used prior to Al metallization, a 2-3 nm Al₂O₃ layer forms at the Al/MoOₓ interface. This insulating interlayer contributes to a large barrier to hole transport, making the Al/MoOₓ contact incompatible with high efficiency heterojunction solar cells. The Al/Ni/MoOₓ contact, however, exhibits no such interlayer. This suggests that Ni may act as a diffusion barrier to O species during solar cell fabrication.

Finally, we show that by using a thin (~1 nm) Al₂O₃ passivation layer at the MoOₓ/c-Si interface, we are able to achieve a minority carrier lifetime of over 1 ms on n-type c-Si.
Recently, Yang et al. have reported 22.1% efficient c-Si solar cell by applying an atomic-layer-deposited (ALD) TiOx thin-layer as electron contact to n-type base [1]. The origin of the electron selectivity of TiOx has been ascribed to the asymmetric current flow at the (n) c-Si/TiOx interface where the conduction band offset is much lower than the valence band offset. On the other hand, we recently found that TiOx can be tuned from electron to hole selectivity by controlling the ALD condition etc. [2]. This offers an interesting possibility that TiOx can be used as a hole selective contact alternative to the widely-used p-type a-Si:H and transition-metal oxides such as MoOx, WOx and V2Ox. In this contribution, we show for the first time that TiOx thin layers can act as efficient passivating hole selective contacts.

TiOx thin layers were deposited by thermal-ALD on c-Si (FZ, 1 Ωcm, (100), planer, n-type). Firstly, carrier selectivity of the deposited TiOx was studied by measuring Voc of solar cells. To decouple the carrier selectivity from its surface passivation an intrinsic a-Si:H buffer layer was inserted between c-Si and TiOx. A standard SHJ structure of either (i-n) a-Si:H/ITO or (i-p) a-Si:H/ITO stack was formed as a counter electron or hole contact, respectively. It is found that Voc of the solar cell is 200-400 mV higher when using our TiOx as hole contact than using it as electron contact. The SPV measurement showed that the TiOx induces large band bending (~900 mV) with respect to (n) c-Si while almost no band bending is created when deposited on (p) c-Si. This implies the presence of the negative fix charge in the TiOx, which is considered as one of the origins of the observed hole selectivity of the TiOx. Furthermore, we found that the carrier selectivity of TiOx depends significantly on the work function (WF) of the capping metal (or TCO) contact. The Voc is increased monotonically with increasing the WF of the capping layer when using TiOx as hole contacts. This indicates that band bending in (n) c-Si is significantly influenced by the WF of the capping layer, as it is well-known in the MIS contact system. By using an ITO/TiOx/(i) a-Si:H stack as an emitter layer on (n) c-Si, we obtained a relatively high Voc of 650 mV. Furthermore, the TiOx is also found to act as a good passivation layer with respect to c-Si. An effective lifetime of >1 ms was obtained by depositing TiOx on (n) c-Si without a-Si:H buffer layer. By optimizing both the surface passivation and the hole selectivity of the TiOx layer, we attained solar cell efficiencies of >18%, demonstrating that TiOx has potential of working as an efficient passivating hole selective contact. We discuss the origin of the hole transport in the TiOx which contradicts to the previous transport model based on the band alignment at the TiOx/Si interface.

great attention worldwide in the last decade. In contrast to the widely investigated and commercially competitive
thin film solar cells such as CuIn_xGa_{1-x}Se_2 and CdTe, Sb_2S_3 is non-toxic and exists naturally as stibnite minerals,
with both while Sb and S are both earth abundant elements. Sb_2S_3 is a binary compound with a single phase,
consisting of linked one-dimensional ribbons. Such a ribbon structure provides a preferential pathway for electron
transfer if with along the desired orientation. Antimony sulphide has high absorption coefficient of \(\alpha > 10^5\) and a bandgap of \(~1.7eV\), making it a suitable top cell candidate for tandem
cells. In this work, we demonstrate several crucial steps to enable this application in industrial cells by looking
into the influence of texture and doping level, oxide preparation method, metal contacting and thermal stability.

Secondly, we show that the SiO_x can be prepared in many ways (RCA, LTO, UV/O_3, NAOS) which all yield good
conductivity (< 1 m\(\Omega\)cm). Therefore, if a proper tunnel contact between c-Si/SiO_x/ZnO can be made,
the ZnO could serve as a full-area passivating, antireflective and lateral transport layer on the front side of a c-Si
solar cell. In this work, we demonstrate several crucial steps to enable this application in industrial cells by looking
into the influence of texture and doping level, oxide preparation method, metal contacting and thermal stability.

Furthermore, the rapid thermal evaporation (RTE) method has been recognized as an effective and reliable method
to grow Sb_2S_3 thin films, achieving an efficiency of 3.5% with a high Voc of 710 mV when using CdS as electron
transport layer (ETL). However, the reported orientation of the Sb_2S_3 is not well controlled when deposited by the
RTE method. In this work, we report the first fabricated Sb_2S_3 thin films with vertical orientation by VTD method.
To better understand the key factor that enables the vertical growth of Sb_2S_3, we use the RTE method as a reference,
which does not create vertically aligned Sb_2S_3 crystals on a CdS buffer layer. We achieved the an efficiency of
4.73% with a high Voc of 710 mV by using the iTO/CdS/Sb_2S_3/Gold configuration via VTD method compared to
370 mV using RTE method. We propose a simple model to describe the growth process.

**Atomic-Layer-Deposited ZnO as a Full-Area Passivating, Contacting and Antireflection Layer for c-Si Solar Cells**

Bart Macco, Marc Dielen, Bas van de Loo, Jimmy Melskens and Erwin Kessels; Eindhoven University of
Technology, Netherlands

The field of c-Si photovoltaics has strongly diversified in recent years with the advent of a wide variety of novel
passivation and passivating contact materials. Recently, we have demonstrated excellent surface passivation using
stacks of ultrathin (~1.5 nm) RCA SiO_x capped with ALD ZnO/Al_2O_3, with an implied open-circuit voltage (i\(V_{oc}\)) of
725 mV on planar c-Si(n) wafers. Within this SiO_x/ZnO/Al_2O_3 stack, the RCA SiO_x enables chemical passivation, similar as in poly-Si passivating contacts. The Al_2O_3 layer on top serves as a dense capping layer: It prevents
effusion of H from the ZnO upon annealing, which is needed to hydrogenate the SiO_x.

The unique aspect of the (doped) ZnO is that it is suited as an antireflection coating (simulated \(J_{sc} \approx 41.6\) m\(\Omega\)cm\(^2\))
which is also conductive (< 1 m\(\Omega\)cm). Therefore, if a proper tunnel contact between c-Si/SiO_x/ZnO can be made,
the ZnO could serve as a full-area passivating, antireflective and lateral transport layer on the front side of a c-Si
solar cell. In this work, we demonstrate several crucial steps to enable this application in industrial cells by looking
into the influence of texture and doping level, oxide preparation method, metal contacting and thermal stability.

Firstly, we verified that the stack also passivates on textured c-Si(n) wafers (i\(V_{oc} \approx 728\) mV) and that its passivation
on \(n^+\) doped surfaces has on par with industrial SiN_x. The stack is thermally stable up to \(~550\) °C, which is
not firing-compatible, but allows for a much higher paste curing temperature than for HIT-type cells.

Secondly, we show that the SiO_x can be prepared in many ways (RCA, LTO, UV/O_3, NAOS) which all yield good
passivation. UV/O_3 however yields the best passivation and is a room-temperature, single-sided treatment which
allows for accurate control over the oxide thickness (~1.65 nm).

Thirdly, in order to be able to contact the ZnO by metal, we can selectively remove the insulating Al_2O_3 capping
layer from the ZnO after hydrogenation by a wet-etch. Interestingly, no proper tunnel contact (\(>10 \Omega\)cm\(^2\)) can be
made on 3 \(\Omega\)cm c-Si(n) wafers, whereas a “first-try” value of ~0.1 \(\Omega\)cm\(^2\) was obtained on \(n^+\) doped surfaces (100
\(\Omega/sq\)). This contact resistivity is sufficiently low to use ZnO as a “hybrid” homo/heterojunction contact on \(n^+\)
surfaces: the $n^+$ doped Si surface provides electron-selectivity and facilitates tunneling, whereas the ZnO provides full-area passivation and aids in lateral transport, potentially allowing for higher Ohmic FSFs. Ongoing work focuses on the effect of the doping levels of both the c-Si and ZnO and the integration of the ZnO on the front of a PERC-type cell.

11:15 AM EN11.10.08/FF05.10.08 Controllable Fixed Charge Densities of TiO$_2$–Based Passivation Layer in c-Si Solar Cells Dohee Kim and Jihun Oh; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Surface passivation of crystalline Si (c-Si) is a key enabler for achieving high efficiency c-Si solar cells. While an Al$_2$O$_3$ surface passivation layer grown by atomic layer deposition (ALD) is known for excellent surface passivation for p-type Si from the negative fixed charges in the Al$_2$O$_3$ layer, low refractive index of Al$_2$O$_3$ demands an additional anti-reflection coating to suppress optical reflection, which leads to extra capital cost in c-Si solar cell manufacturing. Therefore, the multi-functional passivation layer that can provide both the high level of passivation quality and optimum optical property is necessary for high efficiency and cost-effective silicon solar cells. Here, we designed the multifunctional Al-doped TiO$_2$ passivation layer using ALD single process for low cost high efficiency silicon solar cells. TiO$_2$ film grown by ALD is a promising candidate for front multifunctional passivation layer of p$^+$-emitter/n-base structure due to negative fixed charge densities and appropriate refractive index for anti-reflection coating of silicon solar cell. ALD process allows to control the composition accurately and provide excellent passivation quality with thin films. In this work, we controlled the Al concentration in TiO$_2$ film with amorphous phase from 0 to 15.5 % by adjusting the cycle ratio of Al$_2$O$_3$ to TiO$_2$ in ALD process. We then successfully demonstrated that the fixed charge densities of Al-doped TiO$_2$ passivation layer can be controlled from $-8 \times 10^{11}$ cm$^{-2}$ to $-3 \times 10^{12}$ cm$^{-2}$ by varying the amount of Al concentration. As a result, we achieved implied $V_{oc}$ up to 709 mV with 15nm thick Al-doped TiO$_2$ on n-Si by maximizing field-effect passivation. We also investigated the effect of film thickness on surface passivation quality. By Al doping in TiO$_2$ passivation layer it showed significant enhancement of passivation performance compared to TiO$_2$ film from 5 to 55 nm thickness. Al-doped TiO$_2$ film provided high level of passivation quality leading to implied $V_{oc}$ of 700 mV from 15 to 55 nm. Finally, we have conducted research to reduce the total reflectance of silicon by applying Al-doped TiO$_2$ passivation layer of which the refractive index became close to 2.3, ideal refractive index for silicon solar cell. Therefore, we successfully demonstrated that the ALD Al-doped TiO$_2$ multifunctional passivation layer is a suitable candidate for high efficient Si solar cells based on the p$^+$-emitter/n-base structure with excellent optical property and outstanding passivation characteristic.

11:30 AM *EN11.10.09/FF05.10.09 Opening up the Processing Window for Chemical Vapor Deposited Oxides over Lead-Halide Perovskite Photovoltaics to Achieve Improved Performance Ravi D. Raninga1, Robert A. Jagt1, Solene Bechu2,3, Tahmida N. Huq1, Yen-Hung Lin1,2, Zewei Li1, Muriel Bouttemy2,3, Mathieu Fregnaux2,3, Henry J. Snaith1, Richard H. Friend4, Philip Schulz2,3, Judith L. MacManus-Driscoll1 and Robert Hoye1; 1University of Cambridge, United Kingdom; 2Institut Photovoltaïc d’Île de France (IPVF), France; 3Université de Versailles Saint-Quentin en Yvelines, Université Paris-Saclay CNRS, France; 4University of Oxford, United Kingdom; 5CNRS, Institut Photovoltaïc d’Île de France (IPVF), France

The growth of oxides by atomic layer deposition (ALD) over lead-halide perovskites in solar cells is attracting increasing attention for improving environmental and mechanical stability. A wide range of materials have now been investigated, including SnO$_2$, TiO$_2$, Al-doped ZnO and zinc tin oxide. These oxide overlayers have led to unencapsulated perovskite solar cells achieving stable performance for 4500 h in ambient air. However, the range of growth temperatures that can be used to grow the oxide overlayers over the perovskite films is restricted to typical values of only 60 - 100 °C due to the low stability of the perovskites. This limits the mobility and density of the oxide films achievable. In this work, we show that we can open up the processing window of oxides grown over lead-halide perovskites by using atmospheric pressure chemical vapor deposition (AP-CVD). This technique yields oxide films with similar uniformity, density and electronic properties as ALD films at similar growth temperatures, but with orders of magnitude higher growth rates [1]. We investigate the growth of TiO$_2$ over thermally-sensitive
CH$_3$NH$_3$PbI$_3$ films. We achieve a growth rate of 1.19 ± 0.04 nm s$^{-1}$ at a deposition temperature of 150 °C, which allows 7 nm TiO$_x$ films to be grown in 6 s (compared to >30 min for ALD). We show that this rapid deposition enables TiO$_x$ to be directly grown on CH$_3$NH$_3$PbI$_3$ films without damage to the bulk or surface, as shown by our X-ray diffraction, X-ray photoemission spectroscopy and time-resolved photoluminescence measurements. Indeed, we show that the TiO$_x$ overlayers can be grown at temperatures exceeding 180 °C without a significant drop in efficiency in CH$_3$NH$_3$PbI$_3$ solar cells. These results can be generalised to triple-cation perovskite devices, as well as to AP-CVD SnO$_x$ overlayers. In particular, we show that the conformal nature of the oxide overlayers lead to perovskite devices with improved performance (reaching 19.7% for triple-cation perovskite devices using a 60 nm SnO$_x$ overlayer). Our work demonstrates AP-CVD to be a versatile technique for growing high-quality oxides over a wide range of processing conditions.

Passivating Contacts Based on Physical Vapour Deposition Techniques for Silicon Solar Cells Di Yan, Andres Cuevas, Sieu Pheng Phang, Yimao Wan, Wenjie Yang and Daniel Macdonald; The Australian National University, Australia

Surface-passivating, carrier-selective contacts formed by heavily doped silicon films and thin interfacial oxide layers are capable of achieving high performance, leading to record efficiencies for silicon solar cells at both laboratory (25.8% TOPCon on n-type wafers and 26.1% POLO on p-type wafers) and industrial scale (24.6% by Trina Solar on 245 cm$^2$ n-type wafers). This type of passivating contact is increasingly regarded as the basis for the next generation of high performance technology for silicon solar cells. It can also constitute a baseline technology for PV research labs due to its simple implementation and excellent electrical performance. Different approaches have been explored for growing the thin interfacial oxide, depositing the silicon film, and incorporating dopants into it, most of which are based on various forms of chemical vapour deposition. In this contribution, we will present a novel approach based on physical vapour deposition. We have formed p-type passivating contacts based on PVD deposited silicon films doped in-situ with boron atoms. A low recombination current density $J_{oc} = 20$ fA/cm$^2$ and a low contact resistivity $\rho_c = 10$ mΩ-cm$^2$ have been achieved. Such a PVD-formed p-type passivating contact has been successfully implemented as full area rear hole selective contacts in p-type silicon solar cells. The best devices have reached a conversion efficiency of 23% with an open-circuit voltage of 701mV. At the same time, we are working on the development of n-type passivating contacts using a similar approach. In this presentation, we will compare the PVD approach with chemical vapour deposition approaches in terms of their fabrication processes and electrical performance. We will discuss results for PVD p-type passivating contacts and show work in progress for PVD n-type passivating contacts.

2:00 PM *EN11.11.02
Passivating Contacts Based on (Sub-)Monolayers of ALD-Oxides and the Kinetics of Thermal Bulk-Lifetime Degradation in FZ-Si Daniel Hiller; Australian National University, Australia

The first part of the talk will deal with (sub-)monolayers of ALD metal oxides, mainly Al2O3, deposited onto tunnel-SiO2. Wet-chemically grown and dry-thermally oxidized tunnel-SiO2 have a different surface termination, which leads to a different initial deposition during the first ALD-cycles. Despite the deposition of just sub-monolayers the Si-surface passivation can reach very good levels, even before a forming gas annealing, while maintaining a low contact resistivity due to tunneling through the ultra-thin layer stack. The surface passivation is explained via the formation of induced acceptor states in SiO2, which capture electrons from the dangling bonds at the Si/SiO2 interface so that these defects are electronically deactivated, while a negative fixed charge in the...
dielectric layer enables field effect passivation [1,2,3].

In the second part, the kinetics of the thermal activation as well as the annihilation of the grown-in defects in float-zone (FZ) Si wafers are studied. In the critical temperature window between approx. 400-800°C the bulk-lifetime of FZ-Si is decreased by more than 2 orders of magnitude and this degradation takes place on very short timescales. In addition to conventional furnace annealing, rapid thermal annealing (RTA) and millisecond flash lamp annealing (FLA) were studied. It will be demonstrated that also the recovery of the bulk lifetime can be achieved by thermal treatments that are much shorter and at lower temperatures than previously reported. Finally, the role of impurities detected by SIMS and their possible defect configurations (modelled by density functional theory) are discussed.

*Halogenated Semiconducting Polymers for Photovoltaic Conversion* Nicolas Leclerc, Narayanaswamy Kamatham, Olzhas Ibraikulov, Stéphanie Ferry, Pablo Durant, Amina Labiod, Benoit Heinrich, Thomas
Heiser3, Patrick Lévêque3 and Stéphane Méry2; 1ICPEES-CNRS, France; 2IPCMS, France; 3ICube, France

In recent years, partially fluorinated organic semiconducting polymers have aroused a considerable interest, to be used as electron-donating material in organic photovoltaic solar cells and have led to a significant increase in power conversion efficiency.[1-3] There are several reasons for this success, including:

- a planarization of the polymer skeletons via weak bonds between the fluorine atoms and the neighboring atoms and heteroatoms that improves the charge transport and the π-stacking in fluorinated polymers,
- the electro-deficient nature of the fluorine atom, which significantly stabilizes the energy levels of the frontier molecular orbitals.

For similar reasons, the chlorine atom has recently emerged as a suitable substitute for fluorine in some (macro)-molecular structures.[4] However, its larger steric size and reduced electronegativity, as compared to fluorine, is found to significantly modulate its impact.

In this communication, we propose to clarify the architectural principles that govern the properties of fluorinated and chlorinated polymers. In particular, we will discuss the evolution of the structural and optoelectronic properties of two families of organic semiconducting polymers incorporating either of these two halogens, according to their positions and numbers. Finally, through additional molecular engineering work at the level of side chains (in particular via innovative siloxane chain functionalization), we will also discuss the role of these side chains on the polymers solubility, on their orientation on the substrate as well as on their miscibility with electron-accepting materials.

10:15 AM EN12.01.02
Liquid-Crystalline and Semi-Crystalline—Understanding Structure-Function Relationships in n-Type Donor-Acceptor Copolymer Films Sabine Ludwigs; University of Stuttgart, Germany

My talk will give an overview about our recent findings on structure-function relationships of n-type donor-acceptor copolymer films based on P(NDI2OD-T2).1 On the molecular scale the role of 2,6- and 2,7-linked regioisomers in the polymer backbone for the preparation of regioregular (RR) and regioirregular (RI) systems is discussed.2 A specificity of P(NDI2OD-T2) is its strong tendency for aggregation in solution. We find that with increasing regioirregularity the overall aggregation tendency goes down which is beneficial for applications where mixing with other compounds is necessary, e.g. for organic photovoltaics or for chemical doping.

On the other hand the strong aggregation tendency of the RR system is useful for the preparation of highly anisotropic structures. On the mesoscopic scale we give new insights in the structure formation upon solution deposition.3 A morphology analysis shows that the deposited films are based on characteristic fiber morphologies where the fiber and chain directions are coinciding. The involvement of liquid-crystalline phases, in particular nematic-like preordering in highly concentrated solutions is demonstrated. Solvent vapor annealing is shown to lead to large area alignment in spherulite-like superstructures with semi-crystalline structures. Particularly nice is the applicability of blade-coating to achieve highly anisotropic films where both the bulk and the surface morphology can be determined: whereas blade-coated films after 220°C annealing give evidence for face-on orientation in the bulk with segregated stacking in polymorph Form I, 300°C annealing leads to an edge-on orientation with mixed stacking in Form II.3,4 All films have a top edge-on layer. Using these well-defined morphologies we can access detailed insights into electrochemical and chemical doping mechanisms.5,6

1) Y. M. Gross, and S. Ludwigs, P(NDI2OD-T2) Revisited – Aggregation Control as Key for High Performance n-Type Applications, Synthetic Metals 2019, 253, 73.
In this presentation we report the development of novel organic semiconductors, as well as the process engineering, for mechanically flexible transistors and circuits. Particularly, we show that "ultra-soft" polymers comprising naphthalenediimides (NDI) units co-polymerized with "rigid" and "flexible" organic units can change how charge transport is affected by mechanical stress, demonstrating that polymer backbone composition is more important than film degree of texturing. This strategy enables to reduce the elastic modulus of the semiconducting film by >2-4x while retaining good charge transport characteristics. In addition, by fabricating polymer/polymer blends by shear techniques, it provides a new avenue to enhance charge transport and achieve excellent mechanical robustness, which is further increased by modification of the film morphology. Thus, we demonstrate that these materials can enable TFT-based circuits for ultra-flexible displays and sensors on plastics. Finally, new oxide-polymer blends can be used to fabricate high-rectification and stretchable diodes via the self-assembly/phase separation properties of polymers having different surface energy.

Toulon, UMR CNRS 7334, IM2NP, France; ⁵ARMOR, Organic Photovoltaics Division, Armor Sustainable Energies (ASE), France

In the last years, non-fullerene acceptors (NFAs) have strongly burst into the field of organic photovoltaics (OPV) as alternative to fullerene derivatives. NFAs molecules not only have overcome the technical drawbacks associated to the fullerenes, but they also have made possible the increase of the efficiency over 16%¹ in single junction and over 17%² in tandem solar cells. Despite the extensive efforts made to achieve high efficiencies, more investigations are needed to further understand degradation mechanisms and hence improve their stability in order to make OPV technology a viable contender with technologies based on inorganic semiconductors for commercialization. In that context, we developed three new ITIC-like NFAs with extended p-conjugated spacers between the donor and acceptor moieties. We present the synthesis and characterization of these innovative NFAs, the performances obtained in bulk-heterojunction solar cells, in addition to a comparative study of the degradation mechanisms. The fluorination of the acceptor moiety was employed as a strategy to improve the device performance³. The organic solar cells fabricated with the new NFAs combined with PCE12 as the electron donor exhibit, power conversion efficiencies comprised between 5-6 %, as preliminary results. Noticeably, the new NFAs allowed to reach Voc over 1.1 V which is significantly higher than the Voc obtained with the reference ITIC-based devices. Interestingly, one of the new NFA demonstrates remarkable stability compared to ITIC.

In this communication, the synthetic strategies, the optoelectronic properties of the molecules, the performances in devices and the degradation mechanisms under thermal and photochemical stress will be presented and discussed.

Halochromic Switch from the 1st to 2nd Near Infrared Window of Diazapentalene-Dithienosilole Copolymers
Christine Dagron-Lartigau1,2, Wissem Khelifi1,2, Hussein Awada1,2, Katarzyna Brymora1,4, Sylvie Blanc1,3, Lionel Hirsch5,4, Frederic Castet3,4 and Antoine Bousquet1,2; 1Pau University, France; 2CNRS, France; 3ISM, France; 4Bordeaux University, France; 5IMS, France

Up to now, halochromism has mostly been demonstrated on chromophores absorbing in the UV-visible range. However, research in the field of Infra-Red (IR) technologies is in strong development, driven by technological needs in military and civilian applications, such as imaging, optical communications, energy or photodetectors.[1] Also, since 50% of the solar energy falls into the IR spectral region, photovoltaic materials are under development to increase solar cells efficiency.[2] IR-materials are also synthesized for biosensing and bioimaging because IR light penetrates into tissues, the so-called “biological window”.[3] To design organic IR materials, the basic principle is to reduce the bandgap. Specifically, synthesis of electron donor–acceptor (D–A) alternating conjugated copolymers has demonstrated high potential to decrease the bandgap under 1.5 eV, leading to IR-absorbing or emitting materials.[4] For the moment, most of these organic materials showed a maximum absorption peaks falling in the first NIR optical window covering 750−1000 nm. Actually, the second NIR optical window covering 1000−1350 nm is more promising for biological applications due to its higher photothermal conversion and deeper tissue penetration.[5]

In this presentation, we will report the synthesis of a low bandgap copolymer based on the 2,5-diazapentalene (DAP) unit, derived from the diketopyrrolopyrrole (DPP) chromophore. We combine the strong acceptor DAP unit with the dithienosilole (DTS), a photostable electron donor [6] that allows the introduction of solubilizing alkyl chains onto the silicon atom. As the result of the polymerization, an IR-material was synthesized with a maximum absorption at 850 nm in chloroform solution. Upon protonation of the DAP unit with Brønsted acids or its complexation with Lewis acids, the maximum of absorption is further shifted up to 1100 nm (edge at 1500 nm) in the second NIR optical window. To the best of our knowledge, this halochromic behavior is the highest reported up to now. Using a combination of spectrophotometry, cyclic voltammetry and DFT calculations, we identified the Brønsted and Lewis adducts that are formed. We can demonstrate that this optical shift is correlated with a decrease of the copolymers bandgap associated to the decrease in the LUMO energy and enhancement of the pi-electron delocalization along the conjugated backbone, as revealed by the lowering of the bond length alternation.[7]

Excellent Semiconductors Based on Tetraceno-Tetracene and Pentaceno-Pentacene—From Stable Closed-Shell to Singlet Open-Shell

Michel Frigoli1, Tanguy Jousselin-Oba1, Masashi Mamada2 and Chihaya Adachi2;
1Paris-Saclay University, France; 2Kyushu University, Japan

Designing stable open-shell organic materials through the modifications of the π-topology of molecular organic semiconductors have attracted recently considerable attention.1 However, their uses as an active layer in organic field-effect transistors (OFETs) are very limited and the obtained hole and electron charge mobilities are around 10−3 cm2 V−1 s−1.

Herein, we disclosed the synthesis of two peri-fused materials so-called tetraceno-tetracene (TT) and pentacenopentacene (PP) which have low band gap of 1.79 and 1.42 eV, respectively.2 Their ground state natures have been investigated by different experiments including steady state absorption, electron spin resonance, superconducting quantum interfering device (SQUID) and variable temperature NMR along with DFT calculations. TT and PP have closed-shell and singlet open-shell structures in their ground state, respectively, and possess high stability. Their biradical characteristics were found to be 0.50 and 0.64. The origin of the open-shell character of PP is related to the concomitant opening of two tetracenes with the recovering of two extra aromatic sextets and a small HOMO-LUMO energy gap (gap < 1.5 eV). Thanks to the high stability, thin film OFET devices could be fabricated. In TG-BC configuration PP shows remarkably high hole mobility of 1.4 cm2 V−1 s−1 while TT exhibits a hole mobility of 0.77 cm2 V−1 s−1. In configuration of BG-TC, ambipolar behaviors for both were obtained with hole and electron mobilities of 0.21 and 0.01 cm2 V−1 s−1 for PP and 0.14 and 0.006 cm2 V−1 s−1 for TT.

Molecular Strategies to Increase Robustness of Organic Semiconductor Thin Films for Application in Photovoltaic and Photoelectrochemical Devices
Kevin Sivula; Ecole Polytechnique Federale Lausanne, Switzerland

As organic semiconductors attract increasing attention to application in diverse fields such as bioelectronics and artificial photosynthesis, understanding and improving their robust operation in a variety of challenging environments is a critical task. In this presentation, results from our lab are highlighted including our development of a morphology control strategy using conjugation-break spacers [1], demonstration of melt-processed small-molecule OPVs [2], and investigations of covalently-linked block[3] and network polymers[4], which afford tunable charge transport and solvent tolerance—making them promising for application as charge-transport interlayers in all-solution processed devices. In addition the application of bulk-heterojunctions to artificial photosynthesis via photoelectrochemical water splitting[5] will be discussed in terms of the requirements for material stability.

2:15 PM EN12.02.02
Hybrid Field Effect Transistors (HFET) a Fully Covalent Transistor with a Pi-Conjugated Organosilica Material

Olivier Dautel1, Gilles Roche1, Guillaume Wantz2 and Joel Moreau1; 1Charles Gerhard Institute, France; 2Bordeaux INP UMR 5218, France

The use of novel organosilica materials embedding π-conjugated moieties as semiconductor into field effect transistors will be presented. For that purpose, the [1]benzothieno[3,2-b][1]benzothiophene (BTBT),1 has been chosen as π-conjugated core, first functionalized with hydroxyl groups2 and then modified with hydrolysable and cross-linkable triethoxysilyl moieties. After polycondensation, this compound forms a hybrid material composed of charge transport pathways as well as insulating layers (SiOx). However, overall, the material is found to be a semiconductor and can be incorporated into field effect transistors. Taking advantage of the solgel chemistry3 involved here, we built Hybrid Field Effect Transistors that are fully cross-linked with covalent bonds.4 Molecules are cross-linked to each other, covalently bonded to the silicon oxide dielectric and also covalently bonded to the gold electrode thanks to the use of an appropriate additional interfacial monolayer in between. This is the first report of fully covalent transistors. Those devices show impressive resilience against polar, aliphatic and aromatics solvents (even under sonication). This study opens the route towards a new class of hybrid materials to create highly robust electronic applications.

Influence of Alkyl Side-Chain Type and Length on the Thin-Film Microstructure and OFET Performance of Naphthalene Diimide-Based Organic Semiconductors

Adam Welford1, Subashani Maniam1, Eliot Gann2, Lars Thomsen3, Steven Langford4 and Chris McNeill3; 1Monash University, Australia; 2National Institute of Standards and Technology, United States; 3Australian Nuclear Science and Technology Organisation, Australia; 4Swinburne University of Technology, Australia

The effect of side chain length and type on the microstructure and organic field-effect transistor (OFET) performance of solution-processed naphthalene diimide (NDI) thin films will be discussed. Linear side chains with four (C4), five (C5), six (C6), eight (C8) and twelve (C12) carbon atoms are studied along with a branched ethyl hexyl (EH) side chain. Interestingly, relatively high mobilities of up to ~ 0.2 cm²/Vs are achieved for short (C4) and long (C12) side chains with linear chains of intermediate length and the branched side chain producing lower mobilities. The observed mobility trends are explained in terms of the competing influence of changes in crystal packing and changes in thin film morphology with changes in side chain length. Shorter side chains produce changes in the lateral stacking of NDI units which promote higher mobility while longer side chains produce solution-processed thin films with higher film quality evidenced by larger domain sizes and lower orientational disorder. Side chain length is also found to strongly modulate the molecular orientation of the NDI core, with high edge-on orientations observed for long chains, and tilted orientations for short chains. Thin film microstructure is investigated using a range of techniques including atomic force microscopy, grazing incidence wide-angle X-ray scattering and near-edge X-ray absorption fine-structure spectroscopy.

Molecular Design and Structure-Function Relationships in Thermally Activated Delayed Fluorescence (TADF) Materials for Applications in OLEDs Martin R. Bryce; Univ of Durham, United Kingdom

Molecules showing thermally activated delayed fluorescence (TADF) have emerged as a promising alternative to heavy-metal complexes for applications in high efficiency organic light emitting diodes (OLEDs).[1] To date the most successful TADF emitters have been designed with electron donor (D) and electron acceptor (A) units covalently linked with conjugational separation between the units. This separation can lead to a very small excited state singlet-triplet gap (ΔEST) on the order of a few meV. If ΔEST is small, a significant population of the triplet state that occupies upper vibrational levels is able to undergo reverse intersystem crossing (RISC), giving rise to delayed fluorescence. OLEDs fabricated with TADF emitters have shown impressive performances, sometimes with external efficiencies (EQE) above 30%.[2]

We will report how the efficiency of TADF can be controlled by precise molecular design of donor-acceptor linked molecules, with particular emphasis on the rigidity of the molecular framework and the dihedral angle between the donor and acceptor units. Representative building blocks include: phenothiazine, acridine and triazaangulene as donors, and dibenzothiophene-S,S-dioxide and 9,9-dimethylthioxanthene-S,S-dioxide as acceptor units. Synthesis, photophysical studies, theoretical calculations and high efficiency OLED data, including blue/deep-blue emitters will be presented, based on our on-going studies.[3-6]

Optical Properties of TADF Materials by TDDFT Nobuhiko Akino and Yasunari Zempo; Hosei University, Japan

Organic light emitting diodes (OLEDs) have been of great interest for display and lighting applications during decades and have been increasing to be utilized in smartphone and flat-panel display due to many advantages such as self-emission, high contrast, wide viewing angle, and so on. From the OLED material point of view, improvement of emissive exciton generation probability is an important factor for higher efficiency. After the development of fluorescent materials, the phosphorescent materials have been
introduced and have shown to achieve high efficiency. On the other hand, phosphorescent materials require expensive heavy metal such as Ir and Pt. Recently, thermally activated delayed fluorescence (TADF) materials have been developed as a new class of light emitting material where triplet excitons are converted into singlet excitons without heavy metals in phosphorescent materials.[1] Theoretically, an internal quantum efficiency (IQE) of 100%, the same as for phosphorescent materials, can be expected.

In order to study the optical properties of materials, we have employed the time dependent density functional theory (TDDFT), which is one of the most prominent and widely used methods for calculating excited states of various molecules, and it is recognized as a powerful tool for studying their electronic transition. In our calculations, the real-time and real-space (RSRT) techniques are employed in solving time dependent Kohn-Sham equation by the finite difference approach [3] without using explicit bases such as plane waves and Gaussian basis. Within the framework of this approach, we can solve for the wave functions on the grid with a fixed domain, which encompasses the physical system of interests. Furthermore, we have applied the maximum entropy method (MEM) to the optical analysis of the time-series data from the real-time TDDFT. We have confirmed that the MEM technique provides higher resolution in fewer computational steps, compared to the conventional Fourier transform technique.

In this study, we have focused on the spectrum of TADF materials including materials based on DABNA[2], which has recently been studying intensively because of its narrow FWHM (full-width at half maximum) in its spectrum, that is, of its high color purity. Main focus would be to design new materials with small exchange energy required for TADF character and with good color purity, starting from the understanding of existing molecules and the effect of substituents by quantum chemical calculation. The peak emission wavelength seems to be well predicted. In the presentation, we will discuss the correlation between simulation and experiment in peak wavelength and also the spectrum shape.

Acenes with “Butterfly Wings”—Singlet Fission in a Highly Stable Bisalkynylated Derivative of Tetrabenzoanthracene Peter Budden1, Matthias Müller2, Jan Freudenberg2, Uwe Bunz2 and Richard H. Friend1; 1University of Cambridge, United Kingdom; 2Heidelberg University, Germany

Through transient optical and magnetic field measurements we have observed clear evidence for singlet exciton fission to triplet exciton pairs in a “butterfly-shaped” acene derivative, TIPS-tetrabenzoanthracene (TTBP), that has excellent ambient stability imparted by the presence of triphenylene “wings”.

The synthesis and impressive stability of large acenes with triphenylene “wings”, including TTBP, have recently been reported. One property of acenes of great current interest is their ability to undergo singlet fission: that is for photoexcited singlet excitons to generate a pair of triplet excitons each of roughly half the energy of the singlet. The energy of these triplets could be utilised to reduce thermalisation losses in solar cells.

The core of the molecule to which the butterfly wings are attached is Trisopropylsilylthynyl-anthracene (TIPS-anthracene). The total effect of the two wings to the molecular energy levels is similar to that of extending anthracene by one regular benzene ring, i.e. TIPS-tetracene, which itself has previously been shown to undergo efficient singlet fission, albeit with poor ambient stability. Here, the triplet absorption spectrum of TTBP that we observe in transient absorption experiments is remarkably similar to that of TIPS-tetracene, indicating that the triplet exciton is concentrated on the central part of the TTBP molecule that is common to TIPS-tetracene, and the stabilising butterfly wings do not greatly affect the structure of the triplet. We posit that this is key to the surprising persistence of singlet fission.

In TIPS-tetracene, morphology plays a key role in the efficiency of singlet fission, particularly in the separation of the triplet-pair state, which has a broad red-shifted emission. In TTBP, we have observed a similar triplet-pair state emission, along with the characteristic triplet transient absorption spectra, and the magnetic field effect on photoluminescence yield, which is evidence of an equilibrium between singlet fission and triplet-triplet annihilation. The strength of these effects, and therefore the efficiency of singlet fission, can be tuned by film preparation,
especially by the addition of an inert polymer. These findings represent significant progress towards stable and efficient singlet fission materials that can be used commercially to reduce losses in photovoltaics.

Singlet fission (SF) has the potential to significantly enhance solar cell performance if charges can be efficiently generated from the resulting triplet states. Here, we study charge separation from triplet excitons in polycrystalline pentacene using an electrochemical series of electron-acceptor molecules with varied reduction potentials, and follow the SF and charge transfer dynamics using a combination of transient absorption spectroscopy and time-resolved microwave conductivity. We find that even at the optimal driving force the rate constant for charge transfer from the triplet state is surprisingly small, (~10⁷ s⁻¹) when they are produced by singlet fission, but that triplets transferred into the film by a sensitizer dissociate much more rapidly.

**Enabling Efficient Triplet-Fusion Upconversion Using a Tetracene Homodimer**
Christian J. Imperiale¹, Philippe B. Green¹, Ethan Miller², Niels Damrauer² and Mark W. Wilson¹; ¹University of Toronto, Dept. of Chemistry, Canada; ²University of Colorado Boulder, United States

Exciton-mediated photon upconversion (EXUC) can transform low-energy photons into higher-energy fluorescence under low-intensity illumination. A sensitizing species is necessary to generate triplet excitons from absorbed photons and transfer this energy to the triplet state of the acceptor molecules. Here, we demonstrate the use of a structurally rigid, norbornyl-bridged, tetracene homodimer (TIPS-BTc) as a triplet acceptor and emitter for EXUC in solution. Using an organometallic triplet sensitizer (PdPc(0Bu)₈), incident photons of λ=730 nm were upconverted by 0.6 eV to emitted photons of λ=540 nm via triplet fusion (TF). By comparison with Stern-Volmer phosphorescence quenching experiments, we observe that TIPS-BTc can achieve brighter upconversion emission than monomeric controls (rubrene and tri-isopropylsilyl ethynyl tetracene (TIPS-Tc)) for the same number of extracted triplet excitons. We build a rate-equation model to simulate the concentration- and intensity-dependence of the upconverted emission at steady state, and extract rate constants for TF in the monomeric controls comparable to literature. However, for dimeric TIPS-BTc, our kinetic simulation cannot simultaneously reproduce the Stern-Volmer data and the concentration dependence of the threshold for max-efficiency upconversion. This result provides evidence that dimeric annihilators may offer pathways towards triplet fusion that are more efficient than uncorrelated diffusion, and could boost overall upconversion performance when paired with molecular engineering that advances the efficiency of triplet transfer. It also validates the strategy of designing rigid, electronically-decoupled molecular dimers for excitonic upconversion from known monomeric emitters, with the ultimate goal of reducing the collisional dependence of solution-phase exciton-mediated photon upconversion.

**Singlet Fission Molecules Among Known Compounds—Finding a Few Needles in a Haystack**
Daniele Padula¹,², Omer H. Omar¹, Tahereh Nematiaram¹ and Alessandro Troisi¹; ¹University of Liverpool, United Kingdom; ²Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

A large set of candidates for singlet fission, one of the most promising processes able to improve the efficiency of solar cells, are identified by screening a database of known molecular materials. The screening was carried out through a procedure exploiting quantum chemical calculations of excited state energies, carefully calibrated against a substantial set of experimental data. We identified ~200 potential singlet fission molecules, the vast majority of which were not known as singlet fission materials. The molecules identified could be grouped into chemical families enabling the design of further singlet fission materials using the hits as lead compounds for further explorations. Many of the discovered materials do not follow the current design rules used to develop singlet fission materials illustrating at the same time the power of the screening approach method and the need of developing new design
principles.

Relation between Molecular Packing and Singlet Fission in Thin Films of Brominated Perylenediimides
Ferdinand C. Grozema, Kevin M. Felter and Rajeev K. Dubey; Delft University of Technology, Netherlands

Perylenediimids (PDIs) are well-known dyes that have attractive properties for a variety of applications in optoelectronic devices. These properties include strong absorption in the visible, high charge carrier mobility and excellent electron accepting properties. In addition, they also exhibit close to ideal singlet/triplet energetics for singlet fission and triplet-triplet annihilation upconversion. Interestingly, the electronic properties of solid state materials based on these molecules strongly depend on the way the molecules are organized in the crystalline state. This is true for the optical properties, but also for transport of charges, excited state diffusion and for less common photophysical processes such as singlet exciton fission.

A strong relation has been found between the intermolecular packing of the individual packing in the solid state and the efficiency of singlet fission. This can be effectively tuned by changing the substitution pattern on the conjugated core of the molecule. Until now, most modifications involve introduction of different sidechains on the imid-nitrogen. In this work, we show a new approach by introducing bulky bromine atoms directly in the aromatic core of the PDI, leading to a twisting of the core. This significantly affects the solid state packing but also the optoelectronic properties of the individual molecules.

We show that changes in the molecular packing induced by bromination have a strong effect on the temperature dependent photoluminescence, expressed as an activation energy. These effects are explained in terms of excimer formation for PDIs without bay-area substitution, which competes with singlet fission. Introduction of bromine atoms in the bay-positions strongly disrupts the solid-state packing leading to strongly reduced excitonic interactions and excimer formation. The suppression of this competing process leads to an overall higher yield of singlet fission, despite the expected smaller electronic coupling for singlet fission. This shows that optimizing the electronic coupling is not the only factor that is important in optimizing singlet fission yields, suppression of competing processes is also of prime importance.

The Molecular Organization of Non-Fullerene Acceptors for Organic Photovoltaics Pierluigi Mondelli1,2, Priti Tiwana1, Michal Krompiec1,3 and Graham Morse4; 1Merck Chemicals Ltd, United Kingdom; 2Technische Universität Chemnitz, Germany; 3University of Southampton, United Kingdom; 4Natrix Separations Inc., Canada

The topic of Non-Fullerene Acceptors (NFAs) in the field of Organic Photovoltaics (OPV) has become tremendously important to industrial and academic research, as the rapid development of these materials has pushed the device power conversion efficiency over the 15% threshold.1 An efficient chemical design of these molecules has led to a big surge in performance, achieving optimum optical absorptions and reduced voltage losses.2 However, low electron mobilities still represent a major issue for the commercialization of large-scale solution-processed OPV devices.3 Researchers speculate that the highly anisotropic and two-dimensional conjugated structure of these molecules is critical to their organization, which in turn affects their electronic functions (e.g. carrier mobility).2 In our industrial experience, we have also observed unique coating and thermal behaviour of these materials, suggesting the importance of their crystallinity.

Our work aims to provide direct insights into the crystallization of the materials and their charge transport. With this purpose, we compare a large body of newly identified non-fullerene single crystals and previously reported structures, including novel non-fullerene molecules. By meta-analysis, we identify common packing motifs,
elucidate the role of the molecular fragments (sidechains, donor and acceptor groups), perform statistical analysis of close contacts and explore solvated host-guest complexes. Finally, the importance of crystal packing and topological connectivity on the charge transport is explored by linear-scaling Density Functional Theory calculations. Experimental evidences of the influence of the solid-state organization on the charge carrier mobility and performance in OPV devices is the focus of our investigations that are currently underway.

The Role of the Solvent and the Size of the Nanotube in the Non-Covalent Dispersion of Carbon Nanotubes with Short Organic Oligomers—A DFT Study Jolanta B. Lagowski and Ahmad I. Alrawashdeh; Memorial University of Newfoundland, Canada

Among different dispersants of single-walled carbon nanotubes (SWCNTs), conjugated organic oligomers have the ability to interact strongly with SWCNTs and allow for effective dispersion in several organic solvents. Recently, we have carried out two computational investigations (Phys. Chem. Chem. Phys., 2017, 19, 28071 and J. Phys. Chem. C 2017, 121, 4692) on the intermolecular interactions between conjugated organic oligomers and SWCNTs in order to gain insight into an important process of the non-covalent dispersion of carbon nanotubes with short oligomers. These studies highlighted the fact that two additional factors, namely, the effect of the solvent and the carbon nanotube’s size on these interactions need further investigation. In this work (RSC Adv., 2018, 8, 30520), with the help of model compounds (which are molecular fragments of the short oligomers used in our previous investigations) we analyze the significance of these two factors. We employ three dispersion corrected density functional theory (D-DFT) approximations (B97D, wB97XD, and B3LYP-D3) to assess the effect of the DFT method and two basis sets (6-31G(d) and 6-31++G(d,p)) to assess the importance of using a higher basis set in our computations. The main focus of this work is to assess the effect of solvation and nanotube’s size on the structure, electronic properties, and binding energies of the respective pairs of model compounds and segments of carbon nanotubes. No significant differences are found between the results of (6,5) and (8,7) SWCNTs in either the geometrical parameters of interacting oligomers or the general tendency of wrapping of their long side chains (SCs) around the nanotubes. However, we find that the binding energies/atom between nanotubes and model compounds are larger for nanotubes with smaller diameter. The results of electronic properties also show that all model compounds interact more strongly with the (6,5) SWCNT than with the (8,7) SWCNT. Polar solvents such as chloroform lower binding energies relative to those obtained without a solvent or with non-polar solvents such as hexane. It appears that the presence of a solvent weakens the oligomer/nanotube interactions and, presumably, strengthens the oligomer/solvent and nanotube/solvent interactions to facilitate dispersion of SWCNTs.

EN12.04.03
Ultraviolet Post-Treatment Method for the Mass Production of Highly Crystalline Conductive Polymer Thin Films Jun Hwa Park, Lee Jeong Ik and Yeong Don Park; Incheon University, Korea (the Republic of)

Here, we developed a facile post-treatment method using ultraviolet irradiation that produced crystalline polymer nanofibrils in the solid film state. Ultraviolet irradiation over a few minutes effectively transformed the polymer chain conformational structure and promoted polymer chain extension and association in the film state. Brief ultraviolet irradiation of a thin film fabricated using a high boiling point solvent produced well-ordered molecular structures among the extended P3HT chains, whereas ultraviolet irradiation over longer times led to breaks in the chemical structures of the P3HT, resulting in shortened conjugation lengths. Conformational changes in the polymer main chain and resulting nanofibril morphologies induced by ultraviolet irradiation facilitated charge transport in organic transistors prepared using these films. The relationship between the molecular structural order and the electrical characteristics of the films was used to determine the optimum ultraviolet irradiation time.

EN12.04.04
Degradation Mechanism of Organic Light-Emitting Devices Incorporating Thermally Activated Delayed Fluorescent Dopant Materials Yu Kyung Moon1, Sanju Hwang1, Hojin Jang2, Sinheui Kim1, Jun Yeob Lee2 and
Organic light-emitting devices (OLEDs) are advantageous over conventional flat panel display. The success of OLEDs depends significantly on the performance of emitting molecules. Molecules displaying thermally activated delayed fluorescence (TADF) have emerged as promising dopant materials, because they are capable of harvesting all the electrogenerated excitons without relying on precious late transition metals. However, exploitation of the full potential of electroluminescence from TADF materials is retarded by short operational lifetime of devices. We recently proposed the degradation mechanism involving exciton-mediated electron transfer between a host and a phosphorescent dopant within the emitting layers of OLEDs. The electron transfer results in the formation a radical ion pair (RIP), very vulnerable to degradation. RIP was found to be responsible for irreversible degradation of the emitting layer, and its lifetime was governed by the charge recombination kinetics. We hypothesized an occurrence of the identical electron-transfer processes in OLEDs having a TADF dopant in place of a phosphorescent dopant. To verify our hypothesis, we investigated the degradation behaviors of the pairs of a TADF dopant, phenoxazine-1,3,5-triphenyltriazine (PXZ-TRZ), and a series of commercially available host materials, including 4,4′-bis(9-carbazolyl)-1,1′-biphenyl (CBP), 4,4′-bis(9-carbazolyl)-2,2′-dimethylbiphenyl (CDBP), N,N′-dicarbazolyl-3,5-benzene (mCP), 3,3′-bis(9-carbazolyl)biphenyl (mCBP), 1,3,5-tri(m-pyridin-3-ylphenyl)benzene (TmPyPB), and bis[2-(diphenylphosphino)phenyl]ether oxide (DPEPO). Electrochemical measurements predicted positive driving forces (–ΔG_{eT}, 0.69–1.47 eV) for electron transfer from the dopant to host exciton, which suggested the spontaneous formation of RIP between the TADF dopant and hosts. Annihilation of RIP by charge recombination was found to have very positive driving forces (–ΔG_{eT}, 2.62–2.76 eV).

To investigate the electron-transfer processes, we performed steady-state photophysical experiments. The addition of the dopant into a host solution resulted in fluorescence quenching of the host in a concentration-dependent manner. The rate constant for the bimolecular quenching was found to be proportional to –ΔG_{eT}, indicative of the formation of non-emissive RIP. This notion was supported by the observance of strong signals (g = 2.012) in photoinduced electron paramagnetic resonance spectra. The RIP accelerated the degradation of the materials under continuous photolysis, as evidenced by the rates of photodegradation greater than those determined for the individual compound. This result supported RIP being the key intermediate of the intrinsic degradation of TADF emitting layers. Multi-layer electroluminescence devices with a configuration of ITO/DNTPD (60 nm)/BPBPA (20 nm)/PCzAC (10 nm)/host:PXZ-TRZ (30 nm : 10%)/DBF-Trz (5 nm)/ZADN (30 nm)/LiF (1 nm)/Al were fabricated and evaluated. Operation lifetime of the devices was quantitated as the time when the luminance decreased to 90% of the initial value (LT_{90}) under a constant current driving mode. LT_{90} values were 13 h (CBP), 5.9 h (CDBP), 18 h (mCP), 27 h (mCBP), 0.11 h (TmPyPB), and 0.24 h (DPEPO). We found a positive linear correlation between LT_{90} with –ΔG_{eT} for the ‘hole-transporting type’ hosts (i.e., CBP, CDBP, mCP, and mCBP). The significantly short LT_{90}s of the devices having ‘electron-transporting type’ host (i.e., TmPyPB and DPEPO) suggested the presence of a different degradation mechanism, because their –ΔG_{eT} were not very different from –ΔG_{eT} of ‘hole-transporting type’ hosts. The fast charge recombination rate minimized an accumulation of RIP. Collectively, our findings supported that the acceleration of charge recombination within RIP is crucial for device longevity. Our study revealed the importance of electrochemical control between a TADF dopant and a host for realizing long operational lifetimes of OLEDs.

EN12.04.05
**Direct Evidence for Discrete Electronic Traps Induced by Bias Stress in Organic Field-Effect Transistors**
Hamna Haneef1, Qianxiang Ai2, Chad Risko2, John Anthony2 and Oana D. Jurchescu1; 1Wake Forest University, United States; 2University of Kentucky, United States

Organic semiconductors (OSCs) have gained significant attention as active components in various (opto)electronic devices due to low-cost manufacturing, ease of processing, mechanical flexibility, and versatility in chemical synthesis. These attractive properties are a direct consequence of the weak intermolecular interactions of van der Waals type characteristic of these materials. On the other hand, the weak interactions make OSCs susceptible to the formation of localized electronic states in the band gap, which can trap charge carriers at different timescales. Charge carrier trapping is an important phenomenon in electronic devices and its impact on device performance and long-term stability has been extensively studied. However, determining the origin, concentration, and composition of electronic traps in organic semiconductors, as well as their spatial and energetic distribution, is not trivial and remains elusive. In this work, we probe the trap density of states (DOS) using organic field-effect transistor measurements and quantify their energy distribution in response to applying bias stress. DOS analysis provides
direct evidence for the creation of a discrete electronic trap in a solution-processed OSC, namely tri(n-hexyl)silylthynyl benzodithiophene (TnHS BDT) trimer, in response to repetitive electrical measurements performed under ambient conditions. The trap DOS spectrum evaluated over the course of bias stress measurements (total 500 min) shows the dynamics of the trap formation, which starts with an initial broadening of the DOS after 10 min, followed by the appearance of a discrete peak located at ca. 0.3 eV above the valence band edge after 20 mins of bias stressing. The peak is absent in measurements performed under vacuum. The correlation of the trap DOS spectrum with the time evolution of device metrics, including mobility, subthreshold swing, and the threshold voltage, suggests that the generated electronic trap occurs at the interface between the OSC and the dielectric. Density functional theory (DFT) calculations are employed to elucidate the nature of the trap and the mechanism of formation. This work marks as the first of its kind in experimentally detecting electronic traps generated as a result of bias stress and concurrently determining their precise nature by using a combination of trap DOS analysis and DFT calculations.

EN12.04.06
Applications of Organic Field-Effect Transistors in Biomimetic Field Wei Shi; Institute of Chemistry, Chinese Academy of Sciences, China

Organic field-effect transistors (OFETs) possess the accessibility of flexible, large-area, multi-signal detection, and bio-compatibility. For their applications in the biomimetic field, another requirement is the low work-voltage. Usually, the bio-signals are much more difficult to capture compared to the common chemical signals since their magnitudes are very small. Meanwhile, considering that the bio-system is relatively fragile and complicated, the detection method is thus limited. Especially, for the in-situ and non-invasive detection, not only the low work-voltage is required, low/non toxicity and high selectivity are also essential. Here, we mainly focus on the application of OFETs in the field of non-invasive blood glucose detection by introducing the porous film in the OFET device to increase the sensitivity of the OFET device. Usually, the detection of the liquid analyte is realized by the electrochemical transistor since their unique property of integrating the electrochemical gate. The report of using the OFET to detect the liquid analyte is rare. We designed to take advantage of the interface between the organic semiconductor and the dielectric in OFET to achieve the detection of glucose.

Structure-Function-Performance Relationships in Conjugated Polymers for Photocatalytic Hydrogen Generation from Water Sam Hillman1,1, Reiner S. Sprick2,2, Drew Pearce1,1, Lucas Flagg1, Michael Sachs1,1, Duncan Woods2,2, Xingyuan Shi1,1, Anne Guilbert1,1, Andrew Cooper2,2, James R. Durrant1,1 and Jenny Nelson1,1; 1Imperial College London, United Kingdom; 2University of Liverpool, United Kingdom; 3University of Washington, United States

Organic semiconductor materials are attracting increasing interest for catalytic hydrogen generation [1]. Despite this, very few studies [2] attempt to deconvolute the factors (structural, optical, and electronic) that affect photocatalytic performance.

Here we investigate a collection of novel linear conjugated polymer photocatalysts which exhibit high rates of hydrogen photo-evolution from water in the presence of a sacrificial electron donor. Unlike most organic photocatalysts, these materials are solution processable, allowing for greater control of structure to explore the structure-activity relationship. These polymers show a positive correlation between the density of hydrophilic groups and the rate of hydrogen evolution. Using transient absorption spectroscopy (TAS) and spectroelectrochemistry, we observe that catalytic activity is correlated with the density of photogenerated electrons in the polymer. Using electronic structure and molecular dynamics calculations, we then investigate the effect of different hydrophilic groups on charge transfer through their role in structuring the liquid environment close to the polymer backbone. We find that the impact of the polar groups on the dielectric properties of the local liquid environment is critical for controlling the driving energy for charge generation.

Charge generation in both polymer particles and thin films is also highly dependent on their physical microstructures. Hydrogen evolution and TAS measurements suggest that catalytic activity exists not only at the polymer-liquid interface but also within the structures, indicating that the materials are partially permeable to the liquid environment. Using photoluminescence spectroscopy, atomic force microscopy and TAS, we show that this activity can be explained by a combination of solvent penetration and exciton diffusion. We demonstrate that this
understanding can be used to control the structure of the photocatalyst and enhance catalytic performance. Together with the control of the solvent environment, this work provides design rules for improved polymer photocatalyst behaviour.

EN12.04.08

**Heating-Induced-Aggregation to Prepare High Performance Non-Fullerene Organic Solar Cells** Tao Wang; Wuhan Univ of Technology, China

The power conversion efficiency of non-fullerene organic solar cells develops dramatically in recent years. Although tremendous efforts have been dedicated to the design and synthesis of new small molecular acceptors, less is known on how the molecular order and aggregation of these small molecular acceptors will affect the device performance. A high structure order is desired to achieve high charge transport property, however, it can also induce excessive phase aggregation and consequently reduce the exciton dissociation efficiency to reduce device performance. We have discovered that heating-induced molecular ordering and aggregation can be an effective approach. The assistance of heating during film casting can suppress the formation of large-scale spherelite from INPIC-4F non-fullerene acceptor, but encourage the formation of p-pstacks to reduce phase separation to results an efficiency over 13%. Heating also convert COi8DFIC from edge-on and flat-on oriented lamellae to face-on H- and J-type p-pstacks, which broadens the light absorption spectrum and reduces the contact between donor and acceptor molecules for efficient exciton dissociation. An high efficiency of 13.8% was achieved in PTB7-Th:COi8DFIC binary solar cells. Heating-induced-aggregation emerges as a new strategy to optimize the morphology of non-fullerene solar cells for high peformacne.

EN12.04.10

**12.5% Flexible Nonfullerene Solar Cells by Passivating the Chemical Interaction between the Active Layer and Polymer Interfacial Layer** Fei Qin and Yinhua Zhou; Huazhong University of Science & Technology, China

Nonfullerene organic solar cells have been attracting significant attention in the past several years. It is still challenging to achieve high-performance flexible nonfullerene organic solar cells. Nonfullerene acceptors are chemically reactive and tend to react with the low-temperature processed low-work function interfacial layers, such as polyethylenimine ethoxylated (PEIE), which leads to the “S” shape in the current-density characteristics of the cells. In this work, we deactivate the chemical interaction between the nonfullerene active layer and the polymer interfacial layer of PEIE by increasing its protonation. The PEIE processed from aqueous solution shows more protonated N⁺ than that processed from isopropanol solution, observed from X-ray photoelectron spectroscopy. Nonfullerene solar cells (active layer: PCE-10:IEICO-4F) with the protonated PEIE interfacial layer show an efficiency of 13.2%, which is higher than the reference cells with a ZnO interlayer (12.6%). More importantly, the protonated PEIE interfacial layer processed from aqueous solution does not require a further thermal annealing treatment (only processing at room temperature). The room-temperature processing and effective work function reduction enable the demonstration of high-performance (12.5%) flexible nonfullerene organic solar cells.

EN12.04.11

**Transferrable Hybrid Graphene Oxide/Silver Nanowire Transparent Electrode Fabricated by Electrophoretic Deposition** Woo Hyun Chae, Thomas Sannicolo and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Owing to their high conductivity, transparency, flexibility, and compatibility with solution processes, silver nanowire (AgNW) networks have been widely explored as a promising alternative to indium tin oxide (ITO). However, while AgNW networks have been successfully integrated as transparent electrodes in a range of optoelectronic devices, their susceptibility to corrosion and thermal instability remain limiting factors for widespread adoption. To impart stability, hybrid electrodes that combine AgNW with an encapsulating material such as graphene or semiconducting oxides have been explored, although they have relied on costly processes such
as chemical vapor deposition (CVD) or atomic layer deposition (ALD). Graphene oxide (GO) is an appealing barrier material due to its tunable properties, robustness under a range of conditions, and solution-processability. However, thus far the processing methods to fabricate GO/AgNW hybrid structures have been largely limited to various forms of spray deposition that can only be used on flat substrates with optimized wettability and require expensive equipment for scale-up. Furthermore, many aspects of the chemical and electrical stability of GO/AgNW hybrid electrodes have either not been fully demonstrated or remain poorly understood.

In this study, we propose a scalable and economically viable process involving electrophoretic deposition (EPD) to fabricate a highly stable hybrid transparent electrode with a sandwich-like structure, where the AgNW network is covered by GO films on both sides. The use of EPD allows facile control over the thickness of the GO film, leading to tunable transparency. The newly developed process allows the conductive transparent film to be transferred to an arbitrary surface after deposition and demonstrates excellent sheet resistance (15 Ω/sq) and transmittance (75% at 550 nm) on glass substrates. Unlike bare AgNW networks, the hybrid electrode was found to retain its original conductivity under long-term storage at 80°C. This chemical resilience can be explained by the absence of major silver corrosion products for the AgNW encapsulated by GO as indicated by X-ray photoelectron spectroscopy (XPS). In-situ electrical ramping and resistance measurements up to 20V were conducted in order to assess the electrical stability of our electrodes. The results indicate a novel stabilization mechanism enabled by the presence of GO that prevents abrupt divergence of the resistance to the MΩ range experienced by bare AgNW networks. Finally, the application of our hybrid electrode in a full device is demonstrated by solar cell fabrication and characterization.

EN12.04.12
Structure-Function Relationships in a Novel and Highly Stable Singlet Fission System with an Aromatic Triplet State Peter Budden1, Kealan Fallon1, Andrew Musser2, Hugo Bronstein1,1 and Richard H. Friend1; 1University of Cambridge, United Kingdom; 2The University of Sheffield, United Kingdom

We report clear evidence from transient optical measurements and transient electron spin resonance that a family of derivatives of indolonaphthyridine thiophene (INDT) supports singlet exciton fission, and show excellent ambient stability.

Singlet fission offers the potential for the generation of multiple excitons from one photon in organic semiconductors, which could reduce losses to thermalisation in solar cells by exploiting the relatively low energy of the triplet exciton in certain organic materials. This is a characteristic reserved for only a handful of organic molecules due to the atypical energetic requirement for low energy excited triplet states. The canonical systems on which much singlet fission research is focused - pentacene, tetracene and their derivatives - have such conveniently low triplet energies due to their large diradical nature, greatly compromising their ambient stability. In order to move towards photostable singlet-fission-enhanced solar cells, there is a need for materials that undergo efficient singlet fission at no expense to their stability.

To this end, we have used Baird’s rule of excited state aromaticity to manipulate the singlet-triplet energy gap and create novel singlet fission candidates. We achieved this through the inclusion of a [4n] 3-membered heterocycle, whose electronic resonance promotes aromaticity in the triplet state, stabilizing its energy relative to the singlet excited state. Using this theory, we have designed a family of derivatives of INDT with highly tunable excited state energies which are highly stable and clearly undergo rapid singlet fission at morphological “hot spots”. Not only do we access an original class of singlet fission materials, they also exhibit excellent ambient stability, imparted due to the delocalized nature of the triplet excited state. Spin-coated films retained over 80% activity after several weeks of exposure to oxygen and light, whilst analogous films of TIPS-pentacene showed full degradation after four days, showcasing the excellent stability of this class of singlet fission scaffold. Extension of our theoretical analysis to almost ten thousand candidates reveals an unprecedented degree of tuneability and several thousand potential fission-capable candidates, whilst clearly demonstrating the relationship between triplet aromaticity and singlet-triplet energy gap, confirming this novel strategy for manipulating the exchange energy in organic materials.

Through transient absorption spectroscopy, transient photoluminescence, and transient electron paramagnetic resonance, we can reveal a full picture of the dynamic evolution of excitons in these new materials. Singlet fission, an inherently intermolecular process producing two triplet excitons localized on separate molecules, is highly dependent on morphology. We have found that when tuning the energetics by altering the electron-withdrawing substituent groups on the INDT core, the solid state morphology also changes. We find that with a more H-
aggregate-like morphology, with a blue shift of absorption onset and relative suppression of 0-0 absorption peak, singlet fission yields are enhanced. In recent months, we have made further synthetic progress, which has allowed additional exploration of structure-function relationships down two avenues. Firstly, by editing the length of solubilizing chains, which modifies packing, we can explore different morphologies without affecting the relative energies of the localized singlet and triplet. Secondly, by the synthesis of covalent INDT dimers, bridged with phenyl- and fluorene-linkers, we can vary the coupling and conjugation across an isolated pair of molecules. Both of these pathways offer new insights to how local organization and molecular environment can affect singlet fission, exciton-exciton annihilation, and other critical processes in these films which go on to dictate their performance in optoelectronic devices.

EN12.04.13
Tear Resistant Organic Electronics Song Zhang¹, Yu-Hsuan Cheng², Yu-Cheng Chiu² and Xiaodan Gu¹;
¹University of Southern Mississippi, United States; ²National Taiwan University of Science and Technology, Taiwan

Semiconducting polymers are promising for the application of wearable electronics through blending with rubbery elastomers to achieve the softness and stretchability similar to that of biological skin. However, the inherent tear-resistant and self-healing properties of skin are still unexplored areas for electronic active blends. Here, we present the first tear-resistant semiconducting material using a carefully designed blend system, consisting of conjugated polymers and a high-performance elastomer. This blending system demonstrated excellent mechanical performance with the ultra-low modulus (1 MPa), high stretchability (800% strain), and good electronic property with charge carrier mobility of 0.5 cm²V⁻¹s⁻¹. The charge mobility of the blend system is stable at ambient condition and retains at 70% of charge mobility at 100% strain. More importantly, the semiconducting material is insensitive to precut notches and self-healable at room temperature for two pieces of cut films upon contact within seconds on the water surface. The elastomer has low oxygen and water permeability, allowing better device stability over months of operation, which can be generally applied to a variety of semiconducting polymers to achieve improvements in the mechanical performances for the application of wearable electronic devices.

EN12.04.14
Organic Solar Cells with Nitrogen Containing Organic Charge Carrier Extraction Layers—What is Determining Their Efficacy? Rico Meitzner¹,², Juliette Essomba¹,², Kevin Fulbert¹,², Krisna Kuma¹,², Fernanda A. Kathalia¹,², Nora Engel², Ulrich S. Schubert² and Harald Hoppe¹; ¹Center for Energy and Environmental Chemistry, Germany; ²Laboratory of Organic and Macromolecular Chemistry (IOMC), Friedrich Schiller University Jena, Germany

For the reduction of contact resistances as well as shunting currents in organic solar cells it is important to control the two at the interface towards the respective charge collecting electrodes. Many conductive and non-conductive materials have been investigated so far and several of them offer already good solutions. However, the underlying mechanisms for selective charge extraction are not often well understood. We have systematically varied dipole moments anchored in side-chains of small organic non-conductive molecules as well as non-conductive polymers. We observed a clear correlation between the polarity and various photovoltaic parameters. We present a model on how to achieve proper alignment of dipole moments in that charge extraction materials for improved device function and performance.

EN12.04.15
Ultrafast 2D White-Light Spectroscopy of Wrinkled Carbon Nanotube Films for Use in Stretchable Optoelectronic Devices Jessica Flach; University of Wisconsin-Madison, United States

Optoelectronic devices with semiconducting single-walled carbon nanotubes (s-SWNTs) as the absorbing layer require the photogenerated excitons to diffuse to a heterojunction to drive dissociation into charge carriers. However, current device efficiencies are hindered by a short transverse exciton diffusion length of about 5 nm which in turn limits film thickness and number of photons absorbed. In this work, I have created wrinkled s-SWNT films by depositing a thin layer of nanotubes on a pre-strained stretchable substrate and subsequently releasing so the film wrinkles on itself and effectively increases the optical absorption pathlength. We then use ultrafast 2D white-light (2DWL) spectroscopy to study the underlying photophysics of these wrinkled films. Our 2DWL technique uses a broadband supercontinuum spanning from the visible to NIR to collect information on femtosecond timescales. This
technique allows us to monitor the factors that influence device performance such as exciton lifetime, coupling between nanotubes, and the effects of strain on individual tubes. Furthermore, by depositing a bilayer of s-SWNT with C60 as an electron accepting layer on the elastomeric substrate and allowing it to wrinkle, we create a bulk-like heterojunction architecture with high interfacial area to drive exciton dissociation. These wrinkled s-SWNT/C60 layers are incorporated as the active layer in stretchable phototransistors and their device performance is evaluated.

EN12.04.16
Sequential Solvent Dip-Coating for Increase of Molecular Order in Polythiophene Thin Film Lee Jeong Ik, Jun Hwa Park and Yeong Don Park; Incheon University, Korea (the Republic of)

Recent years have seen significant improvements in the performances of organic electronic devices based on conjugated polymers. Among the methods of forming a polymer thin film, the dip coating technique has an advantage that a uniform large-scale polymer thin film having a low roughness can be manufactured. However the solvent with a high boiling point produced inhomogeneous film coverage with dewetted regions on the dip-coated polymer film. In this study we presented a systematic study of a simple post dip-coating method for controlling the structural and electrical characteristics of dip-coated polythiophene thin films through direct exposure to various solvents. Simply dip-coating of polythiophene thin film into various solvents with different solubility parameter improved the intermolecular order in the films, and the polymer FET device performance. When the polythiophene thin film was dip-coated into various solvents before the film is completely dried, the molecular rearrangement was occurred depending on the solubility of the solvent. The small difference in the solubility parameter between the polythiophene and the solvent in post-treatment process induced the strong rearrangement of the molecular arrays and the production of nanowires. The structural and electrical characteristics of dip-coated polythiophene thin films or thin films dip-coated into various solvents were investigated and compared.

EN12.04.18
Analytical Study of Solution-Processed Tin Oxide—New Insights into the Correlation of Chemical and Electronic Properties Valentina Rohnacher1,2, Sebastian Hell1,2, Florian Ullrich3,2, Marc-Michael Barf4,2, Helge Eggers5,2, Sebastian Beck7,2 and Annemarie Pucci1,2; 1Heidelberg University, Germany; 2InnovationLab, Germany; 3Technische Universität Darmstadt, Germany; 4Technische Universität Braunschweig, Germany; 5Karlsruhe Institute of Technology, Germany

Organic electronic devices consist of stacked organic as well as inorganic materials and the device performance is strongly influenced by the interfaces between the layers. The investigation of charge transport across these interfaces is a major key to the basic understanding of the fundamental mechanisms in organic electronics. Thin films of certain metal oxides are known to be excellent charge-selective interlayers in optoelectronic devices due to their outstanding properties such as high optical transparency, suitable energy level alignment and high electron mobility [1-3].

In this study, solution-processed tin oxide (sSnOx) as promising electron transport layer was analyzed by infrared spectroscopy. This non-destructive method gives insight into the chemical composition of the thin film and can monitor orientation of characteristic vibrations or functional groups. We studied the influence of annealing temperature on bulk and surface properties of thin sSnOx. During subsequent annealing from room temperature up to 400°C, the tin chloride precursor is converted into tin oxide. The infrared spectroscopic investigations show the decrease of tin hydroxide and water in the sSnOx films and the higher crystallinity with increasing annealing temperature. Moreover, the phonon modes of sSnOx in the far-infrared region confirm the conversion from tin oxide into tin dioxide between 350°C and 400°C. Furthermore, we discovered that the solvent of the precursor solution has a crucial influence on the film morphology and the conductivity of sSnOx. Together with the results of photoelectron spectroscopy, atomic force microscopy and conductivity measurements a better understanding of the electronic, chemical and morphological properties can be achieved which is important for the improvement of device performance.

Charge Transport of Phenothiazine:TCNQ Cocrystals
Scott Melis and Edward Van Keuren; Georgetown University, United States

Charge transfer cocrystals have interesting applications in the field of organic electronics due to their unique optical and electronic properties. We have studied cocrystals formed from phenothiazine (PTZ) and 7,7,8,8-tetracyanoquinodimethane (TCNQ) as electron donor and acceptor molecules respectively. PTZ:TCNQ cocrystals were found to readily grow using the controlled evaporative self-assembly (CESA) method, in which crystals nucleate at the receding contact line of an evaporating solution. The resulting cocrystals formed an array of long, well-aligned wires that could be easily incorporated into field effect transistors (FETs). Here, we present measurements of carrier mobility in PTZ:TCNQ FETs. In addition, we show that the device performance as a function of temperature agrees with a hopping model of charge transport in the material. Finally, we have investigated the effects of photoexcitation on charge transport in the devices.

Pre-Programmed Organic Semiconductor Assembly with DNA
Jeffrey Gorman1, Florian Auras1, Sarah Orsborne1, Peter Budden1, Afaf El-Sagheer2, Daniel Congrave1, Lisa Sharma3, Raj Pandya1, Akshay Rao1, Hugo Bronstein1, Tom Brown2, Eugen Stultz2 and Richard H. Friend1; 1University of Cambridge, United Kingdom; 2University of Oxford, United Kingdom; 3University of Southampton, United Kingdom

Photosynthetic complexes achieve remarkable spatial control of densely-packed pigments using a protein scaffold to organise multiple organic semiconductors. This promotes strong electronic coupling between adjacent chromophores yielding efficient energy transport and charge separation. In contrast, man-made organic solar cells lack natures precision and are typically limited to a pseudo-random blend mixture.[1] To overcome the limitations of poor assembly we attach acenes, rylene diimides, porphyrins, and push-pull chromophores to DNA. Inspired by how nature uses DNA to encode the structure of peptides, our method allows the unique assembly of monodisperse, hetero-aggregated semiconducting structures; transcribed by Watson-Crick base-pairing. The DNA sequence programs the final aggregate superstructure and give us unparalleled control over an energy landscape encompassing many different molecules. We outline our efforts using on-resin synthetic routes to overcome the incompatibility of large, hydrophobic aromatic molecules used in organic electronics, with hydrophilic DNA.[2, 3] Subsequent DNA hybridisation then forms a scaffolded assembly where a photoexcitation coherently extends over several building blocks.

Using 10-fs time resolution transient absorption spectroscopy we track energy transport and charge separation through a nanoscale heterojunction and energy cascade, where the number of electron donors and acceptors have been predefined by the DNA sequence. Furthermore by instead assembling with acene materials we can control the extent of singlet fission as a function of the number of molecules electronically coupled.

Water/Ethanol-Soluble Naphthalene Diimide-Based Polymer Acceptors for Efficient and Air-Stable All-Polymer Solar Cells
Seungjin Lee1, Youngwoong Kim1, Ziang Wu2, Changyeon Lee3, Seung Jin Oh1, Nguyen Thanh Luan2, Junbok Lee1, Dahyun Jeong1, Kai Zhang3, Fei Huang4, Taek-Soo Kim1, Han Young Woo3 and Bumjoon Kim1; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2Korea University, Korea (the Republic of); 3South China University of Technology, China

Water/Ethanol-processed all-polymer solar cells (eco-APSCs) with superior efficiency and stability were developed for the first time by synthesizing a series of aqueous-soluble naphthalene diimide (NDI)-based polymer acceptors P(NDIDEG-T), P(NDITEG-T), and P(NDITEG-T2). The polymer acceptors were designed by using the backbones of NDI-bithiophene and NDI-thiophene in combination with non-ionic hydrophilic oligoethylene glycol (OEG) side chains that facilitate processability in water/ethanol mixtures without causing any electronic trap sites. While all three polymers exhibited semi-crystalline properties and sufficient solubility in the aqueous medium, the P(NDIDEG-T) polymer with shorter OEG side chains was the most crystalline, enabling the fabrication of efficient eco-APSCs with the maximum power conversion efficiency of 2.15%. To date, this is the highest efficiency reported for devices based on water/ethanol-soluble conjugated materials. Furthermore, these eco-APSCs were fabricated under ambient atmosphere by taking advantage of the eco-friendly aqueous process and, importantly, the devices exhibited outstanding air-stability without encapsulation, as evident by maintaining more than 90% of the initial PCE in air after 4 days. These results provide important guidelines for the design of electroactive polymers for sustainable fabrication of organic electronics.

EN12.04.23
Efficient and Air-Stable Aqueous-Processed Organic Solar Cells and Transistors—Importance of Water Content on Processability and Thin-Film Morphologies of Electroactive Materials Seungjin Lee1, Changyeon Lee1, Hae Rang Lee2, Joonyeong Choi1, Youngkwon Kim1, Nguyen Thanh Luan3, Wonho Lee4, Bhoj Gautam5, Kai Zhang6, Fei Huang6, Joon Hak Oh2, Han Young Woo3 and Bumjoon Kim1; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2Seoul National University, Korea (the Republic of); 3Korea University, Korea (the Republic of); 4Kumoh National Institute of Technology, Korea (the Republic of); 5Fayetteville State University, United States; 6South China University of Technology, China

The authors report the development of a desirable aqueous process for eco-friendly fabrication of efficient and stable organic field-effect transistors (eco-OFETs) and polymer solar cells (eco-PSCs). Intriguingly, the addition of water to ethanol was found to remarkably improve the solubility of oligoethylene glycol (OEG) side chain-based electroactive materials (e.g., the highly crystalline conjugated polymer PPDT2FBT-A and the fullerene monoadduct PC61BO12). A water–ethanol cosolvent with a 1:1 molar ratio provided an increased solubility of PPDT2FBT-A from 2.3 to 42.9 mg mL−1 and that of PC61BO12 from 0.3 to 40.5 mg mL−1. Due to the enhanced processability, efficient eco-OFETs with a hole mobility of 2.0 × 10−2 cm2 V−1 s−1 and eco-PSCs with a power conversion efficiency of 2.05% were successfully fabricated. In addition, the eco-PSCs fabricated with water–ethanol processing were highly stable under ambient conditions, showing the great potential of this new process for industrial scale application. To better understand the underlying role of water addition, the influence of water content on the thin-film morphologies and the performance of the eco-OFETs and eco-PSCs were studied. Additionally, it was demonstrated that the application of the aqueous process can be extended to a variety of other OEG-based material systems.

EN12.04.24
Novel Hole Blocking Materials Based on 2,6-Disubstituted Dibenzofuran and Dibenzothiophene Segments for High-Efficiency and Long-Lived Blue Phosphorescent OLEDs Seokhoon Jang and Youngu Lee; DGIST, Korea (the Republic of)

Since phosphorescent organic light-emitting diodes (PhOLEDs) have four times higher quantum efficiency than fluorescent OLEDs in that they can utilize both singlet and triplet excitons, they are focused on the display market and widely used. Many studies have been conducted to enhance the performance of PhOLEDs, but satisfactory efficiency and lifetime have not been achieved for blue emitters. In order to improve the efficiency of the blue PhOLED, a hole blocking layer (HBL) can be introduced between the electron transporting layer (ETL) and emissive layer (EML). In general, the highest occupied molecular orbital (HOMO) energy level of the ETL is not much lower than that of the EML. Holes reaching the EML from an anode can be migrated into the ETL, lowering their efficiencies. Therefore, it is necessary to introduce a HBL with deep HOMO energy level. In addition, if the triplet energy (E_T) of ETL is lower than that of EML, the triplet excitons created in EML can be quenched at the interface between EML and ETL. Therefore, a HBL should have high E_T as well as deep HOMO energy level. In this work, Novel hole blocking materials (HBMs) based on 2,6-disubstituted dibenzo[b,d]furandibenzo[b,d]thiophene segments, 3,3′,3′′,3′′′-(dibenzo[b,d]furanyl-2,6-diylbis(benzene-5,3,1-triyl))tetrapyridine (26DBFPTPy) and 3,3′,3′′,3′′′-(dibenzo[b,d]thiophene-2,6-diylbis(benzene-5,3,1-triyl))tetrapyridine (26DBTPTPy), are rationally designed and synthesized for high-performance blue PhOLEDs for the first time. Computational
simulation is used to investigate the optimal structure, orbital distribution, and physicochemical property of both molecules. Thermal, optical, and electrochemical analysis show that 26DBFPTPy and 26DBTPTPy possess high thermal stability, deep HOMO energy level (-7.08 and -6.91 eV), and $E_T$ (2.75 and 2.70 eV). Blue PhOLEDs with 26DBFPTPy or 26DBTPTPy as a HBL exhibit low turn-on voltage (3.0 V) and operating voltage (4.5 V) at 1000 cd m$^{-2}$. In addition, the blue PhOLEDs with 26DBFPTPy or 26DBTPTPy show superior external quantum efficiency (24.1 and 23.6%) and power efficiency (43.9 and 42.7 lm W$^{-1}$). They also show a very small efficiency roll-off of about 8.5% from 100 to 1000 cd m$^{-2}$. Details of the correlation between the structure of organic molecules and their properties with OLED performance will be presented.

EN12.04.25
Modification of Electron Injection Property in Organic Light-Emitting Diodes Using Amidine-Type Additives
Tsubasa Sasaki1, Hirohiko Fukagawa1, Kazuma Suzuki2, Munehiro Hasegawa3, Katsuyuki Morii3,4 and Takahisa Shimizu1; 1NHK Science & Technology Research Laboratories, Japan; 2Tokyo University of Science, Japan; 3Nippon Shokubai Co., Ltd., Japan; 4Nippon Shokubai Research Alliance Laboratories, Osaka Univ., Japan

It is essential to tune the carrier injection barrier between organic semiconductors and electrodes in present-day organic electronics, including organic light-emitting diodes (OLEDs), organic thin-film transistors (OTFTs), organic solar cells (OSCs), and perovskite solar cells (PSCs). Although efficient hole injection can easily be achieved by using stable materials, the most commonly used materials for electron injection are reactive alkali metals, which make the organic devices unstable, especially on flexible substrates. Thus, the development of a novel electron injection layer without the use of such reactive materials is necessary for future flexible electronics. Recently, a stable amidine derivative named 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) has been proposed to be effective for controlling the electronic behavior in organic devices. When a DBU-doped layer was used as an electron transport layer in PSCs and an n-channel layer in OTFTs, the performance of these organic devices was enhanced owing to the increase in the conductivity and the Fermi level shift [1]. We focused on the high electron-donating property of DBU, and we evaluated a similar amidine-type derivative as the additive of the electron injection layer in OLEDs. In the present study, the effect of two amidine-type derivatives on the electron injection efficiency was investigated by adding them to the interlayer of inverted OLEDs (iOLEDs) [2,3]. We fabricated iOLEDs in the following device configuration: ITO cathode/ZnO/interlayer/emitting layer/hole transporting layer/hole injection layer/Al anode. The interlayer, which plays a key role in electron injection, consists of two materials: one is the electron-transporting host and the other is the amidine-type derivative [1]. The host material used in the interlayer was a boron compound, which is suitable for demonstrating operationally stable iOLEDs [3]. DBU and 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) were used as the amidine-type derivative. We observed from the current density ($J$)–voltage ($V$)–luminance ($L$) characteristics of the fabricated iOLEDs that the electron injection property was improved by adding each amidine-type derivative to the interlayer. In addition, the DBN-added interlayer exhibited a better electron injection property than the DBU-added interlayer when these amidine-type derivatives were added at the same concentration. The driving voltage of the iOLED with the DBN-added interlayer was about 1.0 V less than that of the iOLED without DBN added to the interlayer. Moreover, the optimized iOLED with a DBN-added interlayer exhibited higher operational stability than the iOLED without DBN added to the interlayer, which suggests that the operational stability of DBN is high. To investigate the mechanism of the efficient electron injection resulting from adding DBN, we measured the energy-level alignment at the ITO/ZnO/interlayer (with or w/o DBN) by ultraviolet photoelectron spectroscopy (UPS). The line shape of the spectrum did not change substantially upon the addition of DBN, whereas a shift toward a higher binding energy and a change in the surface work function were detected for the DBN-added interlayer. A relatively large Fermi level shift of about 0.46 eV was observed by adding DBN. Thus, the electron injection barrier can be significantly reduced by adding DBN, and electrons can be effectively injected. In the previous study on DBU in PSCs, a similar Fermi level shift was observed, which was attributed to the electron transfer from DBU to the host. However, electron transfer from DBU to the host was not clearly observed in this study. Thus, we concluded that the origin of the improved electron injection property in iOLEDs is different from that in PSCs.

Phosphorescent OLEDs Tsukasa Owada1, Hisahiro Sasabe1,2,3, Yoshihito Sukegawa1, Taiki Watanabe1, Tomohiro Maruyama1, Yuichiro Watanabe3, Daisuke Yokoyama1,2 and Junji Kido1,2,3; 1Yamagata University, Japan; 2Research Center for Organic Electronics, Yamagata University, Japan; 3Frontier Center for Organic Materials (FROM), Japan

Electron transport materials (ETMs) play a key role in determining OLED performances, such as driving voltage, efficiency and operation lifetime. In this work, we newly designed and developed a series of chrysene-based ETMs, namely BnTPyCs (n=3,4) modified with terpyridine moieties. BnTPyCs showed high $T_m$ of over 390°C. An OLED with a structure of [ITO (130 nm)/triphenylamine containing polymer: 4-isopropyl-4'-methyl diphenyliodonium-tetrakis(pentafluorophenyl)borate (PPBI) (20 nm)/N,N’-di(1-naphthyl)-N,N’-(1,1’-biphenyl)-4,4'-diamine (NPD) (20 nm)/Ir(ppy)312 wt% doped 3,3-di(9H-carbazole-9-yl)biphenyl (mCBP)/2-(3’-(dibenzo[b,d]thiophen-4-yl)-[1,1’-biphenyl]-3-yl)-4,6-diphenyl-1,3,5-triazine (DBT-TRZ) (10 nm)/20 wt% 8-quinolinolato lithium (Liq) doped-ETL (40 nm)/Liq (1 nm)/Al (100 nm)] were fabricated. The device exhibited maximum EQE of 18% with long operation lifetime at 50% the initial luminance (LT50) of over 250 hours at the initial luminance of approximately 10,000 cd cm–1 (current density: 25 mA cm–2), which was approximately 2 times longer than that with B3PyPC[1] and slightly longer than that with anthracene-based ETM (ZADN)[2] (current density: 25 mA cm–2).

EN12.04.27
Optimising Characteristics of Morphology to Improve the Performance of Polymer Solar Cells Fiyanshu Kaka, Ravi K. Singh, Praveen C. Ramamurthy and Abhik N. Choudhury; Indian Institute of Science, India

Organic-Photovoltaics (OPVs) can potentially provide a less energy intensive means of harnessing solar energy. However, optimum OPV performance depends on understanding the Process-Structure-Property (PSP) correlation in organic semiconductors. The working of Bulk-Heterojunction (BHJ) OPVs is such that the morphology plays a key role in device performance1.

It is experimentally observed that there is an optimal blend ratio of p and n-type organic semiconductor as well as annealing time with respect to device characteristics. In this work, we attempt to understand the characteristics of morphology that maximize the device performance by developing a theoretical framework. We first established process-structure correlations by generating a range of morphologies with different blend ratios of P3HT (p-type organic semiconductor) and PCBM (n-type organic semiconductor) for various annealing times. The morphologies were generated using phase-field simulations. In the phase-field model, the free-energy of polymer-fullerene blend was modelled using the Flory-Huggins function. Since the polymer-fullerene blend undergoes Spinodal decomposition, Cahn-Hilliard formulation was used to model the free-energy functional.

Secondly, we developed effective electronic properties of the morphologies which allows us to characterize the performance of each of the obtained morphologies. The structure-property correlation was derived using diffuse interface approach. The application of diffuse interface model to complex morphologies as are typically encountered in BHJ devices is simpler and numerically more robust than the classical sharp interface model used in semiconductor industry. This completes the theoretical PSP linkage which allows the optimization of the process parameters for device applications. We found that the necessary condition for efficient OPV device is bi-continuous network of donor and acceptor phases as that leads to percolating channels for electrons and holes to their respective electrodes. The percolation of the morphology was found out using Hoshen-Kopelman algorithm. Amongst the percolating morphologies, the ones with higher interfacial area lead to higher short circuit current density ($J_{sc}$) and eventually to higher efficiency since open-circuit potential ($V_{oc}$) is a weak function of morphology. Therefore, the key to an efficient solar cell is optimisation of the two important length scales involved in the working mechanism of OPV i.e., exciton dissociation and carrier conduction through the morphology to the respective electrodes. Exciton dissociation is governed by interfacial area. Efficient carrier conduction results from transportation of the electron and hole to their respective electrode via a well-connected network of phases with minimal leakage of current and recombination of charge carriers. Hence, efficient carrier conduction is governed by higher percolation fraction of the morphology. Another important step during device fabrication is annealing the device after production. It is experimentally observed that initially during annealing, $J_{sc}$ increases and then decreases thus resulting in an optimal anneal time. The initial increase in $J_{sc}$ corresponds to existence of better interface between electrode and active layer2. The depreciation in $J_{sc}$ stems from coarsening of morphology resulting in lower exciton...
dissociation. The depreciation in Jsc has been verified numerically by our simulations.

Improved Exciton Utilization Resulting from Exergonic Reverse Intersystem Crossing in Blue-Electrofluorescent Organic Molecules Seungyeon Yi and Youngmin You, Ewha Womans University, Korea (the Republic of)

Recent advances in organic electroluminescence benefit from molecular emitters capable of harvesting electrogenerated excitons. The successful emitters include room-temperature phosphorescent complexes of late transition metals and pure organic molecules exhibiting thermally activated delayed fluorescence. These compounds, however, suffer from quenching of triplet excitons due to slow rates during the processes of radiative transition or exciton spin flip. To overcome this limitation we have proposed and investigated an exciton-harvesting strategy which employs exergonic, El-Sayed rule-allowed reverse intersystem crossing (ES-rISC) from the triplet n-π* transition state to the singlet π-π* transition state as the key process of exciton collection.

In order to demonstrate our strategy, we designed and synthesized a series of blue fluorescent organic molecules (SY1-6) based on a 9,10-diphenylanthracene (DPA) scaffold. DPA was chosen because the large exchange energy between the singlet and triplet π-π* transition states would suppress non-emissive loss of triplet exciton through internal conversion. Carbonyl units, including acetyl (SY1), benzoyl (SY2), 4-acetylphenyl (SY3), 4-benzoylphenyl (SY4), 3-acetylphenyl (SY5), and 3-benzoylphenyl (SY6) were introduced into DPA, and provided the triplet n-π* transition state higher than the singlet π-π* transition state in energy. Our structural control aimed at achieving exergonic, rapid conversion of triplet excitons into fluorescent singlet excitons through ES-rISC from the triplet n-π* transition state to the singlet π-π* transition state.

The validity of our strategy was supported by quantum chemical calculations which predicted exothermicity of ES-rISC of the SY compounds. The steady-state photoluminescence spectra revealed that blue fluorescence emissions were attributable to the singlet π-π* transition state of DPA. Photoluminescence quantum yield as high as 0.93 was achieved. The applicability of the exciton harvest by ES-rISC was examined by evaluating the performance of organic light-emitting devices incorporating SY compounds as dopants. Devices containing DPA were also fabricated, and served as a singlet exciton only control. The maximum external quantum efficiency of 4.8% was recorded for the SY3 device. This value was higher than that of the control device even though DPA had a photoluminescence quantum yield greater than SY3. Exciton utilization efficiency of the SY3 device was determined as large as 46%, being a two-fold enhancement from the DPA device (~26%). This enhancement was ascribed to exciton harvest by ES-rISC. Control experiments rebutted any contribution from E- or P-type delayed fluorescence and orientation effects on the improvement and unambiguously confirmed the contribution of ES-rISC.

We hope that our research will provide useful guidance to designing molecules capable of rapid harvesting of excitons for high-efficiency electroluminescence.

EN12.04.29
Vacuum Deposited Small Molecule Bilayer Ternary Organic Photovoltaics Yongxi Li¹, Hafiz Sheriff³, Xiao Liu¹, Kan Ding¹, Chun-Kai Wang², Ken-Tsung Wong² and Stephen R. Forrest¹; ¹University of Michigan–Ann Arbor, United States; ²National Taiwan University, Taiwan

Vacuum thermally-evaporated (VTE) small molecule organic photovoltaics (OPVs) have proven to be efficient and intrinsically stable. However, the high thermalization losses impedes the progress of VTE-grown small molecule OPVs. Ternary blend OPVs can improve light absorption and reduce energy losses beyond that of binary blend OPVs, but the difficulties in optimizing the morphology of three component device active regions, results in ternary systems that have heretofore exhibited performance inferior to analogous binary OPVs. Here, we introduce “a-bi-ternary” OPV comprising two individual binary, bulk heterojunctions fused at a planar junction without component intermixing. In contrast to previous reports where the open circuit voltage (VOC) of a conventional, blended ternary cell lies between that of the individual binaries, the VOC of the bi-ternary OPV is that of either one of the constituting binaries depending on the order in which they are stacked relative to the anode. Additionally, dipole-induced energy-level realignment between two constituting binaries was observed only when using d–a–a’ dipolar donors in the photoactive heterojunction. The optimized bi-ternary single junction OPV shows improved performance.
compared to the two constituent binary OPVs, achieving $PCE = 10.6 \pm 0.3\%$ under AM 1.5G 1 sun (100 mW/cm$^2$) simulated illumination, with $V_{oc} = 0.94 \pm 0.01$ V, a short circuit current density, $J_{sc} = 16.0 \pm 0.5$ mA cm$^{-2}$ and a fill factor, $FF = 0.70 \pm 0.01$. These results open new avenues for achieving highly efficient thermally evaporated, small molecule organic solar cells.

EN12.04.31 Flexible, Printed Non-Fullerene Acceptor Based Near-Infrared Organic Photodiodes Maruf Ahmed$^1$, Anthony Vogliano$^1$, Anju Toor$^1$, Maxime C M Babics$^2$, James Ponder$^2$, Iain McCulloch$^{1,2}$ and Ana Claudia Arias$^3$; $^1$University of California, Berkeley, United States; $^2$Imperial College London, United Kingdom; $^3$KAUST, Saudi Arabia

Organic photodiodes (OPD) are an emerging candidate as photosensors because of their wavelength tunability from Ultraviolet (UV) to Near Infrared (NIR), and processability at low-temperature over large area and variety of substrates [1]. Numerous applications can benefit from OPDs such as biomedical signal detection, imaging, communication, proximity sensing, etc. In particular, broadband OPD’s having response extended to NIR could be useful in optical communications, remote control and environmental monitoring [2].

OPDs can be solution-processed and hence can be fabricated using printing methods e.g. blade coating, which combined with a roll-to-roll process would offer high-throughput production over large areas. Further, the use of flexible substrates would enable applications in wearables as flexible OPDs could increase the comfort of use and quality of the acquired signal.

In this work, blade coated OPD’s have been fabricated with a bulk heterojunction (BHJ) containing a polymer donor material and a novel non-Fullerene acceptor (NFA). The donor material used in this work, PBDTTT-EFT, is proven to result in high efficiency and long lifetime of the resultant devices [3, 4]. The acceptor is an Indacenodithiophene derivative NFA (EHIDTBR) [5] having an absorption spectrum extended beyond red light wavelength. Unlike most conventional OPD’s where BHJ contains Fullerene acceptors because of their efficiency of charge separation [6], an NFA has been used in this work. Because, as opposed to Fullerene acceptors NFA’s can offer good absorption at visible and/or NIR wavelengths. As the donor and acceptor have somewhat complementary absorption spectrum the devices in current work exhibit fairly uniform broadband spectral response extending up to 750 nm. And, use of blade coating method which is compatible with roll-to-roll printing ensures device scalability.

OPD devices fabricated with the photoactive layer comprising PBDTTT-EFT polymer donor material and small molecule (EHIDTBR) NFA shows EQE as high as 55% with the simple conventional device architecture. One of the reasons behind this performance is favorable miscibility of the two components of the BHJ that results in excellent blend morphology [5]. For similar reasons, the dark or reverse leakage current is also small, on the order of 100 nAcm$^{-2}$ and comparable to state of the art devices. Overall, the devices show great promise as flexible printed photodetectors.

Optimizing Ordered Nanostructures and Crystallization of Regioregular Polythiophene-Based Block Copolymers via Rapid Solvo-Microwave Annealing Junghun Han, Jin-Seong Kim, Jae Man Shin, Hongseok Yun, Youngkwon Kim, Hyeonjung Park and Bumjoon Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Controlling of crystalline structures of conjugated polymers (CPs) within nanostructured block copolymer (BCP) domains is crucial to enhance their electrical properties. However, it has been a challenge due to the intrinsic incompatibility between crystallization and phase-separation process of CP-based BCPs. Herein, we demonstrate solvo-microwave annealing as an effective method for producing highly ordered thin film structures of poly(3-dodecythiophene)-block-poly(lactic acid) (P3DDT-b-PLA) polymers in very short processing time (~ 3 min). The conventional thermal annealing process even with long annealing time (~24h) resulted in incompatibility between ordered nanostructures and crystallization of the conjugated polymer. In contrast, the solvo-microwave annealing with the combination of heat and solvent vapor treatment was employed to grant enhanced chain mobility and solvent interaction with the π-π structure of the conjugated polymer. As a result, this process rapidly generated highly-ordered nanostructures with very few defects within 3 min and, at the same time, the high-crystalline intermolecular ordering of P3DDT blocks was obtained. Furthermore, we demonstrate the successful transfer of highly-ordered P3DDT structures after the removal of PLA domain, which is important for potential nanolithography and electronic applications.

EN12.04.33
Effect of Plasma Treatment in the Sb2S3 and Sbs(SxSe1-x )3 Solar Cells in Order to Improve Their Photovoltaic Characteristics Araceli Hernandez-Granados1, Horacio Martinez-Valencia1, Jose Escorcia-García2 and Hailin Zhao Hu3; 1Instituto de Ciencias Fisicas, Mexico; 2CINVESTAV-Saltillo, Mexico; 3IER, Mexico

In this work was prepared a mesoporous titanium dioxide films (TiO2-mp) with sol-gel method, using different percentages of the polymer polyvinylpyrrolidone (PVP), and they were deposited by the spin-coating technique. It was done several thermal treatments from 120 to 600 °C for 1 and 3 hours. At temperatures of 500 °C. With a x-ray diffraction (XRD), anatase phase with tetragonal structure with crystal size of 19.5-21 nm was identified. The top view morphology of the films showed a porous range size between 15-30 nm. It was estimated for the first time the volumetric porosity of the material by the volume porosity average with the values of the refractive index. The porosity estimated showed a result between 40.3% and 43-6%, the revolutions per minute (rpm) varied from 1000-2500. These films of mp-TiO2 were used as a scaffold and electro transport layers for 3 types of solar cells:

A) sensitized solar cells with quantum dots. For this type of solar cells, it was prepared heterojunctions of antimony sulfide-selenide (Sb2(S,Se1-x)) in solid solution as the absorbing material and cadmium sulfide (CdS) as a sensitized layer deposited by the successive ionic layer adsorption and reaction (SILAR) technique and the (Sb2(S,Se1-x)) with chemical bath deposition. It was shown by increasing the number of CdS layers the photovoltaic performance was improved by the reduction of the Sb2O3 and promoting a better nucleation with the (Sb2(S,Se1-x)) at the chemical bath. The best photovoltaic performance was obtained with a solar cell with 30 cycles of CdS (CdS-30), a voltage of 434 mV, current density of 9.73 mA/cm2 and an efficiency of 1.69%. B) As well were prepared Sb2S3 solar cells and C) Perovskite solar cells (PVK), several PVK solar cells were fabricated varying the hole transport material, for that reason it was used the Poly(3-hexylthiophene-2,5-diyl) (P3HT) and the spiro-MeOTAD and a variation of the percentage of the PVP was used. For the solar cells with P3HT it was used a 20% of PVP and the variation of the rpm at the spin-coating process. With this was possible to correlate the thickness, the volume porosity and the efficiency of the device. It was found for solar cells prepared at 1500 and 2000 rpm, it was obtained a 203 and 168 of thicknesses and efficiencies of 1.24% and 2.14% respectively. The best solar cell with this configuration and 1000 rpm showed a 308 nm of thickness as well 41.6% of porosity. This one showed a current density of 17.15 mA/cm2, generating a 6.29% of efficiency. By changing the HTL for the spiro-MeOTAD, as well increasing the porosity of the material it was possible to obtained a device with a current density of 24.08%, a fill factor of 49.22 and an efficiency of 11.37%.

As an important part of the improvement of the electrical and morphological characteristics it will be done a plasma
Conjugated polymers are promising materials for flexible electronics and energy-relevant applications due to their combination of semiconducting properties, mechanical flexibility and ease of melt and solution processing. Chain length and dimensions in solution can be key factors in influencing the nanoscale and macroscale properties of polymers during processing including crystal architecture, solubility, phase transition temperatures, rheological response, and charge transport efficacy. These, in turn, have been shown to affect performance in various devices, including transistors, photovoltaics and light emitting diodes. Nevertheless, accurate characterization of the conjugated polymers in solution remains a challenge. Conjugated polymers exhibit unique relationships between coil size and contour length due to their semiflexible nature, while also exhibiting low solubilities relative to traditional polymer systems. This means that methods which rely on measurements relative to flexible polymer standards, such as gel permeation chromatography (GPC), can produce inaccurate results for semiflexible polymers. Using absolute measurement techniques such as static light scattering (SLS) and small-angle neutron scattering (SANS), we determine chain length, conformation, and persistence length for a multitude of conjugated polymer systems. Based on these measurements, we have found that the freely-rotating model (FRM) can accurately predict the persistence length for many conjugated polymers. Using this data, we then show that GPC can be made to produce accurate results for conjugated polymers with a range of persistence lengths and molecular weights. We demonstrate this using two additional in-line detectors: a viscometer in order to employ a universal calibration, as well as a differential refractometer to quantify sample loss in the columns. Using these techniques, conjugated polymer size and solution behavior can be accurately and precisely characterized.

BODIPY Based Non-Fullerene Acceptors for All-Polymer Solar Cells—Effect of CF3 Substituent Gourav Tarafdar1, Bryon W. Larson2, Sandeep B. Satyanarayana1 and Praveen C. Ramamurthy1,1; 1Indian Institute of Science, India; 2National Renewable Energy Laboratory, United States

Until recently fullerenes were the commonly used electron acceptor in Organic photovoltaics (OPVs) and had several drawbacks including low absorption in visible wavelengths and phase separation leading to poor performance. Since 2011 major efforts are given on the development of non-fullerene electron acceptors (NFAs) to fabricate fullerene free solar cells. High extinction coefficient is essential for OPV materials to minimize the active layer thickness. We have been therefore investigating the incorporation of BODIPY, a strongly absorbing organic dye, into polymer backbone for design of newer OPV materials. Though BODIPY polymers have been reported for donor applications, to our best knowledge, BODIPY based NFAs are scarce in literature. Herein we present the design of two new BODIPY based D-A polymers (P7 and P8) with fluorene as the donor subunit. The meso substituent on BODIPY, in the acceptor units, is methylphenyl in case of P7 and trifluoromethyl in case of P8. The polymers were characterized using NMR, GPC, UV-vis spectroscopy and Cyclic voltammetry. A lower band gap of 1.6 eV is observed for the trifluoromethylated polymer P8 compared to 1.8 eV in P7. The trifluoromethyl group is seen to improve the electron mobility of the polymer P8 by two orders compared to P7. Further electron acceptor application of these polymers was investigated. Using time resolved microwave conductivity experiments, a number of donor polymers with varying energy offset with P7 and P8 were screened. Photoinduced electron transfer was observed from the donor polymer PTB7-Th into these polymers. Subsequently all polymer solar cells were fabricated with PTB7-Th:P7/P8 using 1:1 blend ratios. The trifluoromethylated polymer P8 performs better than the methylated counterpart P7. The initial set of devices show low efficiency (~ 0.6 %) but high VOC of ~ 0.85 V. Further optimization of device structure is underway to improve the performance.

The Role of PEDOT:PSS on the Stability of Direct and Inverted Organic Solar Cells Christine Dagron-Lartigau1,2, Alberto Gregori1,2, Hussein Awada1,2, Aurelien Tournebize3,4,5, Stephan Schumann6, Roger C. Hiorns2,1, Thomas Chassé3, Heliko Peisert3, Delphine Flahaut1,2, Luc Vellutini7, Ahmed Allal1,2, Antoine Bousquet1,2 and Sylvain Chambon4,5; 1Pau University, France; 2CNRS, France; 3EKUT, Germany; 4IMS, France; 5Bordeaux University, France; 6Heraeus, Germany; 7ISM, France
In an organic solar cell, in addition to electrodes and the active layer, it is necessary to introduce interfacial layers to optimise the transport of charge carriers, and consequently the efficiency. In direct and inverted architectures, a layer of PEDOT-PSS (poly(ethylene dioxythiophene) doped with poly(styrene sulfonate)) is commonly used mainly to help the collection of holes.

In direct devices, the acidic character of PEDOT-PSS tends to promote the degradation of layers in contact, in particular the ITO (Indium Tin Oxide) electrode. The strategy presented here is to avoid this degradation by replacing the layer of PEDOT-PSS by a thin layer of P3HT (poly(3-hexylthiophene) grafted on ITO. We developed an efficient method to graft P3HT on various surfaces, including ITO, confirmed by XPS measurements [1]. This modified electrode was used to prepare direct solar cells and compared to the one with PEDOT-PSS. Devices stored in air without encapsulation with the grafted P3HT as hole transporting layer exhibited the highest stability.

In inverted solar cells, the problem of chemical degradation of ITO is no longer observed as PEDOT-PSS is deposited on the active layer, on the rear side. While the electrical failure mechanisms in such devices have been thoroughly investigated, little is known about their mechanical stability, which is as important and critical to ensure long term reliability [2]. The characteristic thin films stresses of each layer provide the mechanical driving force for delamination of weak interfaces, leading to a loss of device integrity and performance [3]. In this study [4], we developed a technique to probe weak layers or interfaces in thin multilayer devices, establishing a new set-up for the so-called probe tack making it similar to a pull-off test [5]. The technique has been extended varying both active layers, using different p-type low bandgap polymers for the active layer in combination with two different PEDOT:PSS formulations (CleviosHTL Solar and HTL Solar 2). After mechanical tests, the upper and lower surfaces have been characterized by contact angle and XPS to locate the fracture point, which is dependent on the active layer and PEDOT-PSS formulations.

Acknowledgments: Part of the results were funded in the framework of the European Union Seventh Programme (FP7/2011 under grant agreement ESTABLIS n° 290022) and of ANR-13-JS09-0014-01 INSTEP.

Relationship between Chemical Structure, Microstructure and Interfacial Charge Transfer at Molecular Heterojunctions Jenny Nelson; Imperial College London, United Kingdom

In a molecular photovoltaic device, charge separation and energy conversion result from the evolution of a photogenerated exciton into a charge separated state, in competition with recombination to ground. The efficiency of charge separation is a function of the molecular packing and energy level alignment near the interface, and of disorder in these properties. Understanding the effects of chemical structure, packing, energetics and disorder on the competition between charge separation and recombination helps to identify the factors controlling device photovoltage and ultimately conversion efficiency. Here, we address the factors controlling generation efficiency and photovoltage in molecular donor:acceptor solar cells using a combination of electrical, spectroscopic and structural characterisation techniques along with numerical models. We adapt a recent model [1] of the effect of recombination losses on open-circuit voltage ($V_{oc}$) to incorporate properties of the intermediate charge-transfer state and show how control of these properties, through choice of materials and control of processing, could benefit $V_{oc}$ and device performance [2]. In particular we find that the hybridisation of charge-transfer and local exciton states...
appears to benefit Voc by reducing non-radiative voltage losses [3]. We attempt to develop an improved modeling framework that allows for the evolution of charge states in the molecular environment of the interface. We use our results to consider the importance of chemical structure, phase behaviour and microstructure of the binary system in controlling actual performance and the ultimate limitations placed on solar to electric conversion by the molecular nature of the materials.

Organic Donor-Acceptor Photovoltaic Devices with Ultrabroad Charge Transfer State External Quantum Efficiency Spectra Saeed-Uz-Zaman Khan1, Giacomo Londi2, Xiao Liu1, Michael Fusella1, Gabriele D'Avino3, Luca Muccioli4,5, David Beljonne2 and Barry P. Rand1; 1Princeton University, United States; 2University of Mons, Belgium; 3CNRS and Grenoble Alpes University, France; 4Universita di Bologna, Italy; 5University of Bordeaux, France

The power conversion efficiency of organic photovoltaic (OPV) devices has recently crossed 15%, thanks to the advent of non-fullerene acceptors, improved material and interface engineering and better understanding of energy loss mechanisms. In recent years, consolidated experimental and theoretical efforts led to empirical design rules, that mandate small frontier orbital energy difference between donor and acceptor molecules to reduce the non-radiative energy loss, one of the major bottlenecks in OPVs. Although charge transfer (CT) states mediated recombination in organic donor-acceptor (D-A) interfaces are considered to be the leading non-radiative loss pathway in highly efficient OPVs, the exact mechanisms of such loss processes are not well understood. Most studies in the literature to date on CT mediated loss processes are performed on D-A blends that feature very small frontier orbital energy offsets with CT spectral features buried under and possibly hybridized with the local molecular energy state spectrum. To conclusively determine the role of frontier orbital energy offset in CT mediated non-radiative energy loss mechanisms, we need to identify D-A systems with spectrally well resolved CT states. On that note, in this work, we demonstrate a class of D-A systems that has ~2 eV broad CT external quantum efficiency (EQE) spectra, originating from the large optical gap of the D-A molecules and very low donor-HOMO acceptor-LUMO gap at the interface (i.e. very large frontier orbital energy offset). Being the exact opposite of the material systems recommended by the efficient OPV design rules, these devices are expected to have severe non-radiative recombination loss and thus are ideal candidate to study loss mechanisms in-depth.

We have identified six D-A systems that exhibit ~2 eV broad CT state spectra, despite their dissimilar molecular structures and HOMO-LUMO energy levels. To investigate the origin of the broad CT spectrum in detail, we have chosen N,N'-di(1-naphthyl)-N,N'-diphenyl-(1,1'-biphenyl)-4,4'-diamine (NPB)-1,4,5,8,9,11-hexaaazatriphenylenehexacarbonitrile (HAT-CN) based bulk-heterojunction (BHJ) D-A system, which demonstrates three distinct sub-gap peaks in its EQE spectrum. We have performed comprehensive electrical and optical characterization, along with molecular dynamics and quantum chemical simulations to conclusively prove that the lowest two peaks in the EQE are indeed originating from distinct electronic CT state transitions. We have also found that the lowest energy CT state is non-emissive and acts as a significant non-radiative loss path, possibly due to the large vibrational overlap with the ground state, and as expected from the energy gap law of organic materials. This efficient non-radiative loss pathway in NPB:HAT-CN BHJs results in a photon-energy dependent internal quantum efficiency spectrum and strong voltage bias dependent EQE, unlike most high-performing OPV devices.

Insight into the Structural Dynamics of Bulk Heterojunctions Anne Guilbert1, Mohamed Zbiri2, Peter Finn3, Christian Nielsen3 and Jenny Nelson1; 1Imperial College London, United Kingdom; 2Institut Laue-Langevin, France; 3Queen Mary University of London, United Kingdom

Structural dynamics of the active layer of organic photovoltaic (OPV) devices is known to influence their performance and lifetime. By structural dynamics, it is meant dynamics in its larger extent, covering vibrational as well as diffusive and rotational dynamics in such materials.

We study the structural dynamics of blends of various compositions of poly(3-hexylthiophene-2,5-diyl (P3HT) and
Phenyl-C61-butyric acid methyl ester (PCBM) as a function of temperature, using a combination of inelastic neutron scattering (INS), quasi-elastic neutron scattering (QENS), molecular dynamics simulations (MD) and density function theory (DFT). We use the deuteration technique for a contrast variation purpose to access not only the dynamics of the polymer but also the dynamics of PCBM within the blends. We observe, on the picosecond [1] and nanosecond timescales, that the faster polymer dynamics is increasingly frustrated upon blending with higher PCBM concentration, while the slower fullerene dynamics is promoted upon blending with P3HT. We find a good agreement between the simulated and experimental data on this broad timescale.

The MD simulation suggests that in the amorphous mixtures of P3HT and PCBM, P3HT is partially wrapping around PCBM and we speculate that the partial wrapping of P3HT around PCBM is responsible for the relatively high miscibility of PCBM with P3HT. To further probe this specific interaction, we carry out INS experiment on blends of regiorandom-P3HT:PCBM of different compositions. INS allows us to explore molecular vibrations as well as lattice vibrations without selection rule and covers the entire Brillouin zone. By using a combination of MD, molecular and periodic DFT calculations, we reproduce the full INS spectra (10-3500 cm⁻¹) and validate our wrapping hypothesis.

Phase Behavior, Miscibility and Stability of Non-Fullerene Organic Solar Cells
Harald Ade; North Carolina State University, United States

Organic photovoltaics (OPVs) are considered one of the most promising cost-effective options for utilizing solar energy in high energy/weight or semi-transparent applications. Recently, the OSC field has been revolutionized by the development of novel non-fullerene small molecular acceptors with efficiencies now reaching 16% in many systems. The device stability and mechanical durability of non-fullerene OPVs have received less attention and developing devices with both high performance and long-term stability remains challenging, particularly if the material choice is restricted by roll-to-roll and benign solvent processing requirements and desirable ductility requirements. Yet, morphological and mechanical stability is a prerequisite for OPV commercialization. Here we report our current understanding of the phase behavior of OPV mixtures and the relation of phase behavior to performance, processing needs (e.g., kinetic quench), and morphological stability via meta-stability or vitrification. A large range of miscibility (from hyper-miscibility to strong hypo-miscibility) is observed, including complex temperature dependence that can be a complex mixture of upper- and lower critical solution temperature behavior for both the binodal and the liquidus. The measurements presented should help to create molecular structure-function relationships that would allow some predictive guidance on how desired phase behavior and vitrification properties can be targeted by specific chemical design.

Non-Fullerene Acceptor-Donor Heterojunctions—Do We Need to Re-Write the Electro-Optical Rulebook?
Paul Meredith; Swansea University, United Kingdom

There is no doubt that the recent emergence of the non-fullerene electron acceptors has rejuvenated the field of organic photovoltaics. The current single junction record is now 15.7% and was achieved with an electron-deficient-core-based fused ring non-fullerene (Y6) in combination with a spectrally matched bespoke donor system [1]. Greater than two decades of reliance on fullerenes as the ‘only n-type in town’ is essentially broken although they still have a significant role to play in organic (and indeed perovskite) optoelectronics.

One critical element of the advances made in fullerene-based organic solar cells is a deep understanding of the device electro-optics – the means by which incident light interacts with the cell junction, creates a free carrier distribution profile, and those free carriers are extracted via various transport pathways. This has led to advanced optimization concepts in junction and interlayer design, manipulation of the external quantum efficiency, minimization of parasitic recombination and voltage loss, and structure-property relationships that guide the development of manufacturable thick junctions [2]. The question is – can we reapply the same electro-optical physics for the non-fullerenes, or must we start again?
In my talk I will address this most important of questions, detail some specific areas requiring thought and describe some of our recent work seeking to begin at least, this new electro-optical journey.

11:00 AM EN12.05.06
**Binding Energy for Disordered Organic Heterojunction Photovoltaic Devices** Nir Tessler and Dan Liraz; Technion-Israel Institute of Technology, Israel

One of the puzzles in the field of organic photovoltaic cells (OPVs) is the experimentally deduced low binding energy despite the fact that simple coulomb based arguments ( ) would predict binding energy of at least $E_b=500\text{meV}$ for intrachain excitons and $150-200\text{meV}$ for charge transfer excitons. Such high binding energies are not in line with devices achieving power conversion efficiency (PCE) of $14\%$ or internal quantum efficiency (IQE) that is almost $100\%$.

There have been several suggestions for the reduced effective binding energy as delocalization, disorder, entropy, as well as a combination of entropy and disorder. By entropic contribution, one means that the more dissociation paths there are, the more likely the exciton is to dissociate, and this can be translated into lower binding energy using the entropy gained in the dissociation process. The process becomes less obvious when disorder is introduced as one has to account for the fact that energetic disorder creates a spatial distribution of the local environments. Namely, each CT experiences a different environment through which it dissociates, and the challenges are in translating the overall processes into effective binding energy. We will describe an improved entropy-disorder model that resolves deficiencies of earlier models that predicted the effective binding energy to become negative at high disorder. To test our model we performed voltage and temperature dependent analysis of charge generation in NFA (PTB7-th:ITIC) based device. We find good agreement between modeling and experiment. Specifically, the activation energy of the dissociation efficiency is about $10\text{meV}$ which translates to an effective binding energy of about $\sim 80\text{meV}$, at room temperature. Using the experimental and theoretical analysis we will discuss the implications for higher efficiency materials.

11:15 AM EN12.05.07
**Non-Equilibrium Site Distribution Governs Charge-Transfer Electroluminescence at Disordered Organic Heterointerfaces** Armantas Melianas$^1$, Nikolaos Felekidis$^2$, Yuttapoom Puttisong$^2$, Stefan C. Meskers$^3$, Olle Inganäs$^2$, Weimin M. Chen$^2$ and Martijn Kemerink$^2$; $^1$Stanford University, United States; $^2$Linköping University, Sweden; $^3$Technische Universität Eindhoven, Netherlands

The interface between electron-donating and electron-accepting materials in organic photovoltaic (OPV) devices is commonly probed by charge-transfer (CT) electroluminescence (EL) measurements to estimate the CT energy, which critically relates to device open-circuit voltage. Despite the lack of a quantitative CT-EL model at disordered organic heterointerfaces and lack of quantitative proof, it is generally assumed that during CT-EL injected charges recombine at close-to-equilibrium energies in their respective density-of-states (DOS).

Combining optical and electrical experiments on a wide range of materials with numerical 3D kinetic Monte Carlo simulations of the entire OPV device we explicitly quantify that CT-EL instead originates from higher energy DOS site distributions far above DOS equilibrium energies. We present an experimentally verified and quantitative model of charge-transfer electroluminescence at donor/acceptor interfaces that reconciles the inconsistencies present in the literature. Our CT-EL model quantitatively and simultaneously accounts for charge transport physics in an energetically disordered DOS and molecular vibration induced broadening, using experimentally measured energetic disorder values and spectroscopically determined phonon-mode energies governing CT luminescence.

The lowest-energy CT states are in fact situated $\sim 180-570\text{meV}$ below the 0-0 CT-EL transition, enabling photogenerated carrier thermalization to these low-lying DOS sites when the OPV device is operated as a solar cell rather than as a light-emitting diode (LED). We reveal how DOS sites relevant to sub-gap photovoltaic action and CT-EL relate to the total DOS. The DOS sites sampled during CT-EL are not necessarily the same as those sampled during charge transport and sub-gap absorption measurements.

The non-equilibrium site distribution governing CT-EL rationalizes the experimentally observed weak current-density dependence of CT-EL and poses new research questions on reciprocity relations relating light emission to
photovoltaic action and regarding minimal attainable photovoltaic energy conversion losses in OPV devices.

Hole Transfer in Non-Fullerene (NF) Organic Solar Cells Yanfeng Liu¹, Jianyun Zhang², Jianqiu Wang³, Nannan Yao¹, Yingzhi Jin¹, Xiaozhang Zhu², Yuan Zhang² and Fengling Zhang¹; ¹Linköping University, Sweden; ²Institute of Chemistry, Chinese Academy of Sciences, China; ³Beihang University, China

To efficiently harvest photoinduced current in organic solar cells by extending the coverage of the solar spectrum, many non-fullerene (NF) electron acceptors with complementary absorption spectra are synthesized, which indeed enables the power conversion efficiency of organic solar cells up to 14% in single junction and 17% in tandem devices. There have been intensive studies on electron transfer from electron donors to various fullerene acceptors in fullerene based organic solar cells. However, the mechanism of efficient hole transfer from non-fullerene acceptors (or hole donor, denoted as D_h) to molecular or polymeric electron donors (or hole acceptors, denoted as A_h) is still not fully understood although considerable contribution from non-fullerene D_h materials to photoinduced current in non-fullerene solar cells. There are several reports on high performance non-fullerene organic solar cells with very small or even close to zero LUMO or(and) HOMO offsets between two photoactive components, which challenges the theories on charge generation derived in fullerene based organic solar cells. Currently, to increase the efficiency of organic solar cells, more attention is paid on generating charge with minimized photo-voltage loss by matching energy levels of donors and acceptors. To understand the mechanism of non-fullerene organic solar cells, charge transport and extraction at electrodes also need to be considered.

Here we will present our study on the mechanism of efficient hole transfer from D_h to A_h in non-fullerene organic solar cells. Based on the results, efficient hole transfer from D_h to A_h is not only depends on the offset of HOMOs of D_h and A_h but also charge transport and extraction at electrodes. Therefore, a comprehensive strategy including both charge generation and extraction is desired to further enhancing the PCE of the organic solar cells.

11:45 AM EN12.05.09
Minimum Energetic Driving Force for Charge Generation in Organic Solar Cells Kyohei Nakano¹, Weining Han², Jianming Huang¹, Yujiao Chen¹, Hiroyuki Yoshida² and Keisuke Tajima¹; ¹RIKEN, Japan; ²Chiba University, Japan

Eliminating the excess energetic driving force in organic solar cells leads to a smaller energy loss and higher device performance; hence, it is vital to understand the relation between the interfacial energetics and the photoelectric conversion efficiency. In practice, however, mixing morphology of the donor (D) and the acceptor (A) in bulk heterojunction has a large impact on photovoltaic properties, which prevents us from investigating the minimum energetic driving force at D/A interface for efficient charge generation.

In this study, we systematically fabricate 16 planar heterojunctions of four donor polymers and four acceptors and investigate the relation between state energies at D/A interface and resulting charge generation efficiency. A thin film of donor polymer was transferred onto an acceptor film, forming planar heterojunction, so as to eliminate the effect of morphology. The state energies of singlet excited state, charge transfer state, and charge separated state were experimentally quantified. The charge generation efficiency from donor exciton and acceptor exciton were evaluated using external quantum efficiency combined with transfer-matrix optical modeling with making a simple assumption about exciton diffusion. The charge generation efficiency and its electric field dependence correlated with the energy difference between the singlet excited state and the interfacial charge transfer state. The threshold energy difference is 0.2 to 0.3 eV, below which the efficiency stated dropping and the charge generation became electric-field dependent. In contrast, the charge generation efficiency did not correlate with the energy difference between the charge transfer and the charge separated states, indicating that the binding of the charge pairs in the charge transfer state is not the determining factor for the charge generation.

**Fast Screening Donor:Acceptor Blends for Organic Solar Cells**  
Gitti L. Frey¹, Artem Levitsky¹, Giovanni Maria Matrone², Ilaria Bargigia³, Aditi Khirbat¹, Xiaolei Chu⁴, Adam J. Moule⁴, Carlos Silva³ and Natalie Stingelin³; ¹Technion–Israel Institute of Technology, Israel; ²Imperial College London, United Kingdom; ³Georgia Institute of Technology, United States; ⁴University of California Davis, United States

A significant breakthrough in the efficiency of organic solar cells (OSCs) has been achieved due to the synthesis of new materials offering a plethora of donor:acceptor combinations. However, the device performance is interlinked in a complex way not only with the properties of the individual components but also its strong dependence on the blend’s microstructure and phase morphology. Consequently, identifying high-performing donor:acceptor combinations has so far been an intricate process nearly uniquely relying on tedious and time-consuming trial-and-error materials selection methods. To overcome this unsustainable approach we developed a methodology that rapidly elucidates how blend composition and processing conditions affect the final blend morphology and microstructure. We demonstrate that transient absorption spectroscopy (TAS), vapor phase infiltration (VPI) and differential scanning calorimetry (DSC) measurements can be jointly harnessed to fast-screen OSC blends. VPI infuses inorganic materials into an organic matrix by exposure to gaseous precursors that diffuse into the film and in-situ convert to an inorganic product. In BHJ films, the diffusion process proceeds selectively through domains with high free-volume leading to inorganic deposition selectively along the diffusion paths. The diffusion network is easily visualized with electron microscopy. Using this labelling approach to spatially map OSC BHJ is in concept similar to the staining approach used to image low contrast biological. The spatially mapping of the phase morphology of organic solar cells via VPI giving insights into the size, shape, distribution and connectivity of specific domains, resolved through fast and straightforward HRSEM characterization, the information obtained on the general phase behavior as well as the phase purity (or at least degree of order) via DSC, and the indirect correlations on the fine structure of, e.g., the intermixed phases and phase-pure domains, provided by the charge separation dynamics from TAS, can, when combined, be used to identify best working compositions and deliver understanding why specific deposition methodologies do not lead to well-performing devices.

**Elucidating Interfacial Structure-Function Relationships in Organic Photovoltaics**  
Aram Amassian; North Carolina State University, United States

The distributed bulk heterojunction in organic solar cells is the result of a delicate nanoscale blend of electron donating (D) and accepting (A) material resulting in different interfacial varietals. These include interfaces between aggregated pure D and A phases, mixed interphases exhibiting significantly different energetics and other interfaces between an aggregated phase and the mixed interphase. Revealing the complex energy landscape that results in real-space can be extremely challenging, yet it locks the secrets of light harvesting of organic solar cells. Considerable debate remains about the nature of interfaces and the importance of sharp D-A interfaces versus the mixed interphase on charge generation and extraction. In this talk, we discuss recent developments in the direct imaging of the real-space energetic landscape of BHJ layers via scanning tunneling microscopy and spectroscopy (STM/STS) measurements. This approach is shown to work on BHJ films directly usable in OPV devices and reveal several heterointerfaces with different energetics that surround aggregated D, A and mixed (M) phase domains. We reveal the coexistence of three types of heterointerfaces within the BHJ and, in total, four types of D-A intermolecular interactions exhibiting different energetics. These scenarios are universally present in classical and modern BHJs exhibiting a wide range of power conversion efficiencies (PCE, ca. 3.5 – 10.8%; P3HT:PCBM, P3HT:O-IDTBR and P3H:PCBM). We provide accurate HOMO/LUMO energy diagrams for D/M, A/M and D/A heterointerfaces in these systems and discuss the most likely pathways for charge generation and recombination.

2:15 PM EN12.06.03  
**Understanding and Reducing Energy Loss at the Organic/Anode Buffer Interface in Organic Photovoltaics**  
Kan Ding¹ and Stephen R. Forrest¹,²; ¹University of Michigan, United States; ²University of Michigan–Ann Arbor, United States

---

Final Program 1/13/2020  1114
Understanding various sources of energy loss in organic photovoltaic (OPV) cells is important for achieving high efficiency. In this work we explore energy losses at the interface between a vacuum deposited tetraphenyldibenzoperiflanthene (DBP) donor and C70 as acceptor bulk heterojunction (BHJ) active layer and a MoO3 anode buffer through experimental and computational methods. Material composition at the organic/anode buffer interface is independently controlled to distinguish the energy loss due to the organic/anode buffer interface from that in the BHJ. Interface energy loss is attributed to charge transfer between the organic active layer and anode buffer layer. Monte Carlo simulations are used to quantitatively evaluate the magnitude of the interfacial energy loss and its effect on device performance. A strategy is proposed to reduce this source of loss. Specifically, a thin interlayer is inserted between the organic active layer and anode buffer layer, leading to an increase of up to 6% in power conversion efficiency compared with conventional devices. Finally, basic principles are provided for the design of the interface layer.

2:30 PM EN12.06.04
Emissive and Charge Generating Donor Acceptor Interfaces for Organic Optoelectronics with Low Voltage Losses
Donato Spoltore1, Sascha Ullbrich1, Johannes Benduhn1, Xiangkun Jia1, Vasileios C. Nikolis1 and Koen Vandewal2; 1TU Dresden, Germany; 2Institute for Materials Research (IMO-IMOMEC), Belgium

Intermolecular charge transfer states at the interface between electron donating (D) and accepting (A) materials are critical for the operation of organic solar cells but can be employed also in organic light emitting diodes. Non radiative decay of the charge transfer state is dominant in state of the art D/A organic solar cells and is responsible for large voltage losses as well as electroluminescence external quantum yields in the 0.01–0.0001% range. In contrast, the electroluminescence external quantum yield reaches up to 16% in D/A organic light emitting diodes. In our work we show that proper control of charge transfer state properties allows simultaneously an high photovoltaic and high emission quantum yield within a single system, demonstrating that efficient photogeneration of free carriers and a high electroluminescence quantum yield do not necessarily need to be mutually exclusive in organic semiconductors. This leads to ultralow emission turn on voltages as well as significantly reduced voltage losses upon solar illumination, as low as 0.37eV. These results unify the description of the electro optical properties of charge transfer states in organic optoelectronic devices and encourage the use of organic D/A blends in energy conversion applications involving visible and ultraviolet photons, for example for indoor application and multijunction solar cells.

General Rule for the Energy of Water-Induced Traps in Organic Semiconductors
Guangzheng Zuo, Mathieu Linares, Tanvi Upreti and Martijn Kemerink; Linkoping University, Sweden

Charge carrier traps are generally highly detrimental for the performance of semiconductor devices. Unlike the situation for inorganic semiconductors, detailed knowledge about the characteristics and causes of traps in organic semiconductors is still very limited and surprisingly few systematic investigations to the energetics of traps in organic semiconductors have been conducted.

Here, we systematically investigate the JV characteristics from hole- and electron-only thin-film devices for a large range of organic semiconductors. Trap energies and densities are extracted directly from the JV curves and, more
accurately, using a method based on the logarithmic slope of the JV curves. For all investigated materials, the hole and electron trap distributions are found to be centered at a more or less constant energy offset of 0.3–0.4 eV above the HOMO and below the LUMO level, respectively. For typical preparation and measurement conditions the total trap density is around $0.5–1 \times 10^{23} \text{ m}^{-3}$ for both electrons and holes. We experimentally identify water absorbed in nano-voids as cause. Using density functional theory (DFT) calculations we show that direct interaction of H$_2$O molecules with the conjugated backbone cannot explain specific conformation locks nor the finding of a generic trap. Instead, we show that electrostatic interaction with an ensemble of H$_2$O molecules that for example are enclosed in a nanoscopic void in the film provides a stabilization of both electron and hole polarons on different model systems of conjugated molecule. The mechanism has a broad relevance as it does not rely on any specific interactions with, or properties of the active material like conjugation length, mobility or transport mechanism, and is shown to affect electron and hole transport in a similar manner. The prerequisite of having nano-voids in the molecular morphology suggests this trapping mechanism to be of lesser relevance for single crystals, but also suggests processing routes to suppress the mechanism; an example of the latter is demonstrated.

The current findings are in marked contrast to earlier works that concluded that the electron trap level is about constant and centered at an energy of $\sim 3.6$ eV below the vacuum level. For p-type materials, trap formation has previously been argued to be due to a specific hydrogen bonding interaction of a single water molecule affecting the torsional potential energy profile of the bond connecting the donor and acceptor subunits of a D-A-type polymer.

molecular mechanism of doping these materials with kinetic Monte-Carlo simulations. The availability of first-principles based models to compute key performance characteristics of organic semiconductors may enable in-silico screening of numerous chemical compounds for the development of highly efficient opto-electronic devices.

4:00 PM EN12.07.03
Effects of Ligand Coordination on the Structure and Electronic Properties of Copper(I) Thiocyanate Pichaya Pattanasattayavong1, Daniel M. Packwood2 and David J. Harding3; 1Vidyasirimedhi Institute of Science and Technology (VISTEC), Thailand; 2Kyoto University, Japan; 3Walailak University, Thailand

In recent years, copper(I) thiocyanate (CuSCN) has been established as a high-potential semiconductor with an impressive range of opto/electronic applications demonstrated, including thin-film transistors (TFTs), organic light-emitting diodes (OLEDs), organic photovoltaics (OPVs), extremely thin absorber (ETA) solar cells, and now perovskite solar cells (PSCs). Belonging to the group of coordination polymers, CuSCN has an extended 3D network structure formed by the ambidentate SCN ligand linking the Cu centers together. This gives rise to the electronic structure that leads to its unique properties of optical transparency (wide band gap) and good hole transport (dispersed valence band).

Due to its excellent semiconducting properties and wide-ranging applications, it is of great interest to investigate other derivatives of CuSCN. For coordination polymers, ligand coordination is a common method to modify the structure. Interestingly, CuSCN is routinely processed from dialkyl sulfide-based solutions [Adv. Mater. 2013, 25, 1504; Adv. Energy Mater. 2015, 5, 1401529; Science 2017, 358, 768], and in fact the coordination of these sulfide ligands with Cu center in CuSCN can lead to different 1D structures [Polyhedron 2016, 114, 252]. Moreover, N-containing aromatic ligands have also been reported to react with CuSCN to yield colored compounds with optical absorption/emission variable in the visible range [Inorg. Chem. 2011, 50, 7239]. These examples show the structural versatility and adjustable electronic properties of CuSCN.

In this work, we report a survey of 25 structures of CuSCN-ligand (L) complexes and, for the first time, their electronic structures calculated by density functional theory (DFT). Four groups of ligands were investigated: dialkyl sulfides, aliphatic cyclic amines, aromatic imines, and aromatic diimines. We observed that the dimensionality of the Cu-SCN network decreased with the increasing CuSCN:L ratio. In general, the 3D network of the parent compounds (α- and β-CuSCN) was reduced to 2D sheet or 1D ladder structures when the CuSCN:L ratio was 1:1 and further to 1D zigzag chain or helical chain at 1:2 ratio and 0D monomer at 1:3 ratio. Aromatic diimine ligands resulted in bridged 2D or bridged 1D structures. Importantly, we found the relationship between the Cu-SCN network dimensionality and the width of the top Cu valence band (VB) as well as the energy gap between the Cu and SCN states. With the reducing dimensionality, the Cu VB width also decreases whereas the Cu-SCN energy gap increases. Based on the band structure and the total and partial density of states (DOS) analyses, hole transport prevailed in the 2D structures but became limited in the 1D structures and were completely localized in the 0D structure. Aromatic ligands generated states between the Cu and SCN energy states due to their lower-energy π* states compared to the SCN π* level. As a result, the combination of 2D Cu-SCN network (CuSCN:L ratio less than or equal to 1:1) and aromatic ligands can be employed to tune the electronic properties of CuSCN; we propose that the 2D network should be kept to provide hole transport while using the aromatic ligands to modify the optical absorption/emission properties. In addition, one particular case of the bridging 4,4′-bipyridine (4,4′BPY) ligand was found to exhibit dispersed states both at the valence band and the ligand-dominant conduction band as well as a small fundamental band gap; we speculate that the complex of CuSCN and 4,4′BPY could display ambipolar charge carrier transport properties, expanding further the possible applications of CuSCN-based materials. This work provides a comparative study on the effects of ligand coordination on the structural and electronic properties of CuSCN and could serve as guidelines for further development of semiconductors based on coordination polymers.

4:15 PM EN12.07.04
Ultrafast Nonlinear Photonics in an Organic Superconductor kappa-(ET)2Cu[N(CN)2]Br Shinichiro Iwai; Tohoku University, Japan

Intense light-field application to solids produces enormous/ultrafast non-linear phenomena such as high-harmonic generations and attosecond charge dynamics. They are distinct from conventional photonics. However, main targets have been limited to insulators and semiconductors, although theoretical approaches have been made also for correlated metals and superconductors. Here, in layered organic conductors and a superconductor, anomalous non-linear photonics driven by a nearly single-cycle strong electric field of >10 megavolts /cm are observed as a dynamical localization [1-3], a stimulated emission [4] and a harmonic generation (HG). It should be emphasized...
that they are enhanced by critical fluctuations near a metal-to-insulator transition temperature and a superconducting transition temperature. In particular, observation of the characteristic stimulate emission in an organic superconductor Kappa-(ET)$_2$Cu[N(CN)$_2$]Br on an ultrafast timescale of 10 fs clarifies that the Coulomb repulsion plays an essential role in the superconductor [4]. Moreover, second harmonic generation (SHG) in Kappa-(ET)$_2$Cu[N(CN)$_2$]Br (in which spatial inversion centers exist) shows that the non-perturbative light-driven current can break the inversion symmetry. Temperature dependence, polarization dependence, and carrier-envelope phase (CEP) dependence of the SHG in the organic superconductor will be discussed.

SESSION EN12.08: Organic Photovoltaics, Materials, Processing and Up-Scaling
Session Chairs: Francesca Brunetti and Argiris Laskarakis
Wednesday Morning, December 4, 2019
Sheraton, 2nd Floor, Back Bay C

8:30 AM *EN12.08.01
Organic Photovoltaics—From Lab to Fab Robin Szymanski$^{1,2}$, Uyxing Vongsaysy$^2$, Lionel Hirsch$^{1,3}$, Sylvain Chambon$^{1,3}$ and Guillaume Wantz$^{1,4,3}$; $^1$Univ. Bordeaux, France; $^2$ARMOR, France; $^3$CNRS, France; $^4$Bordeaux INP, France

The communication will display our recent progress Organic Photovoltaics (OPV). Solution-processed organic solar cells are continuously showing increasing performances other the recent years with record power conversion efficiency exceeding 15%. They represent a more and more promising technology with a growing interest from companies and markets. The challenge is surely to maintain the global research efforts in materials development to increase efficiency and stability but also to enable a realistic cost-competitive transfer from lab to fab. Our efforts to increase the stability of OPV cells will be exposed including device engineering and materials developments for thermally stable devices. We have recently shown that impurities such as photo-oxidized fullerene or photo-oxidized polymers (P3HT or PTB7) are responsible for an impressive loss in device performances even in very low amounts. This finding is raising issues for large area manufacturing where organic semiconductors are commonly processed in ambient conditions.

The cost of materials is also a critical when it comes to scale up solar cell production. If the best materials are achieving high PCE, it is crucial that these materials remain as low cost as possible thanks to simplified chemical structures and straightforward synthesis routes and purification steps. If a few simple and efficient polymers are currently emerging, we have been investigating a series of bio-inspired solution-processable compounds derivated from curcuminoids enabling one-pot, one-step synthetized organic semiconductors for OPV.

Finally, large area OPV modules are currently facing two major challenges. (a) The need to be light activated which becomes difficult when the flexible product uses packaging sheets acting as UV filter to promote long lived devices. (b) The fast decay of efficiency within the first hours of usage under illumination; this so-called burn-in effect is still not fully understood and should be overcome. On these two issues, this communication will bring some fundamental understandings and guidelines for more efficient and stable OPV cells.

9:00 AM EN12.08.02
Upscaling of Organic Photovoltaics Using Novel Non-Fullerene Acceptors and Slot-Die Coating Audrey Laventure and Gregory C. Welch; University of Calgary, Canada

Organic photovoltaic stands as one of the most promising clean energy technologies. However, its commercial availability still presents some challenges that have not yet been overcome. To improve the cost effectiveness of the organic solar cell active layer, our group has recently developed a series of N-annulated perylene diimide (PDI) derivatives acting as electron acceptors, one of these is today commercially available. (1) The resulting fullerene-
free photovoltaic devices present a high power conversion efficiency, making them a viable alternative to the more traditional fullerene-containing solar cells. (2) Considering that these molecules can be mass-produced, they are excellent candidates for slot-die coating of large area solar cells. Herein, we present the structure-property relationships of these compounds (3) along with their utility as electron acceptors in bulk heterojunction organic photovoltaics. We also discuss the upscaling results of our efforts towards printing large-scale organic solar cells using slot-die coating. References: (1) Sigma-Aldrich, PDI-DPP-PDI, https://www.sigmaaldrich.com/catalog/product/aldrich/901143); (2) McAfee, S.M., Dayneco, S.V., Josse, P., Blanchard, P., Cabanetos, C., Welch, G.C., Chem. Mater., 2017, 29, 1309; (3) Tintori, F., Laventure, A., Welch, G.C., Soft Matter, 2019, Advance article, 10.1039/C9SM00716D.

9:15 AM *EN12.08.03
Optimization of Large Area Manufacturing of Fully Printed Organic Electronic Devices by Robust In-Line Investigations and Modelling
Argiris Laskarakis1, A. Zachariadis1, C. Kapnopoulos1, Z. Kyroudis, E. Mekeridis2 and S. Logothetidis; 1Aristotle University of Thessaloniki, Greece; 2Organic Electronic Technologies P.C. (OET), Greece

The optoelectronic and charge transport properties of printed semiconductor nano-layers (e.g. polymer donors and acceptors, hybrid perovskites) is mainly controlled by the structural morphology and crystallization dynamics during their fabrication in functional device architectures (as Organic Photovoltaics, Perovskite Photovoltaics, etc). Despite the numerous advances reported on the structure-property relationships on these materials by lab-scale solution-based methods, their reliable manufacturing on flexible substrates by large scale roll-to-roll (R2R) printing processes is accompanied by numerous challenges, such as the formation of structural inhomogeneities, and non-reproducible properties (optical, electrical, structural) and interface quality over large areas. The above limitations provide significant obstacles for R2R printing to meet the requirements for reliable large scale manufacturing of high performance Organic Electronic devices on flexible substrates for commercial applications.

In this work, we present an intelligent in-line optical characterization methodology based on the combination of robust in-line Spectroscopic Ellipsometry (SE) and in-line Raman Spectroscopy (RS) for the investigation of the formation mechanisms and morphology of printed semiconductor nanolayers (e.g. polymer donors as PBDB-T, non-fullerene acceptors as ITIC, and hybrid perovskites based on MAPbI3), on flexible polymer substrates by R2R pilot-to-production lines. In addition, we report on the development of intelligent modelling procedures that can extract from single very fast optical in-line measurements of significant insights from the printed semiconductors properties such as film quality, morphology (surface roughness, voids, pinholes etc), degradation traces and film thickness. By this approach, we demonstrate an optimized fabrication process of fully printed large scale flexible OPV and PPV devices with improved charge transport properties and performance that exceeds 6.5%, and significant device-to-device reproducibility. [1,2] Finally, this methodology will open the way for the reliable scalable nano-manufacturing of high performance flexible electronic devices by large scale processes.

9:45 AM EN12.08.04
Printable High Efficiency Flexible and Free Design OPV Modules for Indoor Application
Sadok B. Dkhil1, Florent Pourcin1, Donia B. Freqj1, Elena Barulina2, Pavlo Perkhun2, Olivier Margeat2, Christine Videiot-Ackermann2, Jörg Ackermann2, Pascal Pierron1, Jérôme Vernet1 and Brice Crucun1; 1Dracula Technologies, France; 2Aix Marseille University, France

Over the last decade, organic solar cells (OSCs) have become a promising technology for next generation solar cells combining novel properties such as light weight, flexibility, or color design with large-scale manufacturing with low environmental impact. However, the main challenge for OSC will be the transfer from lab-scale processes to large-area industrial solar cell fabrication. High efficiencies in the field of OSCs are mainly achieved for devices fabricated under inert atmosphere using small active areas, typically below 0.2 cm². So far, a small lab scale devices have now reached performances above 17% [1].

In this light, inkjet printed organic solar cells and modules with large area were demonstrated. Inkjet printing allows
direct patterning of four layers, including the top electrode, offering full freedom of design without the use of masks or structuring by hardware. Inkjet printed large area (>1 cm²) organic solar cells with power conversion efficiency exceeding 6.5 % deposited from environmentally friendly solvents in an air atmosphere are demonstrated using the same printer. To prove the great advantage of inkjet printing as a digital technology allowing freedom of forms and designs, large area organic modules with different artistic shapes were demonstrated keeping high performance.

The good module performance at low illumination make our OPV modules good candidates for indoor applications, field in full expansion thanks to the Internet of Things (IoT).

Reported results confirm that inkjet printing has high potential for the processing of OPV, allowing quick changes in design as well as the materials.

10:00 AM BREAK

10:30 AM *EN12.08.05
Fully Spray-Coated Polymer Solar Cells and Modules Realized with Green Solvents—Possibilities and Open Issues Francesca Brunetti; University of Rome-Tor Vergata, Italy

In the field of energy generation, several emerging technologies using new PV materials and innovative device concepts have appeared in the last years: Dye solar cells (DSC), Quantum Dot (QDSC), organic photovoltaics (OPV), and perovskite solar cells (PSC). Among these technologies, PSC are the most promising ones, since they have drastically increased their efficiency up to 24.2 % in just a few years, while DSC have reached 11.9 %, OPV 15.6 % and QDSC 16.6%(according to NREL certified efficiencies chart) [1].

The main characteristic of these technologies is that most of the parts of the devices can be processed from solution, allowing to realize light-weight, flexible, transparent, conformable, roll-to-roll compatible, potential low costs devices.

Among these technologies, OPV has seen in the last few year a fast rise in efficiency thanks to the introduction of new materials such as low band gap polymer donors and non-fullerene acceptors [2,3] allowing to reach the actual record efficiency of 16.5% [4].

Such optimal performance are strongly correlated to the use of spin coating technique to ensure reproducible and homogeneous films and chlorinated solvents that help the suitable nanoscale morphology. This procedure, however, is not industry compatible since spin coating does not allow large scale production and chlorinated solvents are poorly tolerated in workplaces since they are harmful towards environment and human health [5, 6, 7]. In this talk, we will present a possible route toward the realization of large area, high-performing inverted polymer solar cells where all the layers, apart from TCO, have been realized via the spray coating technique with green solvents [8,9].

In particular, we will show via atomic force microscopy (AFM) analysis, how this technique affects the morphology at the interface between photoactive layer (PAL) deposited through a non-chlorinated solvent (ortho-xylene) and hole and electron trasporting layers processed from alcohol based solvents. We will consider the interface between PAL and an electron transporting layer (ETL) fabricated using zinc oxide nanoparticles coated with polyethyleneimine ethoxylated (PEIE). For the interface between PAL and the hole transport layer (HTL)/anode three different combination will be shown: i) a mixture of two commercial poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) formulations (CPP:PH1000), ii) an anhydrous PEDOT:PSS (A-PEDOT) solution developed in our laboratory. The electrical performance in terms of PCE of small area devices (10 mm²) realized using these two typologies are 1.7% in the case of PH1000 and 3.6% anhydrous PEDOT:PSS when the devices were illuminated from ITO side. A study of scaling up of the solar cells will be presented for a fully spray coated organic photovoltaic modules (active area: 12 cm²) realized with structure ITO/ZnO-PEIE/PBT7:PC70BM/V2O5/A-PEDOT. For this module, a power conversion efficiency 0.8% is achieved, while large area modules with metallic anode on top PCE of 3%. Finally, a practical application of our solar module is reported.

Influence of Thermal Treatment and Humidity on Work Function of PEDOT:PSS Thin Films
Aman Anand, Rico Meitzner, Shahidul Alam, Moritz Beckenkamp, Ulrich S. Schubert and Harald Hoppe; Friedrich Schiller University Jena, Germany

In the field of optoelectronics, Poly (3,4-ethylenedioxythiophene):poly (styrene sulfonate) (PEDOT:PSS) is the most common and successful commercial conductive polyelectrolyte. Its properties such as high transparency in the visible range, high electrical conductivity, excellent chemical and physical stability, high ductility, good film-forming properties, and high work function enable multiple applications in the field of electronics. The work function is one of the main parameters which control the functionality of an electronic device. Properly tuning the work functions within semiconductor devices is very crucial in terms of performance and may be strongly influenced by unmonitored processing conditions. For example, PEDOT:PSS is highly hygroscopic in nature, which may impact on its functionality. In the present work, we have investigated the influence of the thermal post-production treatments and relative humidity during film casting or storage on the work function of PEDOT:PSS films made from various commercial formulations. We find clear trends between the processing conditions and absolute work function as obtained with a carefully calibrated Kelvin Probe setup. As a conclusion, we can suggest suitable processing parameters for a wide range of formulations and targeted electronic properties.

Annealing Free Solution-Processable MoOx Hole Transport Layer for Bulk-Heterojunction Polymer Solar Cell
Nhan H. Tran and Shinuk Cho; University of Ulsan, Korea (the Republic of)

Electrode buffer layer plays an important role on the performance of polymer solar cell by facilitating the flow of charges via better energy level alignment at the organic/electrode interface. Transition metal oxide material such as MoOx was found as the good material for anode buffer layer due to high conductivity and high stability. In general, the MoOx layer fabricated by wet chemical method needs a post-thermal treatment around 200 °C in air to archive better quality thin film. However, the usage of high temperature makes the transition metal oxide hard to employ in flexible electronics where flexible substrate can’t stand with the temperature above 100°C. In this work, we developed annealing free modified s-MoOx and have applied on bulk heterojunction (BHJ) polymer solar cell based on a blend of p-type polymer PTB7-Th and fullerene derivative PC71BM. The polymer solar cell with non-annealed c-MoOx hole transport layer prepared by conventional sol-gel method showed poor efficiency of 1.37%. If the c-MoOx layer was annealed at 200°C before active layer deposition, the efficiency was recovered to normal range that typically shown in conventional structure PTB7-Th and PC71BM solar cells. However, the polymer solar cell with our modified-MoOx (m-MoOx) prepared using bis(2,4-pentanedionato)molybdenum(VI)dioxide (MoO2(acac)2) exhibited higher efficiency without high temperature annealing. The solar cell with m-MoOx showed higher efficiency and better stability comparable with that of device with PEDOT:PSS hole transport layer. Note that even PEDOT:PSS also needs annealing process around 120°C normally. Furthermore, annealing free m-MoOx allows successful fabrication of inverted PTB7-Th:PC71BM solar cells with solution processable MoOx.

c-MoOx: MoOx with conventional sol-gel method

Additive Solution Deposition of Multi-Layered Semiconducting Polymer Films for Design of Sophisticated Device Architectures
Tucker L. Murrey1, Kunping Guo2, Justin Mulvey1, Owen Lee1, Camila Cendra3, Zaira Bedolla-Valdez1, Alberto Salleo3, Jean-Francois Moulin4, Kunlun Hong5 and Adam J. Moule1; 1University of
Semiconducting polymers (SPs) have received enormous attention due to low-cost scalable solution-processing, and the potential for creating light-weight flexible electronic devices. Most working electronic devices consist of several layers of material, each having a specific optical and/or electronic function. One universal design constraint for complicated device architectures, like organic field effect transistors (OFETs), organic photovoltaics (OPVs) and red-green-blue organic light emitting diode (OLED) displays is that they require multiple components patterned laterally and vertically to operate. Currently, many of these components are comprised of non-flexible inorganic materials. In order to move towards flexible all organic electronic devices, there is a need to develop high precision vertical and lateral patterning methods that are compatible with solution processing techniques. This study demonstrates an additive solution process for depositing multiple layers of semiconducting polymer (SP) films by controlling film solubility with molecular dopants. During multi-layer deposition the bottom layers are exposed to a series of solvent environments that swell the SP films. We use neutron reflectometry (NR) to quantify the film thickness change and solvent content during solvent exposure in a single poly-3-hexylthiophene (P3HT) layer. The film thickness increases by 40-80% with exposure to good solvents. Four layer thin-films composed of alternating protonated and deuterated P3HT layers were additively coated from solution. NR measurements reveal high individual layer purity and that extensive solvent soaking induces no mixing between layers. This facile process enables additive layering of mutually soluble SP films and can be used to design novel electronic device architectures.

SESSION EN12.09: Light Management in Organic and Hybrid Systems

From Light to Information—Indoor Light Harvesting Devices with Copper Coordination Complexes Marina Freitag; Uppsala University, Sweden

Efficient indoor light harvesters introduce a new design paradigm to Internet of Things (IoT) devices to maximize their ability to process, sense, and communicate data.(1) We here implement an adaptive wireless sensor node powered by dye-sensitized solar cells (DSCs) with an adapted sensitizer combination. Co-sensitizing organic dyes enhances the photovoltage of DSCs based on the CuII(tmby)2 redox couple up to 1080 mV and the power conversion efficiency above 11.5% under simulated sunlight. By adding optical density in the spectral region of 400 – 500 nm, the additional dye efficiently compensates for competitive absorption in the CuII(tmby)2 electrolyte. Cosensitized light harvesting systems maintain a photovoltage of 910 mV when lowering the illumination to 1000 lux of fluorescent light, with the power output over 100 µW cm-2 translating to an unprecedented conversion efficiency of 34.0% for ambient light. Subtle drying of the CuII(tmby)2 electrolyte in ambient environment leads to ‘Zombie’ solid-state DSCs with an amorphous solid hole transport material that maintain power output for high stability.(2–4)

We demonstrate a working example of a self-powered wireless ‘IoT’ device (light harvesting area 8 cm2) to power a microcontroller board with supercapacitor as energy buffer. Indoor light harvesters will lead to a new generation of energy-harvesting IoT.

Abundant Organic Semiconductor Catalysts for a Peroxide Clean Energy Cycle

Maciej Gryszel¹, Eva Miglbauer¹, Magdalena Warczak¹, Renata Rybakiewicz¹,² and Eric D. Glowacki¹,²
¹Linkoping University, Sweden; ²Warsaw University of Technology, Poland

Semiconductor-based catalysts can convert solar energy into chemical fuels such as hydrogen, hydrogen peroxide, or hydrocarbons produced via carbon dioxide reduction. Long overlooked due to stability concerns, some organic semiconductors have recently emerged as promising electrocatalysts and photocatalysts for operation in aqueous environments. We have found that organic semiconductors have, in general, a high selectivity for the two-electron reduction of oxygen to hydrogen peroxide. We find this occurs on numerous organic semiconductors and conducting polymers in a pH range from 1 to 12. As cathodic catalysts, organic semiconductors can demonstrate impressive stability. The possibilities of solar energy conversion into the high-energy molecule $\text{H}_2\text{O}_2$ enabling carbon-neutral energy storage in liquid form, in contrast to gaseous $\text{H}_2$, will be discussed. Finally, I will cover recent results on purely photocatalytic systems, where hydrogen peroxide is produced reductively via one- or two-electron mechanisms, while various substrates are oxidized, including water. Organic semiconductors have potential to become a powerful class of intrinsic catalysts, tunable by molecular design.

Structure-Property Studies of Organic Mixed Ionic/Electronic Conductors (OMIECs) in Aqueous Electrolytes

Jonathan Rivnay; Northwestern University, United States

Organic mixed ionic/electronic conductors have gained considerable interest in bioelectronics, power electronics, circuits and neuromorphic computing. These organic, often polymer based, semiconductors rely on a combination or ionic transport, electronic transport, and high volumetric charge storage capacity. Despite recent progress and a rapidly expanding library of new materials, the understanding of stability and transport/coupling of ionic and electronic carriers remain largely unexplored. We highlight recent synthetic and processing approaches used to tailor electrochemical device properties and stability, as well as new opportunities enabled by such advances. Our understanding of critical processes in electrochemical devices further requires us to study these materials in device-relevant conditions, fully considering the effects of ions and solvent on microstructure and transport. To this end, we report on recent efforts towards structure-property relations in high performance organic mixed conductors using ex-situ, in-situ, and operando scattering and spectroscopic techniques.

Boosting Direct X-Ray Detection Performance in Flexible Organic Thin Films by Small Molecules Tailoring

Ilaria Fratelli¹,², Andrea Ciavatti¹,², Laura Basiricò¹,², Stefano Lai¹, Piero Cosseddu¹, Annalisa Bonfiglio¹, John Anthony² and Beatrice Fraboni¹,²
¹University of Bologna, Department of Physics and Astronomy, Italy; ²National Institute for Nuclear Physics, Italy; ³University of Cagliari, Italy; ⁴University of Kentucky, Center for Applied Energy Research, United States

The development of large area ionizing radiation detection system is a crucial task in several areas of human society such as nuclear waste management, citizens security, radiotherapy or personal protection devices. Despite the excellent detecting performance exhibited by the inorganic materials (e.g. a-Se, CZT...), the increasing quest for flexible, portable, low cost and low power consumption sensors pushed the scientific community to look for alternative materials and technologies able to fulfill these new requirements. Electronic devices based on organic materials have already demonstrated to be a promising alternative to achieve a novel class of direct, flexible,
portable and low-cost ionizing radiation detectors [1][2]. In particular, the excellent direct X-ray detection performance exhibited by solution-processed flexible organic thin film transistors (OTFTs) based on 100 nm thick microcrystalline (e.g. 6,13-bis(triisopropylsilylethynyl)pentacene (TIPS-pentacene)) active layer has been recently reported [3][4]. This class of detectors exhibits the highest sensitivity to the ionizing radiation among the other polymeric devices thanks to a photoconductive gain mechanism. This effect is based on the role of minority carrier trap states and it leads to an inner amplification of the photocurrent induced by the high-energy ionizing radiation. However, in organic thin film detectors high-energy photon absorption is challenging because of the small active volume and the small cross section of interaction between radiation and low-Z elements of organic materials. In order to enhance the radiation detection performance of this novel class of organic sensors, different strategies exist.

One possibility could be the optimization of the photoconductive gain effect by increasing the density of minority carrier trap states, e.g. varying the morphology of the organic films and the interfaces of the stacked electronic devices. An alternative approach is to increase the radiation capture cross section by tuning the organic material properties through small molecule tailoring, i.e. by means of the addition of high-Z atoms into the basic molecular structure of the material. In detail, by synthesizing new solution-processable organic molecules derived from TIPS-pentacene and 2,8-difluoro-5,11-bis(triethylsilyl ethynyl)anthradithiophene (diF-TES-ADT), with Ge-substitution in place of the Si atoms, we demonstrate boosted X-ray detection performance, reaching higher sensitivity values (up to $9\times10^5 \mu C \text{ Gy}^{-1} \text{ cm}^{-3}$) and better charge transport, with respect to TIPS-pentacene-based detectors [5].

4:15 PM EN12.10.03
Autonomic Self-Healing of Conducting Polymer Films
Yang Li, Xinda Li, Shiming Zhang and Fabio Cicoira;
Ecole Polytechnique de Montreal, Canada

The recently-discovered water-enabled self-healing ability of conducting polymer polyethylenedioxythiophene doped with polystyrene sulfonate (PEDOT:PSS) makes it a candidate for healable electronics. A wetted PEDOT:PSS film can transform into an autonomic healable conductor, but its autonomic healing ability disappears after the water evaporates. In this work, we reveal an eternal autonomic electrically self-healable conductor through the addition of polyethylene glycol (PEG), demonstrating a fast healing response time and high healing efficiency. We also exhibit that the addition of glycerol can further enhance the conductivity while retaining the autonomic healing behavior. We performed systematic experiments to investigate and explain the underlying mechanisms of autonomic self-healing behavior of PEDOT: PSS films. This work provides a simple method to realize an autonomic healable conductor and paves the way for developing PEDOT:PSS based self-healing electronics for flexible and stretchable bioelectronic applications.

Optical Study of PEDOT:PSS Doped with an Ionic Liquid
Hideo Kishida, Tatsuki Maeda, Yuto Nakamura and Takeshi Koyama;
Nagoya University, Japan

The electric conduction in poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) is significantly affected and controlled by the morphology of the polymers [1]. The clarification of the electronic states governing the electric conduction is an important issue; the electronic state of the PEDOT:PSS can be probed by not only infrared spectroscopy but also terahertz spectroscopy [2] and time-resolved photoluminescence measurements [3]. In this study, we control the electronic states of the PEDOT:PSS with an ionic liquid and observe the change of the electronic states by Raman scattering spectroscopy.

PEDOT:PSS films were fabricated on ITO/CaF2 substrates. We put an ionic liquid on the PEDOT:PSS films. Between the electrode under the PEDOT:PSS film and another electrode on the same substrate, we applied voltage and controlled the doped state. The change in the electronic states was monitored with not only infrared absorption bands but also the broad structure in the Raman scattering spectra. The detail of this broad Raman structure will be discussed in comparison with the electronic Raman scattering signals observed in an organic complex $\alpha$-(BEDT-
Reduced graphene oxide (rGO) reduced by functionalized hydrazine from graphene oxide (GO) is a promising alternative material to PEDOT:PSS as hole transport layer (HTL) because rGO based organic solar cells (OSCs) show much better device stability than PEDOT:PSS based OSCs with similar device performance. However, to date, it has not been systematically investigated about effect of sheet size of rGO on the hole transporting properties. In addition, sheet size of rGO can affect the thin film uniformity as well as the electrical properties of the HTL. The thin film uniformity of HTL has a considerable influence on the device performance in inverted OSCs, because HTLs directly contact with the top metals. Therefore, in this study, we evaluate the size effect of rGO sheets on their thin film uniformity and hole transporting properties. In atomic force microscos analysis, the root mean square roughness of rGO films was decreased from 5.7 to 3.2 nm as the size of the sheets decreased meaning that the film uniformity of rGOs was improved. The hole transporting properties of rGOs having different sheets size were investigated by analysis of J-V characteristics in the light and dark, Jph-Veff curves, the plots of Jsc and Voc with respect to the light intensity, etc. The small size rGO based HTL, which have more uniform film than large size rGO based HTL, show the more efficient hole extraction and electron blocking ability due to the improved interface contact with active layer and top metal (Ag), resulting in suppressed carrier recombination at the interfaces. Thus, a higher power conversion efficiency of 9.07%, corresponding to an approximately 20% efficiency improvement compared with that of a large size rGO HTL (7.65%), was achieved by small size rGO HTL.

EN12.11.02
Improvement of Solar Cell Performance by Crystal Phase Transfer for Zinc Phthalocyanine-Based Photovoltaic Cells Tetsuya Taima, Takafumi Horikawa, Md. Shahiduzzaman, Makoto Karakawa and Koshin Takahashi; Kanazawa University, Japan

The p-type organic molecules of zinc phthalocyanine (ZnPc) adapt a standing-up (edge-on) molecular orientation on the indium-tin-oxide (ITO) substrate. On copper iodide (Cul) substrates, ZnPc molecules take on a molecular orientation lying flat on the substrate (flat-on) owing to π−d orbital interactions between the ZnPc molecules and the Cul. Earlier, Taima et al., (Appl. Phys. Lett., 2012, 100, 233302) reported that flat-on molecular orientation of the ZnPc films enhance the light absorption coefficient and charge carriers transport, resulted improved solar cell performance. When edge-on ZnPc films was heated at 200 °C, crystal phase changes from metastable α-ZnPc phase to stable β-ZnPhc phase, resulted the long wavelength shift of the light absorption region and enhance in absorption coefficient. (J Mater Sci: Mater Electron, 2008, 19, 482486) Herein, we report an efficient approach to further increase of the light absorption by changing crystal phase from α-ZnPc phase to β-ZnPc phase through the heating of ZnPc on Cul substrate, followed by enhancing the performance of organic photovoltaic devices. We reveal that that when the ZnPc films was adapted edge-on orientation on the ITO substrate, the long wavelength was shifted owing to the phase transition from α-ZnPc to β-ZnPc. The phase transition of the ZnPc film improved the quantum
efficiency near 650 nm to 750 nm. The improvement of the power conversion efficiency for the resultant solar cell is mainly caused by an increase in short circuit current \((J_{sc})\) from 2.56 to 3.50 mA/cm². These improvements are caused by the \(\alpha\)-phase to \(\beta\)-phase change of ZnPc on the ITO, whose molecular orientation is the edge-on orientation. In contrast, as the ZnPc films was altered flat-on orientation on the CuI substrate, the long wavelength was further shifted in terms of the phase change from \(\alpha\)-ZnPc to \(\beta\)-ZnPc. In addition, molecular stacking of the ZnPc/CuI film yields a higher light absorption coefficient. From these findings, we expect higher carrier transport efficiency and light absorption coefficient could be attributed to the higher \(J_{sc}\), fill factor and open circuit voltage of the resultant solar cells.

EN12.11.03
Decoupling Charge Transfer State Energy and Driving Force in Organic Photovoltaic Devices Featuring Non-Fullerene Acceptors Kaila M. Yallum1, Philipp Krauspe1, Koen Vandewal2 and Natalie Banerji1; 1Universität Bern, Switzerland; 2Hasselt University, Belgium

A steady-state photoconductivity setup capable of taking sensitive external quantum efficiency (sEQE) measurements was constructed. This experimental setup records sEQE spectra used in determining the Charge Transfer (CT) state energy, the \(S_1\) energy of the system, and the DE between the two, the driving force.

These energy-determining steps have thus far been used in two studies. One study in which electron and hole transfer rates were assessed in different Polymer:Non-Fullerene Acceptor (NFA) blends as a result of varying driving force. The driving forces were varied by using different donor polymers (P3HT, PCDT-BT, PBTTT, J61), with the same NFA (m-ITIC), and determined in the EQE setup. Further work with these systems went on to show that charge transfer remained a sub-picosecond process with near zero driving force. This study dispels the commonly-held belief that there is a trade-off between high-lying CT states which allow for high open-circuit voltages and high driving force which allows for faster charge transfer rates.

In a second study, a Polymer:NFA series in which the donor polymer (P3HT) remained constant and the NFA was varied (ITIC, ITIC-4F, or ITIC-DM), was able to decouple the driving force and CT state energy. While the energy of the CT state varied, the driving force remained relatively constant. Further studies will probe the impact of CT state energy levels on organic photovoltaic performance independent of driving force. This study touches on the effects of CT state energy and how this contributes to increasing open-circuit voltages and over-all power conversion efficiencies.

EN12.11.04
PEDOT/BBL Blend—A New Bipolar Conducting Material Sarbani Ghosh and Igor Zozoulenko; Linköping University, Sweden

There is a growing interest in organic electronic devices based on conducting polymers. Most of the conducting polymers show unipolar conductivity based on either p-type (hole transport) or n-type (electron transport). Organic electronic devices e.g., organic light-emitting diodes (OLEDs), organic field effect transistor (OFETs), organic solar cells (OSCs) are functioned by both the p-type and n-type materials. Although there are a lot of polymers which are being used as the p-type materials, due to the stability issue of the n-type polymers, the usual n-type materials are generally limited to the small molecules e.g., fullerene and their derivatives. However, the benzimidazo-benzophenanthroline ladder polymer (BBL) is a stable polymer which has an electron-affinity (~4.0 eV) in the same range of fullerene. Polymer-blend made of both n-type and p-type polymers can act as a bipolar conducting material by showing both the hole transport and electron transport properties.

Here, in this study we consider a polymer blend system consists of poly(3,4-ethylenedioxythiophene) (PEDOT) as a p-type material and BBL as an n-type material where the two polymers are stacked by pi-pi interaction and electrostatic potential. We studied the electronic structures, optical properties, excitation energy transfer of the PEDOT/BBL blend material using ground-state and time-dependent density functional theory.

We found that the addition of positive charges in the system leads ~90% of positive charges to be collected by PEDOT. On the other hand, upon addition of negative charges, ~90% negative charges are collected by BBL. In this way, the material shows an excellent charge collection property. Therefore, this system can efficiently transport the positive and negative charges towards the opposite electrodes in an electronic device e.g., OLED, OSC. The
Electronic structure calculation shows the unoccupied states are localized on the BBL chain and occupied states are localized on the PEDOT chain. Moreover, the ionization potential of PEDOT is close to the electron affinity of the BBL. Thus, BBL as an acceptor material could be a good counterpart of donor PEDOT to replace the polymer/fullerene OSC to all polymer OSC. Oxidation and reduction of the blend material show oxidized PEDOT and reduced BBL, respectively, by forming positive polarons in PEDOT and negative polarons in BBL. The photo-induced electronic energy transfer calculation shows that the material can also be used as a hetero-junction in organic solar cells to dissociate the photo-induced exciton and consecutively, to transfer the free charges to the counter electrodes. The strong electronic coupling between the photo-excited PEDOT and charge-transferred states indicate an enhanced charge separation process. The obtained electronic coupling value of the PEDOT/BBL blend material is higher than the usual average coupling value of the available materials (e.g., polymer/fullerene).

In summary, this study shows BBL has the capability to replace the conventional n-type (acceptor) material, fullerene in order to fabricate all-polymer electronic devices. The PEDOT/BBL blend is a new bipolar conducting polymeric material which can efficiently be used in many energy application e.g., OLEDs, OFETs and OSCs.

**Epitaxial Growth of Organic Semiconductor Crystals on Charge-Density-Controlled Graphene**

Nguyen Ngan Nguyen, Hyo Chan Lee and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Graphene with its sp2 hybridized surface can function as a growth template for novel nano-microstructure, especially for organic semiconductors. We find that the doping tunability and atomic thickness of graphene allow the organic semiconductor ad-molecules on its surface to “feel” and interact with the doping charge carriers. Such interactions vary the molecular surface dynamics and thus the assembly and growth of the organic semiconductor crystals. For high quality organic semiconductor thin films and clean heterostructures of semiconductor-graphene, we unravel a rule-of-thumb that is tuning graphene’s electronic structure so that the interactions between graphene and ad-molecules are loose enough for free motion of these ad-molecules. The thin films grown at such conditions not only provide favorable pathways for both charge-carriers and exciton transports but form nearly ideal Schottky interface with graphene, both important for organic electronics.

**EN12.11.06**
**Can Zero Gravity Give Us a Better Understanding of Morphology Formation in the Active Layer?**

Ishita Jalan1, Jan van Stam1, Leif Ericsson1, Ellen Moons1, Sandra Hultmark2, Christian Muller2 and Benoît Haut3; 1Karlstad University, Sweden; 2Chalmers University of Technology, Sweden; 3Université libre de Bruxelles, Belgium

Solution-processed polymer bulk heterojunction organic photovoltaic (BHJ-OPV) devices have gained serious attention during the last decade. They are one of the leading next generation photovoltaic technologies for low cost power production [1]. The active layer of a polymer solar cell consists of a thin solid film of an electron donor blended with an electron acceptor. The morphology of the active layer is one of the important factors for the solar cell performance. To control the morphology, one needs to understand the morphology formation on a molecular level.

The active layer of these solar cells is often produced by spincoating in the research laboratory, while dip-coating is an alternative that offers better control over the process parameters. Some of the most important parameters in dip-coating are the viscous drag, the gravitational force, and the capillary force. The viscous drag makes the liquid go upward with the substrate upon withdrawal. This force is proportional to the liquid viscosity and the withdrawal speed. Gravity causes the solution to move downwards.

To gain a deeper knowledge on the morphology formation in the active layer, being a consequence of the partial phase separation that occurs during the evaporation of the solvent [2-5]. In order to slow down the phase separation and, hence, get a better picture of the early stages of this process, we have chosen to prepare thin active layer films under microgravity conditions [6]. Under microgravity conditions, Marangoni flow will be the dominant source of convection during solvent drying. Here we try to understand the effects of gravity on the film morphology for system for co-polymer (TQ1) and a fullerene derivative (PC70BM). The ratio between the donor and the acceptor, as well as the processing solvent, were varied. Films prepared at microgravity conditions and at Earth conditions are compared to each other. We have chosen two commonly used solvents, i.e., chlorobenzene (CB) and ortho-dichlorobenzene (oDCB) and their fluorinated counterparts fluorobenzene and ortho-difluorobenzene (FB and oDFB, respectively). The choice of
solvents allows a comparison of the influence of the solvents’ density, viscosity, and surface tension on the morphology. From our experiments, there is evidence for differences in structure between thin films at 1g and those prepared at microgravity conditions.

Polyfuran-Based Chemical Sensors—Reactivity Analysis via Fukui Indexes and Reactive Molecular Dynamics
Leonardo G. Lascane1, Eliezer F. Oliveira2 and Augusto Batagin-Neto1; 1University of São Paulo State–UNESP, Brazil; 2State University of Campinas, Brazil

Organic polymers are promising materials for the design of active layers of chemical sensors. In this context, polyfuran (PF) derivatives have not been extensively investigated, mainly due to typical drawbacks that have been recently overcome by using appropriate lateral substituents [1]. In the present study we employ electronic structure calculations (based on DFT approach) and molecular dynamics (MD) simulations (based on ReaxFF reactive force field) to evaluate the reactivity of branched PF derivatives and identify promising systems for chemical sensing. Condensed-to-atoms Fukui indexes (CAFI) were employed to identify the most reactive sites on the oligomers structure. The chemical sensing abilities of the most promising systems were evaluated via MD simulations in the presence of distinct gaseous analytes. The results indicate the derivatives PF-CCH and PF-NO2 (i.e. CCH and NO2 as side groups) as the most promising systems for chemical sensor applications, which present higher reactivity on the most accessible sites. An interesting correspondence between DFT and MD results was also identified, suggesting the plausibility of using CAFI parameters for the identification of improved materials for chemical sensors.

Molecular-Reductant-Induced Control of a Graphene–Organic Interface for Electron Injection
Fengyu Zhang1, Chen Klein2, Elena Longhi2, Stephen Barlow3, Seth R. Marder3, Gabby Sarusi2 and Antoine Kahn1; 1Princeton University, United States; 2Ben-Gurion University of the Negev, Israel; 3Georgia Institute of Technology, United States

The outstanding mechanical properties and transparency of graphene make it promising as transparent conducting electrode for flexible organic light-emitting diodes (OLEDs). However, its work function (WF ∼4.5 eV), like that of ITO, is relatively high and typically unsuitable for use as a cathode in OLEDs. Surface doping of graphene by adsorption of reducing organic and metal-organic molecules has been shown to be able to tune the electronic properties of graphene without forming covalent bonds.[1-2] Such molecular doping method preserves the structure of the graphene lattice and is less perturbing than substitutional doping or alkali metal deposition.[1,3] Here we present a study and application[4] of surface n-doping of graphene with the molecular reductant (pentamethylcyclopentadienyl) (1,3,5-trimethylbenzene) ruthenium dimer ([RuCp*Mes]2).[5] Photoemission spectroscopy, contact-potential measurements, and Hall-effect measurements confirm the dopant-induced changes in the electronic properties of the graphene layer. The graphene WF is reduced from 4.5 eV to a remarkably low value of 2.6 eV upon deposition of 1 nm of the molecular reductant [RuCp*Mes]2 and UV photo-activation, which enhances the electron-donation
The majority carriers of graphene switch from holes to electrons upon doping and the sheet resistance is reduced by 25%, despite the moderate decrease in carrier mobility. Photoemission spectroscopy and carrier-transport measurements are combined to investigate doping-induced changes in the electronic structure of the interface between graphene and phenyldi(pyren-2-yl)phosphine oxide (POPy2), a low electron-affinity (2.2 eV) electron-transport material used in OLEDs. Surface doping with 1–2 nm of [RuCp*Mes]2 reduces the electron injection barrier between graphene and POPy2 by more than 1 eV, enhancing electron injection into POPy2 by several orders of magnitude. Graphene/POPy2/Al diodes with doped graphene cathodes exhibit reasonable stability in both nitrogen and air. This investigation allows a better understanding of the interface between graphene and an organic transport layer. These results represent a significant step toward the use of graphene as a transparent cathode for organic devices in general and for OLEDs in particular.

EN12.11.09
Charge Transfer States and Reorganization Energies of Organic Solar Cells as a Function of Electron Donor Concentration Anna Jungbluth, Pascal Kaienburg, Andreas Lauritzen and Moritz Riede; University of Oxford, United Kingdom

Organic semiconductors have attracted interest over the last decades for their easily tunable optoelectronic properties. Organic solar cells, which utilize organic electron donor and acceptor materials to convert sunlight into electricity, have proven their potential as valuable additions to the field of photovoltaics for their low cost and lightweight. Currently, one of the main limitations of organic solar cells are the relatively large voltage losses of often more than 600 meV between the optical gap and the open-circuit voltage due to radiative and nonradiative recombination. In addition, driving forces required to separate strongly bound excitons are a major contribution to the large overall voltage losses. To fully understand free energy losses in organic solar cells, the influence of donor and acceptor energy levels and microstructure contributions to the charge transfer state need to be understood.

In this work we investigate voltage losses as a function of donor energy levels and donor concentration. We use vacuum deposition techniques to pair the commonly used electron acceptor C60 with Zinc phthalocyanine (ZnPc) or its fluorinated derivatives (F3ZnPc, F5ZnPc, F16ZnPc) in a bulk heterojunction. Fluorination of ZnPc has been shown to simultaneously shift the HOMO and LUMO energy levels away from vacuum, thereby keeping the energy of the first allowed singlet transition approximately constant, but directly affecting the charge transfer state energy of the donor:acceptor system. The concentration of donor molecules is sequentially varied from the “dilute” case of 5% donor molecules in 95% acceptor molecules to a 1:1 ratio of donor:acceptor.

Sensitive external quantum efficiency and sensitive electroluminescence measurements are performed to determine the energy of the charge transfer state and reorganization energy as a function of donor energy levels and donor concentration. The effect of changing charge transfer state energies is correlated with the performance and open-circuit voltage of the devices obtained through current-voltage measurements. Our measurements are further enhanced through X-ray measurements of the microstructure of the active layers to obtain a full picture of the effect of changing energy levels and donor concentration on the device performance.

EN12.11.10
Singlet Fission in Combinatorial Diketopyrrolopyrrole–Rylene Supramolecular Films Andrew Levine¹, Christoph Schierl², Bettina S. Basel², Mehroz Ahmed³, Braden Camargo³, Dirk M. Guldi² and Adam B. Braunschweig³; ¹City University of New York, United States; ²Friedrich-Alexander University, Germany

Two diketopyrrolopyrroles (DPPs) and three rylenes (NDI, dPyr PDI, and dEO PDI) were combined to form six
hierarchical superstructures that assemble as a result of orthogonal H-bonding and π−π stacking. The individual components and the DPP–NDI as well as DPP–PDI pairs were cast into films, and their superstructures were interrogated by electron microscopy and advanced spectroscopy. All six superstructures feature different geometries, causing subtle changes in the solid-state packing of the DPPs. Changes in inter-DPP stacking that are scaffolded by the adjacent rylenes have a subtle impact on both the excited-state dynamics and on activating new pathways such as singlet fission (SF). Our studies demonstrate the unique benefits of combinatorial supramolecular assembly in exploring the impact of structure on advanced light management in the form of SF to afford triplet quantum yields, which are as high as 65% for a correlated pair of triplets and 15% for an uncorrelated pair of triplets.

**n-Type Conjugated Small Molecule Organic Semiconductor for Device Applications** Seongdae Kang, João Soares and Manisha Gupta; University of Alberta, Canada

Organic semiconductors are amongst the most important materials in the field of organic electronics. They are used for various devices applications like transistors and photovoltaics. The hole-transporting p-type organic semiconductor is most commonly used for these applications, while electron-transporting n-type organic semiconductors lag far behind because they suffer from moisture and air instability, as well as low electron mobility.¹

In this research, we synthesized a small-molecule n-type organic semiconductor, 2,6-Dibromo-N,N’-bis(2-ethoxyethyl)-2-(2-(2-methoxyethoxy)ethoxy)acetate)-1,4,5,8-naphthalenetetraoxycarboxylicdiamide, (gNDI-Br₂). Due to the redox ability of gNDI-Br₂, it is an electroactive material and can be utilized for organic electrochemical transistors (OECTs). OECTs have a channel material which is an electroactive organic semiconductor and its conductivity changes by the influx of ions from the electrolyte. Reduction and oxidation reactions with metal ions in electrolytes such as sodium or potassium ions occurs at the tetracarboxylic oxygen atoms in gNDI-Br₂ molecules. Due to the conjugated structure of this organic semiconductor, it reacts electrochemically and maintains its structure with the change in its conductivity. In addition, gNDI-Br₂ is easily solution processable because it is soluble in common organic solvents, such as chloroform, due to the ethylene glycol side chains attached to the NDI. Furthermore, these ethylene glycol side chains increase the free volume among the semiconducting molecules, providing gaps for the permeation of the metal ions.

The advantage of this gNDI-Br₂ small-molecule organic semiconductor is the improvement of its electrical property due to its ordered structure. It has less distorted structure compared to semiconducting polymers such as p(gNDI-gT2)³ or poly(benzimidazobenzophenanthroline) (BBL)⁴. Due to the coplanar structure of gNDI-Br₂, it allows for a more organized molecular arrangement, unlike polymeric n-type semiconductors. On account of this more orderly orientation, gNDI-Br₂ shows better electron mobility than previously reported n-type organic semiconductors, which enhances device performance. We will present the material, electrical and electrochemical properties of gNDI-Br₂ based on the different techniques like Electrospray (ESI-TOF) mass spectrometry, Nuclear magnetic resonance spectroscopy (NMR), X-ray diffraction (XRD), Atomic force microscopy (AFM), Scanning electron microscopy (SEM), and Electrochemical cyclic voltammetry (ECV).

**Green-Solvent Processable Semiconducting Polymers Applicable in Dopant-Free Perovskite and Polymer Solar Cells—Molecular Weights and Thermal Stability** Sang Ah Park, Dasol Chung, Seyeong Lim and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)
In this study, we firstly investigate the effects of the molecular weight (MW) of a green-solvent processable semiconducting polymer (asy-PBTBDT) on photovoltaic performance and thermal stability of the devices. The asy-PBTBDT with high MW (132 kDa) has high μ values (4.91 × 10^{-3} cm² V⁻¹ s⁻¹ without dopants and 5.77 × 10^{-3} cm² V⁻¹ s⁻¹ with dopants) as a result of an increase in π–π stacking with higher MW than low MW asy-PBTBDTs (27 and 8 kDa). The high MW asy-PBTBDT with high μ achieves the highest power conversion efficiencies of 18.2% and 20.0% for the non-doped and doped states in PerSCs, respectively, and 5.7% in eco-friendly processed PSCs. Moreover, as the MW of asy-PBTBDT increases, the glass transition temperature increases, indicating an effective decrease of the thermally-induced morphological degradation in the photovoltaic devices. Likewise, an increase in the chain density along with MW induces the good robustness against humidity and oxygen. This material has important industrial significances because of its environmental processability, reproducibility, stability and efficiency of edible solvents.

Daehwan Lee, Taewan Kim, Yelim Choi and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)

Morphologies and optoelectronic/mechanical properties of semiconducting polymers are highly affected by polymer backbone configuration. In this study, thiophene units are introduced into the main backbone chain of semiconducting polymer in either a regular (PffBT-T4) or a random (PffBT-RT4) copolymerization to compare the performance of which semiconducting polymers are suitable in developing more efficient and flexible polymer solar cells. The unit composition ratio of the main chain is same, so both polymers show very similar energy levels. However, PffBT-RT4 has lower crystallinity than PffBT-T4 due to its random arrangement. As a result of the microstructure analysis, PffBT-RT4 shows π-π stacking distance shorter than PffBT-T4. Therefore, since short distance benefits in charge transport, PffBT-RT4 shows higher space-charge-limited current mobility, and has a higher power conversion efficiency (PCE; 8.84%) than PffBT-T4 (7.25%). In addition, the PffBT-RT4 shows good performance in green solvent without additives (7.23%). Moreover, PffBT-RT4 maintains stable efficiency even after bending cycle, compared to PffBT-T4. Therefore, this study demonstrates that the random arrangement is a promising donor-acceptor based semiconducting polymer design strategy for efficient, flexible and green solvent processable polymer solar cells.

Effects of Energetically and Spatially Non-Uniform Distribution of Molecular Energy Levels on Open-Circuit Voltage of Organic Solar Cells
Hansol Lee, Segyo Han, Kyu C. Song, Jinhyeok Choi and Kilwon Cho; POSTECH, Korea (the Republic of)

Here, the effects of non-uniform energetic and spatial distributions of molecular electronic states in active layer on the open-circuit voltage (V_{oc}) of organic solar cells are investigated. Model devices are fabricated using active layers that consist of two sublayers. The sublayers have different donor-acceptor blend compositions. The different compositions offer large change in molecular energy levels of the donor and the acceptor materials. Large difference in the V_{oc} is observed depending on the thicknesses and the stacking order of the sublayers. Optical and electrical analyses suggest that the V_{oc} in these devices is not determined by the energy levels of the spatial region where the photocurrent is generated, and that the V_{oc} is not determined by the relative amount of different CT states within the active layer. Instead, we suggested that the energy levels of the regions where the electrons and holes are populated dominantly are important in determining the V_{oc}. This study would provide a new insight in deep understanding of the origin of V_{oc} in organic solar cells, especially for the systems that have spatial variation of energy levels of organic semiconductors within the active layer.

Facile Tuning Method of Crystallinity and Alignment for Organic Semiconductor Layer through Solution Shearing Process
Kibeom Nam¹, Xinlin Li², Se Hyun Kim³ and Dong Yun Lee⁴; Kyungpook National University, Korea (the Republic of); ²Qingdao University, China; ³Yeungnam University, Korea (the Republic of)

In this study, we introduce an evaporative assembly method which can control the growth and align of the
crystalline material to achieve high-quality organic semiconductor patterns via one-step printing process. Organic semiconductor patterns that have a high crystallinity property and its uniform alignment are essential to realizing their application into the high-performance organic field-effect transistors (OFETs). Organic materials have flexible and lightweight properties compared to metallic compounds. Moreover, the recent development of electrical performances emphasized its importance for next-generation electric devices. However, there are obstacles to pattern crystals into large-area, print circuit cost-effectively.

Various patterning methods (e.g., dip coating, slot-die coating, blade coating, inkjet, and electrohydrodynamic jet printing) have been studied, however, there are some problems. In the case of dip coating, it is hard to make highly integrated patterns because the entire substrate is immersed in a semiconductor solution. Lithography needs tons of steps until patterns are made in place and it is hard to control the direction of the crystal. Inkjet and electrohydrodynamic jet printing show slow patterning speed. Flow coating system fulfills requirements i) simplification of patterning steps, ii) accuracy of patterning on the desired position, iii) speed for patterning process and iv) improving crystallinity and alignment of crystal over the large area.

A flow coating technique is a kind of an evaporative self-assembly method. This versatile method utilized the phenomenon of the “coffee ring effect” coupled to the confined convective flow with a controlled stick-slip motion. When the liquid is placed on the solid substrate, the different evaporation rate between the edge and center of the droplet induces migration of solution to the three-phase contact line and deposits solute. Then, intended stick-slip motions determined the distance and width of patterns. Furthermore, flow coating confines the evaporation of the solvent at the solution guiding blade and it gives shear stress on the solution. It induces one-directional coffee ring effect along the blade and the given shear stress determines the direction and morphology of patterns. Different amount of shear stress was given under the various speed of flow coater. It enhances the directional crystallization of the semiconducting layer and electrical properties.

In this study, 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-PEN) was chosen as a crystalline organic semiconductor and deposited by the solution shearing process. The relationships between shearing of the solution and characteristic property of crystal were determined with p-OM, pUV, GIWAX, and NEXAFS. One-directional solution shearing caused a crystal aligned morphology, anisotropic pUV absorption spectrums. The intensity of crystal was differed by coating speed and verified its tendency through X-ray diffraction. Furthermore, flow coating equipment is controlled by the computer system and each condition can be tuned properly. It is possible that adjusting coating condition in demand during the process with any kind of materials. Therefore, this study is essential for cost-effective printing techniques to achieve high-performance OFETs with high-quality organic semiconducting crystals.

EN12.11.18
Beta-Ray Detectors Using Organic Photodiodes with a Thick Organic Semiconductor Layer Isao Takasu, Atsushi Wada, Kohei Nakayama, Yuko Nomura, Fumihiko Aiga, Sara Yoshio, Hyangmi Jung and Rei Hasegawa; Toshiba Corporation, Japan

We report on the development of beta-ray detectors using organic photodiodes (OPD). Beta-ray detectors are used for surface contamination monitoring at nuclear power plants and similar facilities. Various organic radiation detectors for x-ray have been reported but few examples of radiation detectors for charged particles (alpha and beta particles) have been reported. OPDs are advantageous for beta-ray detection in view of their high beta-gamma ray detectability ratios, since organic semiconductors are composed of light elements and therefore expected to show low gamma-ray detection efficiency. We examined indirect- and direct-conversion organic beta-ray detectors and observed Sr-90 and Co-60 beta particles with the respective detectors and a readout circuit. The indirect conversion detectors are composed of an OPD and a scintillator, which converts beta rays into green light. To realize direct-conversion radiation detectors, the organic semiconductor layer must be much thicker than that of conventional organic photodiodes. Therefore, by forming an organic semiconductor layer of 50 μm thickness, we fabricated OPDs with the following structure: ITO electrode/ buffer layer/ P3HT:PCBM/ Al electrode. We also examined photoconductive properties of the OPDs. The OPD with the 50 μm-thick organic semiconductor layer showed high external quantum efficiency of more than 60% at 530 nm wavelength. In addition, molecular doping in the thick organic semiconductor layer brought about a remarkable lowering of the rising voltage of the photocurrent. In the presentation, we will discuss the relationship between the properties of the radiation detection and the photoconductivity of the OPDs.

EN12.11.19
Molecular Doping by Solid-State Diffusion for Enhancing Charge Injection Properties in Organic Field-
Doping has been a key topic in organic electronics since the demonstration of a metallic conductivity in doped pi-conjugated polymers. However, it has been difficult to prevent dopant-induced structural and energetic disorder, while maintaining a high conductivity. We have developed an efficient doping method based on solid-state diffusion of 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) in poly(2,5-bis(3-hexadecylthiophen-2-yl)thieno[3,2-b]thiophene) (PBTTT) which exhibited a high conductivity of 200 S/cm and one of the highest Hall mobilities for conducting polymers [1]. The observed coherent charge transport in the doped PBTTT could be attributed to a preserved microstructural order upon doping. We have recently employed this doping method to enhance charge injection properties in organic field-effect transistors (FETs) [2]. A selective contact doping of bottom-gated PBTTT FETs by solid-state diffusion of F4-TCNQ achieved a significantly lower contact resistance. In addition, a post-doping treatment on contact-doped PBTTT FETs was shown to be an effective way of improving the device stability. Furthermore, an extra degree of freedom in the choice of gate dielectric material with the bottom-gate structure enabled a low-voltage operation in our contact-doped PBTTT FETs, demonstrating a potential for designing stable and low-power organic electronic devices by utilizing doping of conjugated polymers.

Tailoring Functionality of Metal-Organic Frameworks for Optoelectronics by Ab Initio Calculations Mariana Kozłowska, Ritesh Haldar, Marjan Krstić, Zainab Hassan, Shahriar Heidrich, Xiaojing Liu, Lars Heinke, Christof Wöll and Wolfgang Wenzel; Karlsruhe Institute of Technology (KIT), Germany

Properties of organic semiconductors are highly dependent on the chemical composition, the manner of the molecular organization and the electronic properties of the individual components. At the same time, the intermolecular electronic communication among neighboring molecules defines the photoinduced charge generation, separation and transport properties. Here, we design new, highly ordered organic semiconductor materials integrating the diverse organic molecules into surface-anchored metal-organic frameworks (SURMOFs). Even if metal-organic frameworks are known to be poor conducting materials, we show that their semiconducting properties can be significantly tuned due to the control of their nano/microscale material morphology and structure with the understanding of their physicochemical properties both by theory and experiment.

We use quantum mechanical calculations in the density functional theory formalism to investigate the photophysical properties and the mechanism of charge transport in the SURMOF materials made of anthracene, diphenylethynyl-anthracene, naphthalenediimide and porphyrin linkers. We calculate the transfer rates using the semi-classical Marcus theory approach based on the electronic coupling elements and the reorganization energies between the adjacent MOF linkers. Using the in-house developed ab initio method, we explain highly efficient excited-state transport properties of porphyrin SURMOF [1, 2] and predict the photoinduced charge transport in polycyclic aromatic hydrocarbon based MOF as a function of the type of organic linker. We show the reason of the improved conductivity as derived from the spatially ordered structure of a material [3] and confirm the charge transfer anisotropy through the detailed analysis of the transfer rates for electron and hole transport. Finally, we prove that ab initio calculations enable valuable predictions of new promising candidates for semiconducting organic materials made in spatially ordered fashion in the SURMOF. Our data demonstrates the feasibility of MOF-based crystal engineering approaches that can be universally applied to tailor the photophysical properties of organic semiconductor materials.

Metal-Organic Frameworks (MOFs) with Improved Photoconductivity and Unprecedented Photoluminescent Quantum Yields

Marjan Krstić1, Mariana Kozłowska1, Xiaojing Liu2, Ritesh Haldar2, Qiang Zhang2,1, Antoine Mazel3, Michael Adams2, Fabrice Odobel3, Ian Howard2, Lars Heinke2, Wolfgang Wenzel1 and Christof Wöll2;
1Institute of Nanotechnology, Karlsruhe Institute of Technology (KIT), Germany; 2Karlsruhe Institute of Technology, Germany; 3Université de Nantes, CNRS, France

Metal-organic frameworks are highly ordered structure nanoporous materials with many different properties which can be tailored. In this context, surface-anchored metal-organic frameworks (SURMOFs) are promising subclass of MOFs which offers appealing possibility to tune properties for each specific application. Here, we present recent results of such nanomaterials with focus on photovoltaic activity, photostability and charge transport as well as photoluminescence (PL).

One of the most promising tuning approach is integration of different organic linkers into MOFs with specific properties. Due to their large photoabsorption coefficients for visible light, porphyrin derivatives are widely used in light-harvesting applications, such as photovoltaics and photocatalysis. We use quantum mechanical calculations in order to explain highly efficient excited-state transport properties of porphyrin SURMOF with Pd-coordinated organic linkers [1]. The calculated transfer rates are consistent with experimentally obtained rates, which result in micron-range exciton diffusion length in this MOF. First principle calculations are also applied to understand mechanism of charge transport in Zn-coordinated porphyrin-containing SURMOFs with embedded fullerene molecules [2]. The improved photoconductivity is shown to be derived from the spatially continuous network of donor and acceptor domains in MOF material. Owing to the fact that the porphyrin properties can be tailored by advanced organic chemistry and MOF properties can be tuned for the specific applications, ab initio calculations enable valuable predictions of new promising candidates for light harvesting.

In molecular solids, the intense PL observed for solvated dye molecules is often suppressed by nonradiative decay processes introduced by excitonic coupling to adjacent chromophores. To achieve unprecedented PL quantum yields for MOF crystalline NDI-based materials through predictive crystal engineering and tuning of excitonic coupling we have developed a strategy to avoid this undesirable PL quenching by optimizing the chromophore packing [3]. We integrated the photoactive compounds into metal-organic frameworks (MOFs) and tuned the molecular alignment by introducing adjustable “steric control units” (SCUs). We determined the optimal alignment of core-substituted naphthalenediimides (cNDIs) to yield highly emissive J-aggregates by a computational analysis. Then, we created a large library of handle-equipped MOF chromophoric linkers and computationally screened for the best SCUs. A thorough photophysical characterization confirmed the formation of J-aggregates with bright green emission, with unprecedented photoluminescent quantum yields for crystalline NDI-based MOF materials. This data demonstrates the viability of MOF-based crystal engineering approaches that can be universally applied to tailor the photophysical properties of organic crystalline MOF materials.

Influence of Morphology on the Density of Charge-Transfer States in Organic Donor/Acceptor Blends

Thomas Zeche1, Theresa Linderl1, Alexander J. Hofmann1, Thomas Schröther1, Tomoya Sato2, Kohei Shimizu2, Hisao Ishii2 and Wolfgang Bruetting1; 1University of Augsburg, Germany; 2Chiba University, Japan

Organic small molecule solar cells are used as a test bed to investigate the influence of film morphology on the density of charge-transfer (CT) states. CT states are considered as precursors for charge generation and their energy ($E_{CT}$) as the upper limit for the open-circuit voltage ($V_{OC}$) in organic donor/acceptor solar cells. In this study the
morphological influence of using a crystalline donor diindenoperylene (DIP) versus an amorphous donor
tetraphenyldibezoperiflanthene (DBP) with almost identical ionization energy is investigated. As acceptor material
the widely used fullerene $C_{60}$ is used.

By combining electrical measurements with optical spectroscopy and low-energy ultraviolet photoelectron
spectroscopy (LE-UPS) with different excitation energies, a comprehensive picture is obtained that describes how
morphology and the connected density of states (DOS) influence the device performance and the spectroscopic
signature of CT states. Especially for the crystalline donor material DIP strong exponential tail states reaching far
into the gap are observed in the UPS spectra, which can be related to the presence of grain boundaries. A voltage
dependent filling of these states is identified as the origin of a blue shift of the electroluminescence spectra with
increasing applied voltage.

Different approaches to the description of the reduced electroluminescence (EL) and reduced external quantum
efficiency (EQE) spectra, as proposed by Vandewal, Burke and Kahle, are compared. This is done to verify the
necessity of static disorder in the description of CT emission and absorption spectra of organic solar cells. Despite
the fact that both donors yield almost identical $E_{CT}$ (and, thus, the same open-circuit voltage) the Stokes shift
between EL and EQE spectra and, concomitantly, the width of the CT DOS varies by more than a factor of 2. We
discuss this observation in terms of the donor-acceptor reorganization energy ($\sigma$) as well as an additional
contribution of static disorder ($\sigma$). Remarkably, the more crystalline donor DIP shows a significant contribution of the
latter, while for the amorphous DBP this additional term is not required. This highlights the importance of film
morphology in organic solar cells.

EN12.11.24
Rational Designing of Push-Pull Type Small Organic Molecule Having Ambipolar Characteristics and Rich
Linear and Non-Linear Optical Properties Dwaipayan Chakraborty and Priya Johari; Shiv Nadar University,
India

Organic Semiconductor (OS) is an emerging class of energy materials, for its several advantages over its inorganic
counterpart, such as large area, flexibility, low cost, and most importantly their environment-friendly manufacturing
process. Computational designing and study of new semiconducting organic molecules have come up as a great
support in this regard. Push-pull type small organic molecule has recently gained a huge scientific research owing to
their remarkable charge transfer properties, high non-linear optical response, reduced HOMO-LUMO gap and hence
broad range of absorption spectrum, air stability etc. which collectively promotes this class of molecules as potential
candidate for non-linear optical devices, OFETs and organic solar cells. In this effort, we therefore rationally
designed a promising Donor(D)-π-Acceptor(A) (i.e, push-pull) type molecule trans-4-nitro-4'-dimethylamino-α-
aminostilbene (NNDMNH$_2$), by 'backbone engineering' from a standard NLO (Non Linear Optical) dye. We
predicted its crystal structure starting from the experimental crystal structure of another stilbene derivative and
-calculated the charge transport properties, electronic band structure, gas phase linear and non-linear optical
properties. We also did the Hirshfeld surface analysis and plotted the molecular electrostatic potential to get insight
into the structure-property correlation. We found that this new organic semiconductor owns a high charge carrier
mobility of ~ 7.46 cm$^2$/Vs for hole and 2.14 cm$^2$/Vs for electron, together with desirable electronic and linear and
non-linear optical properties revealing NNDMNH$_2$ as a potential candidate for the optoelectronic devices.

EN12.11.25
Vertical, Electrolyte-Gated Organic Transistors—Continuous Operation in the MA/cm2 Regime and Use as
Low-Power Artificial Synapses Jakob Lenz$^1$, Fabio del Giudice$^2$ and Thomas Weitz$^{3,4}$; $^1$Physics of Nanosystems,
Germany; $^2$Walter-Schottky Institute, Germany; $^3$Nanosystems Initiative Munich, Germany; $^4$Center for
NanoScience, Germany

Until now, organic semiconductors have failed to achieve high performance in highly integrated, sub-100 nm
transistors. Consequently, single-crystalline materials such as single-walled carbon nanotubes, MoS$_2$ or inorganic
semiconductors are the materials of choice at the nanoscale. Here we show, using a vertical field-effect transistor
design with a channel length of only 40 nm and a footprint of $2 \times 80 \times 80$ nm$^2$, that high electrical performance with
organic polymers can be realized when using electrolyte gating. Our organic transistors combine high on-state
current densities of above 3 MA cm$^{-2}$, on/off current modulation ratios of up to 108 and large transconductances of
up to 5,000 S m\(^{-1}\) [1]. Given the high on-state currents at such large on/off ratios, our novel structures also show promise for use in artificial neural networks, where they could operate as memristive devices with sub-100 fJ energy usage.

**EN12.11.26**

**Temperature Dependent Studies of IDT-BT Reveal Liquid Crystalline-Like Phase Behavior** Abigail M. Fenton, Ralph Colby and Enrique D. Gomez; The Pennsylvania State University, United States

Some of the highest charge transporting conjugated polymers to date such as Indacenodithiophene-co-benzothiadiazole (IDT-BT) have shown weak to no crystallinity which is puzzling as it deviates from traditional evidence that the higher order of semi-crystalline polymers is needed for high charge mobility. Stiffer conjugated polymers can have liquid crystalline phases, and many of the most common high mobility semi-crystalline conjugated polymers, such as PBTTT, have liquid crystallinity. Using oscillatory shear rheology, X-ray scattering, DSC and polarized optical measurements we have investigated the morphology and phase behavior of IDT-BT as a function of temperature. We have identified the backbone and hexadecyl side chain glass transition temperatures (Tg’s), discovered two phase transitions that are likely disordered liquid crystalline transitions as well as evidence of biphasic behavior. We have also fabricated IDT-BT field effect transistors and annealed them at different temperatures in the disordered phases to track how mobility changes in regard to these phases. We hypothesize that because polymer chains are not restricted to a certain packing structure dictated by crystallization, chains in a liquid crystalline polymer are able to adopt conformations that can maximize interchain charge coupling.

**EN12.11.28**

**Single Solvent Aerosol-Jet Printed Multi-Layers—A New Route for Efficient Blocking Layers in Organic Photodiodes** Mervin Seiberlich\(^{1,2}\), Noah Strobel\(^{1,2}\), Marta Ruscello\(^2\), Ulrich Lemmer\(^{1,3}\) and Gerardo Hernandez-Sosa\(^{1,2}\); \(^{1}\)Karlsruhe Institute of Technology, Germany; \(^{2}\)InnovationLab, Germany; \(^{3}\)InnovationLab GmbH, Germany

The development of high-performing organic photodiodes (OPDs) is presently an intense field of research motivated by its potential applications in the field of imaging, health-care, or environmental monitoring. Yet only a limited number of publications report on fabrication routes that enable fully-printed device architectures facilitating the cost-efficient integration of OPDs in novel sensing applications. One main difficulty lies in the hindrance of device functionality through the successive deposition of the required multi-layer stack. The ink deposition can lead to disruption of film morphology, intermixing of materials and short circuits, reducing the figures of merit such as spectral responsivity, detectivity, or detection speed. To circumvent this problem an orthogonal solvent approach is commonly used. However, as the number of device layers increases, this approach exponentially restricts the palette of materials with suitable optoelectronic properties.

In this work, we present a route to overcome the need of orthogonal solvent systems utilizing Aerosol-jet printing for the fabrication of OPDs. By fine adjustment of the aerosol properties in terms of droplet temperature, solvent concentration and material flow rate, we gain control of the film drying dynamics without negatively affecting the underlying layers. Following this approach, we print a P3HT blocking layer on top of a P3HT:PC\(_{60}\)BM bulk-heterojunction from the same solvent system. The P3HT blocking layer spatially separates the lowest unoccupied molecular orbital (LUMO) of the acceptor from the electrode effectively reducing the flow of electrons from the contact. By following this approach, we demonstrate a reduction of the dark current from 176 mA/cm\(^2\) in a device without the blocking layer down to 0.2 mA/cm\(^2\) at 4 V reverse bias. This leads to a significant increase of the specific detectivity of the device up to 1.2E\(^{11}\) Jones, ~3 orders of magnitude higher than that of the reference device.

Morphological Engineering of Thiazolo[5,4-d]thiazole Based Conjugated Polymers for Optoelectronics
Nimisha Kaippamangalath; Indian Institute of Science Bangalore, India

Conjugated polymers (CP) have gained considerable attention due to their brilliant applications in electronic devices and optoelectronics. We designed and synthesized thiazolo[5,4-d]thiazole (TT) and benzo[1,2-b:4,5-b]dithiophene (BDT) planar fused rings containing donor-acceptor type conjugated polymers (viz., poly[thiazolo[5,4-d]thiazole thiophene-2-yl bis(dodecyloxy)benzo[1, 2-b:4,5-b]dithiophene] (PTDBT), poly[thiazolo[5,4-d]thiazole thiophene-2-yl 2-dodecyl-2H benzo[d][1,2,3]triazole (PTDBDT) and poly[thiazolo[5,4-d]thiazole thiophene-2-yl 9,9-dihexyl-9H-fluorene] (PTOF) with improved optoelectrical features. The molecular engineering of fused hetero-cyclic thiazolo[5,4-d]thiazole based π-conjugated polymers via introduction of substituted donor-acceptor units as backbones could enhanced the optoelectrical features. Conjugated polymers showed bright luminescent properties in yellow-red region of the electromagnetic spectrum having emission maxima in the range of 595-887 nm. PTDBT, PTDBDT and PTOF showed homogeneous morphologies with root-mean-square (RMS) roughness of ca. 0.255 nm, 0.464 nm and 0.303 nm, respectively. Band gaps obtained from cyclic voltammetric analysis are 2.27 eV, 2.04 eV and 2.4 eV, indicating the semiconducting nature of the synthesized systems. The impedance studies of these materials are done for a comprehensive understanding of their capacitive behavior in terms of the components of complex impedance. These all results indicate the application of synthesized systems as active layers in optoelectronics.

Ion Phase Separation upon Electrochemical Doping in Conjugated Polymers
Connor G. Bischak, Lucas Flagg, Kanrong Yan, Chang-Zhi Li and David S. Ginger; 1University of Washington, United States; 2Zhejiang University, China

Conjugated polymers undergo structural changes upon electrochemically-driven ion insertion. The nature of these structural changes influences both the kinetics of doping and electronic mobility of the doped state, impacting the operation of many technologies that rely on the dual ionic/electronic conductivity of conjugated polymers, such as organic bioelectronics, neuromorphic computing, and supercapacitors. Typically, the polymer crystal lattice changes continuously to accommodate ions. We find that the lattice can also expand discontinuously, resulting in phase separation between ion-rich and ion-poor regions of the film. This phenomenon is routinely observed in inorganic materials, yet the flexible nature of conjugated polymers typically prevents phase separation from occurring. Using a combination of ex situ and in situ grazing incidence wide angle X-ray scattering (GIWAXS), as well as observations of ion distributions and migration with photoinduced force microscopy (PiFM), we characterize the phase-separated doped state of poly[2,5-bis(thiophenyl)-1,4-bis(2-(2-(2-methoxyethoxy)ethoxy)ethoxy)benzene] (PB2T-TEG), a conjugated polymer with glycolated side chains. We find that phase separation has important implications for polaron transport within conjugated polymers, as lattice expansion rather than polaron diffusion can restrict transport.

Solution Processed n-Doping of a Low Electron Affinity Polymer for Electron Injection in OLEDs
Hannah L. Smith, Stephen Barlow, Seth R. Marder and Antoine Kahn; 1Princeton University, United States; 2Georgia Institute of Technology, United States

Adding n-dopants to the electron transport layer (ETL) of an organic light emitting diode (OLED) increases its conductivity and improves electron injection into the emissive layer of the device. However, n-doping becomes very challenging when dealing with large gap, low electron affinity (EA ≤ 3 eV) ETLs used in green or blue OLEDs. In this work, we address the problem of solution n-doping of such a material, i.e. the polymer F8BT [poly(9,9-dioctylfluorene-alt-benzothiadiazole)], via incorporation of the air-stable n-type dimeric dopant [RuCp*Mes]₂ [1]. Characterization of the undoped F8BT with ultra-violet and inverse photoelectron spectroscopy (UPS and IPES) places the highest occupied molecular orbital (HOMO) at 3.8 eV and the lowest unoccupied molecular orbital (LUMO) at ~2.8-3.0 eV below vacuum level. As the dopant is incorporated into the F8BT film, the energy levels shift by 0.6 eV, pushing the Fermi level of the material closer to the LUMO. n-Doping with [RuCp*Mes]₂ results from the dimer cleavage mechanism described in previous work, whereby an initial electron transfer to the host is immediately followed by cleavage and release of a stable 18-e⁻ monomer cation and a highly reducing 19-e⁻
monomer [1,2]. In the case of the low EA F8BT, as was shown previously for other low EA hosts [1], photoactivation (here with a 375 nm UV LED) is required to initiate the first electron transfer. The conductivity of the F8BT film is improved by four orders of magnitude. The doped F8BT film is incorporated as an electron transport layer in a TPBi:Ir(ppy)_3-based OLED and found to improve the luminance by over three orders of magnitude, bringing the external quantum efficiency (EQE) to about 14%. The utility of these powerful, air-stable n-dopants, previously demonstrated in the context of vacuum processing of low EA organic electronic materials [2,3], is therefore now also established for solution-based doping of an OLED ETL polymer with an EA as low as 2.8-3.0 eV.

EN12.11.32
Long-Lived Free Charge Carriers at Heterojunctions between Semiconducting Single-Walled Carbon Nanotubes and Perylene Diimide Electron Acceptors
Hyun Suk Kang1, Obadiah Reid1, Thomas J. Sisto2, Samuel Peurifoy2, Boyuan Zhang2, Colin Nuckolls2 and Jeffrey L. Blackburn1; 1National Renewable Energy Laboratory, United States; 2Columbia University, United States

Semiconducting single-walled carbon nanotubes (s-SWCNTs) have been intensively studied as the components of various photovoltaic cells due to several advantages such as spectral tunability, giant aspect ratio, chemical robustness, hydrophobicity, and absence of charge-transfer (CT) states. In the previous study, it was reported that the heterojunctions between s-SWCNTs and perylene diimide (PDI)-based electron acceptors produce long-lived charge separated states whose lifetimes are more than 1.5 µs. Besides the potential of PDI-based electron acceptors to substitute fullerene-based electron acceptors, this study emphasized the significance of the molecular geometries of PDI-based electron acceptors which result in molecular aggregation and the associated charge delocalization in the acceptor phase. However, there is no clear understanding yet for why the charge carriers for these heterojunctions live so long. For instance, it was not determined how much of the charge carriers generated at these heterojunctions are free or trapped. Moreover, the nature of the charge recombination process from these heterojunctions was not yet revealed to be either monomolecular-like or bimolecular-like. In this study, we explored the nature of charge carriers for the heterojunctions between two singly chiral s-SWCNTs and two different PDI-based electron acceptors by combining two effective spectroscopic techniques: transient absorption (TA), probing charge carriers spectrally, and time-resolved microwave conductivity (TRMC), probing free charge carriers only.

Two PDI-based electron acceptors, hPDI2-pyr-hPDI2 and Trip-hPDI2, were synthesized and coated on (6,5) or (7,5) s-SWCNT films to form donor-acceptor heterojunctions. To compare the charge carrier characteristics from these heterojunctions to those from s-SWCNT/fullerene acceptor heterojunction, C60 was also deposited on singly chiral s-SWCNT films. The charge recombination kinetics across the singly chiral s-SWCNT/PDI-based acceptor heterojunctions, deduced from TA and TRMC studies, are well-matched, indicating that most charge carriers from these heterojunctions are free, not trapped. These studies also presented that the charge carrier dynamics from s-SWCNT/PDI-based acceptor heterojunctions remain similar over four orders of magnitude in the absorbed photon fluences of PDI-based acceptors. However, TRMC studies of s-SWCNT/C60 heterojunctions revealed that the fast decay dynamics at early delay time contributes more significantly at high C60 absorbed photon fluences than at low fluences. It is attributed that the fast bimolecular charge recombination processes such as charge collision become more probable at high C60 absorbed photon fluences. The substantially smaller molecular size of C60 than those of PDI acceptors may induce the greater degrees of donor-acceptor intercalation, resulting in the lower probability of the charge carrier extraction out of the donor-acceptor interface at early stage. For each s-SWCNT heterojunction, the charge recombination decay time constants from TRMC studies are independent of absorbed photon fluences of electron acceptors, and this fluence independence indicates that most of free charge carriers from s-SWCNT heterojunctions recombine ‘pseudo’-monomolecularly. The unconventionally high free charge carrier generation and strong suppression of bimolecular charge recombination from these s-SWCNT heterojunctions may be attributed to the high carrier mobility and good charge delocalization in s-SWCNTs.
These photophysical studies provide the fundamental understandings of the charge generation process in s-SWCNT-based heterojunctions and how different electron acceptor materials can influence the nature of charge generation with respect to the heterojunction energetics and molecular orientations. The results can inform rational design strategies for s-SWCNT-based optoelectronic applications.

**Influence of Partially-Oxidized Silver Back Electrodes on the Electrical Properties and Stability of Organic Semiconductor Diodes** Zhongkai Cheng, Yan Wang and Deirdre O’Carroll; Rutgers, The State University of New Jersey, United States

Silver is an important material for electrodes in high-performance organic optoelectronic devices due to its high reflectivity and low parasitic absorption loss at visible wavelengths. However, the electronic work function of Ag is not ideal for use as either the cathode or anode in many organic optoelectronic devices. Here, we investigate the formation of an ultrathin surface oxide layer on a Ag electrode and its impact on hole injection into an organic conjugated polymer semiconductor. The surface oxide is formed by exposing the Ag electrode to a low-power O2/Ar plasma and it changes the electrical properties of the pure Ag electrode. We study the morphology and the chemical composition of the Ag electrode surfaces after different plasma treatment times through X-ray photoelectron spectroscopy, scanning electron microscopy and dark-field optical microscopy. After plasma exposure the surface oxide is composed of both AgO and Ag2CO3. As plasma exposure time increases from 1 s to 7 s, the fraction of AgO increases while Ag2CO3 decreases gradually. Both the turn-on voltages and barrier heights of poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT) hole-only devices decrease with partial oxidation of the Ag electrode surfaces indicating that the work function of the Ag surface is increased by the surface oxide. F8BT hole-only devices with a thin MoO3 layer and a thicker AgOx layer on the electrode are found to be stable compared to thinner surface oxides and untreated Ag electrode surfaces [1].

**Chemical Reduction of Phosphomolybdic Acids by Metal Dopants for Post-Treatment Free Solution-Processed Hole Injection Layers in Organic Light-Emitting Devices** Yuki Chikayasu, Satoru Ohisa, Kohei Endo, Takayuki Chiba and Junji Kido; Yamagata University, Japan

Abstract: We report novel solution-processable highly efficient hole injection materials, metal-doped phosphomolybdic acids (M-PMAs). PMA includes MoO3 units and works as a hole injection material as reported in the previous papers [1, 2]: however, thermal reduction of PMA at high temperature is indispensable for realizing high hole injection capability, and the thermal treatment is not desired for cost-effective manufacturing. In this work, we reduced PMA chemically by using reactions with various kinds of metals including Mg, Al, Ti, Mn, Fe, Co, Ni, Cu, Zn, Mo, Ag, Sn, Sb, and W metals. Powders of the metals were added to yellow-colored PMA solutions, and the reaction between PMA and the metals proceeded at room temperature to give the chemically reduced blue-colored M-PMA solutions. The M-PMAs were applied to hole injection layers in organic light-emitting devices with a structure of [ITO/M-PMA or thermally reduced PMA (rPMA) (10 nm) / N,N'-di(1-naphthyl)-N,N'-diphenyl-(1,1'-biphenyl)-4,4'-diamine (30 nm) / 4,4'-Bis(N-carbazolyl)-1,1'-biphenyl: 8 wt% tris(2-phenylpyridinato)iridium(III) / bis(8-hydroxy-2-methylquinoline)-(4-phenylphenoxy)aluminum (10 nm) / tris(8-hydroxyquinolinato)aluminum (40 nm) / 8-quinolinolato lithium (1 nm)/Al (100 nm)]. Here, the rPMA film was formed by baking at 200°C of a PMA film, and has been already known to show high hole injection capability similar to well-known poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) [1]. On the other hand, the M-PMA films developed in this work were formed without any post-baking process. Among the various kinds of metals, the Mn, Co, Cu, Zn, Mo, and Sb-PMA-based devices showed similarly low driving voltages to the rPMA-based device. Moreover, the M-PMAs-based devices showed much longer operation lifetime than the rPMA-based device. Thus, we succeeded in the development of post-treatment free, highly efficient, highly stable hole injection materials.

**EN12.11.35**

**Self-Organization of Small Molecules via Solvent Vapor Annealing for Use in Organic Photovoltaic Cells** Sora
Oh\textsuperscript{1,2}, Chang Eun Song\textsuperscript{1,2} and Sang Kyu Lee\textsuperscript{1,2}; \textsuperscript{1}UST, Korea (the Republic of); \textsuperscript{2}KRICT, Korea (the Republic of)

It is reported the synthesis of two bis-benzodithiophene (BDT\textsubscript{2})-based small molecules, SM1 and SM2, and the effects of solvent vapor annealing (SVA) on their molecular ordering, optical, and photovoltaic properties. Although SM1 and SM2 have similar backbones, they exhibit different photophysical and electrochemical properties, charge carrier mobilities, and morphologies in blend films. SVA profoundly affected the molecular structure and photovoltaic properties. Solvent vapor annealing remarkably enhanced the photovoltaic properties of SM2, increasing the power conversion efficiency (PCE) from 1.47\% to 8.66\% by inducing a favorable molecular orientation, a miscible morphology, and enhanced mobility. The relationship between the morphologies of the active layers comprising SM1 or SM2 with PC\textsubscript{71}BM submitted to SVA and the device performances were elucidated using 3D transmission electron microscope tomography.

SESSION EN12.12: Morphology, Optoelectronic Properties of Active Layers, Device Interlayers

8:30 AM *EN12.12.01
In the Light of Recent Developments in Perovskite Thin Films and Quantum Dots—Morphology, Structure and Composition Ana F. Nogueira; University of Campinas, Brazil

Organic inorganic hybrid perovskites (OIHP) is the most promising material to achieved high power conversion efficiency (PCE) at low cost. The high-quality optoelectronic properties in combination with solution-based preparation methods are responsible for the currently certified PCE record of 24.2\%, which is close to the PCE of single crystal silicon solar cells (26.1\%). The properties of the perovskite film are direct related to film morphology, composition and crystalline structure, thus a clear understanding of how and when the intermediate and the perovskite phases are forming, as well the distribution of these multiple phases in the bulk and grains boundaries are important questions to be addressed in order to improve perovskite film properties and consequently the PCE of the devices. In this presentation, we will summarize our most recent results using \textit{in situ} time-resolved grazing incidence wide angle x-ray scattering (GIWAXS) and synchrotron infrared nanospectroscopy (nano-FTIR). GIWAXS experiments allowed us to understand the influence of the relative humidity, type of solvent and time to drop the antisolvent during the preparation of mixed cation perovskite films. We also identified intermediates formed before and during the spin coating process of mixed cations precursor solutions. Nano-FTIR technique was applied for the first time on OIHP. Our results revealed a spatial heterogeneity of the vibrational signal, which are associated to different chemical composition.

Colloidal perovskite nanocrystals (PQD) and nanoplates are very interesting for LED, however, the most used synthetic method to prepare them relies on a mixture of oleylamine (OLA) and oleic acid (OA) as surfactants. We will discuss an amine-free synthesis that utilizes tetraoctylammonium halides (TOAX) for preparation of OA capped CsPbX\textsubscript{3}PQDs without the need of post-anion exchange methods. As an alternative to cubic nanocrystals, we will present our recent results on the formation of perovskite nanoplates (PNP) using SnX\textsubscript{4} (X = Cl, Br, and I) salts as the halide source. The dynamic equilibrium between OLA, OA and the formation of a complex with Sn(IV) dictate the morphology and size, allowing us to prepare a range of efficient 2D quantum well materials.

Interface Engineering for Stable Halide Perovskite Solar Cells Monica Lira-Cantu; Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC and the Barcelona Institute of Science and Technology (BIST), Spain

Highly efficient halide perovskite solar cells (PSCs) can only be cost-competitive if their operational stability is ascertained. Defect control and passivation in the halide perovskite absorber and at the interface with the transport layers, is crucial for stability improvement. Defect act as recombination centres and, under continuous light irradiation can reduce the stability of the solar cell. In this presentation we report our latest results on the engineering of defects at the oxide/perovskite interface and within the halide perovskite structure. We will show the
application of binary and complex oxides as ETL. We will give special attention to the application of ferroelectric oxides, such as PZT, where O\textsubscript{vac} are employed for the creation of defect-dipoles responsible for photo-carrier separation and current transport, evading device degradation. We will also show a new method to passivate defects in the halide perovskite thin film, as a result we are able to fabricate PSC with > 21 % efficiency and 1000 h stability under 1 sun continuous light irradiation. Understanding the mechanism of defect passivation in PSCs materials and interfaces can facilitate the development of highly stable PSCs.

9:30 AM EN12.12.03
Enhanced Environmental Stability of Organic Optoelectronic Devices via a Transparent Superhydrophobic Surface Daekyoung Yoo\textsuperscript{1}, Youngrok Kim\textsuperscript{1}, Keehoon Kang\textsuperscript{1}, Heebeom Ahn\textsuperscript{1}, Woocheol Lee\textsuperscript{1}, Jinsu Pak\textsuperscript{1}, Seungjun Chung\textsuperscript{2} and Takhee Lee\textsuperscript{1}; \textsuperscript{1}Seoul National University, Korea (the Republic of); \textsuperscript{2}Korea Institute of Science and Technology, Korea (the Republic of)

For last decades, organic electronic materials have been widely used for realizing large-area flexible device applications, such as organic field-effect transistors (OFETs), organic light-emitting diodes, and optoelectronic sensors fabricated by low-cost and non-vacuum solution processing. Because of their inherent weakness of environmental instability, many researches have been conducted to improve the reliability of organic devices for further practical applications. Specifically, water-based threats could significantly degrade the electrical performances of organic materials, therefore, one of the key challenges is to integrate effective protection layers against external threats in daily conditions. In this context, introducing superhydrophobic layers has been regarded as an attractive solution because their excellent water-repellency can be helpful to protect organic devices from harmful dusts or water-based threats efficiently. In our previous study, we reported that organo-compatible superhydrophobic protection layers could improve the environmental stability of OFETs [1]. However, the employed TiO\textsubscript{2} nanoparticle-based superhydrophobic layers having a thickness over 10 μm can be a critical hurdle to be utilized in optoelectronic applications due to theiropaque\textsuperscript{ness} [1]. For providing transparency to the nanoparticle-based protection layers, the control of their thickness and surface roughness should allow the enhanced transmittance via reduced light scattering. Specifically, because the high surface roughness is a key parameter for maintaining the superhydrophobicity, the investigation on the optimized conditions for achieving transparent superhydrophobic surfaces is highly desirable as well as organo-compatible low-temperature processing.

In this presentation, we will report a facile method to realize a transparent superhydrophobic layer onto organic phototransistors through an organo-compatible solution process. TiO\textsubscript{2} nanoparticles coated with fluorinated silane molecules are dispersed in a highly fluorinated solvent, so we can introduce a superhydrophobic surface onto organic devices directly. The optimized transmittance over 90 % in the visible wavelength region is attributed to the controlled roughness parameters of our superhydrophobic layer. The transparent superhydrophobic layers exhibit good water repellencies without critical delamination issues even after or during bending and stretching tests. Moreover, flexible organic phototransistors with the transparent superhydrophobic layers show self-cleaning abilities from excellent water repellency, therefore harmful contaminants on the surface can be eliminated by dropping water droplets while preserving their optoelectronic characteristics. This work can provide a key pathway to implement a transparent self-cleaning layer for more reliable organic optoelectronic devices.

9:45 AM EN12.12.04
Anionic Conjugated Polyelectrolytes for Anode Interfacial Engineering in Inverted Organic Solar Cells Silvia Luzzati\textsuperscript{1}, Elisa Lassi\textsuperscript{1}, Benedetta Maria Squeo\textsuperscript{1}, Guido Scaivia\textsuperscript{1}, Marta Penconi\textsuperscript{1}, Simona Mrakic-Sposta\textsuperscript{2}, Maristella Gussoni\textsuperscript{1}, Umberto Giovanella\textsuperscript{1}, Francesco Galeotti\textsuperscript{1} and Maria Cecilia Pasini\textsuperscript{1}; \textsuperscript{1}Istituto per lo Studio delle Macromolecole ISMAC-CNR, Italy; \textsuperscript{2}Istituto di Bioimmagini e Fisiologia Molecolare-CNR, Italy

Interfacial engineering has been identified as a fundamental strategy for maximizing the performances and stability of organic solar cells. To this aim, conjugated polyelectrolytes (CPEs) received increasing attention thanks to their ability of improving the performances of organic solar cells through processing from orthogonal solvents. Most of the CPEs have been utilized as cathode modifiers while their use as anode interfacial layer (AIL) materials was less frequently reported. Recently it was demonstrated that self-doped anionic CPEs are a promising PH-neutral alternative to PEDOT:PSS AIL for organic solar cells\textsuperscript{1}. Actually the library of efficient CPEs anode modifiers has enlarged\textsuperscript{2},\textsuperscript{3}, helping to identify the key CPEs characteristics for effective anode interfacial engineering.
In spite of these advancements, the use of CPEs AILs in organic photovoltaics has been limited to devices prepared with conventional direct architecture, while their application in devices with inverted geometry hasn’t yet been addressed.

In this view we have prepared three conjugated copolymers modifying by chemical design conjugated backbone or alkyl-sulfonate side chain architecture. Their functional behavior as anode modifiers in inverted P3HT:PCBM61 solar cells is herein investigated.

The results indicate that anionic CPEs can be effectively applied for anode interfacial engineering in inverted organic solar cells. Comparable photovoltaic performances to a classical thermally evaporated inorganic MoOx AIL have been achieved. Some insights and guidelines for future development of efficient CEPs anode modifiers for inverted devices are discussed.

**Interface Energetics and Transport in Organic Semiconductor Blends** Karl Leo; Technische Universität Dresden, Germany

Organic semiconductors with conjugated electron systems are currently intensively investigated for many novel electronic and optoelectronic applications. Their key advantages are flexibility, low cost, and low resource usage since the mostly carbon-based materials are fabricated in nano-meter scale thin film devices. Recently, we have introduced the novel principle of band structure engineering into organic semiconductors [1]: Long range Coulomb interactions allow to continuously tune the energy levels, offering to finely adjust energy levels without synthesis of new molecules. We have now directly proven the electrostatic nature of these phenomena by experiments which show the strong influence of these quadrupole effects at interfaces [2]. This also dramatically changes the interface energetics of organic solar cells, depending on quadrupole moments and molecular orientation. Recently, we have furthermore shown in a detailed study of the conductivity of doped organic semiconductors that the quadrupole interacts play an important role in the activation energy of ground state charge transfer pairs [3]. This opens a new path for the optimum design of host-dopant interactions to achieve the highest possible conductivities.

11:00 AM EN12.13.02

**Charge Transport in Highly Doped Organic Semiconductors Limited by Coulomb Pseudo-Gap** Miina Leiviskä¹, Marten Koopmans¹, Jian Liu¹, Michael C. Heiber² and Lambert Jan Anton Koster¹; ¹University of Groningen, Netherlands; ²Northwestern University, United States

In order to make rational improvements of the charge transport properties of organic semiconductors, a thorough
understanding of this rather complex process is needed. Charge carrier transport in organic semiconductors is usually described as a series of events where a charge carrier hops from one localised state to the next. In this type of description, the disordered nature of such systems leads to a broad distribution of site energies. As a result, the mobility of charge carriers increases as more charge carriers are introduced unless the number of charges is relatively low [1].

While it has been recognised that Coulomb interactions between dopants and charge carriers are important, carrier-carrier interactions in doped organics have received less attention. In a doped organic semiconductor, however, the number of (free and bound) charge carriers equals the number of reacted dopants. As a result, both types of interactions are of importance for a proper description of the transport properties of doped organic semiconductors. However, it has been proposed that carrier-carrier interactions is significantly weaker than the effect of Coulomb interactions between dopants and charge carriers [2].

In this contribution, we use a kinetic Monte-Carlo model to study the transport properties in the presence of dopants and including both carrier-carrier and carrier-dopant interactions. In particular, we can simulate up to the relatively high doping densities that are experimentally relevant even though numerically challenging. We find that the density of states (DOS) of such systems shows a pseudo-gap at the Fermi level due to Coulomb interactions between the charge carriers. Such Coulomb gaps are a manifestation of the carrier-carrier interactions and have been predicted to exist in hopping systems [3], but are usually washed out at anything other than very low temperatures. In contrast, we observe these pseudo-gaps at room temperature, which is a consequence of the low dielectric constant and highly localised charges that are typical of organic semiconductors. We wish to point out that the pseudo-gap is a sole consequence of carrier-carrier Coulomb interactions and is not a result of the dopants. This has profound implications for electrical conductivity as the pseudo-gap limits charge carrier transport at high doping densities. The corresponding (absolute) Seebeck coefficient remains approximately constant in this regime.

Experimentally, we observe that the electrical conductivity of a large number of organic semiconductors shows a maximum: Upon increased doping levels the conductivity decreases and the (absolute) Seebeck coefficient remains approximately constant. This type of behaviour is commonly attributed to changes in the microstructure as a consequence of doping. However, we find that even when using vapour doping, where there are no observable changes in the microstructure, this behaviour persists. The experimental findings match the Monte-Carlo data (drop in conductivity and saturation of the Seebeck coefficient at high doping) very closely, which implies that the Coulomb pseudo-gap is at the root of the limited conductivity at high doping densities.

As a major consequence of our findings, we stress that both dopant-charge carrier as well as carrier-carrier interactions need to be considered when designing new materials for efficient and highly conductive doped organic semiconductors and thermoelectrics.

11:15 AM EN12.13.03
Doping of organic conjugated materials has been proven to be crucial to achieve high conductivities and thus the exploration of their fundamental properties is essential to maximize their potentials for applications in electronic devices. This has motivated the intensive study of the long-range transport properties of doped organic materials that are governed by weak intermolecular interactions, however their intrachain motion has been much less explored. Thus, we have used THz spectroscopy to gain information about the local transport properties of doped organic conjugated polymers in the non-excited state and access the carriers nanoscale mobility. We show that these measurements can serve as a tool to determine the doping efficiency of doped organic materials. Due to the short THz pulse duration, we selectively probe the intrachain motion of the mobile charge carriers in doped organic materials. Moreover, we aim to give an insight on how these properties are affected by the strong interactions...
between the charge carriers formed on the conjugated backbone and the charged dopants necessary to counterbalance the organic material and the impact of the formation of partial charge transfer complexes or structural disruption by external dopant molecules on their local transport properties.

11:30 AM EN12.13.04
n-Doping of Organic Semiconductors—Bulk and Interfaces Frank Ortmann, Sebastian Schellhammer, Christopher Gaul and Sebastian Hutsch; Technische Universität Dresden, Germany

Doping is a key technology in semiconductor physics to tune bulk and interfacial electronic properties. In organic semiconductors, efficient doping may be dominated by different effects, which are presently not well understood and cannot be explained by standard semiconductor models. An improved microscopic picture would therefore be highly desirable.

In our contribution, we will discuss and compare some examples of our current research comprising n-doped bulk systems, organic-organic interfaces and metal-organic ones where we have analyzed the effect of doping in microscopic detail from density functional theory to the statistical description of the resulting Fermi level position. A consistent description is emerging from these different systems. Our discussion finally includes a comparison to various experimental results.

11:45 AM EN12.13.05
Insights into Molecular Doping by Electron Paramagnetic Resonance Alberto Privitera, Ross Warren, Junjie Liu, Arzhang Ardavan and Moritz Riede; University of Oxford, United Kingdom

Molecular p- and n-doping of organic semiconductors has been key for the successful commercialisation of OLEDs and promises to significantly advance the field of organic solar cells and transistors. As recent reports have shown, in-depth comprehension of the doping process is required to guide the design of improved semiconductor materials and molecular dopants [1,2]. In this context, electron paramagnetic resonance (EPR) spectroscopy is a technique ideally suited to study molecular doping as it is sensitive to the nature and dynamics of the paramagnetic species generated upon introduction of dopant molecules into films of organic semiconductors [3].

In this contribution, EPR spectroscopy and electrical measurements are carried out to investigate p-type doping of a layer of ZnPc (host) with the acceptor F6-TCNNQ (dopant) at different dopant concentrations (0 - 5 wt.%) and temperatures (80K – 280K). The samples are fabricated through thermal evaporation under vacuum to achieve a high control over the composition, the thickness and the morphology of the thin films. The EPR analysis performed at different dopant concentrations and at room temperature reveals the presence of two different paramagnetic species distinguished by two different g-tensors. We attribute these two species to the ZnPc positive polaron and the F6-TCNNQ anion. The quantification of the number of paramagnetic species in the film allows us to provide an estimate of the doping efficiency and to clarify the ground-state charge transfer mechanism underlying charge generation in doped films. Furthermore, from the EPR lineshape analysis, we delve into the microscopic transport dynamics of the polarons. The results are in line with conductivity measurements. The analysis performed at different temperatures discloses a further wealth of information on the temperature dependence of the charge transfer process and the thermally-activated transport properties of polarons and elucidates the role of trap states in the framework of the multiple trap-and-release (MTR) model [4]. The results are supported by electrical conductivity measurements performed at different temperatures from 100 to 280K.

With the aim to further validate our investigation, we are currently expanding our work to different energy level offsets between the host and the dopant. Taking advantage of the band structure engineering reported by Schwartze et al. [5], we are using different blended host materials, ranging from ZnPc to fluorinated derivatives FxZnPc (x= 4, 8, 16), co-evaporated with F6-TCNNQ (dopant). The investigation will unravel how the doping process depends on energetic offset and will help us to define novel design rules to control molecular doping.

Emerging Approaches to Measure Orientational Order in Organic Semiconductors  Dean M. DeLongchamp; National Institute of Standards and Technology, United States

Organic semiconductors typically exhibit a rich variety of ordered phases. Orientation occurs during processing, often by passing through lyotropic liquid crystalline phases, and dried films exhibit orientation at many length scales. Liquid crystallinity appears almost ubiquitous in organic semiconductors we have studied, including behaviors similar to nematics, smectics, or sanidics. Uniaxial orientation where the conjugated plane exhibits a preferential “face on” or “edge on” orientation is the most commonly characterized aspect of orientational order, and mature techniques such as near edge X-ray absorption fine structure (NEXAFS) spectroscopy and grazing incidence X-ray diffraction (GIXD) are frequently employed to measure it. Significant challenges remain, even for this seemingly simple aspect of orientational order. For example, these approaches are often found to be insufficient when films exhibit a complex depth profile of orientation, composition, or both.

As the materials diversity of organic semiconductors increases thanks to achievements in synthetic chemistry, and as the complexity of formulation, blending, and coating increases as process design knowledge matures, there is a commensurate need for more advanced approaches to characterizing orientational order. Biaxial orientation is increasingly observed, where “face on” or “edge on” preferences are combined with an in-plane preference imparted by a substrate or processing vector. Domain-relative orientations are also been observed, with correlations in domain-to-domain orientation thought to influence charge transport.

I will describe some emerging approaches to measure orientational order in organic semiconductors. Resonant soft X-ray reflectivity (RSoXR), a method capable of measuring thin film depth profiles using the spectroscopic principles of NEXAFS, will be discussed. I will also summarize progress on in-situ spectroscopic and scattering-based structure measurement techniques that are combined with ex-situ probes including imaging and image analysis to determine how orientation originates during the processing of organic semiconductors. These new measurements will support science-based approaches for orientation control and optimization, helping to maintain the rapid pace of organic semiconductor technology development in an era where increasing complexity renders matrix-style empirical approaches too inefficient to contemplate.

Key Roles of Structural Order and In-Plane Alignment of (Semi)-Conducting Polymers on their Optical and Charge Transport Properties  Laure Biniek; CRNS, University of Strasbourg, France

This presentation focuses on recent advances in growth control and oriented crystallization of (semi)-conducting polymers for organic electronic applications. The performance and lifetime of organic electronic devices are critically dependent on the morphology of the active layers and structural order of the materials. For instance both molecular and crystalline orientations of the polymers determine optical and charge transport properties in thin films since these properties are by essence highly anisotropic.

Particular emphasis will be given to the progress made in high-temperature rubbing of conjugated polymers films. This effective large scale alignment method can orient a large palette of semiconductors with n- or p-type character without the use of alignment substrate. High degrees of crystallinity and in-plane alignment can be obtained which provide well-defined electron diffraction patterns essential for structure refinement. The concurrent roles of polymer molecular weight distribution and rubbing temperature ($T_R$) on the in-plane orientation are rationalized for P3HT and PBTTT. Correlations are drawn between nanomorphology/crystallinity on one side and charge transport and optical properties on the other side. It is shown that the exciton bandwidth in P3HT crystals is determined by the
The length of the average planarized chain segments in the crystals. The high alignment and crystallinity observed for \( T_R > 200 \) °C cannot translate to high hole mobilities parallel to the rubbing because of the adverse effect of amorphous interlamellar zones interrupting charge transport between crystalline lamellae of semi-crystalline P3HT.\(^2\) As opposite, hole mobilities along the polymer chains of rubbed PTB7 films are observed to be 6 times higher than the non-rubbed films.\(^3\) This is due to the smectic-like character of this alternated donor-acceptor copolymer. Interestingly high-Tr rubbing and post annealing process of PTB7 provide well-defined electron diffraction pattern. Combined with DFT calculation, this helps refining the structure and the chain conformation of this benchmark electron donor polymer for OPV application.

In a second part of this presentation, we show that soft doping of aligned P3HT yields highly oriented conducting polymer films with anisotropic charges and thermal conductivities. The thermoelectric properties are enhanced along the rubbing direction. The unique in-plane orientation in such conducting polymer films helps rationalizing the mechanism of redox doping.\(^4\)

The electrical properties of organic thin film transistors (OTFTs) are strongly influenced by the structural characteristics and thin film morphology. Understanding the growth dynamics that lead to preferential molecular orientation and changes in crystal structure remain an important factor in the design of new high-performance OTFTs as well as in their fundamental studies.

In this contribution, we have investigated the thin film growth behavior of 5,5′-Bis(naphth-2-yl)-2,2′-bithiophene (NaT2) and 5,5′′-bis(naphth-2-yl)-2,2′:5′,2″-terthiophene (NaT3) during the deposition process using real-time grazing incidence X-ray diffraction (GIXRD) *in situ*. The thin films were prepared by vacuum sublimation atop various substrates, including monolayer graphene on 90 nm SiO\(_2\), in a custom-built ultra-high vacuum (UHV) chamber with a 360° cylindrical beryllium window that allows for *in situ* X-ray measurements within realistic deposition time scales. The crystal structure analysis revealed that the preferred orientation of the molecules were dictated by the substrate and that the unit cell underwent significant changes when transitioning from monolayer to multilayer structure. The changes of the unit cell were not readily observed when measuring thin films of corresponding thicknesses *ex situ*, suggesting that the molecules undergo further re-organization/relaxation upon terminating the deposition. From the evolution of the crystal structure, a connection to the film growth mode and kinetics is made. These findings are rationalized based on the surface energies of the studied substrates and supplemented with AFM and helium ion microscopy. Finally, the crystal structure and morphology are correlated with charge transport properties of the final thin films.

Semiconducting Polymers for High Performance Organic Transistor Applications
Iain McCulloch; King Abdullah University of Science and Technology, Saudi Arabia

The evolution of organic electronics has now reached the commercial phase, with the recent market introduction of the first prototypes based on organic transistors and organic solar cell modules fabricated from solution. Understanding the impact of both the organic semiconductor design and processing conditions, on both molecular conformation and thin film microstructure has been demonstrated to be essential in achieving the required optical
and electrical properties to enable these devices. Polymeric semiconductors offer an attractive combination in terms of appropriate solution rheology for printing processes, mechanical flexibility for rollable processing and applications, but their optical and electrical performance requires further improvement in order to fulfil their potential. Synthesis of conjugated aromatic polymers typically involves carbon coupling polymerisations utilising transition metal catalysts and metal containing monomers. This polymerisation chemistry creates polymers where the aromatic repeat units are linked by single carbon-carbon bonds along the backbone. In order to reduce potential conformational, and subsequently energetic, disorder due to rotation around these single bonds, an aldol condensation reaction was explored, in which a bisisatin monomer reacts with a bisoxindole monomer to create an isoindigo repeat unit that is fully fused along the polymer backbone. This aldol polymerization requires neither metal containing monomers or transition-metal catalysts, opening up new synthetic possibilities for conjugated aromatic polymer design, particularly where both monomers are electron deficient. Polymers with very large electron affinities can be synthesised by this method, resulting in air stable electron transport, demonstrated in solution processed organic thin film transistors. We present an electrical, optical and morphology characterisation of polymer thin films, illustrating structure-property relationships for this new class of polymers.

Charge Transport in Conjugated Polymers and the Importance of Order—From Atomic to Mesoscale  
Alberto Salleo; Stanford University, United States

Carrier mobility in conjugated polymers continues to increase with recent reports of field-effect mobilities exceeding 10 cm²/V.s. Charge transport is intrinsically dependent on processes occurring across multiple length scales. In order to access order parameters at the molecular scale we use charge modulation spectroscopy combined with theory. Furthermore, we study the mesoscale organization of polymers using a new technique in the transmission electron microscope. These techniques are used on homopolymers and donor-acceptor copolymers. Such multiscale studies of microstructure are instrumental in guiding our understanding of charge transport in conjugated polymers.

Charge Transfer State Lifetimes in P3HT:F4TCNQ Co-Processed Films  
Bharati Neelamraju, Kristen Watts, Jeanne Pemberton and Erin L. Ratcliff; University of Arizona, United States

Doping is a fundamental strategy to increase the carrier density and conductivity of organic electronic layers for opto-electronic devices. The model system for p-doping is poly(3-hexyl)thiophene (P3HT) with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ), whereby increases in conductivity occur through integer charge transfer (ICT) to form mobile carriers in the P3HT. Extensive work in the organic electronics field has revealed the interplay between film microstructure, the opto-electronic properties, and conductivity.

This talk asks the simple question: How stable are ICT states in doped films? An alternate undesired reaction pathway is formation of a partial charge transfer complex (CPX), which results in a localized, trap-like state for the hole on P3HT. Starting first with our recent observation that both ICT and CPX states exist simultaneously in a single film, this talk will focus on thermodynamic and kinetic pathways that lead to conductivity loss in F4TCNQ-doped P3HT films. Both reaction chemistries and microstructural effects will be discussed.

Self-Assembled Conjugated Polymer on Water Surface for Wafer-Scale Ultrasensitive Organic Heterojunction Phototransistors  
Yuanhong Gao and Jia Li; Chinese Academy of Sciences, China
The advent of solution-processed organic semiconductors makes it possible for the realization of heterojunction phototransistor architectures with the feasibility to break through the photodetection limitations in conventional organic photodetectors such as the trade-off in balancing the separation, transport, and recombination of photogenerated charges. The appealing progress was reported in recently with the well-tailored device structure in which the light absorption and carrier transport take place in separately optimized bulk heterojunction (BHJ) photoactive layer and conduction channel, respectively. However, a critical issue hindering the further improvement of this type of device is that the solution-processed upper photoactive layer would degrade the underneath channel layer or induce high-density defect states at their interface, which would significantly lower the carrier mobility and affect the charge transfer process. In this presentation, we will present an ultrafast and scalable approach to fabricate large-area and high-performance organic phototransistors in ambient condition by using solution-floating method (SFM) to prepare both the high-quality channel layer and the BHJ photoactive layer. Based on this approach, the highly smooth and uniform conjugated polymer films with precise control of film thickness at a monolayer level can be prepared, offering the potential to realize low-cost, large-area and mass-manufacturable optoelectronic devices. In addition, the solution-floated organic films can theoretically be transferred to any kind of substrate. With this SFM process, we fabricated the hybrid-layered phototransistors by sequential transferring of channel layer and BHJ photoactive layer on rigid or flexible substrates. And we further demonstrate that carrier mobility was significantly boosted as compared to the spin-coated counterpart, and the high mobility can be well maintained after the covering of the BHJ photoactive layer. Resultantly, high photodetection performance can be expected for the phototransistors due to its excellent light absorption efficiency, highly-efficient charge transfer and high conductivity enabled by the high-quality organic films and interfaces. More importantly, employing SFM to prepare high-quality and well-controlled organic semiconductor film is not only technologically promising for high-performance organic phototransistors, but also opens up new opportunities control charge transfer and electronic transport properties for more efficient optoelectronic devices in general.

**Novel In Situ Tensile Platform for Thin-Film Characterization** Luke Galuska, Xiaodan Gu and Dakota Ehlenberg; The University of Southern Mississippi, United States

The study of semiconducting polymer deformation mechanics is a challenging area that needs to be thoroughly understood for flexible and stretchable electronics to become a reality. The main challenge lies in handling and measuring these materials, which at the device scale are a mere 100 nm in thickness or less. The Gu research group has specialized in the pseudo free standing tensile test to characterize the thin film mechanical property while supported in a water bath, however there is a question as to what effect, water has on these films. Here, we developed a new free-standing (in air) tensile platform to not only confirm the effect of water on sub-100nm films, but also establish a route for in-situ tensile characterization to probe the morphological change upon deformation. This is accomplished through what our group has termed Supported Shear Release, a gentle transfer method capable of obtaining macroscopic sub-100 nm thin films, which has enabled the tensile characterization of polystyrene and poly(3-hexylthiophene-2,5-diyl) films down to thicknesses of 38 and 80 nm respectively. We have registered negligible differences between the modulus obtained from on water and in air measurements, leading us to conclude that water plays an insignificant role in these hydrophobic films despite other factors such as confinement, which remain evident in the polystyrene system. Our current work is to utilize this newly developed free-standing tensile platform for in-situ UV-vis characterization of mechanochemical polymers. Upon tensile strain, these polymers exhibit a transition marking the appearance of conjugation which is detectable with UV-Vis spectroscopy. Thus, enabling a thorough understanding of the structure property relationships for these systems as well as establishing this novel tensile platform as a multimodal characterization tool for the in-depth understanding of thin film deformation mechanics across multiple length scales.

**EN12.15.03**

**Computational Insight on Solvent Effects on Aggregation in Core-Chlorinated Naphthalene Tetracarboxylic Diimide** Xiangyu Chen1, Geoffrey Purdum2, Nikita Sengar1, Paulette Clancy1 and Lynn Loo2; 1Johns Hopkins University, United States; 2Princeton University, United States; 3Cornell University, United States

Small-molecule organic semiconductors are well studied for applications from cell phones to solar cells due to their electronic properties, flexibility and lower manufacturing cost. Charge transport in these organic materials is normally localized among a π-conjugated core of carbon atoms, making charge transport highly anisotropic, with
higher electron transport in the plane of the π-π bond. Thus, slight differences in π-π stacking can significantly change this transport. As a result, researchers are interested in understanding how to manipulate the processing of organic semiconductor crystals and how to control the formation of specific polymorphs with desirable charge transport properties.

One molecule receiving such attention is the class of core-substituted naphthalene diimide molecules (c-NDI). In this presentation, we studied core-chlorinated naphthalene tetracarboxylic diimide (NTCDI) where the chlorinated core has as an electron-withdrawing effect to lower the LUMO energy level and improve chemical stability by discouraging interactions with oxidants. The Loo group found that using different solvents during the solvent-vapor annealing of NTCDI thin-film transistor resulted in thermodynamically reversible α and β-phases. Here, we have used ab initio density functional theory and molecular dynamics calculations to study how solvent choice (acetone, chloroform, dichloromethane, toluene) affects NTCDI processing. Some force field parameterization was necessary for this study, largely missing dihedrals. For the DFT, we used HF-3c and a continuum solvation model based on charge density.

We found “boat-” and “chair-” like conformations of NTCDI molecules in solvents that cannot be observed experimentally and showed that it has a high-energy barrier that prevents inter-conformer conversion. We calculated the binding energy between two NTCDI molecules immersed in solvent and determined that the tendency of NTCDI aggregation was low in chloroform/dichloromethane, intermediate in acetone and high in toluene. To ensure that entropic as well as enthalpic considerations were made we calculated the free energy of the affinity between two NTCDI molecules in solvent to better understand solvent-NTCDI phenomena. NTCDI molecules preferred to be solvated in chloroform as the free energy decreased when the distance between NTCDI increased. In contrast, in acetone, NTCDI monomers as well as aggregated complexes co-existed, evidenced by two local free energy minima at both short and long distances. Importantly, although our binding energy calculation indicated that NTCDI shows the strongest binding in toluene, it does not necessarily aggregate in toluene. This is because the toluene-NTCDI molecules tend to form a sandwich-like complex in solution and π-π interactions between NTCDI and toluene aromatic carbons played an key role here. We also observed strong differences among the radial distribution function of solvent-NTCDI interactions as a result of solvent choice; e.g., the first maximum in \( g(r) \), around 4 Å, for toluene-NTCDI is significantly higher than in other solvents. All these findings validate experimental results obtained by our collaborators, Dr. Geoffrey Purdum, Dr. Yuen-Lin Loo, and others. But they also offer exquisitely detailed atomic-scale insights, which cannot be observed experimentally and which will help the community understand the small-molecule organic semiconductor processing of thin-film transistor and help researchers achieve more control over preferable crystal structures.

**Tight Binding Models Accurately Predict Electronic Structures for Copolymer Semiconductors**

Prithvi Tipirneni, Michael J. Janik and Scott T. Milner; The Pennsylvania State University, United States

Conjugated polymers possess a wide range of desirable properties including accessible band gaps, plasticity, tunability, mechanical flexibility and synthetic versatility making them attractive for use as active materials in organic photovoltaics. In particular, push-pull copolymers, which are made of alternating electron-rich and electron-deficient moieties, are increasingly used due to their broad optical absorption, ease of tunability of relevant orbital energy levels (HOMO/LUMO and band gap) and increased charge transfer between the monomer units. However, the existence of a large number of possible copolymers makes the screening for ideal copolymers for OPVs through first-principles strategies computationally intensive. Connecting small molecule (monomer,dimer) or homopolymer properties to copolymer properties helps avoid expensive first-principles calculations on the copolymer itself to determine its electronic properties. Several studies utilizing high throughput computational screening for novel OPV materials have focused on calculating small molecule properties. Revisiting these calculations with a reliable model to predict copolymer band structures eliminates the need for a first-principle calculation. This is useful for day to day predictions and aids the screening for novel materials. Therefore, this work aims to build a recipe to construct copolymer band structures from the monomers involved while avoiding expensive first-principle calculation on the copolymer itself. For this, we use the Tight Binding (TB) approximation to build models, with parameters determined using Density Functional Theory (DFT) calculations on monomers/homopolymers. These models are then used to construct copolymer valence and conduction band structures and validated by comparing them to the DFT calculated electronic structures of the copolymers. In addition, we discuss how such band structures can be qualitatively constructed from monomer HOMOs and LUMOs; available in materials databases, and a simple
estimate of the electronic coupling between monomers of the same kind.

*Fabrication of PEDOT Organic Electrochemical Transistors by Electropolymerization*  
Michel Bilodeau-Calame, Jo'Elen R. Hagler, Nicolò Rossetti and Fabio Cicoira; École Polytechnique de Montréal, Canada

The conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) is widely used as channel material for organic electrochemical transistors (OECT), due to its mixed ionic-electronic conductivity, chemical stability and biocompatibility. The study presented here aims to explore and optimize the fabrication of OECTs by electropolymerization of the monomer, EDOT, bridging the gap between microfabricated source and drain electrodes. Various types of dopants, namely poly(styrenesulfonate), perchlorate and tetrafluoroborate were used. The channel length and the deposition time were also varied to control the channel dimensions. These parameters were chosen to study their impact on overall film morphology and uniformity, which are known to strongly affect electrical properties, and hence, transistor behaviour. The electropolymerization, which is a relatively simple technique, could therefore be used to fabricate OECTs in bioelectronics.

*Low-Resistance Ohmic Contacts on Graded InGaN*  
Reem E. Alhelais, Morgan Ware, Pijush Ghosh, Chen Li and Najla Alnami; University of Arkansas–Fayetteville, United States

There is an increasing demand for high-power electronic components and optoelectronic devices with low losses and high efficiency. The III-nitride semiconductor materials have demonstrated great potential for high-power, high-frequency, and high-temperature applications because of their remarkable and wide-ranging electronic and physical properties. For example, In$_x$Ga$_{1-x}$N alloys have optical bandgaps ranging from infrared to ultraviolet, between 0.7 eV and 3.4 eV. A recently explored area of InGaN research is in grading the composition of the alloy to achieve such novel properties as polarization induced p-type doping. However, these graded composition alloys do not yet have well-characterized metal contact materials. Thus, we will present a study of low resistance ohmic contacts characterized by using the transmission line method, on graded layers of InGaN grown on semi-insulating GaN. Carrier concentration and mobility are subsequently characterized in the graded films by temperature-dependent Hall-effect measurements.

*Morphological Engineering of P3HT Thin Films via Halogen-Bonding for High Performance Electronic Applications*  
Jonathan J. Montes, Harold O. Lee and Sam-Shajing Sun; Norfolk State University, United States

Polymeric conjugated materials are very promising for developing future soft material-based semiconductors, conductors, electronic and optoelectronic devices due to their inherent advantages such as lightweight, flexible shape, low-cost, ease of processability, ease of scalability, etc. There are numerous ways to tune material properties via post-processing treatments such as annealing, solvent additives, or doping. One challenge of solution processed organic thin film electronics is the repeatable and well-defined morphological control of the resulting thin films. In this study, we observed that the addition of para-substituted halogenated benzenes to poly-3-hexy-thiophene (P3HT) solutions can affect the morphological properties of P3HT thin films. These additives have been shown in literature to exhibit halogen bonding interactions with other small molecules. Here we seek to use this interaction to see if this interaction can be used to promote polymer self-assembly on the nanometer-scale. Techniques such as UV/Vis spectroscopy, Raman spectroscopy, X-ray diffraction, and Atomic Force Microscopy were used to probe the evolution of the film morphology as the additives were added to the solutions. This study could reveal new knowledge and insights of approaches that would enhance the solid-state morphology of thin films for high performance electronic applications.

**EN12.15.08**

*Effects of Diiodo-Alkane Additives to P3HT Thin Films for High Performance Electronic Applications*  
Shelita Hall, Harold O. Lee and Sam-Shajing Sun; Norfolk State University, United States

Polymeric conjugated materials are very promising for developing future soft material-based semiconductors, conductors, electronic and optoelectronic devices due to their inherent advantages such as lightweight, flexible...
shape, low-cost, ease of processability, ease of scalability, etc. There are a number of ways to tune material properties via post-processing treatments such as annealing, solvent additives, or doping. One challenge of solution processed organic thin film electronics is the repeatable and well-defined morphological control of the resulting films after deposition. In this study, we observed how the addition of diiodo-alkanes to poly-3-hexy-thiophene (P3HT) solutions effect the formation of resulting thin films. These additives have various boiling points that will affect the drying properties of cast thin films. We also sought to observe if any halogen bonding interaction between iodine and sulfur occurs and if this interaction can be used to promote polymer morphological self-assembly. Techniques such as UV/Vis spectroscopy, Raman spectroscopy, X-ray diffraction, and Atomic Force Microscopy were used to probe the evolution of the film morphology as the additives were added to the solutions. This study may result in a new technique that can be used to enhance the solid-state morphology of thin films for high performance electronic applications.

EN12.15.09  
Nanoscale Analysis of Physical, Mechanical and Electrical Properties of Undoped and Doped Conjugated Polymer Thin Films **Hemanth Meddali**, Krystal House and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Conjugated polymers like polyacetylene, polypyrrole, polythiophene and polyaniline have been studied extensively in terms of their bulk optical and electrical properties due to their potential for various applications in optoelectronic devices. These polymers have various desirable characteristics such as low processing cost and solubility in common solvents, in addition to possessing useful physical properties like light weight and flexibility. The most exciting feature of these polymers is the delocalization of “pi” bonds along the chain axis that makes them intrinsically conductive. The versatility of conjugated polymer materials is increasing due to the introduction of additional electro-active behavior via doping. Doped conjugated polymers have the potential to exhibit electrical conduction that approaches that of metals, which gives rise to altered optical transparency. These optical and electrical properties are of interest for both photonic and organic electronic devices. In recent history, investigations of the nanoscale properties of matter have proven to be fruitful in terms of understanding and exploiting unique characteristics of materials. Studying nanoscale properties of doped conjugated polymers could provide more information on the distribution of dopant sites, which is necessary for improving the charge conduction in these polymers.

In this study, we focus on comparison of nanoscale topological, mechanical and electrical properties of poly(3-hexylthiophene) (P3HT) and doped P3HT thin films. P3HT was spin coated onto an indium-tin oxide (ITO) coated glass substrate followed by electrochemical doping using tetrabutylammonium perchlorate (TBAP). Atomic force microscopy (AFM) was used to perform topography and phase imaging (tapping mode) of both undoped and doped P3HT and their crystallinity was compared to assess the effects of doping. There was a clear loss in crystallinity caused by doping, according to the phase images, and it was found that domains of varying crystallinity were not correlated with film topography. The mechanical properties of the thin films were studied by performing fast force mapping (FFM) using an AFM tip with a lower spring constant and adhesion to the polymer surface. Young’s modulus was calculated from FFM and a relation was established between the modulus and crystallinity for both undoped and doped P3HT at the nanoscale. The crystalline domains in both the polymer thin films exhibited higher Young’s modulus when compared to the amorphous ones. Conductive AFM imaging (CAFM) was employed to perform scans of the local current distribution of the polymer films with the application of a bias voltage. The current values increase by at least 3 orders of magnitude on going from undoped to doped samples. Also, evidence that nanoscale crystalline polymer domains conduct more current than nearby amorphous ones was found by simultaneously acquiring topography FFM and CAFM scans.

EN12.15.10  
Versatile Reductive Interlayers for Efficient Electron Injection of Organic Field-Effect Transistors and Non-Volatile Memory **DongEun Kim** and Kang-Jun Baeg; Pukyong National University, Korea (the Republic of)

Recently, pi-conjugated organic molecules have been attracted a great attention due to their low-temperature processability on flexible substrates and low-cost applications via graphic arts printing techniques. For enabling the high performance electronic and optoelectronic devices, both electron and hole charge carrier injection have to be efficiently controllable. Here, we report an efficient electron injection layer for high-performance n-type organic
field-effect transistors (OFETs) using solution-processed reducing agents. The reductive interlayer plays many different roles depending on an energy level alignment between the reduction potential of a reducing agent and frontier molecular orbitals of organic semiconductors. Basically it induces better electron injection properties so that electron mobility is significantly improved. Moreover, the reducing agent could induce doping effect by direct charge transfer to the semiconductors with the highest unoccupied molecular orbital. Operation modes of ambipolar OFETs could also be changed by completely regulating the hole current, thereby initial ambipolar OFETs converts to n-type only unipolar mode device. Those interlayers increase memory capacity of non-volatile transistor-type memory via changing the operation modes from unipolar to bipolar.

EN12.15.11
Temperature and Solvent Effects on P3HT:PCBM Bulk Heterojunction Morphology—An Atomistic Molecular Dynamics Simulation Approach Marlene N. de Morais, Ranylson M. Savedra and Melissa F. Siqueira; Universidade Federal de Ouro Preto, Brazil

Organic solar cells (OSCs) are an important eco-friendly technology to produce clean and renewable energy, using flexible, low-cost, and lightweight devices. Poly(3-hexylthiophene) (P3HT):[6,6]-phenyl-C61-butyric acid methyl ester (PCBM) bulk heterojunctions have stood out among the active layer compositions due to its prominent power conversion efficiency [1]. Experimental data have shown that the chosen conditions for the manufacture processing - as solvent evaporation rate and thermal annealing - can lead to different morphologies. It is well known that the bulk heterojunction microstructure directly influences on the OSC performance. However, due to the amorphous nature of these materials, the physicochemical characterizations are still limited [2]. In this work, we have performed atomistic molecular dynamics simulations aiming to estimate the morphological characteristic of the P3HT:PCBM blend. The evaporation process is reproduced in the simulations, and solvent removal has been carried out in a multistep process until the film formation [3]. At first, we simulated three systems at room temperature: (i) a P3HT film, (ii) a PCBM film, and (iii) a P3HT:PCBM bulk heterojunction. After that, in order to investigate the temperature influence on the arrangements of the backbone chains for the final film morphology, the simulations of these systems were performed under thermal annealing. We evaluated the structural properties of the oligomer backbone chains on both, P3HT film and bulk heterojunction. In addition, we analyzed the distribution of PCBM in the bulk heterojunction, which behavior has a good agreement with experimental results available in the literature.

Charge Carrier Transport in a Polymeric Semiconductor—Poly(3-hexylthiophene-2,5-diyl) (P3HT) Zhaojing Gao1, Arthur Yelon1,2, Clara Santato1 and Manuel Reali1; 1Polytechnique Montréal, Canada; 2Regroupement québécois sur les matériaux de pointe (RQMP), Canada

Organic semiconductors are now widely employed in electronic and optoelectronic devices due to their solution processability and compatibility with flexible substrates. 1 The Meyer Neldel (MN) Rule or isokinetic (IK) law means that a set of comparable samples exhibit kinetic behavior independent of activation energy at an IK or MN temperature.2 It is obeyed by the electron or hole mobility, µ, in many organic semiconductors, including pentacene3, fullerene4, N-Alkyl Perylene Diimides,5 etc. The existence of MNR is still not widely known. Further, despite considerable evidence in its favor, the multi-excitation entropy (MEE) model of its origin is still frequently contested. We fabricated organic field effect transistors (FETs) based on regioregular poly(3-hexylthiophene-2,5-diyl) (RR P3HT) of three different values of molecular weight, MW, and studied the dependence of the mobility upon the gate bias, $V_g$, and temperature, $T$. For all values of MW, we found that in the range 200 to 290 K (low $T$), the $\mu$ of the FET carriers exhibits an exponential dependence upon $1/T$ for different $V_g$, with an MN temperature about 290K. Between this temperature and 350K (high $T$), $\mu$ increases more rapidly than it did below, and is independent of $V_g$. We believe that, in the low $T$ regime, the polaronic carriers hop along the polymer backbone chain. We attribute the high temperature behavior to the alpha relaxation of the polymers, that is to the movement of the backbone chains. We believe that in this regime, the polaronic carriers move with the mobile chains.
Exciton to Charge Conversion in Pristine Non-Fullerene Acceptors—A Computational Study

Anastasia Markina¹, Nicola Gasparini², Derya Baran¹ and Denis Andrienko¹; ¹Max Planck Institute, Germany; ²King Abdullah University of Science and Technology, Saudi Arabia

Organic solar cell efficiencies can be boosted by replacing fullerene acceptors with strongly-absorbing dye molecules, namely, non-fullerene acceptors (NFAs). In fact, even pristine non-fullerene acceptors can serve as efficient exciton charge converters, thereby enhancing the total solar cell efficiency. In this presentation, we explain why excitation dissociation into a charge transfer (CT) state and the splitting of the CT state into charge separated (CS) state are efficient in pristine NFAs.

First, we consider exciton dissociation into particular CT states. Evaluation of dielectric solvation of excited and CT states shows that there is enough driving force for the transition, due to a stronger dielectric stabilization of charges as compared to the localized excited state. We then evaluate electrostatic potential at a disordered interface between NFA domains with different acceptor orientations and show that it provides electrostatic potential bending, sufficient to overcome the Coulomb binding energy of the CT state. Both effects can be traced back to molecular quadrupole moments and their long-range contributions to solid-state ionization energies and electron affinities. The present study demonstrates that the electrostatic configuration of NFA molecules is important for both stages of charge conversion and suggests several design rules for NFAs with efficient charge separation in photovoltaic applications [1,2].

electrical conductivity and UV-Vis-NIR dedoping signatures, independent of the polymer:dopant system and of the dopant concentration. The layer thickness, varying from 15-200 nm, presented a non-negligible impact over the kinetics of the doping degradation. We highlighted the detrimental impact of moisture and/or O2(H2O)n hydrated complexes by evaluating the p-doping stability under different atmospheres (ambient air, anhydrous air and nitrogen). Using X-ray Photoelectron Spectroscopy (XPS) we were able to assign the p-doping instability in ambient air to changes in the oxidation state of the dopant molecules and some degradation signatures. Deeper investigations on the impact of water in the stability of neutral and ionized p-dopant molecules are carried out by Nuclear Magnetic Resonance (NMR) Spectroscopy, Electron Paramagnetic Resonance (EPR) and UV-vis-NIR to better elucidate on the possible degradation mechanism. This work invites to reconsider the requirements for air-stable p-doping of OSCs as a first step towards air-processable thin p-doped layers.

EN12.15.15
Factors Determining Transfer Energetics for Organic Photovoltaics
Shahidul Alam1,2, Ulrich S. Schubert1,2 and Harald Hoppe1,2; 1Center for Energy and Environmental Chemistry Jena (CEEC Jena), Friedrich Schiller University, Germany; 2Laboratory of Organic and Macromolecular Chemistry (IOMC), Friedrich Schiller University, Germany

Recently, non-fullerene acceptors have received increasing attention for use in polymer-based bulk-heterojunction organic solar cells, as they have demonstrated considerably improved photovoltaic performances over classical polymer-fullerene blends. Part of the success of these materials has been attributed to an increased contribution to the overall absorption of the solar cells, thanks to relatively low bandgaps in these materials. In this study a systematic comparison between two acceptor materials, the classical fullerene-derivative PCBM and the non-fullerene-acceptor 2,2′-[[6,6,12,12-Tetrakis(4-hexylphenyl)-6,12-dihydridithieno[2,3-d:2′,3′-d′]-s-indaceno[1,2-b:5,6-b′]dithiophene-2,8-diy]bis[methylidyne(3-oxo-1H-indene-2,1(3H)-diylidene)]bis[propanedinitrile] (ITIC) was performed in combination with a statistically substituted anthracene-containing poly(p-phenylene-ethynylene)-alt-poly(p-phenyleinvinylene)s (PPE–PPV) copolymer (AnE-PVstat), as well as with two other commonly applied materials called Poly[[4,8-bis[5-(2-ethyhexyl)-2-thienyl]benzo[1,2-b:4,5-b′]dithiophene-2,6-diy]-2,5-thiophenediy][5,7-bis(2-ethylhexyl)-4,8-dixo-4H,8H-benzo[1,2-c:4,5-c′]dithiophene-1,3-diy] polymer (PBDB-T) and Poly[N-9′-heptadecanyl-2,7-carbazole-alt-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole) poly][9-(1-octyl)9H-carbazole-2,7-diy]-2,5-thiophenediy-2,1,3-benzothiadiazole-4,7-diy]-2,5-thiophenediy] (PCDTBT).

We find several cases in which the polymer-fullerene blend does function properly in photovoltaic terms; however, when exchanging the fullerene-derivative with ITIC, photovoltaics function seizes down dramatically. While cyclic voltammetry derived energy levels suggest successful charge transfer from the polymer to the ITIC, blend films and photovoltaic studies indicate the opposite. Numbers of spectroscopic methods like ultraviolet-visible spectroscopy (UV-Vis), photoluminescence spectrum (PLS), electroluminescence spectrum (ELS), energy-resolved electrochemical impedance spectrum (ER-EIS), transient absorption spectroscopy (TAS), fourier-transform infrared spectroscopy (FTIR), electron spin resonance spectroscopy (ESR) as well as quantum chemical calculations have been used for finding an explanation.

EN12.15.16
High Electron Affinity Molecular Dopant for Sequential Solution Doping of DPP Copolymer Films
Zaira I. Bedolla-Valdez, Goktug Gonel, Jan Saska, Sean Aronow, Nikolay Shevchenko, Alexander Dudnik, Mark Mascal and Adam J. Moule; University of California Davis, Mexico

Semiconducting polymers (SPs) have received a lot of attention in recent years due their potential for creating low cost solution processable electronic devices. The SP conductivity can be tuned by several orders of magnitude by molecular doping. The molecular dopant 2,3,5,6-tetfluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ) has been extensively explored as a p-type dopant for poly-(3-hexylthiophene) (P3HT). With the synthesis of novel high mobility conjugated copolymers with higher ionization potentials, such as diketopyrrolopyrrole (DPP)-based copolymers, there is a need to develop stronger molecular dopants. Recent studies have reported stronger molecular dopants than F4TCNQ, however, most of them present poor solubility that makes them unable to be use for solution...
In this work we present the synthesis and characterization of a new soluble dopant with high electron affinity (-5.5 eV) 2,2',2″-(cyclopropane-1,2,3-triyldene)-tris(cyanoacetate) (TMCN3-CP). Using sequential solution processing we demonstrate that conjugated copolymers such as PDPP-4T, PDPP3T, and PDPP-T-T-T achieve high conductivities when they are p-type doped with TMCN3-CP. To our knowledge, this is the first report of sequential solution doping of these high ionization energy polymers.

EN12.15.17
Polaron Hopping Barriers and Rates in Conjugated Polymers—A Tight Binding Study on Poly(3-hexylthiophene) Joel H. Bombile, Michael J. Janik and Scott T. Milner; The Pennsylvania State University, United States

Semiconductors are the subject of much investigation as next-generation materials for organic electronic devices. The ability of these materials to transport charges is a key factor limiting the performance of these devices. Charge carriers in conjugated polymers are localize by disorder and polaronic effects. As such, charge transport in these materials is often described as non-adiabatic hopping transport, with a rate given by Marcus Theory. An important variable which determines the temperature dependence of Marcus rate is the activation energy barrier for polaron hopping. We use a tight-binding polaron model, in which charge carriers are stabilized by nuclear reorganization and by dielectric polarization to map out the potential energy curve for polaron hopping, and thus determine barriers and rates relevant to intrachain and interchain charge hopping processes in P3HT crystalline lamellae and amorphous melts. We find that the barriers largely depend on polarization effects, and on the electronic coupling between the initial and final location, which penalize hopping events involving longer distances. We also find that transport is limited by interchain hopping in P3HT crystals and amorphous melts. Along the chains, transport is fast and relatively insensitive to dihedral disorder. Our predicted barriers and rates are in excellent agreement with experiment.

EN12.15.18
Eco-Friendly Polyimide Gate Dielectric via Aqueous Solution for High Performance OTFT Yuri Jeong1,2, Hyunjeong Ahn1,2, Yu Jin So4, Hyunjin Park1, Jong Chan Won1,2 and Yun Ho Kim1,2; 1Korea Research Institute of Chemical Technology, Korea (the Republic of); 2University of Science & Technology, Korea (the Republic of)

Solution-processed organic thin-film transistors (OTFTs) have received extensive attention over the past decade due to their noteworthy features: low-material consumption, low-cost manufacturing, and large-area processability. However, hidden behind the virtues is potential damage to environment and human health by using detrimental organic solvents that are not adaptable for future industrial scale. Here, we propose a water-based polyimide (PI) as gate dielectric layer for green chemistry to substitute harmful aprotic solvents that emit toxic vapors during drying process. We find that a water-based precursor shows considerably better compatibility with facile thin film fabrication than a N-methyl-2-pyrrolidone-based precursor. To adopt the water-based precursor facilitates not only escape from a hindrance in humid air through hydrolytic stability buy also use of less thermal energy through faster imidization. As a result, pentacene-based TFTs using water-based PI spin-coated in relative humidity of 43 % exhibit average mobility of 0.132 cm² V⁻¹ s⁻¹, on/off current ratio of over 10⁵, and high yield nearly 100 %. Under the same conditions, on the other hand, OTFTs using NMP-based PI exhibit poorer device performance with lower yield as low as 50 %. The results indicate that the newly designed water-based PI shows a viable path to development of electronic packages using harmless processing with less sensitivity to ambient atmosphere.

EN12.15.19
An Investigation of Acceptor-Unit Steric Bulk on Charge Transport and Photovoltaic Device Performance in Polymer Organic Solar Cells Abigail A. Advincula and John Reynolds; Georgia Tech, United States

In this work, the role of side-chain bulk on the acceptor unit in a Donor-Acceptor (DA) polymer on charge generation and power conversion efficiencies in PCBM blend bulk heterojunction solar cells is investigated through the design and synthesis of novel polymer families and device fabrication. The PCE11 repeat unit is used as a high performing solar polymer whose acceptor unit lacks a sidechain. It was hypothesized that the lack of a substituent on the acceptor unit contributed to better fullerene docking on the acceptor units and facilitated more efficient charge transfer from the DA polymer to the fullerene, enhancing OPV performance (Graham, et. al., J. Am. Chem. Soc. 2014). Previously, we reported a family of PCE11 analog polymers designed with comparatively small methyl...
substituted acceptor units for use as donor phase materials in bulk heterojunction (BHJ) OPV applications. These polymers make use of common acceptor moieties thieno[3,4-c]pyrrole-4,6-dione (TPD), diketopyrrolopyrrole (DPP), and isoindigo (ii) with methyl sidechains to provide sterically unhindered sites for enhanced interactions with a molecular acceptor (MA), either PC71BM or ITIC in this study. The resulting polymers were utilized in BHJ OPV devices where the highest performing DA polymer, P(T4-TPD-M), obtained a maximum PCE of 7.5% with PC71BM and 4.0% with ITIC. These results indicate that minimally sized methyl sidechain derivatives of TPD, DPP, and il can be useful acceptor moieties in DA polymers. As a further effort to probe the effect of acceptor unit bulk on power conversion efficiency, a family of TPD-based polymers with sidechains of increasing bulk, but similar solubility, was synthesized. Devices were fabricated with these polymers under similar conditions to ensure the only variable was the side chain bulk on the acceptor unit. Photophysics studies followed device fabrication to study the nature of charge separation in the respective polymer systems. By using these polymers with precisely controlled side chain bulk, a connection between acceptor side chain bulk steric and charge transport and solar cell performance is probed.

EN12.15.20
Correlation between Morphology and Device Performance of PBDTTT-EFT: PCDTBT: PC71BM Ternary Organic Solar Cells Javed Alam Khan, Ajay Singh Panwar and Dipti Gupta; Indian Institute of Technology, Bombay, India

In recent years, ternary organic solar cells (t-OSCs) have offered the potential of high-power conversion efficiency due to enhanced photon absorption or energy level complimentary materials as the second donor or acceptor based on a single bulk heterojunction architecture. For well promoting the development of t-OSCs, we fabricated ternary blend OSCs with two donors, including one low bandgap PBDTTT-EFT, one wide bandgap polymer PCDTBT, and one inorganic acceptor PC71BM. The incorporation of a wide bandgap PCDTBT polymer as a third component in to the binary blends improve fill factor of 71.62% with high PCE of ~9% and high $J_{sc}$ (16.55 mAcm$^{-2}$) of t-OSCs were observed than those of the binary OSCs with enhanced light absorption, efficient energy transfer and better blend morphology. This increased PCE attributed to not only non-radiative Forster resonance energy transfer (FRET) and enhancement of absorption between two donor polymers but also the formation of a bicontinuous interpenetrating network in ternary blends. The addition of a wide bandgap polymer into binary blends open up a new door for enhancing device performance in a simple, effective and promising way.

EN12.15.21
The Influence of Halogenation on Energetics in Pure and Mixed Phases in Model Organic Semiconductors Composed of Anthradithiophene Derivatives and C60 Ashkan Abtahi1,1, Samuel Mazza1,1, Sean Ryno1,1, Kirkbride Loya1,1, Ruipeng Li2, Sean Parkin1, Chad Risko1,1, John Anthony1,1 and Kenneth R. Graham1,1; 1University of Kentucky, United States; 2Cornell University, United States

Halogenation, particularly fluorination, is commonly used to alter the energetics, stability, and morphology of organic semiconductors. In the case of organic photovoltaics (OPVs), fluorination of electron donor molecules or polymers at appropriate positions can help improve PV performance. In this contribution, we present insights into how halogenation influences the bulk solid-state energetics of model anthradithiophene (ADT) materials, their interfacial energetics with C$_{60}$, and the energetics of various ADT:C$_{60}$ blend compositions using ultraviolet photoelectron spectroscopy, external quantum efficiency measurements of charge-transfer (CT) states, and density functional theory calculations. In agreement with previous work, nonhalogenated ADT molecules show higher energy CT states in blends with C$_{60}$ and lower energy CT states in ADT/C$_{60}$ bilayers. This trend is reversed in the halogenated ADT/C$_{60}$ systems, with the CT state energies of ADT:C$_{60}$ blends lying at lower energies than those in the bilayers. In bulk-heterojunction photovoltaics, the lower energy CT states present in the mixed phase with the halogenated ADT derivatives will likely decrease the probability of charge separation and increase charge recombination. These less favorable energy landscapes observed upon halogenation suggest that the benefits of fluorination observed in many OPV material systems may arise primarily from morphological factors.

EN12.15.23
Fine Tuning of HOMO/LUMO levels of Building Blocks via Thiophene Incorporation into the Indolo[3,2,1-jk]carbazole Scaffold Dorian Bader, Paul Kautny and Johannes Fröhlich; TU Wien, Austria
Triphenylamines are an important class of donor building blocks in the field of organic electronics. Crucial electronic properties such as triplet energy ($E_T$), HOMO/LUMO levels and donor strength can be tuned via modifications of its molecular structure e.g. planarization. Specifically, the donor strength decreases with increased planarization, with the completely planar indolo[3,2,1-\textit{jk}]carbazole (ICz) even exhibiting weak acceptor characteristics. In this contribution an increase in donor strength of the building block, while retaining full planarity, is presented. This is achieved by the incorporation of electron rich thiophene into the scaffold. Furthermore, a fine tuning of the electronic properties depending on the substitution positions is realized. A synthetic approach towards the target molecules employing Ullmann condensation as well as CH activation will be presented. Furthermore, the electrochemical as well as photophysical characterizations of the novel building blocks will be discussed.

EN12.15.24
Characterizing Mechanical Properties of Organic Thin Films for Directed Energy Transport Kanak Datta, Xiaheng Huang and Parag B. Deotare; University of Michigan, United States

We experimentally study organic dye thin films under mechanical strain using engineered microstructures and extract mechanical properties that are essential to the design of next-generation strain based excitonic devices. Such mechanically strained architecture provides a simpler and energy efficient platform to achieve directed energy transport in organic materials. In our measurements, we estimate the elastic modulus of the thin film of red luminescent dye 4-(Dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4H-pyran (DCM), embedded in Tris-(8-hydroxyquinoline) aluminum (Alq$_3$) matrix to be within 3.6-7.2 GPa. Reported values in literature lie in the range of 1- 100 GPa [1] [2] and so, our results demonstrate a new non-destructive characterization approach based on solid state solvation effect [3] that greatly reduces the range of uncertainty in the measurement of elastic modulus of organic thin films. The effect of strain gradient on energy transport in organic thin films is currently under investigation.

Our device platform consists of buckled silicon di-oxide (SiO$_2$) microbeam patterned using optical lithography and reactive ion etching, followed by deposition of 30 nm Alq$_3$:DCM. 50 nm 2,2′,2″-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole) (TPBi) thin film is evaporated to protect the active layer during the subsequent XeF$_2$ gas phase etching used to release the microbeams. Due to internal compressive stress in the oxide, the microbeams are buckled upwards, inducing tensile strain on the organic thin film. The buckling was quantified using optical white light interferometry, to extract the tensile strain on the film.

The Photoluminescence (PL) of the strained organic thin films was characterized using a 450 nm excitation laser in a nitrogen (N$_2$) environment. We observed gradually increasing blueshift in the PL emission towards the center of the microbeam, with the maximum blueshift occurring at the center of the beam. The spectral blueshift is attributed to a change in local molecular concentration that changes the local electric field surrounding the DCM molecules.

We fitted the observed spectral blueshift with respect to the applied tensile strain, using a simple linear equation:

$$E_{\text{Emission}} = B \varepsilon + C; \text{Here, } E_{\text{Emission}} \text{ is the emission energy of DCM from PL measurement, } B \text{ and } C \text{ are fitting parameters, } \varepsilon \text{ is the tensile strain on the thin film.}$$

and estimated the elastic modulus of the organic thin film to be within 3.6-7.2 GPa. By engineering the strain at microscale, we have successfully measured mechanical property on an organic thin film that are vital to the development of wearable and flexible energy conversion devices such as photovoltaics and light emitting diodes.

Photo-Excited Carrier Dynamics of Organic Thin-Film Solar Cell Souichiro Sato, Tomoki Miyake, Shota Fujikawa and Mitsuru Inada; Kansai University, Japan

We prepare CuPc/C$_{60}$ organic thin-film solar cell structure and investigate the photo-excited carrier lifetime by using time of flight method to reveal the carrier transport dynamics of the structure.
The structure of the sample was ITO/CuPc(30 nm)/C60(40 nm)/BCP(5 nm)/Al. These layers were deposited on SiO2 substrate by using vacuum evaporation. After the depositions, the sample was taken out into the atmosphere, and then, it was immediately sealed with epoxy resin. Optical absorption spectra for each thin-film layer were measured by ultraviolet to visible light absorption spectrometer (JASCO V-630). Current density-voltage characteristics of the sample were measured using YOKOGAWA GS820 source measure unit with conventional two-terminal method. The spectral sensitivity characteristics were measured using a lock-in amplifier (Stanford Research SR830) and a xenon lamp as the irradiation source. The transient photocurrent properties were investigated irradiating third harmonic (532 nm) of pulsed Nd-YAG laser light (Quantel CFR200, pulse width: 7 ns) and the current decay characteristics were observed on a screen of digital oscilloscope. All measurements were carried out at room temperature and in air.

The obtained carrier lifetime (transit time) was 58 μs. This value is much longer than that of estimated lifetime from the mobility of thin-fillm layers. This means the carrier transport cannot be described by a general carrier drift model. In addition, the carrier lifetime become short (5 μs) under white halogen light illumination. The results suggest that the photo-excited carrier transport is affected by trapping levels in the organic layers.

EN12.15.26
Novel Semiconductors Based on Mixed-Metal Thiocyanate Compounds from Mechanochemical Reactions
Chayanit Wechwithayakhlung1, Pichaya Pattanasattayavong1 and Satoshi Horike2; 1Vidyasirimedhi Institute of Science and Technology, Thailand; 2Institute for Integrated Cell-Material Sciences (WPI-iCeMS), Institute for Advanced Study, Kyoto University, Japan

Copper(I) thiocyanate (CuSCN) has become a well-known transparent semiconductor with wide-ranging applications, such as organic photovoltaic cells1, perovskite solar cells2 and organic light-emitting diodes3. CuSCN is a coordination polymer with a 3D extended network; its unique properties of wide band gap and good hole mobility are resulted from its electronic structure which consists of Cu 3d states in the valence band and SCN states in the conduction band. With the objective to develop novel semiconductors based on coordination polymers, we have recently reported on tin(II) thiocyanate [Sn(NCS)2], which was found to exhibit high optical transparency and promising hole transport states of Sn 5s in the valence band4. In this work, we expand the concept of modifying the metal centers of the thiocyanate compounds further by synthesizing mixed-metal thiocyanates via mechanochemical reactions. Starting from CuSCN which has already exhibited excellent semiconducting properties, we experimented with a number of thiocyanate compounds of other metal ions and found that Zn(II), Co(II) and Ni(II) thiocyanates were suitable candidates. After mechanical grinding CuSCN, Zn(SCN)2, Co(SCN)2 and Ni(SCN)2, the powder X-ray diffraction (PXRD) showed that their diffraction peaks appear in the same position but become significantly broadened. This suggested that their lattice structures were sufficiently soft to allow amorphization but at the same time stable enough to retain the same phases. This showed the potential that these compounds could be mixed and reacted using mechanochemical processes. Subsequently, CuSCN and the thiocyanate compounds of Zn(II), Co(II), and Ni(II) were mixed by the solvent-free ball-milling process to realize the homogeneous metal ion combination without an environmental issue from toxic organic solvents. The PXRD results of the final compounds were completely different from the starting thiocyanate materials, suggesting the successful synthesis of new structures of mixed-metal thiocyanates. Analyzing the powder samples with the energy dispersive X-ray spectroscopy (EDX) under a scanning electron microscope (SEM) showed homogeneous distribution of the mixed metal ions. Other characterization results from Fourier-transform infrared spectroscopy (FTIR) and thermogravimetric/differential thermal analyses (TGA/DTA) also confirmed different physical properties of the new compounds compared to the starting materials. In particular, TGA/DTA results showed that some of the compounds display melting behavior at temperatures around 300 °C; this could lead to thiocyanate-based inorganic semiconductors that can be processed into films form melt. Further studies on the electronic properties and applications of these compounds are ongoing. This work shows that the solvent-free mechanochemical processes are promising for the synthesis of new coordination polymers as well as expand the material library of semiconductors based on coordination polymers.

EN12.15.27
New Wide Band Gap Inorganic Semiconductor Tin(II) Thiocyanate [Sn(NCS)2] and Its Application in Organic Photovoltaics Jidapa Chaopaknam1, Chayanit Wechwithayakhlung1, Fumiya Hamada2, Akinori Saeki2 and Pichaya Pattanasattayavong1; 1Vidyasirimedhi Institute of Science and Technology, Thailand; 2Osaka University, Japan
Coordination polymers feature a large library of materials; however, their applications in electronic devices have been mostly unexplored. One recent example that has been demonstrated as a novel semiconductor with extensive device applications is copper(I) thiocyanate (CuSCN).[1-3] We have been developing other coordination polymer semiconductors and recently reported on tin(II) thiocyanate [Sn(NCS)₂] which exhibited a wide band gap and promising hole transport properties due to the dispersed Sn 5s electronic states at the top of the valence band giving rise to a small hole effective mass.[4] Another promising aspect of Sn(NCS)₂ is that it can be solution-processed from common solvents with high polarity, such as alcohol-based solvents. This is in contrast to CuSCN which is normally deposited from alkyl sulfides or aqueous ammonia which are either malodorous or corrosive. Herein, we report the optimization of solution-based thin-film processing of Sn(NCS)₂ and its application as a hole transport interlayer in organic photovoltaics (OPVs). We found that the thin-film formation of Sn(NCS)₂ was not straightforward due to its strong tendency to form clusters and islands resulting in discontinuous and inhomogeneous films. These films led to the absence of conduction pathway in the planar direction and short-circuits in the vertical direction. To resolve this issue, we dried the films at room temperature under inert atmosphere for an extended period of time after the spin-coating step and consistently obtained high-quality Sn(NCS)₂ thin films. These films were highly transparent due to contact with ITO substrates. As such, Sn(NCS)₂ thin films were employed as the hole-transporting/electron-blocking layer in OPVs based on PTB7-Th:PC70BM as the active light-absorbing layer. OPV cells yielded impressive power conversion efficiencies (PCE) up to 7.98% (Jsc= 16.06 mA cm⁻², Voc = 0.80 V, FF = 0.62) with a device area of 0.181 cm². The average PCE from 10 devices was 7.5%. This remarkable result demonstrates the potential of Sn(NCS)₂ in thin-film electronic applications and provides a strong foundation for further development of semiconductors based on coordination polymers.

EN12.15.28
Improving Hole Mobility in CuSCN Films by Anti-Solvent Treatment and Application in Thin-Film Transistors
Pimpisut Worakajit, Fumiya Hamada, Pinit Kidkhunthod, Akinori Saeki and Pichaya Pattanasattayavong; 1Vidyasirimedhi Institute of Science and Technology, Thailand; 2Osaka University, Japan; 3Synchrotron Light Research Institute (SLRI), Thailand

Copper(I) thiocyanate (CuSCN) has been demonstrated as a promising coordination polymer semiconductor with extensive opto/electronic applications owing to its p-type characteristic with high hole mobility, excellent optical transparency, and solution processability. CuSCN has been used as a transparent p-type active channel layer in thin-film transistors (TFTs), usually exhibiting filled-effect hole mobility (μFEh) on the order of 0.01 cm² V⁻¹ s⁻¹.[1,2] In order to challenge p-type metal oxide semiconductors, further optimization of the film processing is required to improve the hole transport properties. A few techniques have been reported to enhance μFEh of CuSCN films leading to higher TFT performance; one of the novel examples is the molecular doping of CuSCN with C₆₀F₄₈ to increase the hole concentration and fill the trap states, enhancing μFEh by tenfold.[3] However, the use of such dopant may not be widely applicable. Herein, we report a simple and versatile approach of using anti-solvent treatment that can enhance μFEh in solution-processed layers of CuSCN by fivefold. Acetone (Ace), tetrahydrofuran (THF), methanol (MeOH) and isopropyl alcohol (IPA) were employed as anti-solvents and spin-coated onto CuSCN films which had been prepared from diethylsulfide (DES) solution also by spin-coating. The treated films exhibited similar electronic properties to the neat films, i.e., an optical band gap of 3.9 eV and a valence band maximum at -5.5 eV. Interestingly, the anti-solvent treatment demonstrated a significant effect on CuSCN film morphology with the root-mean-square (RMS) roughness of the films decreased from 4 nm to 1.7, 1.5 and 1.3 nm after treated with MeOH,
Ace and THF, respectively, due to the reduction in CuSCN grain size. This analysis was also corroborated by the results of the extended X-ray absorption fine structure (EXAFS) of S K-edge X-ray absorption spectroscopy, which was employed to study the coordination between Cu and S. THF-treated film showed the highest number of surface Cu-S coordination that resulted from CuSCN grain size reduction. As a result, TFT measurements revealed a significant improvement of $\mu_{FE}$ in THF-treated CuSCN film to 0.05 cm² V⁻¹ s⁻¹ accompanied by a decrease in the turn-on voltage ($V_{on}$) and trap density. In addition, Ace- and MeOH-treated devices could also raise $\mu_{FE}$ to 0.024 cm² V⁻¹ s⁻¹ and 0.012 cm² V⁻¹ s⁻¹, respectively. The trend in the mobility was also further substantiated by microwave conductivity measurements that also showed the mobility of untreated films to increase with anti-solvent treatment in the order: MeOH < Ace < THF. This study shows that the anti-solvent treatment can be used to significantly improve film morphology and hole transport properties in CuSCN thin films. This simple method relies on common chemicals and standard procedures, and thus can be applicable to a wide range of thin-film opto/electronic device processing.

Enhanced Aggregation of Low-Bandgap Polymer in Polymer/Polymer Blend Films
Anjar T. Hidayat, Hiroaki Benten, Hirotaka Kojima, Min-Cherl Jung and Masakazu Nakamura; Nara Institute of Science and Technology, Japan

Blend films of conjugated polymers have been attracting attention as an active layer of organic electronic devices. Nanostructures inside the blend films play essential roles in determining the overall device performance. For instance, the ordered regions of the conjugated polymer could support charge transport while the amorphous counterpart blocks it due to the sizeable energetic barrier. However, it is difficult to expect the nanoscale self-assembly tendency of conjugated polymer chains. Therefore, a systematic study on the structure in the blend films is still limited so far. In this study, we conduct experiments to measure and identify the change in the conformation and aggregation structures of a conjugated polymer, which arises characteristically by blending with another conjugated polymer by the spin-coating method.

Blend films composed of a low-bandgap polymer (PCPDTBT) and a wide-bandgap polymer (P3M4HT) were prepared by spin-coating from the Chlorobenzene solution which dissolves the polymers with different weight ratios. For these blend films, UV-Vis absorption spectroscopy and Grazing-incidence wide-angle X-ray scattering (GIWAXS) measurements were performed to characterize structures of the PCPDTBT dispersed in the P3M4HT matrix. Both of the vibrational structure from UV-Vis absorption spectra and the scattering intensity from GIWAXS cleared that fraction of the ordered PCPDTBT aggregates relative to the amorphous PCPDTBT counterpart increases by blending. Furthermore, the GIWAXS analysis reveals that the correlation length of the PCPDTBT chain ordering increased in both its alkyl-stacking and chain backbone directions. These structural ordering of PCPDTBT was enhanced with the decreasing the PCPDTBT weight ratio in the blend film.

Our result concludes that blending of conjugated polymers by spin-coating causes an enhancement of ordering of the polymer chains rather than the corresponding neat film. These changes in the aggregation structure of conjugated polymer chains are beneficial for the improvement of charge transport and the device performances.

EN12.15.30
Achieving Balanced Ionic-Electronic Coupling for Self-Powered Electrochemical Transistors
Abhijith Surendran1, Xihu Wu1, Jieun Ko1, Oliver Filonik2, Eva M. Herzig3, Peter Muller-Buschbaum2 and Wei Lin Leong1;
1Nanyang Technological University, Singapore; 2Technische Universität München, Germany; 3Universität Bayreuth, Germany

Owing to their excellent transconductance property, organic electrochemical transistors (OECT) have been found to be an attractive choice for various kinds of transducers such as biological sensors and neuromorphic devices. Historically, attempts to enhance the ionic-electronic transport focussed on additives that improved the PEDOT packing resulting in better electronic transport. However, the densification of PEDOT domains deleteriously affects the ionic transport. Here, we present a novel approach to engineer these intricately interrelated properties to
simultaneously enhance these figures of merits (μC*) through structural reorganization of the domains with the help of an ionic liquid [1]. Further, owing to their excellent stability, we evidence its application in point of care devices using a self-powered OECT for sensing applications. Our work highlights for the first time, a highly efficient, ambient stable perovskite photovoltaic (PV) powered OECT, whose transconductance (~60.50 μS) is nearly unaffected by the incident light intensity (0.13 – 100 mW/cm²) owing to the excellent balanced electron-hole transport and a nearly non-existent trap assisted recombination processes in the solar cell. Our findings therefore demonstrate the great potential of PV-OECT device for various indoor and outdoor luminance conditions.

EN12.15.31
Tailored Morphology Control of PBDB-T:ITIC Blend for Printable Non-Fullerene Organic Solar Cells
SangHyun Park, Insu Jin and Jaewoong Jung; Kyunghee University, Korea (the Republic of)

The non-fullerene organic solar cells (NFOSCs) has recently have emerged as a promising photovoltaic technology due to their potential in large area printable solar cells with low costs. The typical film casting for the photoactive blend is spin-coating, but it is not suitable to be utilized in actual industries. Thus, the printing technique such as blade-coating has been demonstrated as an efficient method of high-throughput large area coating for NFOSCs. The morphology generation kinetics in the blade-coated blend films are totally different to that of the spin-coating because the amount of residual solvents, the concentration of the photoactive components, and the drying time of the as-cast wet films. In this work, we systematically investigated the influence of the solvent additive (1,8-diiodooctane) and substrate temperature on the blend film morphology, and their correlations with charge transport and photovoltaic properties were analyzed. We also figured out the optimal condition for the blade-coated NFOSCs that surpasses the spin-coated devices.

EN12.15.32
Molecular Factors Governing the Stability of Thermally Activate Delayed Fluorescence Molecules
Sanju Hwang¹, Yu Kyung Moon¹, Hojin Jang², Sinheui Kim¹, Jun Yeob Lee² and Youngmin You¹; ¹Ewha Womans University, Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

Organic molecules producing thermally activated delayed fluorescence (TADF) have emerged as promising dopant materials for electroluminescence. The emergence benefits from the capability of TADF molecules to harvest all the electrogenerated excitons through a thermal equilibrium between singlet and triplet excitons. However, utility of organic light-emitting devices (OLEDs) having TADF dopants is yet to be fully exploited because they suffer from short operation lifetime. The short lifetime of the devices was ascribed to intrinsic degradation of TADF molecules during normal device operation. Various studies have been conducted to identify the chemical mechanism underlying the intrinsic degradation of TADF molecules. Previous studies revealed the occurrence of irreversible bond rupture of TADF compounds upon the formation of exciton or trap of charge carriers. However, the chemical mechanisms underlying the degradation have not been fully elucidated.

To understand the degradation mechanism, we investigated the molecular factors that governed the stability of a series of TADF molecules. Archetype TADF molecules having a 1,3,5-triphenyltriazine (TRZ) acceptor and different cyclic donors, including phenoxazine (PXZ), 10H-phenothiazine (PTZ), 9,10-dihydro-9,9-dimethylacridine (ACR), 10,11-dihydro-5H-dibenzo[b,f]azepine (AZP), and carbazole (Cbz) were synthesized. Our synthetic control aimed at semi-quantitative assessments of the molecular parameters, including an exchange energy, excited-state energy and lifetime, and a bond dissociation energy. Degradation behaviors were monitored during continuous photoillumination (white light, 1.7 × 10⁻⁷ einstein s⁻¹) of an Ar-saturated THF solution of the dopant (500 μM). The photolysis yielded degradation byproducts after the cleavage of the C-N bond connecting the donor and acceptor moieties. We observed that the degradation rate (kₐvg) depended on the identity of the cyclic donor unit.

Multi-layer OLEDs having the donor-TRZ dyad TADF molecules were constructed with a configuration of ITO/DNTPD (60 nm)/BPBPA (20 nm)/PCzAC (10 nm)/mCBP: dopant (30 nm : 10%)/DBF-Trz (5 nm)/ZADN (30 nm)/LiF (1 nm)/Al. Operation lifetime was determined when the luminance reached 90% of the initial value (L₉₀) under a constant current driving mode. A positive linear relationship was found between L₉₀ of the devices and the intrinsic stability (1/kₐvg) of the TADF dopants. This linearity provided firm evidence that intrinsic stability of the
Unexpectedly, we found that the excited-state properties, such as excited-state energy and lifetime, were not the governing factors of both the stability of TADF materials (i.e., $1/k_{dgr}$) and the device longevity (i.e., $LT_{90}$). The two stability parameters increased in proportion with the ratio between the quasi equatorial and the quasi axial forms of the cyclic donors in the TADF molecules. X-ray crystal structure analyses and quantum chemical calculations performed at the CAM-B3LYP level of theory supported this notion. Cleavage of the C-N bond was predicted to be exergonic from the singlet intramolecular charge-transfer ($1\text{ICT}$) transition state of the quasi axial form. On the contrary, the bond cleavage from the $1\text{ICT}$ transition state becomes endergonic in the quasi equatorial form. Our finding established that the equilibrium between the conformers determines intrinsic stability. We believe that our research will provide useful insights into the molecular strategies to achieving prolonged device lifetime.

EN12.15.33
Using Intrinsically Luminescent Charge-Transfer State to Achieve Low Non-Radiative Recombination Loss and Charge Generation in Organic Solar Cells Yun Liu and David S. Ginger; University of Washington, Seattle, United States

An ideal solar cell requires efficient carrier generation as well as minimized carrier recombination loss. Recombination loss in organic photovoltaics (OPVs) mostly originates from non-radiative recombination. Recent studies have demonstrated efficient OPV blends with low non-radiative recombination loss by: 1) reducing the energy difference between the local exciton of inherently bright acceptor materials and donor/acceptor charge-transfer (CT) states to achieve wavefunction mixing and luminescence intensity borrowing; and 2) demonstrating increased photoluminescence yield due to radiative non-geminate carrier recombination.

In the widely accepted carrier dynamics scheme of organic photovoltaics, photogenerated excitons on the acceptor and donor molecules may form charge-transfer states at the donor/acceptor interface, a portion of which then dissociate and generate free carriers. Charge carrier recombination occurs via the CT states. Thus, it naturally follows that increasing the radiative efficiency of the CT states is critical to reduce the overall energy loss in OPVs. We herein propose a new route to reduce non-radiative recombination loss by using intrinsically luminescent system with charge-transfer characteristics—thermally activated delayed fluorescence (TADF) exciplex, as the carrier generation interface in OPVs. We demonstrate a model TADF OPV system with maximum of 10% external quantum efficiency and 40% internal quantum efficiency with ~2% electroluminescence quantum efficiency at 1-Sun injection carrier density. Moreover, photoluminescence efficiency spectrum obtained by scanning through excitation wavelengths and measuring PL quantum yield matches with the photoaction spectrum, indicating that the TADF exciplex is responsible for charge generation, consistent with the OPV carrier generation scheme. We observed fluence-dependent micro-second photoluminescence decay in this system, suggesting radiative non-geminate recombination of photogenerated carriers. Our preliminary results show promise for a proof-of-concept highly emissive and charge-generating OPV device. Furthermore, the large binding energies of excitons and charge-transfer states induce significant energy losses in organic solar cells and poses questions on the equilibrium or the lack thereof between charge carriers and CT states. We aim to understand carrier dynamics in the TADF model OPV blend by directly monitoring charge carrier decay via transient photovoltage experiments and correlating it with photoluminescence emission decay.

Non-Photolithographical Patterning Method for Silver Nanowire-Based Transparent Electrode by Controlling Adhesion between Substrate and AgNW Dongwook Ko1, Yoo Han Ma1, Jongbok Kim1 and Junyeong Lee2; 1Kumoh National Institute of Technology, Korea (the Republic of); 2Kyungpook National University, Korea (the Republic of)

AgNW(Silver nanowire)-based transparent electrodes are considered as the most suitable alternative ITO(indium tin oxide) due to excellent electrical, optical and mechanical properties. But, when we apply AgNW-based transparent electrode to optoelectronic devices such as LCD(liquid crystal display), OLED(organic light emitting diode), organic solar cells, a patterning process is essential. Generally, AgNW-based electrodes are patterned by a photolithographical technique and a laser direct technique. Although it is possible to fabricate very fine pattern shapes through photolithographical technique and laser direct patterning method, these methods are required complex processing and environmental hazard. Therefore, researching of a novel patterning method for AgNW-based electrode is indispensable. In this study, we control the surface energy of substrate by UV-Ozone treatment.
system, so we control the adhesion between the substrate and AgNW to form the patterned AgNW-based electrode. And we apply a patterned AgNW-based electrode to organic solar cells.

Hydrophilic treatment such as UV-Ozone, oxygen plasma can increase the surface energy of substrate, thus adhesion between substrate and materials can be increased due to absorption mechanism. So, we control the adhesion between the substrate and AgNWs through UV-Ozone treatment system. When we treat UV-Ozone on substrate, the adhesion between the substrate and AgNWs is strong. So, AgNWs remains on the substrate when the photocurable polymer is peeled off. On the other hand, when we do not treat UV-Ozone on substrate, the adhesion between the substrate and AgNWs is weak. So that, we can fabricate embedded AgNWs-based electrode. For that reason, we fabricate patterned AgNW-based electrode by adhesion patterning method. SEM (scanning electron microscopy) and EDS (energy dispersive spectrometry) mapping are used to confirm patterned line (500, 300, 100, and 50μm). When we apply patterned AgNW-based transparent electrode to organic solar cells, we get the good characteristics of organics solar cells.

As a result, we can control adhesion between the substrate and AgNWs by UV-Ozone treatment system. So, we can fabricate patterned AgNW-based electrode. When AgNW-based electrode is applied to organic solar cells, we confirm that organic solar cells with patterned AgNW-based electrode are exhibited similar or better performance than organic solar cells with ITO transparent electrode.

EN12.15.35
Concurrent Optimisation of Organic Donor-Acceptor Pairs through Machine Learning Daniele Padula1,2 and Alessandro Troisi1; 1University of Liverpool, United Kingdom; 2Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

In this work we deal with an instance of the general problem occurring when optimising multi-component materials: can components be optimised separately or the optimisation should occur simultaneously? We investigate this problem from a computational perspective in the domain of donor-acceptor pairs for organic photovoltaics, since most experimental research reports optimisation of each component separately. We use a collection of organic acceptors and donors we recently analysed [Kuzmich et al., Energy Environ. Sci., 2017, 10, 295, Padula et al., Mater. Horiz., 2019, 6, 343] to train non-linear Machine Learning models of different families to predict the power conversion efficiency of donor-acceptor pairs, considering computed electronic and structural parameters of both components. The trained models are then used to predict photovoltaic performance for donor-acceptor combinations for which experimental data are not available in the data set. We critically assess data structure, and the usefulness of the trained models by predicting some donor-acceptor pairs that recently appeared in the literature, and we propose the best combinations as worth investigating experimentally.

EN12.15.36
Tuning of Thermally Activated Delayed Fluorescence (TADF) Emitter Based on Naphthalimide toward Efficient and Deep Red Organic Light-Emitting Diode (OLED) Seyoung Jung, Chi Hyun Ryoo, Ji Eon Kwon and Soo Young Park; Seoul National University, Korea (the Republic of)

While countless donors and acceptors for TADF emitters have been reported, there is still a thirst for efficient and deep red emitter compared to blue and green emitters because of the potential of brightness and color gamut. One of noticeable acceptor core, 1,8-naphthalimide (NI), has great electron withdrawing property due to its carbonyl group and unique low excited state level, which sounds out about applicability for high-efficiency red TADF emitter. From this, some of orange TADF emitters with outstanding light emitting performance using NI as acceptor core were reported1,2, but there exists possibility for way longer wavelength range of emission to become a deep red TADF emitter.

In this work, deeper and more efficient red TADF emitter using NI as acceptor was realized through two tracks, using phenoxazine as more electron-donating donor moiety and introducing trifluoromethyl group as auxiliary electron-withdrawing group to N-phenyl-naphthalimide. Three newly synthesized materials and PNIDMAC (which is
Functionality of Non-Fullerene Electron Acceptors in Ternary Organic Solar Cells

Ternary organic solar cells, a single active layer comprising three different components, have been demonstrated to be one of the most efficient ways to approach high-performance organic solar cells. But nevertheless, most of the ternary organic solar cells were characterized by the steady-state measurements, which are helpful but inadequate to fully understand the underlying charge carrier behavior at a short time scale. In this work, a comparison of the steady-state and time-dependent measurements was used to investigate the functionality of non-fullerene electron acceptors in ternary organic solar cells. The steady-state measurements indicate that non-fullerene electron acceptors can enlarge the absorption range of photoactive layer, suppress charge carrier recombination, reduce charge carrier transfer resistance and thereby increases photocurrent in ternary organic solar cells. The time-dependent measurements demonstrate that short charge carrier extraction time and high charge carrier mobility are responsible for enhanced photocurrent in ternary organic solar cells. Our studies provide a comprehensive method understanding underlying of enhanced efficiency of ternary organic solar cells.

Synthesis and Characterization of Multi-Substituted Carbazole Derivatives for Optoelectronic Properties—An Approach to Modulate Aggregation-Induced Emission Effect

Extensive research has been done in recent years for the development of fluorescent small organic molecules with aggregation-induced emission (AIE). The application of such solid-state organic luminogens has been widely used in organic light-emitting diodes (OLEDs), biological probes and fluorescent sensors due to their potential enhancement of emission in either solid states or in an aggregated state provided by the aqueous media. In order to produce efficient AIE materials, organic π-conjugate fluorophores play a crucial role with varying the photophysical and electrochemical properties which are strongly dependent on linking position of π-conjugates as well as the design of building blocks. It is believed that there are ample possibilities to modify these characteristic properties to successfully tune their optoelectronic properties. To increase the efficiency of an OLED device, it is desirable to develop a molecule with twisted conformation to generate AIE-active material which not only prevents the π-π stacking but also block the quenching channels. Carbazole being explored as one of the favourite synthon for materials chemists because of its unique characteristics such as rigid molecular structure, amorphous nature, inexpensive of the starting material, good chemical stability assisted by its fully aromatic system, excellent thermal and photochemical stability, good hole transporting ability and high triplet energy (~ 2.9 eV). Apart from these attractive features, due to its electron-rich nitrogen atom carbazole framework can allow large structural diversity to modulate the functional properties of the materials systematically. Therefore, carbazole based functional materials have been exemplified as a promising family for optoelectronic applications such as organic light-emitting diodes (OLEDs), solar cells (OPVs), field-effect transistors (OFETs) and in molecular sensors. It is important to note that multi-functionalization of mono and di-substituted dicyanovinyl carbazole derivatives are rarely reported in the literature. On the basis of above stated discussion, a series of carbazole based derivatives with different functional groups comprising of mono- and disubstituted dicyanovinyl functionalities (MD1, MD2, DD1, DD2) have been designed, synthesized and systematically characterized to effectively modulate the aggregation-induced emission effect by changing the linking position of carbazole and explore the simple structure-function relationship phenomenon. Dyes consist of N-phenylcarbazole (MD1 and DD1) and N-butylcarbazole (MD2 and DD2) as donor substituted at the various position of central carbazole with dicyanovinyl group as acceptor. The substitution effect of different donors on optical, electrochemical and thermal properties on carbazole-dicyanovinyl derivatives is unraveled. The dyes MD2 and DD2 showed red-shifted absorption and higher molar extinction coefficient as...
compared to MD1 and DD1 attributed to extended conjugation tendency of 3-substituted N-butylcarbazole as compared to N-phenyl linked carbazole. The photoluminescence studies revealed the role of auxiliary chromophores loading at C1, C6 and C8 positions of the central carbazole moiety in the excited state. All the compounds showed positive solvatochromism in excited states attributable to intramolecular charge transfer. The higher thermal stability of all the dyes reveals rigidity of carbazole derivatives. Interestingly, all the dyes in particular dyes consist of N-phenylcarbazole substituents (MD1 and DD1) showed aggregation-induced emission properties in THF-H2O mixtures attributable to increased distortion in molecular configuration and restricted π-π stacking among adjacent molecules. OLED device was fabricated based on these dyes as dopant emitter along with a host (CBP) and experiencing the best performance in a doped device of MD2 with 3 wt% having EQE of 4.2% (current efficiency of 13.1 cd A\(^{-1}\)) and maximum brightness \(L_{\text{max}}\) of 6180 cd/m\(^2\).

**Study on Correlation between Surface Morphology and Work Function of Aluminum Film in Nanoscale**

Kenta Sasagawa\(^1\), Hiroyuki Kuwae\(^1\), Hiroshi Goto\(^2\), Minoru Sakata\(^2\), Takuo Yasuda\(^2\), Jian Lu\(^3\), Hiroshi Itoh\(^3\), Akinori Honda\(^3\), Shuichi Shoji\(^1\) and Jun Mizuno\(^4\);

\(^1\)Waseda University, Japan; \(^2\)GCE institute Inc., Japan; \(^3\)National Institute of Advanced Industrial Science and Technology, Japan; \(^4\)Nanotechnology Research Center, Waseda University, Japan

This paper reported correlation between surface morphology and work function in nanoscale. Surface nanoscale-morphology of an aluminum film was controlled using colloidal lithography. After the nanopatterning, the averaged work function was decreased from 4.24 eV to 3.94 eV. In addition, high resolution (resolution of 200 nm) Kelvin probe measurement revealed that there was work function difference of 0.31 eV between the top and bottom of the prepared nanospikes. These results indicate to develop stable low work function electrodes.

Low work function materials are essential for electrodes of electronic devices, for example organic light emitting diodes and organic solar cells. Generally, such low work function materials show high reactivity and are unstable, causing surface property changes when they are used in devices. On the other hand, some research reported that work function can be controlled by adjusting the surface roughness with the same material. In general, increment of surface roughness of a metal film causes reduction of the work function based on effect of the dipole barrier, as reported by Saito. However, detailed correlation between surface nanoscale-morphology and work function has not been clarified. Hence, in this study, we studied correlation between surface morphology and work function “in nanoscale” using an aluminum film. The aluminum film was patterned by colloidal lithography, and the work function of the film was evaluated in both millimeter and nanometer-level.

An aluminum film of 100-nm-thick was prepared on a silicon substrate by ion-beam sputtering. In order to analyze correlation between surface morphology and work function, surface of the aluminum film was nanostructured via colloidal lithography. The detailed fabrication process is as follows. Firstly, polystyrene nanoparticles (100 nm in diameter) dispersed as colloidal water solution were regularly aligned on the aluminum film by spin-coating. Then, the nanoparticles were slightly etched by oxygen plasma to separate each nanoparticle. The aluminum surface was etched to form nanospikes using etchant of acids mixture (phosphoric acid, acetic acid, and nitric acid) through the nanoparticles as a mask. Finally, the polystyrene nanoparticles were removed by oxygen plasma. In addition, an aluminum film without nanopatterns was also prepared as a reference. The work functions of the samples were measured by Kelvin probe method. We evaluated not only averaged work function of about 3 mm\(^2\) area, but also nanoscale work function, resolution of 200 nm.

From atomic force microscopy evaluations, we observed that the aluminum film having nanospikes was successfully fabricated with 5.8 nm in arithmetical mean roughness and 49.5 nm in maximum peak to valley height. In the millimeter-level observation, the work function of the aluminum film with the nanospikes was decreased to 3.94 eV compared to that without the nanospikes (4.24 eV). This result indicated that work function of the aluminum film was decreased with increasing the surface roughness, as previously reported. On the other hand, in the nanometer-level observation, the work function changing was obtained along with the surface nanoscale-morphology changes. The maximum difference of the work function between the top and bottom of the nanospike was 0.31 eV. It is a first time to show the relationship between surface morphology and work function in nanoscale to the best of our knowledge. This result implies that electrons are easier to be emitted from top of the nanospikes rather than bottom of them. This is a promising step for developing stable low work function electrodes.

**EN12.15.41**

**Using SnS\(_2\) Underlayer to Reduce the Schottky Barrier between Ag\(_2\)S and FTO**

Yan Lei, Zhi Zheng and
Weiwei He; Xuchang University, China

Ag$_2$S thin film can absorb the sun light from ultraviolet (UV) to near infrared (NIR) region due to its direct narrow band gap ($E_g = 0.9 \text{ eV} \sim 1.1 \text{ eV}$). For such a narrow band gap semiconductor, the related photoelectric conversion efficiency (PCE) can reach to about 30% in an ideal solar cell. It can be a promising semiconductor for next generation solar cell application, even the PCE is still low.

To obtain high PCE, the photoinduced charge carrier recombination at the interface of heterojunction or at the electrode surface must be reduced. Some works have been reported addressing this consideration, such as doping element to tune the Fermi level of Ag$_2$S, using electron transfer layer between the electrode and Ag$_2$S thin film and introducing intermediate layer to form cascade band structure. Despite these efforts, the Ag$_2$S thin film based solar cells are still featuring low PCE. One of the problems is how the electrode/Ag$_2$S interface affecting the photoinduced charge carrier recombination has not been well studied. Therefore, we should furtherly check out the photoinduced charge carrier transportation and recombination in mechanism. To our knowledge, the Schottky barrier will generate at the interface of n-type semiconductor and electrode, once the Fermi levels are different. The band is bending upward at each side of n-type semiconductor and form a “V-type” band structure in electrode/n-type semiconductor/p-type semiconductor structure. The photoinduced charge carrier recombination will happen at the inappropriate interface of electrode and n-type semiconductor. To achieve higher photoelectric performance, such recombination at the electrode surface should be suppressed. Here, FTO surface was modified by SnS$_2$ layer to tune the Fermi level of FTO, which was deposited by thermal evaporation and post thermal annealing treatment. Photoelectrochemical method was carried out to evaluate the variation of charge carrier transfer resistance between the Ag$_2$S/FTO interface. KPFM technique was used to study the Fermi level alignment of Ag$_2$S/FTO interface. Transient surface photovoltage (TSPV) technique has been employed to investigate the photoinduced charge carrier transportation and recombination between the Ag$_2$S/FTO interface. Basing on these results, a more clear charge carrier recombination mechanism at the Ag$_2$S/FTO interface is obtained, which may give more opportunities to furtherly increase power conversion efficiency of new type photoelectric system.

EN12.15.42

Synthesis and Characterization of New Nonfullerene Electron Acceptors for Organic Photovoltaics

Chang Woo Koh$^1$, Jae Hoon Son$^1$, Ziang Wu$^1$, Hwa Sook Ryu$^1$, Hyewon Cho$^2$, Md Al Mamunur Rashid$^1$, Kyungwon Kwak$^1$, Jin Young Kim$^2$ and Han Young Woo$^1$; $^1$Korea University, Korea (the Republic of); $^2$Ulsan National Institute of Science and Technology, Korea (the Republic of)

Recently, non-fullerene acceptors have attracted significant attention for organic photovoltaics (OPVs) due to their frontier energy levels and absorption spectra tunability and good photo/chemical stability rather than fullerene based acceptors. Moreover, with the superior compatibility with several donor polymers exhibiting well-aligned energy levels, complementary absorption and appropriate morphology, outstanding PCEs over 15% have been achieved. However, most of the high performance non-fullerene acceptors are A-D-A type based on linear core structure which contains electron donating core unit and two electron deficient end-capping groups. Although the 2-dimensional (2D) star-shaped molecule has potential to exhibit good efficiency in solar cells, such as improved molar absorption coefficient and face-on oriented columnar packing structures enhancing charge mobility in a vertical direction, little studies have been done. In particular, a number of p-type star-shaped materials which contain electron-rich polycyclic aromatic hydrocarbon structures have been studied, but the advancement of star-shaped n-type materials is still lagging behind.

In this study, triazine-based n-type 2D star-shaped molecules were designed and synthesized. Intramolecular non-covalent cumbic interactions and rigid molecular structure were introduced to induce the structural planarity for enhanced the packing property and the D-A type structures are designed to control the optical/electrical properties with a push-pull effect. The optical/electrochemical properties were monitored by UV-Visible absorption spectroscopy and cyclic voltammetry, and the film morphology and crystallinity were analyzed by grazing-incidence wide-angle scattering and differential scanning calorimetry. It has also been applied as an n-type active layer material for OPVs, and will be presented in detail.

Measuring Energetic Disorder and Quantifying Order and Disorder in Organic Semiconductors Thuc-Quyen Nguyen; University of California, Santa Barbara, United States

Characterizing the density of states (DOS) width accurately is critical in understanding the charge-transport properties of organic semiconducting materials as broader DOS distributions lead to an inferior transport. From a morphological standpoint, the relative densities of ordered and disordered regions are known to affect charge transport properties in films; however, a comparison between molecular structures showing quantifiable ordered and disordered regions at an atomic-level and its impact on DOS widths and charge transport properties has yet to be made. In this work, the DOS distribution widths of two model conjugated polymer systems are characterized using three different techniques. A quantitative correlation between energetic disorder from band bending measurements and charge transport is established, providing direct experimental evidence that charge carrier mobility in disordered materials is compromised due to the relaxation of carriers into the tail states of the DOS. Distinction and quantification of ordered and disordered regions of thin films at an atomic-level was achieved using solid-state NMR spectroscopy. An ability to compare solid-state films morphologies of organic semiconducting polymers to energetic disorder, and in turn charge transport, can provide useful guidelines for applications of organic conjugated polymers in pertinent devices.

Elucidating Structure-Function Relationships in Organic Semiconductors with Coupled Electrical and Optical Spectroscopy Elizabeth von Hauff; Vrije University, Netherlands

Organic semiconductors offer many advantages for energy conversion, saving and storage applications. However the underlying processes that govern electrical processes such as charge transport, the separation of photogenerated charge, and carrier recombination, are not well-understood. New experimental and theoretical approaches to correlate molecular structure with electronic processes in organic semiconductors are valuable for gaining insights into smart design for this class of materials. In this talk I will discuss our recent results on coupling electrical and optical spectroscopies to study structure-function relationships in organic semiconductors, such as polaron formation and transport in donor-acceptor polymers for photovoltaics and the influence of molecular morphology on the performance of piezoelectric polymers. By combining optical spectroscopy with device physics and theoretical modeling, we are able to identify relevant aspects of molecular structure and morphology that determine the electronic response of organic semiconducting films.

Multimodal Time-Resolved Kelvin Probe Force Microscopy Investigations of Organic Donor–Acceptor Blends
Benjamin Grevin1, Olivier Bardagot2, Lydia Cabau2 and R Demadrille2; 1CNRS, France; 2CEA, France

The development of third generation photovoltaics is massively based on the use of materials displaying a heterogeneous morphology at the meso or nanoscopic scales, or nanostructured by purpose. Whatever the technology, understanding how the nanostructure impacts the electronic transport and photocarrier dynamics is vital for device optimization. This is especially true for organic bulk heterojunctions (BHJs) based solar cells, whose performance continue to be improved over time thanks to the joint efforts of chemists, physicists and material scientists. Despite fierce competition with hybrid perovskites, organic photovoltaics have indeed still a stay in the competition, thanks in particular to the introduction of novel non-fullerene acceptors. As in the case of their fullerene-based elders, optimizing the film morphology and phase composition of novel donor-acceptor blends remains the key to achieve an efficient photocarrier generation, to balance properly the carrier mobilities and to minimize the losses by recombination.

Since their introduction in the 1980s, scanning probe microscopy (SPM) techniques have been continuously improved, and have reach the ability to map not only the surface topography but also a huge range of local functional mechanical, chemical, electronic and optical properties at the nanoscale. Several advanced modes of the atomic force microscope (AFM) are nowadays commercially available from SPM manufacturers, and are (or could be) widely used in routine by the OPV community to characterize the BHJs morphology and phase composition (for instance by quantitative nanomechanical imaging) and their optoelectronic properties (by photo-conducting AFM or surface photovoltage imaging). Some others are still confidential, but will probably experience strong growth in the coming years. In particular, time-resolved electrostatic and potentiometric variants of the AFM [1-6] hold great promise, for they are developed with the aim to map the photo-carrier dynamics and lifetime at the nanoscale.

In this communication, we will present the works undertaken in our group to implement time-resolved imaging modes of the charge dynamics based on the Kelvin Probe Force microscope (tr-KPFM for time-resolved KPFM) combined with non contact AFM under ultrahigh vacuum. Two complementary modes will be introduced: KPFM under frequency-modulated illumination [5] and pump-probe KPFM [6], both operated in spectroscopic data cube mode. These techniques have been applied to model BHJ systems including PTB7-PCBM and NFA-based blends, which phase composition was pre-characterized by quantitative nanomechanical imaging in peak force AFM. It will be shown that in these systems, the surface photovoltage decays probed by tr-KPFM originates from trap-delayed process. Our results stress also the crucial need to combine several KPFM modes to disclose the full temporal range of dynamical process that can coexist in these materials.

Pushing the Resolution Limits of Imaging Conjugated Polymers in the Transmission Electron Microscope
Brooke Kuei and Enrique D. Gomez; The Pennsylvania State University, United States

Transmission electron microscopy (TEM) of conjugated polymers has remained a challenge because resolution is limited by the electron dose the sample can handle. We have characterized the effects of beam damage on poly(3-hexylthiophene) (P3HT), poly(3-dodecylthiophene-2,5-diyl) (P3DDT), and poly[(5,6-difluoro-2,1,3-benzothiadiazol-4,7-diyl)-alt-(3,3’’’-di(2-octyldodecyl)-2,2’’,5’’,2’’’’-quaterthiophene-5,5’’’’-diyl)] (PffBT4T-2OD) via electron diffraction and electron energy-loss spectroscopy (EELS). Critical dose $D_C$ values were calculated.
from the decay of diffraction and low-loss EELS peaks as functions of dose rate, temperature, beam size, and the addition of antioxidants. At room temperature, $D_C$ first increases then decreases with increasing dose rate, whereas at cryogenic conditions this dose rate dependence is less pronounced and the overall $D_C$ increases; these results suggest that the main mechanism for beam damage in conjugated polymers is diffusion of free radicals. Thus, we show with both $D_C$ experiments and high-resolution TEM that the addition of free radical scavengers such as butylated hydroxytoluene (BHT) mitigates beam damage at room temperature. We also observe that $D_C$ increases with decreasing beam size, suggesting that convergent beam techniques are amenable for beam-sensitive materials. Thus, we demonstrate the use of scanning nanodiffraction to map $\pi-\pi$ stacking in several conjugated polymers.

*Digitally-Printed Organic Bulk-Heterojunction Photodetectors—Device Architectures, Polarization and Color Detection* Gerardo Hernandez-Sosa$^{1,2}$; $^1$Karlsruhe Institute of Technology, Germany; $^2$InnovationLab, Germany

Printing technology is set to enable the high-throughput low-cost and customized fabrication of optoelectronic and sensors devices. For this goal to become a reality, this functional printing approach should encompass a material process development which enables high device performance and industrial compatibility, thus enabling a facile transfer of research results into consumer applications.

In this contribution, I will present the fabrication of fully printed organic photodiodes (OPDs) by digital printing techniques (e.g. aerosol and inkjet). The devices show mechanical flexibility, semitransparency and an excellent reproducibility. Moreover, I will demonstrate their integration into fully printed OPD 256-pixel arrays. This was performed through a micro-patterning process based on printed dewetting structures that guide the self-alignment of the functional inks, improving printing resolution, registration accuracy and performance reproducibility. Secondly, I will discuss the use of the ink formulation as way to access and tailor material optoelectronic properties. In this direction, we have focused on the control of the molecular order in organic semiconductors though an inkjet printing process. This enabled us to deposit functional polymers with a high degree of alignment and explore its use in polarization sensitive OPDs. Finally, I will outline our recent efforts in the fabrication of inkjet printed OPDs based on novel non-fullerene acceptors (NFAs). The devices show a photo-response up to 800nm and reach record responsivities of 400mA/W as well as cut-off frequencies surpassing 2MHz. Furthermore, we demonstrate the successful decoupling of the optical and rheological properties by using a visibly transparent polymer donor and color-selective NFAs. This approach offers spectral flexibility without the need for a variation in process parameters. The choice of NFA enabled devices with color selectivity in the ranges of 400-600nm and 500-800nm.

**Conducting Polymer Fibers and Yarns for Thermoelectric Textiles** Christian Muller1,2; 1Chalmers University of Technology, Sweden; 2Wallenberg Wood Science Center, Sweden

Recent advances in ubiquitous low-power electronics call for the development of light-weight and flexible energy sources. The textile format is highly attractive for unobtrusive energy harvesting. In my talk, I will present some of our recent work on thermoelectric textiles. I will discuss how n- and p-type yarns can be prepared by coating or dyeing of natural materials such as silk, as well as by melt or wet spinning of conjugated polymers. Some of these fibers and yarns feature a high degree of ambient stability as well as the ability to withstand both machine washing and dry cleaning. Embroidery of base fabrics with such conducting yarns readily permits the fabrication of thermoelectric modules.

**Remarkably High Thermoelectric Performance of Flexible and Robust Predominantly Double-Walled Carbon Nanotube Yarn** Yasuhiko Hayashi1,2, Kazuki Omoto1, Shogo Iemoto1, Hirotaka Inoue1, Masaki Hada3,1 and Takeshi Nishikawa1; 1Okayama University, Japan; 2Tokyo Institute of Technology, Japan; 3University of Tsukuba, Japan

Carbon nanotube (CNT) yarns have attracted considerable attention as they are not only flexible, robust and lightweight but also can generate high Seebeck coefficient, $S$ and high electrical conductivity, $\sigma$, they realize remarkably high thermoelectric generators (TEGs). One promising application is a small wearable electronics which can generate electricity from heat gradients between the human body and atmosphere in order to harvest waste heat. One of the critical challenges is the tuning of electrical and thermal transport since they interrelate against the high performance of thermoelectric properties. Although the thermal and electrical properties of CNT yarns are likely to enhance their properties by the post-high temperature annealing process, the phenomena underlying the improvement of properties have not explicated yet. The interface between the components governs the performance of the TEGs made by CNT yarns, but the debates have not expanded to characterization and modification of their complicated interface. Then the thermoelectric properties were characterized for the DWCNT yarns without treatment, with Joule heating, with n-type polyethylenimine (PEI) doped, and with PEI doped after Joule heating. High quality dense and tall vertically aligned CNT forest on Si was grown rapidly by a water vapor free thermal chemical vapor deposition using Fe catalyst, and it consists of more than 80% of double-walled CNTs (DWCNTs). DWCNT yarns were fabricated from CNT forest by a dry spinning process. We doped PEI to realize n-type DWCNT yarn. Electrical Joule heating was done on the DWCNT yarns with and without PEI dope in the vacuum at the temperature of 1800–2000 K for 1 min.

Pristine DWCNT yarn is a p-type semiconductor which exhibits a positive Seebeck coefficient of +25 μV/K. The Joule heating process did not change the polarity of the DWCNT yarn; in contrast, the Seebeck coefficient was enhanced to be +100 μV/K. In case of n-type DWCNT yarn, after Joule heating, PEI was effectively doped in the DWCNT yarn, and the Seebeck coefficient was enhanced to be −100 μV/K (quite high power factor $PE=1000 \mu W/mK^2$). To the best of our knowledge, these positive and negative of 100 μV/K are the highest Seebeck coefficients ever observed in CNT yarn and are close to those of inorganic thermoelectric materials. Raman characterization of the joule-heated CNT yarn, we observed the $G^*$ peak at a wavenumber of 2400 cm$^{-1}$, originated from the double resonance process in graphene or graphite, indicating the presence of graphene or graphite. The computation analysis reviled that the residual amorphous carbon in the interface between CNTs changes into the graphene-like structure. Our results indicate that the improvement of TE properties is due to graphene layers. Our results provide a guiding principle for designing DWCNT yarns and applying them for thermoelectric devices.

**Metal-Organic Frameworks as Thermoelectric Materials—Uncoupling Thermal and Charge Transport and the Role of Defects** Mark D. Allendorf1, Michael E. Foster1, Vitalie Stavila1, Christian Schneider2, Gregor Kieslich2, Roland Fischer2, Monica So3 and Alec Talin1; 1Sandia National Laboratories, United States; 2Technical University of Munich, Germany; 3California State University, Chico, United States
The structural and design versatility of Metal-Organic Frameworks (MOFs) is stimulating considerable activity to develop them for a wide range of applications for which nanoporous materials are extensively used, such as chemical separations and catalysis. However, MOFs also represent a unique opportunity to solve a vexing problem faced in the field of thermoelectrics; namely, the difficulty of uncoupling thermal and electrical transport so that high Seebeck coefficient and power factor can be achieved. In principle, the extremely low density of MOFs, many of which are comprised primarily of empty space, and the poor phonon coupling across the discontinuous covalent vs. coordination bonding in their structures, should inhibit thermal transport. Recent research suggests that electrically conducting MOFs are feasible, although so far the conductivities achieved are very low compared with the best thermoelectric materials. In most cases, electronic coupling in MOFs is weak due to the ionic nature of the bonding, leading to low band dispersion and insulating behavior. Nevertheless, the number and variety of electrically conducting Metal-Organic Frameworks (MOFs) continues to grow and both 2- and 3-dimensional MOFs with conductivities as high as 160 S/cm are known.

This presentation will discuss mechanisms of electronic charge conduction in MOFs and the related class of materials known as Covalent Organic Frameworks (COFs). We will describe theoretical investigations we performed to probe thermoelectronic transport properties and compare these predictions with charge transport and spectroscopic data to gain insight into the intrinsic conductivity mechanisms and their dependence on MOF structure, chemical composition, and morphology. Our studies provide guidance needed to design MOFs suitable for thermoelectric and other design applications. In addition, through a combination of experiments with MOFs infiltrated with guest molecules under highly controlled conditions, ab initio simulations, and band transport theory, we assessed the influence of structural and interface defects on the electronic structure of 2D and 3D MOFs. The results show that interface defects can introduce a transport barrier in 2D MOFs by breaking the π-conjugation, and/or by decreasing the dispersion of the electronic bands near the Fermi level. Both defect types cause a small band gap to form (in the range of 15-200 meV), which is consistent with the experimentally inferred hopping barrier. In 3D MOFs, the guest molecule, which can be considered a defect in much the same way that dopants are in conventional semiconductors can enhance electrical conductivity but also lead to phase transformations that change the majority charge carrier. These results provide strong evidence supporting the ongoing speculation that the charge transport properties of MOFs are strongly influenced by defects, in much the same way as conventional inorganic and organic conducting materials.

2:45 PM EN13.01.04
Signatures of Coherent Phonon Transport in MAPbI3-Based Ruddlesden-Popper Phases Alexander D. Christodoulides1, Lingyun Dai1, Peijun Guo2,3, Richard Schaller2,3 and Jonathan A. Malen1,1; 1Carnegie Mellon University, United States; 2Argonne National Laboratory, United States; 3Northwestern University, United States

We report thermal conductivity measurements of methylammonium lead iodide (MAPbI3) based Ruddlesden-Popper Perovskites which exhibit signatures of coherent phonon transport. The hybrid organic-inorganic halide perovskite, MAPbI3, has exhibited exceptional power conversion efficiency when used in solar cell devices. However, this material is unstable in oxygen and moisture-rich environments, particularly at high temperatures which are practically unavoidable given its ultra-low thermal conductivity. A two-dimensional, layered Ruddlesden-Popper phase similar to MAPbI3, (BA)2(MA)3n-1PbI3n and (BA)2(MA)3n-2PbI3n-1 (where n denotes the number of perovskite layers per two organic layers), has shown improved stability compared to its three-dimensional counterpart due to the inclusion of hydrophobic spacer cations, n-butylamine.

In order to learn about heat dissipation and phonon properties in the Ruddlesden-Popper phase, we measured the thermal conductivity of (BA)2(MA)3n-1PbI3n+1 for n = 1-6 using a non-contact pump-probe technique called frequency-domain thermoreflectance. We find that the thermal conductivity initially decreases at a function of n for n = 1-3 then levels off for n = 4-6. Decreasing thermal conductivity with increased interface spacing is a signature of coherent phonon transport, and opposite to our expectation for diffuse phonon transport. Our results agree with the Simkin-Mahan model which was formulated to describe the wave nature of phonons in superlattices [1].

While Ruddlesden-Popper organic perovskites can be synthesized by solution processes, coherent phonon transport has previously only been observed in superlattices of GaAs and AlAs [2], and SrTiO3/CaTiO3 and SrTiO3/BaTiO3 [3] grown painstakingly by MBE processes. Our work suggests that low n (BA)2(MA)3n-1PbI3n+1 are both more chemically stable and thermally conductive than MAPbI3. These properties may make the Ruddlesden-Popper phases more desirable for photovoltaics, while the demonstration of phonon coherence may open a pathway to...
additional applications in phonon optics and thermoelectricity.

Controlling Interplay between Graphitic Carbon and Polymers for Enhanced Electronic and Ionic Thermoelectric Effects Choongho Yu; Texas A&M University, United States

Voltage generation in a conductor can be resulted from electron or/and ion transport due to a temperature difference. When a thermoelectric voltage is induced by electron, it is typically much smaller than that of ion transport, particularly for organic thermoelectric materials. Here this study shows how to enlarge the small thermopower of carbon nanotubes (CNTs) using a polymer by controlling electronic transport at the junctions of CNTs with an organic electrochemical transistor configuration where poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) channel was disposed between two separated CNT films. The PEDOT:PSS channel could create energy barriers for abating the contribution of metallic CNT (m-CNT) to thermopower as well as injecting holes to CNT films so that charge imbalance upon imposing temperature gradients can be enlarged. The thermopower was raised up to ~150 mV/K and a remarkably high PF was obtained up to ~1.3×10³ μW/m-K², which is ~460% improvement compared with that of pristine CNT. This study provides not only better understanding of thermoelectric behaviors for organic thermoelectric materials, but also a practical method for suppressing the electronic transport from m-CNT, which would be widely applicable for other organic materials for thermoelectrics and beyond. On the other hand, with the extremely large voltage based on thermally induced ion transport, novel simultaneously harvesting and storing electrical devices using graphene oxides and polystyrene sulfonic acid have been developed without losing the benefit of solid-state non-moving part devices like conventional thermoelectrics. We called the device thermally chargeable supercapacitor (TCSC), and arrays of TCSC have been batch-fabricated, and connected together to raise the output voltage up to 2.1 V, suggesting excellent suitability for roll-to-roll mass manufacturing and practical implementation of thermal energy harvesting. The outcomes suggest that it is feasible to supply power to various distributed electronic systems whenever and wherever a temperature gradient is present.

4:00 PM EN13.02.02
Asymmetric Thermo-Electrochemical Cell for Low-Grade-Heat-to-Electricity Conversion Shien Ping Feng; The University of Hong Kong, Hong Kong

Low-grade thermal energy (<100 °C) is abundantly available in the form of waste heat or in the environment. Current technologies using liquid-based thermo-electrochemical cells (TECs) is both cost-effective and scalable for low-grade heat harvesting, and their temperature coefficient (mV/K) is one order of magnitude higher than that of solid-state thermoelectrics. The research on TECs has mainly focused on the exploit of thermal gradient or thermal cycle, but the potential of these approaches has been limited by the poor energy conversion efficiency or the need of external electricity. We invent a new asymmetric thermoelectrochemical cell (a-TEC) for low-grade-heat-to-
electricity conversion under an isothermal condition without the aid of the thermal gradient across two electrodes or the thermal cycle. The a-TEC consists of graphene oxide (GO)/platinum nanoparticles (PtNPs) cathode and polyaniline (PANI) anode and an aqueous Fe²⁺/Fe³⁺ electrolyte, which can be thermally charged in the open circuit condition. Under isothermal operation, the pouch cell configuration of a-TEC with a short distance between two electrodes can be employed for improving electrolyte conductance and rapid heating. Notably, the thermal voltage is generated based on thermo-pseudocapacitive reaction at the GO-electrolyte interface, demonstrating a very high temperature coefficient of 5.0 mV/K and the a-TEC exhibits the energy conversion efficiency of 5.19% at 70 °C (39.6% of Carnot efficiency). The great applicability of this new thermo-electrochemical system has been demonstrated on supplying power for an electrochromic smart window by immersing a-TECs in a hot water and lightening up an organic light emitting diode by placing a-TECs on a running compressor.

4:15 PM *EN13.02.03
Mixed Ionic Conductive Polymers for a Thermoelectric Capacitor Funkyoung Kim; Yonsei University, Korea (the Republic of)

As conducting polymers are intrinsically semi-metallic, the charge carriers inducing a thermal voltage can be tuned from electronic (hole) to ionic by doping. In particular, controlling the ionic doping level is crucial for maximizing the power factor of thermoelectric materials, as it optimizes the free ion concentration and carrier mobility. Due to the contribution from both electronic and ionic carriers, the thermopower in a mixed ionic electronic conduction (MIEC) system is synergistic and can produce a stable thermal capacity under constant temperature gradient. A robust thermoelectric harvester was explored from an ion doped mixed ionic conductive polymer film to give a high a Seebeck coefficient of over 16 mV K⁻¹ and a thermal voltage of 80 mV for a temperature gradient of 5 K. The thermal charging on the MIEC film device afforded high thermal voltage and current output, reproducibly, to show cumulative thermoelectric nature. Environmentally sustainable thermoelectric harvesting will be demonstrated by introducing a self-humidifying bilayer system.

4:45 PM EN13.02.04
Graphene-Carbon Nanotube Aerogel as ‘Organic’ Thermoelectrochemical Energy Harvesters Sanju Gupta; Western Kentucky University, United States

Three-dimensional scaffolds comprising different ratio of graphene nanosheets and multi-walled carbon nanotubes (GA-MWCNT) macro-assemblies. The resulting hydrothermally synthesized hydrogels are freeze-dried and thermally reduced to yield graphene and graphene-carbon nanotube aerogels with ultralow densities and tunable mesoscopic pore sizes. These ‘all carbon’ aerogels prepared as monolithic solids from suspensions of few-layer graphene oxide nanosheets and small diameter multiwalled carbon nanotubes in which organic wet chemistry is used to cross-link the individual sheets and with carbon nanotubes. In contrast to methods that utilize physical cross-links between graphene oxide nanosheets, this approach with polymeric linkers and organic functionalization provides covalent carbon bonding among the graphene sheets and molecular attachment with carbon nanotubes, respectively, thus facilitating rapid and facile electron transport. As a result they are expected to exhibit improved electrical conductivities, moderate thermal conductivity, highly interconnected multiplexed topology with large internal surface areas thus promoting enhanced surface ion adsorption which makes these mesoporous materials viable candidates for use in harvesting thermo-electrochemical energy and energy storage technologies. Thermoelectric property measurements for both the carbon nanotube aerogels by themselves and for hybrids with graphene nanosheets revealed promising and unprecedented (p-type and n-type) thermopower values especially with electrolyte with an upper bound to 3.2 mV/K. We used complementary analytical techniques including electron microscopy, temperature dependent electrical property, and Raman spectroscopy while evaluating performance to establish microstructure-processing-property-performance correlations. Supported in parts by KSEF-RDE Grant, KY NASA EPSCoR and KY NSF EPSCoR Grants.

Simulation of Thermoelectric Properties of Complex Materials and across Interfaces Zhiwei Ding, Qichen Song, Qian Xu, Jiawei Zhou and Gang Chen; Massachusetts Institute of Technology, United States

This talk will discuss our recent work to simulate electron and phonon thermoelectric transport in complex materials and across interfaces based on the density-functional theory and atomic Green’s function. One example of the complex material is Mg$_2$Sb$_3$, which has been recently reported to have high figure of merit. We compare the charge defect scattering due to different dopants using first principle calculation and find weak impact of defect on mobility. Instead, the intrinsic carrier-phonon scattering is the major scattering mechanism. Only specific polar optical phonon modes make dominant contribution to the scattering rates, which we attribute to the atomic structure and electrostatic interactions in Mg$_2$Sb$_3$. For transport across interfaces, an important question to ask is if electron and phonon scatterings conserve lateral momentum, i.e., if they experience specular or diffuse scattering, in the presence of interfacial atomic mixing. We employ atomic Green’s function to simulate electron and phonon transmission across interfaces for SiGe interface with mode-by-mode resolution. We find the angular dependent interfacial transport for electron and phonon are behaving differently, which provides new opportunities for optimizing thermoelectric performance. This work is supported by DARPA MATRIX program (Grant No. HR0011-16-2-0041).

8:45 AM *EN13.03.03/EN14.11.03
Amorphous-Like Thermal Conductivity in Crystalline Solids Saikat Mukhopadhyay and Thomas Reinecke; U.S. Naval Research Laboratory, United States

Thermoelectric materials (TEs) could play an important role in future energy management through environmentally sound cooling and power generation, e.g., converting waste heat into electricity. Efficient TEs inhibit the propagation of heat (low thermal conductivity, $\kappa$) but conduct electricity well (high power factor, PF). Although $\kappa$ in a given material can be reduced via alloying and nanostructuring, identifying materials with intrinsically low $\kappa$ is still needed. It has already been known that soft phonon modes due to weakly bonded atoms and $s^2$ lone-pair electron are common to materials with low-$\kappa$. Here, we predict a series of new materials which are weakly bonded systems with same constituent elements but different stoichiometry either with $s^2$ lone-pair electron or high mass density. Due to giant phonon anharmonicity and low phonon group velocities, they offer extremely low $\kappa$ (0.3-0.6 W/mK) at 300K approaching to those found in the amorphous/disordered regime. In addition to low-$\kappa$, high Seebeck coefficients and electrical conductivities in these materials may provide a new opportunity for designing high-efficiency thermoelectrics at room temperature.

9:00 AM *EN13.03.04/EN14.11.04
New Horizons in Thermoelectric Materials—Inorganic-Organic Hybrids and Machine Learning for Inorganic Crystals Kedar Hippalgaonkar$^{1,2}$; $^1$Nanyang Technological University, Singapore; $^2$Institute of Materials Research and Engineering, Singapore

For the next revolution in thermoelectrics, development of new physics as well as new materials needs to go hand-in-hand. In this talk, I will introduce new perspectives such as correlated electron physics, wave effects in phonons as well as opportunities for new inorganic-organic (hybrid) materials$^1$. Then, I will introduce specifically the case of CuTe:PEDOT thin films and using this as a test case, describe the design principles for creating the next generation of hybrid materials$^2$. In addition, I will describe how data-driven approaches can augment our knowledge: used in conjunction with the right material and transport descriptors, these can prove prescient in predicting new TE materials. I will end with a specific example of how we’ve used a Crystal Graph Convolutional Neural Network (CG-CNN) with training data from Materials Project to learn about TE properties. In addition, we use high-throughput, high-fidelity DFT calculations with the Electron Phonon Averaging (EPA) approximation to calculate carrier relaxation times, we propose that the transport effective mass remains an effective single descriptor that can guide inorganic TE material screening.

9:30 AM EN13.03.05/EN14.11.05
Thermoelectric Transport Descriptors in Data-Driven Thermoelectric Screening Ady Suwardi1, Deng Tianqi2, Daniil Bash1, Hong Kuan Ng1, Jose Recatala Gomez1, D V M. Repaka1, Pawan Kumar1, Anas I. Abutaha1, Michael Sullivan2, Shuo-Wang Yang2 and Kedar Hippalgaonkar1; 1IMRE, Singapore; 2Institute of High Performance Computing, Singapore

With the maturity of sophisticated, high throughput computational tools and the advent of machine learning applications in materials science, identifying the appropriate fundamental level descriptors has never been more relevant and pressing in data-driven materials discovery domain. In this work, we first present the inertial effective mass as an important descriptor in thermoelectric transport. The conclusion was obtained by analyzing data from 1617 compounds of all crystal structures mined from the materialsproject.org. Data was analyzed using polycrystalline averaging Seebeck, effective mass, as well as electrical conductivity. In addition, constant relaxation time approximation was used in all data analysis, which is known not to necessarily reflect experimentally measured compounds.

Subsequently, we present a state-of-the-art approach of using electron-phonon averaging (EPA) to obtain contribution of all possible scattering mechanisms to the relaxation time and challenge the initial assumption of constant relaxation time. More interestingly, we sought to evaluate the veracity of insights and conclusions drawn under constant relaxation time approximation from the EPA point of view and indeed confirm that effective mass is an important descriptor. Further insights gained from analysis of scattering times provide us additional insight towards prediction of new thermoelectric compounds.

9:45 AM EN13.03.06/EN14.11.06
Thickness-Dependent Thermal Conductivity of Titanium Trisulfide Nanoribbon Chao Wu1, Chenhan Liu1, Yongkang Wang1, Juekuan Yang1, Qingyu Yan2 and Yunfei Chen1; 1Southeast University, China; 2School of Materials Science and Engineering, Singapore

The two-dimensional layered materials with interlayer van der Waals (vdWs) bonding such as graphene have attracted tremendous interests in scientific community. Recently, layered materials composed of transition metal trichalcogenides with strong in-plane anisotropy, which show unusual properties based on theory, have been successfully synthesized so that their properties can be explored through experiment. For instance, due to theoretically calculated ZT value (3.1) of monolayer titanium trisulfide along y direction at moderate carrier concentration, layered titanium trisulfide nanoribbons with intralayer covalent bonding and interlayer vdWs bonding burst extensive research, which inspires us to investigate the lattice thermal conductivity of the nanoribbon and the size effects on the thermal conductivity because lowering the thermal conductivity can increase the ZT value significantly. In order to better understand the thermal transport in the titanium trisulfide nanoribbon, the theoretical calculation combined with the experiment are adopted. Through solving the phonon Boltzmann transport equation (implemented in ShengBTE package) with the first-principles second- and third-order force constant (implemented in VASP package), the thermal properties of titanium trisulfide are obtained. The calculation results reveal that the thermal conductivity monotonously decreases with the number of titanium trisulfide layers increasing from one to three and displays a strong in-plane anisotropy as the temperature range from 40 to 500 K. For example, the thermal conductivity along y direction is 2.7 times larger than x direction at room temperature. Compared to layered graphite, due to the weaker interlayer coupling strength, the out-of-plane thermal conductivity (around 1.1 W/m-K) at the room temperature is 5 times lower.

Based on the results of theoretical calculation, we synthesized the titanium trisulfide nanoribbons with different thicknesses and measured the thermal conductivity using a suspended micro-thermometry from 20 to 300 K. The experimental results show that the in-plane thermal conductivity of titanium trisulfide nanoribbons decreases monotonously as the thickness increases, which is same as the theoretical calculation. Interestingly, the thermal conductivity keeps decreasing as the thickness is smaller than 272 nm, which is quite different from multi-layer graphene. In detail, the thermal conductivity decreases rapidly as the thickness is below 60 nm and becomes slowly beyond 150 nm. Due to the computational cost, 4 layers or thicker titanium trisulfide cannot be calculated. The giant large layer thickness dependent in-plane thermal conductivity is surprising and confusing. We speculated that this phenomenon may stem from weak interlayer coupling strength and unique atomic structure, which needs further investigation.
Design and Engineering of Flexible Thermoelectric Devices  
G. Jeffrey Snyder; Northwestern University, United States

Thermoelectric semiconductors directly convert heat into electricity. These solid-state devices have been used reliably in space for over 40 years without maintenance. Temperature gradients and heat flow are omnipresent in natural and human-made settings and offer the opportunity to scavenge energy from the environment recovering waste heat from industry or replacing the need for batteries in remote sensor networks or mobile devices. Particularly attractive is the ability to generate electricity from body heat that could power medical devices or implants, personal wireless networks or other consumer devices. This talk will discuss the design principles for thermoelectric generators using a generalized electrical transport model combined with an effective thermal conductivity approach [1, 2]. Such design principles provide good estimates of the power that could be produced and the size and complexity of the thermoelectric generator that would be required. In addition these design principles can guide the search and optimization new thermoelectric materials. In organic and polymer semiconductors the optimum doping is identified and the peak \( zT \) for a given class of materials can be determined. Also, a complete system design shows the misconception that power factor rather than \( zT \) should be optimized for a TE generator. The power factor misconception also leads to misleading strategies for optimization and discovery of new TE materials. The materials requirements for flexibility, leading to a flexibility figure-of-merit will be discussed.

Hybrid materials consisting of inorganic nanostructures embedded in conducting polymer matrices have emerged as promising systems for room temperature thermoelectric applications. They are attractive due to their intrinsic low thermal conductivities, the ability to engineer interfaces for energy filtering effects and phonon scattering, and their ability to take advantage of high-throughput and solution processable manufacturing. Most polymer and hybrid materials reported in the literature have been p-type, owing to difficulties in n-type doping of conducting polymers in conjunction with the nature of the applied nanocrystals. This has resulted in a strong drive to develop new n-type materials, since both are necessary for module development. Here we explore our recent developments in the synthesis chalcogenide nanowires encapsulated in poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) that are used as templates for the synthesis of Ag2-xE (where E=Te, Se) via topotactic chemical transformation processes. This synthetic method allows us to engineer the composition of our hybrids, whereby we are able to directly influence the thermoelectric properties, including the production of both p-type and n-type materials from the same parent material. We detail the structural and morphological development of our materials with changing stoichiometry during aqueous based synthesis via X-Ray diffraction (XRD), X-Ray photoelectron spectroscopy (XPS), and transmission electron microscopy (TEM) and relate this to their thermoelectric performance. We take the example of one of our n-type Ag2Te/PEDOT:PSS hybrid materials and further manipulate its performance via post-deposition (de)doping schemes, whereby the PEDOT:PSS is reduced by treatment with Tetrakis(dimethylamino)ethylene (TDAE). This process is followed by UV-Vis spectroscopy and electron paramagnetic resonance spectroscopy (EPR) to detail how this (de)doping process affects the charge carrying species. Control of the competing charge carrier concentration allows further improvement in the n-type hybrid device performance.

11:30 AM EN13.04.04/EN14.12.04
Flexible Cellulose Fiber-Based Hierarchical Porous Bismuth Telluride for High-Performance Thermoelectrics and Energy Harvesting Device Kaiping Tai, Qun Jin and Yang Zhao; Institute of Metal Research, China

Porous modification is general approach to endowing the rigid inorganic thermoelectric (TE) materials with considerable flexibility, however, by which the TE performances are severely sacrificed. Thus, there remains a struggling against the trade-off between the TE properties and flexibility. Herein, we develop a novel strategy to combine the Bi2Te3 thick film with the ubiquitous cellulose-fiber (CF) print-paper via unbalanced magnetron sputtering technique (ACS Appl. Mater. Interfaces 10, 1743, 2018). The Bi2Te3/CF TE composites with tailorable shapes and dimensions were successfully obtained by our approach, which have reasonable internal resistance as components of TE devices with in-plane configurations. Owing to the hierarchical nano-micro porous microstructures and the excellent fraction resistance of the Bi2Te3/CFs constructions, the prepared TE composites with Bi2Te3 nominal deposition thickness of tens of micrometers exhibit mechanically reliable flexibility, of which the bending deformation radius could be as small as a few millimeters. Meanwhile, the thermal conductivity was remarkably reduced, due to the phonon-nanopore scattering effects. Enhanced Seebeck coefficients were observed comparing with the dense films and the power factors of ~250 to 400 μW/mK2 were obtained for the composites from room temperature (RT) to 473 K, which can be further improved by optimizing the carrier concentrations. As a result, the TE figure of merit, ZT, is as high as ~0.38 at 473K. Moreover, Fig. 1 depicts the photograph, structure, and working principle diagram of the flexible TE device consisting of 12 pairs of p- and n-type legs integrated on the double sides of CF paper sheet employing a laser beam micro-cutting system, which displays great potential as flexible TE device for thermal energy harvesting. When the light bulb works for about a few minutes, the temperature of the central side rises quickly, the temperature difference between the center and periphery is about 50 K from the infrared image, and the TE device generates an output voltage of 0.144 V. This kind of flexible TE device can realize the collection and recovery of heat energy in daily life to power flexible electronics, such as wearable devices and environmental monitors, which also promotes the development of paper-based and thin-film electronics.

11:45 AM EN13.04.05/EN14.12.05
Creep Behavior of Thermoelectric Materials Muath M. Al-Malki1,2, Qinyi Qiu3, Tiejun Zhu3, G. Jeffrey Snyder1 and David Dunand1; 1Northwestern University, United States; 2King Fahd University of Petroleum and Minerals, Saudi Arabia; 3Zhejiang University, China

Since the 1960’s, NASA has implemented Radioisotope Thermoelectric Generators (RTGs) to supply energy for
many of its satellites and space probes. Similar generators for industrial and automotive waste heat recovery have been proposed and many new thermoelectric generator materials have been investigated. Nonetheless, mechanical integrity for the full operational life of the thermoelectric modules, which can extend to decades, has not been given much consideration in such applications. Among many contributors, clamping forces, vibrational stresses, and thermally-induced mismatch stresses may combine to give stress levels high enough to deform the thermoelectric module by creep, thus diminishing its useful lifetime. To date, few thermoelectric materials have been tested for creep, including Bi$_2$Te$_3$, PbTe, Mg$_{1.96}$Al$_{0.04}$Si$_{0.97}$Bi$_{0.03}$, and TAGS-85.

In the present talk, we show the case of the compressive creep deformation behavior of two thermoelectric materials; half-Heusler n-type Hf$_{0.3}$Zr$_{0.7}$NiSn$_{0.98}$Sb$_{0.02}$ and n-type skutterudite (Yb-CoSb$_3$) alloys, at 500-705 °C. When subjected to uniaxial compressive stresses at 600°C, the n-type half-Heusler alloy Hf$_{0.3}$Zr$_{0.7}$NiSn$_{0.98}$Sb$_{0.02}$ exhibits Newtonian flow, consistent with diffusional creep of its fine-grain (1-7 μm) microstructure achieved via spark-plasma sintering of powders. In addition to its promising thermoelectric performance at high temperatures, this alloy sustains very high compressive stresses at 600°C (from 21 to 359 MPa, for ~ 23 days) without macroscopic failure. However, the brittle nature of the alloy leads to the formation of numerous cracks at such high stresses, which in turn deteriorate the thermoelectric performance. A more realistic creep stress range (15-46 MPa, for ~ 4 days) preserves the high thermoelectric figure of merit $zT$. Among thermoelectric materials mechanically creep-tested to date, the ZrNiSn-based Half Heusler alloy has the highest creep resistance. On the other side, the n-type skutterudite (Yb-CoSb$_3$) alloy showed acceptable creep resistance under protected environment.

Given their high melting temperature, stiffness, and creep resistance, half-Heusler alloys appear uniquely suited for long-term thermoelectric applications where high stresses and temperatures are present.

Advanced Materials and Their Infusion into Efficient Thermoelectric Power Generation Systems Jean-Pierre Fleurial and Sabah Bux; California Institute of Technology, United States

Thermoelectric power sources have consistently demonstrated their extraordinary reliability and longevity for deep space missions as well as terrestrial applications where unattended operation in remote locations is required. The discovery of new, more efficient materials, and the development of practical, robust elements and device technologies are the key to improving existing space power system performance and versatility and expanding the use of thermoelectrics into efficient, cost-effective terrestrial applications using medium to high grade heat sources. We present an overview of NASA-funded collaborative research efforts to identify advanced bulk thermoelectric materials, capable of quadrupling current state-of-practice average ZT values over the available operating temperature range of 1275 K to 475 K, through the exploration of structurally complex compounds allowing for a wide range of chemical tuning and the possibility of forming stable nano- and micro-scale composites. Materials- and device-level experimental performance validation accomplished to date, technical challenges, progress and plans for technology infusion into future thermoelectric power systems are discussed.

2:00 PM EN13.05.02/EN14.13.02
Understanding Thermoelectric Devices at the Micro Scale Nicolas Perez, David A. Lara Ramos, Vida Barati, Javier Garcia, Heiko Reith, Guodong Li, Gabi Schierning and Kornelius Nielsch; IFW Dresden, Germany

Energy harvesting and thermal management are required for applications in the internet-of-things, autarkic sensors, or highly integrated electronic devices. Thermoelectric generators and coolers are promising technologies for localized energy harvesting and thermal management. These devices are currently well optimized for near-room temperature operation at the macroscopic scale. However, the high integration density of today’s most significant applications requires an increasing degree of miniaturization. Using finite element calculations, we gained insight on
the design guidelines for micro thermoelectric devices with realistic material properties, and with concurring size and geometry constraints [1]. Understanding the interplay between thermal and electrical heat fluxes at the micro scale allowed our group to fabricate micro thermoelectric devices for thermal management, efficient enough that can be integrated in electronic packages [2]. Our relevant findings about the design of micro thermoelectric devices will be presented.

2:15 PM EN13.05.03/EN14.13.03
Dual Sensors of Fluid Temperature and Dynamics Based on Engineering Design Using Thermoelectric Effect
Seo Byungseok, Hayoung Hwang, Sunggu Kang, Youngsun Cha and Wonjoon Choi; Korea University, Korea (the Republic of)

The detection of temperature and dynamics of working fluids, including water, is important for experimental and industrial applications, such as detection of precise changes in fluid environment, monitoring of drainage or cooling water at factory facilities, micro / nano flow analysis. However, due to the spatial limitations or complex geometry of fluid channel interfaces, it is important to accurately detect multiple parameters that are optimally integrated into the operating platform. Also, many fluid sensors necessarily disrupt the natural flow within the platform, and even though the installation of the sensing device should not affect the intrinsic properties of the target element in fluid applications. In this work, we develop a flexible, attachable dual-output sensor for fluid temperature and transfer dynamics based on structural design of thermoelectric materials (SDTM). The SDTM flexible substrates using PET was developed to detect real-time changes in temperature and peak voltage reflecting fluid dynamics. Simple sputtering deposition of Bi2Te3 through a patterning mask has allowed the fabrication of dual-power sensors which do not affect the fluid flow shape. When the working fluid contacts the surface, thermoelectric structure pattern induces continuous double thermal wave and time interval without disturbing the natural flow of working fluid. The raw voltage signal induced by thermal gradient wave provides the magnitude of the first peak voltage and the duration between the two peaks, which show the real time temperature and the moving velocity of the working fluid. Furthermore, as a demonstration of an expandable platform using SDTM, a scalable sensor array comprising multiple SDTMs was fabricated as a large-area device for sensing a fluid temperature flow dynamic sensing device. Its performance with respect to sensing the fluctuation of working fluid temperature and kinematics was verified using a 4 × 4 SDTM array. As a result, the new methodology using SDTM can contribute to the development of entirely new technologies for next-generation sensors that require advanced features such as multi-element detection and a variety of integrated flexible and removable features.

Thermoelectric Cooling Using a New p-Type Material Zhifeng Ren; University of Houston, United States

Bi2Te3-based p-type Bi0.5Sb1.5Te3 and n-type Bi2Te2.7Se3 have been the only materials used for thermoelectric cooling for decades. Even though the progress on advancing the thermoelectric figure-of-merit (ZT) has been significant especially the materials with peak ZT at high temperatures, materials with high enough ZT around room temperature are very rare. Up to now, in addition to Bi2Te3-based ones, the only reported is p-type MgAgSb with ZT of ~0.8 at room temperature. There is no report on any n-type material exhibiting ZT similar to that of the n-type Bi2Te2.7Se3. In this talk, I will present a new n-type material that has a ZT of ~0.7 at room temperature, which is comparable to that of n-type Bi2Te2.7Se3. The cooling performance of a unicouple consisting of the new n-type material and the p-type Bi0.5Sb1.5Te3 is also in par with the commercial legs consisting of the p-type Bi0.5Sb1.5Te3 and

Modeling the Temperature Dependent Seebeck Coefficient of Metastable Amorphous Ge$_2$Sb$_2$Te$_5$ and Impacts of Thermoelectric Effects on the Operation of Phase Change Memory Devices
Jake Scoggin, Noah Del Coro, Md Tashfiq Bin Kashem, Sadid Muneer, Helena Silva and Ali Gokirmak; University of Connecticut, United States

Thermoelectric effects play a significant role in phase change memory (PCM) and Ovonic threshold switch (OTS) devices used as access devices in PCM cells [1]. Typical PCM cells are two-terminal nanometer-scale resistive memory devices which can be reversibly switched between a low-resistance crystalline and a high-resistance amorphous state via nanosecond electrical pulses. Amorphization in PCM devices is achieved by self-heating the phase change material, typically a chalcogenide, close to its melting temperature, followed by a sudden quench. Crystallization is achieved by self-heating the phase change material above its glass-transition temperature. OTS devices typically use amorphous chalcogenides that do not crystallize during normal device operation.

The local current densities in PCM and OTS devices can reach 10$^8$ A/cm$^2$, giving rise to local temperatures in excess of 900 K and thermal gradients as high as 50 K/nm; hence, Peltier effects at material interfaces and Thomson heating within the active area are substantial. Accurate modeling of thermoelectric effects requires knowledge of temperature dependent electrical resistivity and Seebeck coefficients of these materials. These parameters can be measured at low temperatures on as-deposited amorphous films [2]. However, melt-quenched amorphous materials’ parameters tend to differ from as-deposited films, and PCM materials rapidly crystallize at higher temperatures. High-speed metastable electrical resistivity measurements can be performed on nanoscale devices using electrical pulses to uniformly amorphize devices up to approximately 200 nm in diameter [3], but larger devices tend to form current filaments and hence do not amorphize uniformly. On the other hand, measurement of the Seebeck coefficient ($S_e$), which is vital to understanding thermoelectric effects, is very difficult at small scales.

In this work, we model the Seebeck coefficient for metastable amorphous Ge$_2$Sb$_2$Te$_5$ (aGST) based on high-speed experimental results [3] and an energy band diagram proposed by Muneer et al. [4] from 300-850 K [3], [5], and we analyze thermoelectric effects in PCM cells using finite element phase change device simulations [6]–[9]. We calculate the electron and hole Seebeck contributions $S_e$ and $S_h$ in metastable aGST with the band diagram in [4] and find that $S_h$ is similar in both magnitude and slope to $S$ measurements on as-deposited aGST thin films in 300-400 K range [5], [10], consistent with the unipolar conduction assumed when deriving the band gap in [4]. We use $S_h$ as the Seebeck coefficient in metastable aGST and simulate reset and set operations in a PCM double mushroom cell and find that the Seebeck differential between crystalline and amorphous GST results in significant heating/cooling at amorphous-crystalline junctions during both crystallization (set) and melting (reset).

Flexible Thermoelectric Materials by Organic Intercalation of Two-Dimensional Layered Compounds
Chunlei Wan1, Kunihito Koumoto2 and Kun Zhang; 1Tsinghua University, China; 2Nagoya Industrial Science Research Institute, Japan

Flexible materials with high thermoelectric performance have attracted growing interest recently. By intercalating organic molecules into the van der Waals gap of varieties of inorganic two dimensional layered compounds, we
developed a large family of thermoelectric materials with excellent mechanical flexibility. The inorganic and organic monolayers are alternatively stacked to form an inorganic/organic superlattice, in which the high electronic transport properties of the inorganic component has been maintained and the thermal conductivity was dramatically suppressed by the organic components, finally resulting in boosted ZT value. We have demonstrated this idea in several two dimensional host materials, including TiS$_2$, Bi$_2$Se$_3$ and TaS$_2$, etc. The abundant choice of the organic molecules also brings new opportunities to optimize the thermoelectric performance, such as the dielectric screening effect and the quantum confinement effect. We finally developed a solution-processed strategy to fabricate large area flexible thermoelectric foil based on this inorganic/organic superlattice, which enables easy integration into energy-harvesting electronic devices.

4:45 PM EN13.06.04/EN14.14.04
Diffusion Behaviors of Bonding Interface of Bi–Te Based Thermoelectric Materials with Ni/Au Barrier Fabricated by Different Deposition Processes Ekubaru Yusufu$^{1}$, Tohru Sugahara$^{1}$, Michio Okajima$^{2}$, Shutaro Nambu$^{2}$ and Katsuaki Suganuma$^{1}$; $^{1}$The Institute of Scientific and Industrial Research, Osaka University, Japan; $^{2}$E-ThermoGentek Co., Ltd., Japan

Recently, our group developed a Bi–Te-based TEG device by using conventional semiconductor packaging technology. In that device, Ni/Au was used as the diffusion barrier, and Sn–Ag-based solder was used as the bonding material. Although Bi–Te-based TE materials can be used up to approximately 300°C, the maximum operating temperature of the device was limited to approximately 150°C owing to the low melting point of the Sn–Ag-based solder (~150°C) that bonds Bi–Te-based TE materials and Cu electrodes. Therefore, in order to apply higher temperature differences to the device, in this study, we attempted to develop a bonding interface resistant to heat up to 250°C. Ni/Au was retained as the diffusion barrier layer, but Ag paste was chosen as the bonding material, instead of the Sn–Ag-based solder, because it has many advantages such as high-temperature stability (melting point ~ 960°C), printability, low electrical resistivity, high thermal conductivity (150 Wm$^{-1}$K$^{-1}$), and a temperature requirement of less than 300°C for sintering-bonding. The Ni/Au diffusion barrier layer was prepared using two different deposition processes, sputtering and electroplating, and the element diffusion behaviors of these two bonding interfaces at 250°C were investigated.

In the bonded sample with sputtered Ni/Au, the Cu electrode diffused violently into the chip and formed a Cu–Te-rich phase. On the other hand, in the bonded sample with electroplated Ni/Au, the diffusion of Cu was blocked, but a NiTe phase formed on the chip side. The above results demonstrate that, with sputtered Ni/Au, grain-boundary diffusion is predominant and Cu electrodes diffused along the grain boundaries, while with electroplated Ni/Au, self-diffusion is predominant because of the instability of the monocristalline–amorphous phase. These results suggest that the highly crystalline Ni layer, which has dense grain boundaries and no pores, is a highly effective diffusion barrier.
to simultaneously increase Seebeck coefficients and electrical conductivities. The combined effect on electronic and structural properties is proven with the help of spectroscopy and x-ray scattering experiments.

8:30 AM EN13.07.02
**Fabrication of PEDOT:PSS/GST Hybrid Composites for High Thermoelectric Performance** Jae-Hong Lim¹, Young Soo Yoon¹, Kyu Hyoung Lee² and Woon-Ik Park³; ¹Gachon University, Korea (the Republic of); ²Yonsei University, Korea (the Republic of); ³Korea Institute of Ceramic Engineering & Technology, Korea (the Republic of)

The thermoelectric performance of organic/inorganic hybrid composites is strongly governed by interfacial interactions where the energetic mismatches provide effective charge carrier scattering for high Seebeck coefficient. In addition, the conformation of polymer chain at the interfaces could engineer electronic structure for a favorable hopping mechanism. Herein, we report on the template-assisted fabrication of PEDOT:PSS/Ge₂Sb₂Te₅ (GST) nanowires hybrid composites for improvement in electrical conductivity and Seebeck coefficient. The GST nanowires array fabricated by a solvent-assisted nanotransfer printing technique was participated as a template to align the PEDOT:PSS. Significantly enhanced thermoelectric performance of PEDOT:PSS/GST nanowires hybrid composites compared to their individual counterparts is because of energy filtering effect at the GST nanowire/PEDOT:PSS interfaces.

The alignment effect of PEDOT:PSS chains on the electrical conductivity was elucidated by measurement in parallel and perpendicular to the GST nanowires. The best power factor of 1560 µWm⁻¹K⁻² was achieved in parallel-direction owing to not only the high Seebeck coefficient but also the conformationally ordered PEDOT:PSS interfacial layer at the GST nanowires template.

8:45 AM *EN13.07.03
**From 2D Roll-to-Roll Printing to 3D Low-Cost Thermoelectric Generators** Ulrich Lemmer; Karlsruhe Institute of Technology (KIT), Germany

Thermoelectric generators (TEGs) transform heat to electricity without any movable parts. These devices will play an important role in energy harvesting for wearables, autonomous sensor nodes, and the Internet-of-Things (IoT). Conjugated polymers as well as printable inorganic nanomaterials offer the unique advantage of being processable on printing machines. They have recently made strong progress in their thermoelectric properties. This opens a pathway for the fabrication of powerful thermoelectric generators with unprecedented low costs for mass applications. We have developed novel printable PEDOT formulations and novel printable inorganic materials for a device layout which allows for a roll-to-roll printing process on ultrathin plastic foils. The TEGs are then subsequently fabricated by an automated folding process which allows to adapt the geometry of the devices such that the desired thermal resistance is matched to the specific thermal boundary condition. Using this approach in combination with designed low power electronics forms the basis for several wireless sensor nodes. The talk will cover our recent developments on printable organic and inorganic nanomaterials.

**Enhanced Performance of Thermoelectric P-Type Composite Films Using Naturally Occurring Chitosan Binder and Mechanical Pressure** Deepa Madan, Eunhwa Jang and Priyanshu Banerjee; University of Maryland, United States

Printable thermoelectric generators (TEGs) are attractive to researchers because of their potentially higher power density, scalability and lower cost than rigid conventional TEGs. This additive manufacturing of TEGs requires active thermoelectric (TE) particles to be dispersed in a polymeric binder to synthesize printable slurry inks, and printed films to be subsequently subjected to a long and high temperature curing for grain coalescence and enhancing electrical conductivity. A large quantity of polymeric binder in composite TE films results in a sizable loss of the electrical conductivity and TE performance. Moreover, an energy intensive long and high-temperature curing process is another challenge for printable TEGs.

We report a novel approach eliminating the long and high temperature curing requirements for the printable thermoelectric generators but attain enhanced electrical conductivity. This work presents the feasibility of using a small amount of naturally occurring chitosan as a binder for p-type thermoelectric composite films. Less than 10⁻³ weight ratio of chitosan was sufficient to hold the thermoelectric particles together in the form of composite films. Samples of various weight ratios such as 1:2000, 1:5000, and 1:7000 between binder and TE materials were
prepared and tested. Various particle sizes of the TE materials were also explored to observe their effect on electrical conductivity. These various samples were drop casted and cured at relatively lower temperature (150°C) for shorter time (5 minutes). These cured films were further subjected to uniaxial pressure for densification of the films by reduction of pores, voids and also merge of small particles between big particles to give bulk like structure. Analysis of the obtained samples indicated that a wide range sizes of particles with chitosan binder in composite films under the application of mechanical pressure lead to plate structure which resulted in improved electrical conductivity of the composite films.

The highest power factor achieved for best performing p-type Sb$_2$Te$_3$ composite films is 1236±110 µW/mK$^2$, and the figure of merit (ZT) is 1.236 at room temperature (300K). The highest ZT obtained for p-type Bi$_{0.5}$Sb$_{1.5}$Te$_3$ film is 0.838 at room temperature.

**9:30 AM EN13.07.05**

Vapor-Printed Polymers for Wearable Thermoelectric Generators Linden K. Allison and Trisha L. Andrew; University of Massachusetts at Amherst, United States

Wearable thermoelectric generators are a promising energy source for powering activity trackers and portable health monitors. However, known iterations of wearable generators have large form factors, contain expensive or toxic materials with low elemental abundance, and quickly reach thermal equilibrium with a human body, meaning that thermoelectric power can only be generated over a short period of wear. Here, we create an all-fabric thermopile by vapor printing persistently p-doped poly(3,4-ethylenedioxythiophene) (PEDOT-Cl) onto commercial cotton and integrate this thermopile into a specially-designed, wearable band that generates thermovoltages >20 mV when worn on the hand. We show that the reactive vapor coating process creates mechanically-rugged fabric thermopiles that yield notably-high thermoelectric power factors at low temperature differentials, as compared to solution-processed counterparts. Further we describe best practices for naturally integrating thermopiles into garments, which allow for significant temperature gradients to be maintained across the thermopile despite continuous wear.

Reliability of Flexible Thermoelectric Devices under Cyclic Loading Seungwoo Han$^{1,2}$;  
$^1$Korea Institute of Machinery and Materials, Korea (the Republic of);  
$^2$University of Science and Technology, Korea (the Republic of)

As the demand of wearable devices increases, flexible thermoelectric devices are attracting attention as alternative power sources of them. Because wearable devices are worn on the human body, it is possible to create electricity using thermoelectric devices from body heat without the need for other heat sources. In addition, flexible thermoelectric devices have been studied due to their potential for using arbitrary heat source shapes without an additional heat exchanger.

The biggest issue to make a flexible thermoelectric device is that the thermoelectric device has flexibility so that it can maintain its performance even when bent during use. Unlike conventional thermoelectric devices, materials, fabrication processes, and device design have to be changed in order to impart flexibility to thermoelectric devices. Existing rigid ceramic substrates cannot be used. The use of bulk thermoelectric materials limits the flexibility of thermoelectric devices. The joint between the electrodes and the thermoelectric legs in a thermoelectric device reduces its flexibility. If necessary, the structure of the thermoelectric device may need to be changed.

Flexible thermoelectric devices are subjected to cyclic loading during continuous use. The repetitive load generates cracks inside the thermoelectric device, thereby increasing the internal resistance of the device and eventually causing failure of the thermoelectric device. Therefore, in order to develop and commercialize a flexible thermoelectric device, it is essential to establish a method of evaluating the reliability of the thermoelectric devices under cyclic loading.
In this study, the current state of flexible thermoelectric devices research is reviewed in terms of materials, devices and applications. A method for evaluating the reliability of a flexible thermoelectric device is presented.

10:45 AM EN13.08.02
Enhanced Energy Conversion Performance of Compliant Thermoelectric Generators via Intrinsically Stretchable Heat Collectors and Conformal Contacts Hyeon Cho1,2, Byeongmoon Lee2, Kyung Tae Park1, Heesuk Kim1, Seunjun Chung1 and Yongtaek Hong2; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

Emerging energy generators has expanded the potential of electronics in the way that they can operate wireless-interconnected Internet of Things (IoT) devices without the assistance of additional power sources or batteries. Among promising candidates, thermoelectric generators (TEGs) have offered attractive opportunities for realizing self-powered electronics due to their energy conversion ability from waste heat to electricity. For the realization of high-performance TEGs, the maximized temperature difference across the thermoelectric (TE) layers is the most important factor in given temperature boundaries and TE material properties, therefore, efficient heat collection and heat transferring to TE materials is necessary to achieve high energy conversion efficiency. In this context, the demands for compliant TEGs which can collect thermal energy from arbitrary-shaped heat sources minimizing parasitic heat loss have increased, which is not allowed to conventional rigid TEGs. In this regard, there have been many efforts to integrate high-performance cuboid-shape inorganic Bi2Te3 –based TE rods into soft platforms. As a representative approach to realize rod-based compliant TEGs, the infiltration of soft medium and flexible interconnection have been introduced to provide acceptable mechanical tolerance despite brittle and rigid nature of the inorganic alloys. However, unexpected lower TE performances and imperfect conformal contacts have been reported due to parasitic heat loss in hundreds μm-thick polymer substrates and metal contacts, respectively. Therefore, optimized module designs with the minimization of parasitic heat loss and fully soft interconnections have to be developed toward highly efficient compliant TEGs. In this presentation, we will report a new strategy to improve heat collection from arbitrary shaped-heat sources via the soft heat collector embedded in ultra-thin polymer supporting layers. The selectively patterned and aligned thermally conductive soft composites are lined up with Bi2Te3 bulk legs; thus the significantly improved heat transfer ability can be delivered toward in the out-of-plane direction with the minimization of parasitic thermal energy loss, allowing conformal thermal contacts simultaneously. These results indicate that the heat transfer ability of soft heat collectors is much superior to that of the previously used compliant substrates, such as PDMS, pure and engineered Ecoflex, even comparable with that of thermo-pads. In addition, the embedded soft interconnection and infiltrated PDMS offer the opportunity to realize further compliant TEGs. The excellent adhesion property between the Bi2Te3 legs and soft interconnection via the optimized highly conductive epoxy layer also improves the mechanical reliability preventing delamination issues. Finally, we will show, for the first time, facilely customized large-are TEGs with high yields fabricated by fully automatic additive manufacturing.

11:00 AM EN13.08.03
Electrical Properties of Conducting Polymers for Enhancing the Performance of Organic Thermoelectric Devices and Modules Jeonghun Kwak1, Sung Hyun Kim2 and Han Young Woo3; 1Seoul National University, Korea (the Republic of); 2Wonkwang University, Korea (the Republic of); 3Korea University, Korea (the Republic of)

Organic thermoelectric (TE) devices have attract attention as a low thermal energy-harvesting device. Organic materials can be synthesized and processed by tuning the electronic structures and molecular ordering in a solid state. They can be also fabricated with solution-based deposition techniques, such as inkjet printing, spray printing, and spin-coating. These properties are highly related to their electrical properties which are important for practical implementation of organic TE devices and modules. In this presentation, we will present the advances on improving the electrical properties of various p-type polymers, i.e., >70 S/cm for polypyroles and ~4000 S/cm for poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PPS), by tailoring the molecular ordering and by changing the carrier concentration via acid-based doping. The Seebeck coefficients and power factors were also measured and optimized along with the modification. The film properties were systematically investigated to reveal the origin of the enhancement. Also, we will briefly discuss on the performance of TE modules.

11:15 AM EN13.08.04
Design and Manufacturing Textile Shaped Thermoelectric Generators Kun Zhang and Yuanyuan Zheng; Donghua University, China
In this work, we report the design and manufacturing of textile shaped thermoelectric generators (T-TEGs). Carbon nanotube yarns were selected as the base materials to create segmentally-impregnated yarns with p-type materials (PEDOT: PSS) and n-type (PEI), which was assembled into a spacer fabric by an industrial knitting machine. The effect of n-type PEI doping and fabric structure on the thermoelectric performance of T-TEGs will be carefully investigated. Moreover, the potential application of the T-TEG will be demonstrated.

11:30 AM *EN13.08.05
Mobility and Structure Preservation in Conductive Doped Thermoelectric Polymers Howard E. Katz; Johns Hopkins University, United States

The mechanical flexibility, low temperature processing, potential printability, capability of blending to form composites, and use of common elements are attractive features for the use of polymers in thermoelectrics. This presentation focuses on polymers blended with dopants and polymer additives to tune the charge carrier density and Fermi energy-transport energy difference while maintaining charge carrier mobility. Two thiophene polymers, poly(bisdodecylquaterthiophene) and poly(bisdodecyl thioquaterthiophene) (PQT12 and PQTS12, respectively), were used initially. Cyclic voltammetry and current-voltage measurements indicated that the introduction of sulfurs into the side chains induces traps in films containing PQTS12. Doping the polymer with sulfur in side chains (PQTS12) with the strong oxidant nitrosonium tetrafluoroborate (NOBF4), we obtained an especially high conductivity up to 350 S cm\(^{-1}\). Furthermore, the high conductivity is stable in air without extrinsic ion contributions. The thermoelectric power factor compared favorably with prior reports for p-type polymers that were made by the alternative process of immersion of polymer films into dopant solutions, and fit the established models and newly performed simulations for thermoelectric polymers. Additional data obtained from thiophene copolymers containing the ethylenedioxiithiophene and thieno[3,2-b]thiophene subunits supported these conclusions. Blend microstructure, assessed using grazing incidence X-ray scattering, and mobility evaluated in field-effect transistors, was not adversely affected by the blending. This structural preservation is a key aspect of designing additional polymer compositions with high power factor, including n-type polymers. The value of using such polymers as matrices of composites with inorganic thermoelectric particles will be considered.

SESSION EN13.09: CNT/Graphene based Composites for Thermoelectrics

1:30 PM *EN13.09.01
Flexible Thermoelectric Generators Using Organic Materials by Printing Process Song Yun Cho; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Thermoelectric (TE) energy conversion is an attractive and environmentally friendly way to recover energy from industrial waste heat or natural heat because of its potential for improving the energy efficiency. As TE materials, organic materials have unique advantages, such as cost effectiveness, low intrinsic thermal conductivity, high flexibility, and amenability to large area applications. With increasing attention on flexible or wearable power-conversion devices, intensive research efforts have been devoted to flexible organic TE modules to replace the brittle inorganic ones. First, a highly integrated and flexible TE module with a novel device architecture based on a carbon nanotube (CNT) web is proposed. The pristine CNT web shows superior electrical conductivity of 998.3 S cm\(^{-1}\), owing to the increased longitudinal carrier mobility derived from the highly aligned structure. To realize optimal TE property, the pristine CNT web is alternately doped with p- and n-type carriers using FeCl\(_3\) and benzyl viologen, respectively, via a brush-casting method. Brush-casting is the simple doping process that enables large-scale and continuous fabrication of flexible TE modules by allowing precise doping of the localized area without a shadow mask. Flexible TE modules were then fabricated by repeated brushing and folding of the CNT webs. Owing to the synergic effect of the highly integrated high-performance TE material (highly aligned CNT web) and the facile doping process
(brush-casting), flexible TE modules consisting of 120 \textit{p-n} couples over an area of 8 cm\(^2\) show a maximum power output of 5.3 μW for a temperature difference of 11.7 K.

Second, a rapid solvent evaporation method based on the triple point of a processing solvent to prepare CNT foam with a porous structure for TE power generators is presented. The rapid solvent evaporation process allows the preparation of CNT foam with various sizes and shapes. Furthermore, the density and porosity of the CNT foam are precisely and easily controlled by manipulating the initial CNT/solvent ratio. The obtained highly porous CNT foam with porosity exceeding 90\% exhibits a low thermal conductivity of 0.17 W m\(^{-1}\) K\(^{-1}\) with increased phonon scattering, which is 100 times lower than that of a CNT film with a densely packed network. The aforementioned structural and thermal properties of the CNT foam are advantageous to develop a sufficient temperature gradient between the hot and cold parts to enhance TE output characteristics. To improve the electrical conductivity and Seebeck coefficient further, \textit{p-} and \textit{n-} molecular dopants are easily introduced into the CNT foam, and the optimized condition is investigated based on the TE properties. Finally, optimized \textit{p-} and \textit{n-} doped CNT foams are used to fabricate a vertical and flexible TE power generator with a combination of series and parallel mixed circuits. The maximum output power and output power per weight of the TE generator reach 1.5 μW and 82 μW g\(^{-1}\), respectively, at a temperature difference of 13.9 K.

2:00 PM EN13.09.02
Simultaneous Enhancement of Electrical Conductivity and Seebeck Coefficient in SWNT/PEDOT:PSS Thermoelectric Nanocomposites Siqi Liu\(^1\), Hui Li\(^1\) and Chaobin He\(^{1,2}\); \(^1\)National University of Singapore, Singapore; \(^2\)Institute of Materials Research and Engineering, A*STAR (Agency for Science, Technology and Research), Singapore

High electrical conductivity and high Seebeck coefficient are the two important prerequisites for achieving high power factor in organic thermoelectric (TE) materials. However, these two properties are quite often in conflict. In this work, we demonstrate that incorporating CNT in a conducting polymer PEDOT:PSS could facilitate the formation of stable and effective conductive channels, which provides an effective approach to optimize the TE parameters with simultaneously enhanced electrical conductivity and Seebeck coefficient against the initial organic TE materials. With further tailoring charge concentration of the SWNT/PEDOT:PSS composite by base treatment, the TE performance could be improved. Nanocomposite of 60 wt\% SWNT and PEDOT:PSS exhibits high TE power factor of \(\sim 526 \text{ μW m}^{-1}\text{ K}^{-2}\) with Seebeck coefficient of 55.6 μV K\(^{-1}\) and electrical conductivity of 1701 S cm\(^{-1}\), which is by far one of the highest power factors among the reported organic TE nanocomposites. The enhancement in both Seebeck coefficient and electrical conductivity could be attributed to the carrier concentration optimization as CNT conductive networks retains the ability for charge transfer, which is revealed by Raman, XPS, UV-Vis and Hall effect measurements. Considering thermal conductivity around 0.4–0.6 W/m K, the highest estimated ZT value of our TE nanocomposite can approach 0.39, demonstrating the feasibility of this strategy to enhance TE performance of organic composite materials.

2:15 PM EN13.09.03
Junction Tunneling-Dominated Thermoelectric Transport in Carbon Nanotube Networks Je-Hyeong Bahk\(^1\), Radhika Prabhakar\(^1\) and Md Sharafat Hossain\(^2\); \(^1\)University of Cincinnati, United States; \(^2\)The University of Melbourne, Australia

As emerging flexible thermoelectric (TE) materials, polymer composites with embedded carbon nanotube (CNT) networks have shown promising properties such as high electrical conductivity through CNT networks, low thermal conductivity by polymer matrix, and high mechanical flexibility provided by both components. However, the thermoelectric transport in CNT networks has not been fully understood to achieve their optimal performance in thermoelectric energy conversion. In this talk, we present a combined experimental and theoretical study on carbon nanotube networks embedded in polydimethylsiloxane (PDMS) elastomers. PDMS offers excellent CNT dispersion within its large thickness (> 1 mm) and volume, along with many other advantages such as low-cost, light-weight, bio-compatibility, and high flexibility, thus making it suited for wearable TE application. Since PDMS is electrically insulating, carrier transport occurs only through the CNT networks, which makes the composites an excellent material system for studying carrier transport in CNT networks with no parasitic transport paths. We synthesize and characterize CNT:PDMS composites over a wide range of CNT content, and analyze the thermoelectric properties using Landauer theory. We find that the simultaneous increase in Seebeck coefficient and electrical conductivity with increasing CNT content up to \(\sim 40\%\) CNTs can be attributed to the tunneling transport at CNT junctions with the junction distance decreasing with increasing CNT content. Beyond \(40\%\) CNTs, both properties are reduced and
saturated due to the reduced PDMS content and increased material non-uniformity, which effectively replaced the PDMS gap with an air gap at the junction, thus imposing a higher potential barrier to reduce the properties. We find that a figure of merit $\zeta T$ greater than 10 at room temperature is possible by doping optimization with appropriate junction parameters in semiconducting single-walled CNT networks. Our results and analysis provide important insights into material optimization for hybrid thermoelectric composites based on CNT networks and many other nanoscale fillers.

2:30 PM EN13.09.04
Non-Oxidized Graphene Flakes for High Power Factor Flexible Thermoelectric Films Travis G. Novak, Jin Kim, Jungmo Kim, Anand P. Tiwari and Seokwoo Jeon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Research into flexible thermoelectric materials has greatly expanded in recent years as interest in waste heat recovery and wearable electronics has increased. 2D graphene is a potentially high-performance, stable material for thermoelectric applications, but its practicality is somewhat limited by traditional synthesis routes. For graphene produced through oxidative top-down methods, such as Hummer’s Method, numerous defects and oxygenous groups remain in the basal plane of the flakes. These oxygenous groups not only adversely affect electrical conductivity, but also create uncontrollable doping in the graphene flakes because certain oxygenous groups p-dope graphene while others n-dope graphene. This leads to a low overall Seebeck coefficient (typically <20 $\mu$V/K) and reduces the effectiveness of any post-synthesis doping strategies. As an alternative, we introduce a synthesis route of non-oxidized graphene flakes (NOGF) through an intercalation method and demonstrate their superior properties as a thermoelectric material. These non-oxidized graphene flakes (NOGF) show an extremely low defect ratio ($I_d/I_g < 0.1$) and minimal oxidative damage, along with a high aspect ratio. By changing the adsorbed surfactant during graphene synthesis, both n and p type graphene can be synthesized. The n-type NOGF showed electrical conductivity, Seebeck coefficient, and power factor of 3300 S/cm, -45 $\mu$V/K, and 670 $\mu$W/mK², respectively, demonstrating performance that is vastly superior to oxidized graphene flakes in thermoelectric applications. In addition, preliminary results for p-type NOGF revealed values of 650 S/cm, 52 $\mu$V/K, and 180 $\mu$W/mK², which may improve with future optimization. The films were also stable under bending conditions (<3% resistance change after 1000 bending cycles at a bending radius of 3 mm), and a full thermoelectric device based on n-type and p-type NOGF generated stable power output over a wide temperature range (RT to 300 °C). These results demonstrate the potential of NOGF for highly robust, flexible, and high-performance thermoelectric devices.

Doping Semiconducting Polymers for Thermoelectrics Michael L. Chabinyc; University of California, Santa Barbara, United States

The thermoelectric properties of materials are strongly dependent on their carrier concentration. The effects of electrical doping of semiconducting polymers are complex due to the interplay between transport properties and microstructure. We will discuss our recent work in understanding the mechanisms of electrical doping of semiconducting polymers and the impact of processing on electrical properties. The thermopower of doped polymers depends on changes in the electronic density of states (DOS) upon doping. We have used electrochemical transistors to control the carrier concentration in semiconducting polymers to study their thermoelectric properties. In-situ X-ray scattering revealed the changes in microstructure of poly(3-hexylthiophene) during gating. In P3HT, and other polymers, a sharp change in the structure of crystalline domains occurs at high carrier concentration. Our results show that chemical doping leads to a broadening of the DOS making it more difficult to predict electronic properties as a function of carrier concentration. Recent models to explain the connection between electrical
conductivity and thermopower in disordered systems will be discussed. A power law form for the electronic density of states of doped semiconducting polymers near the Fermi level provides a reasonable fit to the dependence of transport and thermopower on carrier concentration. The implications of this behavior for improvement of the thermoelectric properties of polymers will be discussed.

Charge Transport and Paracrystallinity in Conducting Polymers Anas I. Abutaha1, Pawan Kumar1, Erol Yildirim2, Shi Wen2, Shuo-Wang Yang2, Gang Wu2 and Kedar Hippalgaonkar1; 1Institute of Materials Research and Engineering, Singapore; 2Institute of High Performance Computing, Singapore

Despite their significant impact on electronic applications, charge transport in conducting polymers is still debated due to disorder (paracrystallinity). It has been reported that charge transport in polymers is correlated with paracrystallinity [1]. The shape of the electronic density of states (DOS) determines transport properties in solids. In this work, we establish the missing link to understanding charge transport by connecting paracrystallinity to transport properties of conducting polymers. First, we confirm that the DOS in conducting polymers is represented by a Gaussian distribution by performing tight-binding model calculations supported by density functional theory and Molecular dynamics simulations. We find that the DOS broadening ($w$) increases exponentially with paracrystallinity. Second, by using Gaussian DOS in the Boltzmann Transport Equation, we find that charge transport can be fully described by the energy dependent scattering parameter ($r$) and the ratio of the total number of energy states to broadening, $N_t/w$.

For a wide variety of conducting polymers, we find that $r$ affects all transport properties, while $N_t/w$ affects only electrical conductivity. For example, by fitting literature data of electrical conductivity and thermopower of conducting polymers, we show that PEDOT:Tos ($w$~0.2 eV) is less disordered compared to PEDOT:PSS ($w$~0.8 eV). Furthermore, due to their distinct monomer structure, PEDOT:PSS and PEDOT:Tos, for instance, exhibit $r$=0.5, while P3HT and PBTTT exhibit $r$=1.5. Moreover, we show that charge mobility in conducting polymers is predominantly determined by $r$. For example, our calculated Hall mobility is consistent with the measured values reported for PBTTT and PEDOT:PSS [2], demonstrating different values of $r$. Finally, we provide a design principle for future organic electronics, where $r=1.5$ polymers are exciting as they can exhibit higher mobilities and are also well suited for thermoelectrics.

Designing Mixed Ion and Electron Conductors Elayne Thomas, Dakota Rawlings, Michael L. Chabinyc and Rachel Segalman; University of California, Santa Barbara, United States

While highly conductive polymers are now commonplace, they generally demonstrate lower thermopower at a given conductivity than inorganic counterparts. Ion conducting materials have previously been demonstrated to have very large Seebeck coefficients, but ions generally have much lower mobility than electronic charge carriers. We have recently shown that doping with protic ionic liquids and other proton conductors can be used to control the thermoelectric power factor. In this talk, I will discuss how electrochemical transistor geometries can be used to understand the scaling of thermopower with carrier concentration and to begin to untangle the intertwined ion/electron effects in mixed conductor thermoelectrics. Further I will discuss how the presence of ionic charges can be used to control the mesoscopic self-assembly of conducting polymers.

Significant Enhancement in the Thermoelectric Properties of PEDOT:PSS by Using Ionic Liquids Jianyong Ouyang; National University of Singapore, Singapore

Intrinsically conductive polymers have promising thermoelectric application due to their high mechanical flexibility, high electrical conductivity while low thermal conductivity. But their Seebeck coefficient is usually lower by inorganic thermoelectric materials by 1-2 orders in magnitude. It is important to significantly improve the Seebeck coefficient of thermoelectric polymers. Here, I will present some methods by our lab to significantly enhance the Seebeck coefficient and thus the overall thermoelectric properties of PEDOT:PSS by using ionic liquids. These
methods can enhance the figure of merit (ZT) to ~0.75 at room temperature, comparable to inorganic thermoelectric materials.

4:45 PM EN13.10.05
Effect of Heteroatom and Doping on the Thermoelectric Properties of Poly(3-alkylchalcogenophenes) Shawn A. Gregory¹, Akanksha K. Menon², Shuyang Ye³, Dwight Seferos³, John Reynolds¹ and Shannon Yee¹; ¹Georgia Institute of Technology, United States; ²Lawrence Berkeley National Laboratory, United States; ³University of Toronto, Canada

This talk will discuss the thermoelectric properties of poly(3-alkylchalcogenophene) thin films as a function of heteroatom (sulfur, selenium, tellurium), and how these properties change with ferric chloride dopant concentration. Using UV-Vis-NIR spectroscopy, electrical conductivity, and Seebeck coefficient measurements, we observed that as the heteroatom is substituted from S to Se to Te, the susceptibility to doping increases. The increased doping susceptibility leads to poly(3-alkyltellurophenes) requiring less dopant to achieve an optimal thermoelectric power factor (ca. 10 µW/m-K²) in comparison to the sulfur and selenium derivatives. Poly(3-alkylchalcogenophene) films' electrical conductivities and Seebeck coefficients at each dopant concentration was also measured as a function of temperature and compared with relevant charge transport. We observed that the electrical conductivity increases with increasing temperature, but the Seebeck coefficient is effectively temperature-independent; this is similar to the findings of Crispin, Emin, and coworkers who studied NOPf₆ doped P3HT charge transport using a model similar to the Mott Polaron Model. We therefore analyzed our temperature-dependent charge transport data in the context of the Mott Polaron model and found that as the heteroatom is substituted from S to Se to Te the activation energy required for charge transport decreases. Overall, this talk will cover a systematic study of charge transport in doped poly(chalcogenophenes) and will demonstrate that tuning the heteroatom may lead to optimized thermoelectric performance.
electronics, such as wearable devices and environmental monitors. The inorganic thermoelectric (TE) semiconductors are still the most possible candidates for this technique due to their best efficiencies, although the pristine materials cannot be directly used as their intrinsic brittleness and rigidity. Therefore, great efforts from various interdisciplinary fields have been dedicated to searching solutions to improve the flexibility of conventional inorganic TE materials. Herein, we present a novel approach to fabricate flexible TE hybrids through depositing Bi$_2$Te$_3$-based alloys on the free-standing transparent single-walled carbon nanotube (SWCNT) scaffold (Nature Materials, 18, 62–68, 2019). The nanocomposite reveals well-ordered and porous microstructures, which consists of (000l) textured Bi$_2$Te$_3$ nanograins grown on the SWCNTs with good adhesion and perfect alignment along the Bi$_2$Te$_3$ <-12-10> and SWCNT axes (Fig.1). The freestanding Bi$_2$Te$_3$-SWCNT hybrid exhibits remarkable mechanically reliable flexibility over hundreds bending circles, of which the bending deformation radius could be as high as a few millimeters. Large power factors of ~1600 to 1100 μW/mK$^2$ are obtained for the Bi$_2$Te$_3$-SWCNT hybrids room temperature to 473 K. Owing to the high density of defects, such as Bi$_2$Te$_3$-SWCNT interfaces, stacking faults and nanopores, the in-plane thermal conductivity is as low as 0.53 W/mK. Such high-power factor and low thermal conductivity give rise to a ZT of ~ 0.89 at room temperature. Moreover, flexible n-type Bi$_2$Se$_3$-SWCNT and p-type Sb$_2$Te$_3$-SWCNT TE hybrids with similar crystal structure were also fabricated, indicating that our approach opens a new way to fabricate free-standing flexible TE materials with high performance.

**Two-Dimensional Conductive Coordinated Polymers for Thermoelectric Power Generator** Yuanhui Sun$^{1,2}$, Dionisius Hardjo Lukito Tjhe$^1$, Ryojun Toyoda$^3$, Ekaterina Selezneva$^1$, Chen Chen$^1$, Ian Jacobs$^1$, Martin Statz$^1$ and Henning Sirringhaus$^1$; $^1$University of Cambridge, United Kingdom; $^2$Xi’an Jiaotong University, China; $^3$The University of Tokyo, Japan

Thermoelectric generators (TEGs) are solid-state devices that can directly convert temperature differences into electrical voltages via Seebeck effect, which neither requires moving parts nor consumes liquid or gas media, implying favorable qualities, such as high reliability and eco-friendliness. Given the ubiquity of heat and the versatility of electricity, thermoelectrics have long been recognized as a highly promising transformative technology to address our global energy needs. At present conventional inorganic TE materials have achieved tremendous advances, which however have drawbacks such as high cost of production, scarcity of materials, toxicity as well as limited scope of application. To overcome these intrinsic issues, organic thermoelectric materials as alternatives has emerged since they are based on abundant elements, together with low cost, light weight, mechanically flexibility and low-temperature solution processing over a large area. Moreover, organic thermoelectric devices (OTEs) can employ low quality heat. All of these imply that OTE materials have wide application prospects, especially in the development of personal, portable, wearable and flexible heating devices and near-room temperature energy generation. However, for the lacking of high performance OTE materials and proper device architecture design, the efficiency of thermoelectrics is still lower than other energy conversion technologies. It remains full challenges before fully realizing their potential. In 2016, research on poly(Ni-ethylenetetrathiolate) brought our attention to conjugated coordination polymers, which provided the best thermoelectric performance among n-type OTE materials, with an optimum power factor over 453 μW/mK$^2$, benefit from the well-ordered arrangement and stronger π-π interaction of molecular. In metal-organic conjugated coordination polymers, high electrical conductivity can be achieved, whether 1D or 2D coordination polymers (CPs). It is an essential advantage for developing efficient OTE materials. By the targeted design with proper metal and ligand and precisely controlling the oxidation or reduction, the Fermi level, band gap and density of state etc. can be modified, which will significantly affect the thermoelectric performance of polymers. Therefore, it is reasonable to believe the research on TE properties of 2D coordination polymers will be greatly accelerated while providing high-efficient materials for OTEs design. We aim to explore a feasible strategy for developing high-performance 2D coordination nanosheets polymers, reveal the internal transport mechanisms and obtain a better-performing OTE device based on the 2D materials we obtained. It will open up new possibilities for the development of organic thermoelectrics.

**EN13.11.04**

**Understanding Hybrid Organic Polymer Nanowires Interfaces for Optimized Thermoelectric Performance** Xinyi Chen; Donghua University, China

Energy filtering phenomenon has been evidenced in hybrid organic-inorganic composites. It has been reported that appropriate barrier on the organic-inorganic surface is beneficial for the enhancement of thermoelectric performance. However, in the hybrid organic-organic system, the existence of energy filtering phenomenon has not
been strongly confirmed in organic system, nor it is clear that if it shares same rules as the inorganic thermoelectric system. In this work, we develop a novel organic thermoelectric composite composed of poly(3,4-ethylenedioxythiophene) nanowires (PEDOT) and polypyrrole nanowires (PPy) at different contents for the optimization of ZT and power factor. The optimized thermoelectric performance is achieved at 0.5 wt.% PPy. By varying the treatment time of PPy with ferric chloride (FeCl₃), the degree of oxidation of polypyrrole is tuned, which further influences the value of energetic barrier. The relationship between thermoelectric performance and the barrier has been verified. To the best of our knowledge, we are the first to quantitatively investigate the effect of energy filtering on thermoelectric performance of organic composite. By comparing experimental data with the series-parallel model, it is found that energy filtering is possibly an important factor the enhancement of Seebeck coefficient and power factors due to that energy filtering can selectively scatter low-energy carriers.

**EN13.11.05**

**Improvement of Thermoelectric Output of PEDOT:PSS by Controlling Electrostatic Interaction**
Duckhyun Ju, Daegun Kim, Sanghyo Kim, Jiwoo Min and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

To improve thermoelectric output, we positively deviated the thermoelectric trade-off rule of electrical conductivity and the Seebeck coefficient by modifying the electrostatic interaction between conductive polymers and dopant molecules, i.e., poly(3,4-ethylenedioxythiophene):poly(styrene-sulfonate) (PEDOT:PSS), by addition of alkylsulfonate anions. We analyzed the conformational change of PEDOT:PSS by the added anions from a solution level to a film morphological level, and verified that the intervention of added anions brought about molecular ordering in PEDOT domain by pulling down existing tight-bounded state between PEDOT and PSS. Furthermore, different lengths of alkyl chains of added anions controlled the oxidation levels of PEDOT backbone by changing the chain-chain interaction between PEDOT and PSS to different extents. As a result, we found that these changes could augment both electrical conductivity and the Seebeck coefficient of PEDOT:PSS simultaneously, which produces a remarkable power factor of 715.2 uW/mK².

**EN13.11.06**

**Polyaniline/SnS Nanocomposites for Flexible Thermoelectric Materials**
Lenin Ramanujam, Ajit Singh and Chandan Bera; Institute of Nanoscience and Technology, India

The addition of nanomaterials into the polymer matrix has been shown increased thermoelectric properties due to the internal organization of the polymer molecules at the nanomaterial template. The preparation methods, the concentration of the nano-inclusions, nature of the nanotemplates (oxidised or reduced) defects, and impurities in the nanotemplates affect the organization of the molecules at the surface of the nanotemplates and eventually influences the thermoelectric properties. The internal organization of the molecules at the interface plays a major role in the enhancement in electrical conductivity and Seebeck coefficient eventually affects the power factor of the thermoelectric material. The effect of the interface at the polymer and nanomaterial on the power factor or the conversion efficiency of the thermoelectric material is still not well understood. The conducting polymer polyaniline (PANI) has many attractive features such as inexpensive, environmental stability, easy synthesis protocol, easy processability, and tunable electrical conductivity etc. over the other conducting polymers. The SnS is more earth-abundant material and easy to synthesize, moreover, it has lower thermal conductivity, high Seebeck coefficient and it has good thermoelectric properties. We mainly focused on the synthesis of polymer nanocomposite by mixing the SnS nanoparticles into the polyaniline matrix and studied their thermoelectric properties.

**A Study on a Flexible Thermoelectric Generator for Wearable Energy Harvesting System**
Jeong Hun Kim, Jong-Pil Im, Solyee Im, Jiyong Woo and Seung Eon Moon; Electronics and Telecommunications Research Institute, Korea (the Republic of)
In this paper, we proposed the fabricated process of a flexible thermoelectric generator (TEG) module that can use body heat and evaluated its electrical performances. The metal/ceramic materials have been widely used for substrate of TEG but there is a difficulty of conformal contact because of their rigidity, therefore, flexibility of the module is required in order to maximize the use of curved heat sources such as the human body. For this reason, we suggest a manufacturing method of flexible thermoelectric devices based on inorganic thermoelectric material. As a thermoelectric element for fabrication of TEG, we used BiTe-based material which is most widely used for TEG system. It has much better performance than other organic materials such as carbon nanotube and PEDOT:PSS used for flexible TEG.

In previous researches, metal electrodes were formed by a deposition process followed by the printing of thermoelectric material. And a flexible device was fabricated by laser-lifting method with filling of flexible polymer. In this research, we have proposed a novel fabrication process that using the flexible silver electrodes. The silver electrodes were printed on the sacrificial layer which can be removed by an etching process to obtain a flexible thermoelectric device. Through this method, flexible TEG can be easily fabricated without complex laser process or organic materials or by using sacrificial layers such as PVA and PVP that can be etched by water.

We also have studied the performance changes of the TEG by various polymer materials that have different thermal conductivity. As a supporting layer which have flexibility, the filler material is needed after the etching of the sacrificial layer. Also, because external pollution can make degradation of TE in the actual usage, passivation is required. But high thermal conductivity of polymer filler reduces temperature difference between hot and cold side that concludes the output power of the TEG. We compared the electrical performance of the TEG modules by different filler material, and it was confirmed that the porous polyurethane foam can be good candidate of wearable TEG system.

Though metal fin is most widely used structure for the heat sink, but it is not suitable for wearable system because of the rigidity and bulky structure. To overcome those limitation, inspired by nature, we introduce an artificial perspiration membrane that automatically regulates the evaporation by programming a deformation of thermo-responsive hydrogels. The thermo-responsive hydrogel is patterned with pinwheel-like shape and supported by backbone through copolymerizing at the interface to control the evaporation area depending on the temperature. To prevent the unintended evaporation through the hydrogel, the stretchable rubber is selectively coated, which layer leaves the water path for swelling of the hydrogel. Our heat sink can absorb the water and its latent heat can decrease the temperature of the cold side during drying process. Compared to metal fin heatsink, it was confirmed that the power of TEG module increased more than 2.5 times.

EN13.11.08
Manufacturing Multifunctional Textile Based Thermoelectric Generators Yuanyuan Zheng and Kun Zhang; Donghua University, China

Wearable flexible organic thermoelectric materials harvesting low-grade heat especially human body’s heat have drawn a lot of attention because of their lightweight, flexible, nontoxic and easy-processing et al. In this work, we report organic-based T-TEGs by assembling segmentally-impregnated carbon nanotube yarn with PEDOT: PSS (p-type) and PEI (n-type) into a spacer fabric. The T-TEG shows multi-functionality with superior electrical power output, ultrahigh sensitivity to tactile touch and excellent wearing performance. Finally, this kind of CNT yarn based thermoelectric fabric can be continuously and automatically produced in bulk using traditional knitting machine. In addition, we successfully demonstrate an all-in-one T-TEG based self-charging power package for wearable electronics, which has never been succeeded in previous studies. This package can power a series of essential electronics in extreme environment when the battery cannot work even damaged (T< -20 degrees Celsius). All these results make the T-TEG outperforming all reported flexible organic-based TEGs. The developed strategy can inspire the manufacturing of cost-effective smart T-TEGs using well-established textile industrial processes.

EN13.11.09
Induced Energy-Filtering Effect in Organic Composites for Enhanced Thermoelectric Efficiency Daegun Kim, Seong Hyeon Kim, MinKyu Kim and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Thermoelectric (TE) composites have turned out to be a promising way to enhance the $ZT$ value of organic TE materials. However, a comprehensive study on TE charge transport in composite material has been scarce. Here we demonstrate that designed physical and energy structures in TE composite materials cause all three critical TE parameters to contribute to the improvement of the $ZT$ value. Adding the carbon quantum dot (CQD) to poly(3,4-
ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) provided additional charge transport pathways, which also acted as an energy-selective mobility enhancer. These contributed to increase both the electrical conductivity and the Seebeck coefficient, simultaneously. Addition of the CQD also reduced the thermal conductivity by increasing the interfaces in the film. With an optimized interfacial potential gap between CQD and PEDOT:PSS, the composite film showed significant increases in the power factor and the $ZT$ value.

EN13.11.10
Development of Thermoelectric Simulation of Carbon Nanotube Thin Films Kotaro Fujisaki and Takahiro Yamamoto; Tokyo University of Science, Japan

Nanocarbon materials are expected to be potential candidates for nontoxic and flexible thermoelectric materials with high power, which are suitable for wearable power generation technology [2][3]. Carbon Nanotube (CNT) thin films being the network consisting of randomly distributed numerous CNTs is one of nanocarbon materials. CNT films require high electrical conductance and Seebeck coefficient to enhance the performance of the films. In order to increase the conductance and Seebeck coefficient of CNT films, we have to understand the relation between the CNT network structure and its electrical and thermal transport properties.

To understand the relation between the CNT network structure and its thermoelectric performance, we theoretically investigate the effect of several parameters such as nanotube length and nanotube density on thermoelectric performance using the thermal circuit theory, electrical circuit theory, and the percolation theory. First, we generated a two-dimensional random network by changing the nanotube density and the nanotube length and calculated the temperature distribution by solving thermal circuit equations for the CNT networks. Then, we calculated the voltage of CNT own and contact between CNTs generated by temperature difference using the temperature distribution. Finally, we calculated the Seebeck coefficient and electrical conductivity by solving electrical circuit equations for the CNT networks. The obtained results in this study are summarized as follows.

1. The electrical conductance of the film increases with the nanotube length.
2. The Seebeck coefficient of the film is almost dependent on the contact between CNTs in any nanotube length from 0.5µm to 1.5µm.

Enhanced Output Characteristics of All-Printed Organic Thermoelectrics by Reducing Internal Resistance Seongkwon Hwang1,2, Inho Jeong1,3, Hoichang Yang4, Jeonghun Kwak5 and Seungjun Chung1; 1Korea Institute of Science and Technology, Korea (the Republic of); 2University of Seoul, Korea (the Republic of); 3Korea University, Korea (the Republic of); 4Inha University, Korea (the Republic of); 5Seoul National University, Korea (the Republic of)

Thermoelectric generators that can directly convert wasted heat into electricity have gained much attention as a sustainable energy generator. Specially, for the last decade, organic-based thermoelectric materials have attracted interests due to their inherent flexibility that offer great opportunities to realize geometrically versatile energy harvesting systems with high degree of design freedom. However, there are still challenges on the low output power of organic thermoelectrics compared to that of rigid inorganic based counterparts. The practical strategy for enhancing the output power is to increase the number of organic thermoelectric legs; therefore, emerging solution processing, especially additive printing technologies, have been widely used due to its large-area processability in ambient. In addition, the efficient reduction of internal resistance can pave a key pathway for further improved output power of large-area organic thermoelectric applications.

In this presentation, we will present all-printed organic thermoelectric modules using the combination of spray printing and inkjet printing. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and nanoparticle-type Ag inks were used for the thermoelectric and highly conductive metallic layers formation, respectively. Especially, spray printing enabled us to make few-µm thick organic films onto large area flexible substrates, resulting in the higher output power compared to that of counterparts fabricated by using conventional
Spin coating. To reduce the internal resistance of organic thermoelectrics, functionalized interlayers are introduced between the PEDOT:PSS legs and Ag electrodes using inkjet-printing that significantly reduce the contact resistance by modulating the dominant carrier injection mechanism. With these efforts, the interface-engineered organic thermoelectrics exhibit the two times higher output power comparing to the pristine counterparts. These results will provide a practical solution to realize high-performance printed organic thermoelectric modules.

**Effect of Conformation in Main-Chain with Pyrene-Based Conjugated Polymers for Selective Dispersion of Single-Walled Carbon Nanotube on Thermoelectronics**

Kyoungtae Hwang1, Dae-hee Lim1, Yeon-Ju Kim1, Jong-Jin Park1, Min-hye Lee2 and Dong-Yu Kim1; 1Gwangju Institute of Science and Technology, Korea (the Republic of); 2Korea Research Institute of Chemical Technology, Korea (the Republic of)

Single-walled carbon nanotube (SWNT) has been regarded as one of the nanomaterials for future electronic devices because of their outstanding mechanical and electrical properties. For these reasons, researches for implementation of their electronic applications such as field-effect transistors and thermoelectric devices have been substantially promoted. Therefore, various techniques to isolate the electronically-pure SWNTs have been developed for the utilization in electronic devices. In particular, conjugated polymer wrapping of SWNT has specially aroused great attraction as a method for isolation of SWNTs due to their advantages of high selectivity toward semiconducting (sc-) SWNT and simple polymer sorting process. Various wrapping polymers such as polyfluorene and polythiophene derivatives have been studied for the selective dispersion of sc-SWNT, but the selection rule between the main chain of polymer and specific sc-SWNT still remain question. In this research, we introduce the pyrene moiety to control the conformation over the main-chain on polymer. New pyrene-based conjugated polymers were carefully designed and synthesized via suzuki polymerization. Their dispersion selectivity and diameter of sc-SWNTs enriched by pyrene-based conjugated polymers were characterized by various measurements such as UV-vis absorption spectra, Raman spectroscopy and Photoluminescence analysis.

**EN13.11.13**

**Thermoelectric Application of CNT Composite Threads Patterned with Different Kinds of CNTs**

Ryota Arakaki and Takahide Oya; Graduate School of Engineering Science, Yokohama National University, Japan

Nowadays, as one of environmental problems, it is focused that much consumed energy is wasted as heat. Therefore, to realize a "low-carbon society," the way to utilize the wasted heat is required. As one of candidates for the solution of this problem, the thermoelectric power generating technologies are focused. Carbon nanotubes (CNTs) are expected to be new thermoelectric materials because they have high electrical conductivity and thermoelectromotive force, but there are the following issues in using them as thermoelectric materials. First, low thermal conductivity is required for efficient thermoelectric generation, but CNTs have high thermal conductivity. Second, CNTs are generally produced as powders and are difficult to handle. To solve these problems, we have proposed using carbon-nanotube-composite threads (CNTCTs). CNTCTs are composite materials produced by coating cotton thread fibers with CNTs. It is expected that CNT can be easily handled by combining it with thread, and cotton thread with low thermal conductivity also prevents heat diffusion. In previous study, we examined methods to fix CNTs on cotton thread surface efficiently, and succeeded in producing CNTCTs that can be used as thermoelectric materials. In this study, we examined a method of coating two types of CNT on thread with a pattern suitable for thermoelectric power generation in order to fabricate thermoelectric elements using CNTCTs. CNTCTs are produced by traditional dyeing methods. In concrete, we prepare CNT dispersion by mixing CNT (Sigma-Aldrich, (6,5)-chirality) and sodium dodecyl sulfate as dispersant in pure water and ultrasonication for them, firstly. After that, the cotton thread is dipped in the CNT dispersion, taken out, dried, and washed with pure water. By performing the above operation, CNTCTs in which the same kind of CNT uniformly covers the thread surface are obtained. However, if CNTCTs in which two types of CNTs having different Seebeck coefficients cover the thread surface at equal intervals can be obtained, the thermoelectric generation element can be easily manufactured. This is because when the thread is sewed on a cloth, it becomes a structure like a π-type thermoelectric generator. So, in addition to the operation described above, we carry out the process called "fusenori" in this study. Fusenori is a Japanese traditional dyeing method to partially prevent the dye from being fixed to the thread. In concrete, we prepare a rubber paste by dissolving latex in tetrachloroethylene, and apply the rubber paste at intervals of 1 cm to cotton thread before the above-mentioned dyeing operation. Because tetrachloroethylene is volatile, the latex covers the thread surface when it is dried. The latex is hydrophobic and keeps covering the thread surface without melting out of the CNT dispersion. Therefore, it can be expected to prevent CNT from being fixed on the surface of the cotton thread in the
part coated with rubber paste. After the dyeing operation is performed on the thread, the latex is removed from the thread surface by washing with tetrachloroethylene heated to 80°C. The resistance value and Raman spectrum of the produced CNTCTs were measured, and it was confirmed that the CNTs were hardly fixed at the place where the rubber paste was applied. After removing the latex, we apply a rubber paste to the portion where the CNTs are fixed, and perform the above-mentioned dyeing operation using CNT (Nanocyl, multi-walled) whose Seebeck coefficient is different from that used previously. The CNTCTs obtained by the above operation were sewed on a cloth, and it was confirmed that an electromotive force was generated when only one side of the cloth was heated. From the above results, it was confirmed that CNTCTs whose surface is covered two different types of CNTs at intervals of 1 cm by fusenori, and a thermoelectric element could be produced simply by sewing it.

EN13.11.14
Fluorinated Polyimide Gate Dielectrics for Transparent Organic Field-Effect Transistor and Logic Gate Circuit with Electrical Stability Hong Gi Min1, Seongchan Kim2, Benzheng Lyu3, Hyungseok Kang4 and Jeong Ho Cho5; 1Yonsei University, Korea (the Republic of); 2Sungkyunkwan University, Korea (the Republic of)

Fluorinated polyimides gate dielectric based on 6FDA-BisAAF-PI and 6FDA-TFDB-PI were synthesized to use as a gate dielectric to fabricate high performance organic field-effect transistors (OFETs). The fluorine substituted into polyimide chain was improved the efficiency of solution-process to make uniform film. These fluorinated polyimide make it possible to fabricate transparent devices. Especially, OFETs based on 6FDA-TFDB-PI which has low surface energy have high-performance because defect density formed by grain boundary is lowest. The OFETs based on 6FDA-TFDB-PI gate dielectric have high carrier mobility (1.83 cm²V⁻¹s⁻¹ for the p-type pentacene FETs and 0.56 cm²V⁻¹s⁻¹ for the n-type PTCDI-C8 FETs) and a high on/off ratio exceeding 10⁶. And, we check that the devices have excellent electrical stability from measured bias stress experiment. The 6FDA-TFDB-PI film was used to fabricate complementary inverters that have high gain value. Lastly, the logic gate circuit (NAND, NOR) were successfully fabricated using 6FDA-TFDB-PI gate dielectric.

EN13.11.15
Effect of Dopant Clustering on Thermoelectric Properties of Polymer Films Michael Lu-Díaz, Connor Boyle, Meenakshi Upadhyaya, Zlatan Aksamija and Dhandapani Venkataraman; University of Massachusetts Amherst, United States

Heavily-doped conjugated polymers are among the most promising organic materials for thermoelectric applications due to their outstanding charge transport properties and low thermal conductivity. These properties are well-known to be dependent on the structural arrangement of the polymer, disregarding the state and position of the dopants. In this study, we utilize Kelvin Probe Force Microscopy to track iodine dopants across P3HT and PDPP4T films and show that their distribution within the polymer film alters the distribution of the density of states. As a consequence, it impacts the shape of the Seebeck coefficient—electrical conductivity curve and thus its thermoelectric properties. Our study shows that it is necessary to control the distribution of dopants within the films for optimal properties in thermoelectric and other organic electronic applications.

EN13.11.16
Thin-Film Heater with Thermally Evaporated WO₃ₓ/Ag/WO₃ₓ Multilayer Electrode and Optimization by Controlling Deposition Rate Sang-Hwi Lim, Jin H. Park and Han-Ki Kim; Sungkyunkwan University, Korea (the Republic of)

We investigated method to improve properties of thermally evaporated WO₃ₓ/Ag/WO₃ₓ (WAW) multilayer using the deposition rate of WO₃ₓ layer and Ag layer as parameters, in order to fabricate flexible and transparent thin film heaters (TFHs). In this work, we demonstrate increase of grain size and reduce interface roughness and enhance electrical and optical properties of WAW multilayer by simply control of deposition rate. And we analyzed properties of WAW multilayer in aspects of electrical, optical, morphological, and mechanical properties. Especially, unlike conventional research which were just focused on and thickness control of each layer to optimize oxide/metal/oxide multilayer, our work presents you how deposition rates affect to properties of WAW multilayer and suggest another way to optimize OMO multilayer. For evaluation, we measured electrical properties and optical properties of WAW multilayers by hall measurement and UV-Vis measurement to optimized performance of WAW multilayer. When WAW multilayer deposited at optimized deposition rate of 2.5 Å/s, 10 Å/s, 2.5 Å/s, showed low sheet resistance of 3.78 ohm/square and high transmittance of 92.16 % at 550 nm wavelength. Morphological
properties of surfaces, interfaces are investigated by FE-SEM, XRD, and mechanical stability and flexibility were investigated bending test, rolling test, twisting test. In mechanical deformation test, after 10000 times of inner and outer bending tests, there were no sheet resistance change in WAW multilayer compare to WAW multilayer before the test. Furthermore, we fabricated the WAW based TFHs to investigate heating profile of WAW multilayer based TFHs. Compare to typical ITO based TFHs, WAW based TFHs show low DC voltage to achieve 120 °C due to its low sheet resistance. Moreover, WAW based TFHs show higher convective heat transfer coefficient than ITO based TFHs. Therefore, WAW based TFHs are promising as flexible and transparent highly efficient convection TFHs.

EN13.11.17
Sticky Thermoelectric Materials for Flexible Thermoelectric Module Norifusa Satoh1, Masaji Otsuka1, Yasuaki Sakurai2, Takeshi Asami2, Yoshitsugu Goto2, Takashi Kawamori1, Takeshi Masaki2, Go Yatabe1, Jin Kawakita1 and Takao Mori1; 1National Institute for Materials Science, Japan; 2Denka Company Limited, Japan; 3Hitachi Chemical Company, Ltd., Japan

To examine our hypothesis of sticky thermoelectric (TE) materials to ease the fabrication processes of flexible TE modules at reasonable cost, we investigated hybrids of inorganic TE powders and low-volatilizable solvents as a series of sticky TE materials. Through our previous study, we have specified that common electric conductive adhesives (ECAs) do not have enough electric conductivity and mechanical strength to hold the structure of flexible TE modules when rolled. As a possible research direction, we have hypothesized sticky TE materials, which can adhere to electrodes pressure-sensitively without ECAs and transform the shape to cancel the mechanical stress when bent. In this study, we prepared p-type and n-type sticky TE materials from antimony and bismuth and examined electric contacts and measured thermoelectric voltages. This presentation discusses the outcomes in details.

Flexible Organic Thermoelectric Device Based on PEDOT:PSS and Oxygen Plasma Treated Polyimide Substrate Juheon Lee, Kiho Nam, Seohyun Kim, Haksoo Han and Hyanghee Choi; Yonsei University, Korea (the Republic of)

Flexible organic thermoelectric devices based on poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and Polyimide (PI) were fabricated and investigated in this work. PI was selected as a substrate because of its excellent mechanical property to secure from repeated bending cycles of flexible device. However, due to hydrophobicity of PI, there was limited research on utilizing PEDOT: PSS and PI for flexible devices. A facile method, oxygen plasma treatment was adopted on PI’s surface. The effect of the surface treatment with oxygen plasma on the synthesized PI substrate was significant. The polar component of surface free energy of PI was increased from 2.8 mJ/m2 to 31.8mJ/m2. Therefore, PEDOT: PSS could be stably coated on the PI substrate. The power factor of PEDOT:PSS on the PI substrate was increased from 25.86μW mK-2 to 43.78μW mK-2. Also, as a result of 10k times of bending test, the electrical performance consistency and the mechanical stability of the fabricated devices were confirmed. This verified fabricated flexible organic thermoelectric devices based on PEDOT: PSS and PI are suitable for the various applications

This research was supported by the Mid-career Researcher Program through the National Research Foundation of South Korea (NRF) funded by the Science and Engineering (NRF-2017R1A2B4012051).

EN13.11.19
Improved Thermoelectric Properties of Flavin-Extracted Semiconducting Single-Walled Carbon Nanotubes Angana Borah and Tsuyohiko Fujigaya; Kyushu University, Japan

Single-walled carbon nanotubes (SWNTs) have remarkable electrical conductivity, ($\sigma$), Seebeck coefficient ($S$), light weight, mechanical toughness and flexibility which makes them ideal candidates for thermoelectric (TE) applications. Among SWNTs, semiconducting SWNTs (s-SWNTs) have been found to have larger $S$ than metallic SWNTs (m-SWNTs) both theoretically and experimentally. However, SWNTs are synthesized as a mixture of s-SWNTs and m-SWNTs, which limits the maximum possible $S$ for SWNTs. Therefore, it is of utmost importance to extract s-SWNTs having high purity as a TE material. Among the various extraction methods, Flavin derivative (dmc12) extraction method reported by Kato et. al. is profitable due to its many advantages, namely, high yield of s-SWNTs, easy operation of the extraction method, low damage to the s-SWNTs and easy removal and recycling of
In this study, we investigated the effect of doping s-SWNTs extracted by dmc12 having different bundle size of s-SWNTs. Purified SWNTs (eDips, Meijo Nano Carbon) were used to extract s-SWNTs and the extracted s-SWNTs were collected by vacuum filtration. The addition of CH2Cl2 to remove dmc12 before and after the filtration provided bundled and isolated s-SWNT sheets, respectively. The bundled sheet represented thicker bundles of s-SWNTs in the sheet while the isolated sheet comprised of thinner bundles. The sheets were doped at various concentrations with triethyloxonium hexachloroantimonate (OA) and 2-(2-methoxyphenyl)-1,3-dimethyl-2,3-dihydro-1H-benz[d]imidazole (o-MeO-DMBI) as p- and n-dopant, respectively. The highest obtained $S$ for p- and n-doped s-SWNT sheets were 83.3 $\mu VK^{-1}$ and -89.5 $\mu VK^{-1}$, respectively. Both values are higher than the values attained previously for doped-unsorted SWNT sheets (p-doped: 54 $\mu VK^{-1}$, n-doped: -49 $\mu VK^{-1}$). Moreover, it was found that the isolated s-SWNT sheet showed larger $S$ value than the bundled sheet in the n-doped region. We consider doping is more effective for isolated than bundled sheets as the power factor of 126.3 $\mu W m^{-1} K^{-2}$ was achieved for isolated sheets.

Strategic Design of Conjugated Polymer for High Doping Efficiency and Correlation of Resulting Conductive Pathway with Thermoelectric Effect Sang Eun Yoon1, Jaehong Park2, Bong-Gi Kim2 and Jong H. Kim1; 1Ajou University, Korea (the Republic of); 2Konkuk University, Korea (the Republic of)

The low dielectric constant of organic materials and inhomogeneous distribution of molecular dopants in a conductive matrix impose difficulties in populating free charge carriers in organic materials, leading to practical challenges in developing highly conductive organic materials. We designed a novel conjugated polymer (PIDF-BT) having long side chains and a strong electron-donating moiety in a way that the PIDF-BT strongly interact with molecular dopant, 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethan (F4-TCNQ), and the doping efficiency was further enhanced through the management of the diffusion degree of F4-TCNQ into CP matrix. With these strategies, dramatic enhancement of electrical conductivity over 200 S/cm, was achieved from PIDF-BT, which is much larger than that obtained from the conventional blending approach (5 S/cm). Furthermore, the doping level was scalable with the exposure duration in the F4-TCNQ solution as well as the solution’s concentration. The diffusion degree of F4-TCNQ was systematically correlated with physical properties (glass transition temperature and crystallinity) of PIDF-BT through the characterization of electrical conductivity according to the thermal annealing temperature of the pre-deposited PIDF-BT films. Finally, characteristic connections between charge carrier density, mobility and thermoelectric effects were extracted with doping level-controlled PIDF-BT films prepared under different thermal annealing conditions.

Modification of Producing Way for "Thermoelectric Power Generating Paper" Using Carbon-Nanotube-Composite Paper to Improve Its Performance Ayumu Miyama and Takahide Oya; Yokohama National University, Japan

We propose a unique thermoelectric power generation material based on a carbon-nanotube(CNT) composite paper that a composite material of the CNT and a paper, i.e., “thermoelectric power generating paper.” Recently, thermoelectric power generation is attracted attention because it can effectively use heat that is often discarded. However, there is a problem that many of the currently used thermoelectric materials are rare metals. For this, we focus on CNTs because CNTs have been confirmed to have high electrical conductivity and thermal conductivity. Moreover, showing a high Seebeck coefficient has been found in recent studies. However, the CNT is difficult to handle because it exists in powder form. Also, having high thermal conductivity is a disadvantage for the thermoelectric generation. Therefore, we are developing a thermoelectric power generating device as the CNT composite paper by combining the CNT with the paper that is easy to handle and has the thermal insulation. In this study, we are aiming to improve the performance of thermoelectric power generating paper. In the previous
work, we studied the suitable amount ratio of the CNTs and pulps to make the CNT composite paper. Because if there was little pulp or more CNTs, it was unable to maintain the temperature difference between both ends. For obtaining low thermal conductivity, we found the ratio. However, the following problems remained. They are that the resistance value of the CNT composite paper was high and enough current could not be obtained.

In this report, we conducted following things to improve the performance of our thermoelectric power generating paper. First, we tried to modify the making method of the CNT composite paper. We here use the “kamisuki” that is Japanese washi paper making method. In “kamisuki,” we prepare a pulp dispersion and a CNT dispersion. Then, we mix the two dispersions and remove moisture by using a fine net. Finally, we dry it and finalize making. Previously, we used “silicone case method” not “kamisuki.” In “silicone case method,” we use the silicone case to evaporate the moisture. Therefore, the CNT composite paper contains many dispersants. Because dispersants are insulator, the resistance value of the CNT composite paper become high, i.e., the dispersant remains on the paper. In contrast, in “kamisuki,” the dispersant is expected to flow with water. So, we change the production method of CNT composite paper “Silicone case method” to “kamisuki.” As a result, we succeeded in lowering the resistance value by about 13%.

Second, the semiconducting CNT usually behaves p-type property in the atmosphere. For efficient thermoelectric generation, not only p-type but n-type semiconducting CNTs are required and they must be connected alternately. So, we applied a doping way to our CNT composite paper for obtaining n-type property. As results, we found temperature dependence of the doping, i.e., there was suitable temperature condition for the doping. Moreover, we also found sustainability of the n-doped CNT composite paper.

We believe our CNT composite paper will be used as flexible thermoelectric power generating elements in near future.

**The Effect of Single Selenophene Substitution on the Thermoelectric and Charge Transport of Highly Doped Polythiophene Polymers**

Chen Chen¹, Ian Jacobs¹, Martin Statz¹, Lu Zhang¹, Yuanhui Sun¹, James Ponder², Cameron Jellett³, Iain McCulloch³ and Henning Sirringhaus¹; ¹University of Cambridge, United Kingdom; ²Imperial College London, United Kingdom

Heavy heteroatom substitution of the backbone is an effective strategy to improve charge delocalization and increase ionised potential of organic polymers. This facilitates the doped states of those materials more conductive without sacrificing the seebeck coefficient a lot at the fixed doping level. Here, we report the effect of the single selenophene replacement on the thermoelectric transport mechanism of polythiophene polymers at different doping levels. By feat of a novel doping method, we achieve the maximum conductivity of ~700S/cm for doped selenophene polymer, which is 3 times higher than its counterpart thiophene polymer with the metallic-like seebeck coefficients of ~25 uV/K for both. Interestingly, temperature dependence of conductivity for the highly doped selenophene shows upturn behaviour (metal-semiconductor) while the seebeck coefficients show linear dependence versus temperature. This indicates we approach a regime where the conductivity is decoupled with the seebeck coefficient. By introducing heavy atom into polymer backbones, it is potentially possible to improve the thermoelectric performance via conductivity boost.

EN13.11.23

**Enhanced Thermoelectric Performance of FeCl₃ Doped Cyclopentadithiophene-Benzothiadiazole Based Copolymer Films**

Juhyung Park¹, Yeran Lee², Han Young Woo² and Jeonghun Kwak¹; ¹Seoul National University, Korea (the Republic of); ²Korea University, Korea (the Republic of)

For a decade, π–conjugated semiconducting polymers have attracted great attention for thermoelectric materials because of their easy tunability, solution processability, and mechanical flexibility. Molecular doping is widely used to improve the thermoelectric properties of the polymer films, because it can easily control the electrical conductivity ($\sigma$) by changing the carrier concentration ($n$). Among various molecular doping methods, solution mixing is typically performed due to its simplicity. However, it is not easy to heavily dope the polymer film due to solubility limit. In addition, the presence of a significant amount of dopant molecules in the doped polymer films can distort the film morphology, limiting the thermoelectric properties. Therefore, it is important to select appropriate doping methods to enhance the thermoelectric properties. Previously, we reported the organic thermoelectric device using p-type conjugated polymer poly[(4,4’-bis(hexyldecylsulfanylmethylene)cyclopenta[2,1-b:3,4-b’]dithiophene)-alt (benzo[c][1,2,5]thiadiazole)] (PCPDTSBT), showing the electrical conductivity of 7.47 S cm⁻¹ using BCF as a dopant. In this study, we changed
the dopant to FeCl₃, and introduced a overcoating method to dope the PCPDTSBT film, demonstrating high electrical conductivity up to 300 S cm⁻¹, which is ~40 times higher than that of the BCF-doped film. The resulting power factors of FeCl₃-doped PCPDTSBT film was 29.75 μW mK⁻², which is ~4 times higher than that of the BCF-doped film. The reason of rapid increase in \( \sigma \) is systemically investigated using various analysis methods like UV absorption, Grazing-Incidence Wide-Angle X-ray Scattering (GIWAXS) and impedance spectroscopy. Kang-Snyder model is also used to investigate the charge transport in the PCPDTSBT film.

**EN13.11.24**

**Impact of Polar Side Chain Engineering of CDT-Based P-Type Polymers on Thermoelectric Devices**

Ayushi Tripathi¹, Juhyung Park², Nguyen Thanh Luan¹, Miso Kim¹, Yeran Lee¹, Jeonghun Kwak² and Han Young Woo¹; ¹Korea University, Korea (the Republic of); ²Seoul National University, Korea (the Republic of)

Driven by the prospects of organic thermoelectric(OTE) devices, which have the potential for energy generation, have gathered considerable attention worldwide. We compared various properties of poly[(4,4’-(bis(hexyldecylsulfanyl)methylene)cyclopenta[2,1-b:3,4-b’]dithiophene)-alt (benzo[c][1,2,5]thiadiazole)] (PCPDTSBT) and its analogue with oligoethylene glycol (OEG) side chains in place of alkyl ones (PCPDTSBT-A), before and after doping. Incorporation of polar OEG side chains improves intermolecular ordering and exhibits ‘self-doping’ with enhancement in doping efficiency, thereafter resulting in higher electrical conductivity and power factor of PCPDTSBT-A surpassing those of PCPDTSBT. OEG chains improve the miscibility of dopant solution and polymer film during sequential doping which was performed by casting dopant solution (by varying the concentration of F4TCNQ in acetonitrile) onto the film. This study emphasizes the importance of the polar side chain engineering to modulate doping efficiency, inter-chain packing, crystalline morphology and miscibility whose outcome is revamped electrical and thermoelectrical properties.

**Thermoelectric Performance Improvement of Polymer Nanocomposites by Selective Thermal Degradation**

Daniel L. Stevens¹, Aaron Parra¹ and Jaime C. Grunlan¹,²,¹; ¹Texas A&M University, United States; ²Texas AM University, United States

Our current energy production results in a tremendous amount of waste heat. In an effort to more efficiently utilize dissipated heat, multilayer thin films, comprised of poly(diallyldimethylammonium chloride) (PDDA), graphene, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and double-walled carbon nanotubes (DWNT), were prepared using layer-by-layer assembly followed by heating in an inert atmosphere to degrade film constituents to varying degrees. PEDOT:PSS was used to stabilize graphene and DWNT. A 20 QL thin film, that is 21 nm thick, heated to 425 °C for 60 minutes exhibits a simultaneous increase in electrical conductivity and Seebeck coefficient as compared to an unheated film. This behavior is not commonly observed in bulk thermoelectric materials. The power factor of this film is 153 uW m⁻¹ K⁻², which is an order of magnitude larger than the unheated control. This marked improvement in thermoelectric performance is the result of degrading the insulating PDDA:PSS complex from the film, while maintaining the highly ordered conductive network formed during layer-by-layer deposition. This strategy of thermally degrading non-conductive material required for film fabrication can be used to prepare numerous high performing thermoelectric materials.

**EN13.11.26**

**Mechanically Robust Conducting Polymer-Polyurethane Blends for Plastic Thermoelectrics**

Desalegn Alemu Mengistie¹,², David Kiefer¹ and Christian Muller¹; ¹Chalmers University of Technology, Sweden; ²California Polytechnic State University, United States

PEDOT:PSS is considered as the most promising p-type material for organic thermoelectrics due to its high electrical conductivity, high power factor, stability and solution processability from an aqueous dispersion. However, the neat PEDOT:PSS lacks flexibility and stretchability. Here, we demonstrate mechanically robust thick free-standing films of PEDOT:PSS blended with waterborne polyurethane (PU). As the blend is prepared from water dispersions, it is solution processable and convenient for large area coating and printing. We explored the mechanical properties, nanostructure and thermoelectrical performance of the blend with different PU loading. Films with ≤50% PU are mechanically robust with high electrical conductivity while those with >50% PU are stretchable but show low conductivity. At 50% PU loading, the blend film maintained a power factor of ~10 μW m⁻¹ K⁻² with excellent flexibility and even twistability. The blend film with 75% PU loading withstands 1000 stretching cycles at
10% strain with no loss in power factor.

Synthesis and Thermoelectric Characterization of Hollow Spherical \( \text{Ca}_3\text{Co}_4\text{O}_9 \) Particles
H. Merve Ertugrul and Ahmet Macit Ozenbas; Orta Dogu Teknik University, Turkey

The aim of this study is increasing power factor and decreasing thermal conductivity simultaneously through the production of hollow spherical \( \text{Ca}_3\text{Co}_4\text{O}_9 \) and air composite materials. This structure comprises of hollow spherical \( \text{Ca}_3\text{Co}_4\text{O}_9 \) particles and porosities dispersed in the matrix. This means that air having very low thermal conductivity is trapped in the structure, so thermal conductivity of the materials can be decreased. Also, high amount of porosity provides increase in Seebeck coefficient. \( \text{Ca}_3\text{Co}_4\text{O}_9 \) is environment friendly, nontoxic, humidity resistant at high temperatures, oxidation resistant, abundant, chemically and thermally stable in air and light. Also, \( \text{Ca}_3\text{Co}_4\text{O}_9 \) is favored due to its natural layered structure composing of conduction and insulation layers alternately which provide electronic transport and phonon scattering layers separately. Therefore, natural superlattice structure of \( \text{Ca}_3\text{Co}_4\text{O}_9 \) brings about high thermopower and low electrical resistivity at the same time.

Ultrasonic spray pyrolysis (USP) method is used to obtain hollow spherical particles. Many parameters have an effect on forming hollow spherical structure such as frequency of ultrasonic generator, the concentration of initial solution, the temperature of reactor and the flow rate of the carrier gas which influence the morphology, dispersity, structure and the phase composition of the end product. High evaporation rate and high mass transfer are required for getting hollow spherical structure. Three different solutions were prepared using deionized water, dimethylformamide and methanol. These solvents were chosen according to their capability of producing an aerosol. Being nontoxic and eco-friendly, deionized water was determined as the solvent in USP technique.

The production of high porosity structure was achieved by using pressure-less sintering method. Furthermore, the surfaces of hollow spherical particles comprising of nanoscale constituents are about 2D, so this leads to quantum confinement effect and energy filtering which increase the power factor and phonon scattering at interfaces resulting in a decrease in lattice thermal conductivity. The temperature dependence of Seebeck coefficient and electrical resistivity were measured using a lab-made system in the temperature interval from 300 K to 900 K. Seebeck coefficients of the samples having 2.3 mm, 1.5 mm and 500 nm diameter at 900 K are 204.8 mV/K, 216.9 mV/K and 228.4 mV/K, respectively. Electrical resistivities of the samples having 2.3 mm, 1.5 mm and 500 nm diameter at 900 K were measured as 18.6 mW.cm, 12.4 mW.cm and 8.1 mW.cm, respectively. Power factors of the samples having 2.3 mm, 1.5 mm and 500 nm diameter at 900 K are 0.23 mW/mK², 0.38 mW/mK² and 0.64 mW/mK², respectively. It was shown that, by reducing the particle size to submicron range, Seebeck coefficient and power factor values were successfully increased together with a decrease in electrical resistivity using our air composite approach employed in this work.

8:45 AM EN13.12.02
Improved Thermoelectric Performance by Incorporating Pores/Defects in PEDOT/Tosulate Films
Balwinder Kaur, Ezaz Hasan Khan, Lian Li, Jayant Kumar and Dionysios Christodoulou; University of Massachusetts Lowell, United States

Poly 3,4-ethylenedioxythiophene (PEDOT) is a conducting polymer that has thermoelectric properties that has been studied extensively. The majority of the studies, however, were focused on the thermoelectric properties of PEDOT:PSS. PEDOT:tosulate could exhibit up to two times higher thermoelectric efficiency than PEDOT:PSS but a limited number of studies have been devoted to the optimization of the performance of PEDOT:tosulate films. After a systematic study of the parameters that could affect the efficiency of the films of PEDOT:tosylate (e.g., oxidative status, introduction of defects in the film, secondary dopants, improving thermal conductivity) we have concluded that the incorporation of defects/pores in the PEDOT:tosulate films increase the thermoelectric efficiency of the films significantly (from a ZT value of 0.39 to 1.07). A proof-of-concept, flexible thermoelectric device that
contain strips of porous PEDOT/tosulate films as p-type elements and strips of bismuth films as n-type elements was prepared and its performance in realistic conditions was evaluated.

9:00 AM EN13.12.03
Improved Thermoelectric Performance of Polymer Nanocomposites by Salt Doping Daniel L. Stevens1, Geethal Amila Gamage2, Zhifeng Ren2 and Jaime C. Grunlan1,1,1; 1Texas A&M University, United States; 2University of Houston, United States

Thermoelectric materials that have a large Seebeck coefficient and electrical conductivity are required to effectively convert waste heat into electricity, but their interdependence makes simultaneous improvement a significant challenge. To address this problem, multilayers of poly(diallyldimethylammonium chloride) (PDDA) and double-walled carbon nanotubes (DWNT), stabilized by KBr-doped poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) were deposited using layer-by-layer assembly (LbL). Doping PEDOT:PSS with KBr before LbL assembly results in a simultaneous increase in the Seebeck coefficient and electrical conductivity. A maximum power factor of 534534 μW m⁻¹ K⁻² was achieved after doping with 3 mmol KBr, which is a six-fold improvement compared to the undoped control. This improvement in thermoelectric properties is attributed to charge screening effects between PEDOT and PSS from the added KBr, which leads to a denser deposition of DWNT. This facile salt-doping strategy can be used to prepare high performance PEDOT:PSS-based thermoelectric materials for lightweight, low temperature applications.

9:15 AM EN13.12.04
Pro-Quinoid Based Conjugated Polymers for High Performance Solution-Processed Thermoelectrics Teck Lip Dexter Tam and Jian Wei Xu; IMRE, Singapore

Here we will show the use of pro-quinoid moieties like benzobistriazole and benzobisthiadiazole in conjugated polymers as an effective strategy towards high performance solution process thermoelectrics. The pro-quinoid character of these moieties allow efficient doping and the formation of highly delocalized polarons even by sequential solution-phase doping. This led to high electrical conductivities, and enhancement in Seebeck coefficient due to carrier-induced softening could be observed. As a result, power factor approaching 70 μW m⁻¹ K⁻² was achieved. These results are among the highest for conjugated polymer thermoelectric using solution-phase doping.

9:30 AM EN13.12.05
Effect of Doping Distribution on Charge Transport Dynamics in Polymer Thermoelectrics Meenakshi Upadhyaya, Connor Boyle, Michael Lu-Díaz, Dhandapani Venkataraman and Zlatan Aksamija; University of Massachusetts Amherst, United States

Organic semiconductors (OSC) hold tremendous potential to address the demand for cheap and sustainable thermoelectric (TE) materials. OSCs offer a major advantage with their inherently low thermal conductivity, but have to be heavily doped to improve the electrical conductivity which has the undesirable effect of significantly reducing their Seebeck coefficient. Hence efficient design of organic TEs requires deep understanding of the role of doping and charge transport dynamics on the Seebeck vs. electrical conductivity trends. In this work, we investigate the TE properties of disordered OSCs, and establish the effect of disorder and correlation in energy and position on the Seebeck coefficient, electrical conductivity, and the Lorenz number. We find that the electronic and morphological properties of the polymer alone cannot account for the experimentally observed Seebeck and conductivity trends. Importantly, it is the doping and the clustering of dopants within the polymer films that dictates the slope of the Seebeck vs. conductivity plots. Our charge transport model is based on electron hopping between localized sites with a modified Gaussian disorder model to account for the impact of doping and clustering of dopants on the energies. We iteratively solve the non-linear Pauli’s master equation to compute the time-averaged occupational probabilities of the sites from which relevant transport quantities are calculated. We measure the Seebeck coefficient and electrical conductivity across a broad range of dopings by a de-doping technique where the sample is measured continuously while gradually de-doping over time. We then fit experimentally determined data of iodine-doped P3HT and PDPP4T to our hopping simulations, which revealed that the shape of the DOS is responsible for the observed Seebeck and conductivity trends. The physical distribution of dopant molecules within the sample affects the carrier DOS (fortified by Kelvin probe force microscopy), with dopant clustering dramatically increasing the energetic disorder resulting in a heavy-tailed distribution [3], whereas homogenous doping maintains
a Gaussian DOS. This ‘change in shape’ of the DOS results in a qualitative change of the Seebeck vs. conductivity curve. A Gaussian distribution leads to a sharp drop off in Seebeck at high conductivity values, whereas, a heavy-tailed distribution leads to a gradual decrease in Seebeck with increasing conductivity and a flatter curve. This can be correlated to the value of the Kang-Snyder transport parameter ‘s’ [4]. Seebeck vs. conductivity curve from a Gaussian DOS is best fit by a lower value of s (mostly<1), whereas, one from a heavy-tailed DOS distribution can only be partially fit with higher s values, indicating the limitations of a band model in predicting transport in highly disordered systems. Our results highlight the importance of tuning the energetic disorder using spatial distribution of dopants to obtain the highest power factor for TE applications. We conclude that it is not just how much the semiconductor is doped; thermoelectric performance is affected by how the semiconductor has been doped across all carrier concentrations.

10:15 AM EN13.12.06
Increasing the Thermoelectric Power Factors in Pi-Conjugated Polymer Blends through Combining Experiment with Theory Ashkan Abtahi1,1, Stephen Johnson2, So Min Park1,1, Xuyi Luo3, Zhiming Liang1, Jianguo Mei1 and Kenneth R. Graham1; 1University of Kentucky, United States; 2Transylvania University, United States; 3Purdue University, United States

Conjugated polymers can be used in mechanically flexible and low cost thermoelectric (TE) devices, but their thermoelectric performance must be improved to make them commercially viable. The performance of thermoelectric materials depends on the electrical conductivity, Seebeck coefficient and thermal conductivity. However, higher electrical conductivity is typically accompanied by a decrease in the Seebeck coefficient. Blending two or more π-conjugated polymers together provides a means of manipulating charge transport properties and potentially improving the performance of organic thermoelectrics by minimizing this tradeoff between electrical conductivity and the Seebeck coefficient. By modifying the model introduced by Bässler and Arkhipov, we model how the electronic properties of the individual polymers influence the Seebeck coefficient, electrical conductivity, and power factor in the polymer blends. These calculations show that gains in the power factor should be attainable when the homogenous blend of two polymers have a small (e.g., 0.1-0.2 eV) offset in their density of states (DOS) distributions and the polymer with the higher energy DOS has a wider DOS distribution and a larger localization length, where the larger localization length translates to higher charge-carrier mobility. Experimentally, power factors in an appropriate polymer blend are demonstrated to exceed the power factors of the individual polymers by nearly two-fold. With the combined theoretical and experimental approach presented, this work provides insight into designing higher performing organic thermoelectric materials based on π-conjugated polymer blends.

10:30 AM EN13.12.07
A New Approach for High Performing N-Type Polymer Thermoelectrics—Heavily P-Doped Polymers Kenneth R. Graham1, Zhiming Liang1, Hyun Ho Choi2, Ashkan Abtahi1, Alex M. Boehm1, Xuyi Luo3, Jianguo Mei1 and Vitaly Podzorov2; 1University of Kentucky, United States; 2Rutgers, The State University of New Jersey, United States; 3Purdue University, United States

Conductive polymers are promising thermoelectric materials, particularly for use in devices where mechanical flexibility or low-cost are primary considerations. Currently, the record power factors of P-type polymer thermoelectric materials are approximately 20 times greater than that of record N-type polymers. We have recently discovered that heavy P-doping of donor-acceptor based conjugated polymers can change the sign of the Seebeck coefficient from positive to negative, which for some polymers can lead to near record N-type power factors. Moderate P-doping of a DPP-containing polymer leads to a P-type power factor of 24.5 µW m⁻¹ K⁻¹, while further increases in doping concentration lead to an N-type power factor of 9.2 µW m⁻¹ K⁻², where 9.2 µW m⁻¹ K⁻² is a near the record power factor for an N-type donor-acceptor (D-A) conjugated polymer. Additional investigation into the origin of the sign change through a combination of ultraviolet and inverse photoelectron spectroscopy measurements
shows that the density of unoccupied and occupied states converges upon heavy doping; thereby giving rise to either positive or negative Seebeck coefficients based on the relative charge-carrier mobilities and density of states near the Fermi energy for electrons and holes. AC Hall effect measurements of heavily doped polymers confirm that the dominant band-like carriers are indeed electrons. This work provides fundamental insight into the thermoelectric behavior of heavily doped conjugated polymers and shows a promising route to developing P- and N-type polymer thermoelectrics based on the same polymer-dopant combination.

10:45 AM EN13.12.08
Control of Chemical Doping and Functionality of Conjugated Polymers via Anion Exchange Yu Yamashita1,2, Junto Tsurumi2, Masahiro Ohno1, Ryo Fujimoto1, Shohei Kumagai1, Tadanori Kurosawa1, Toshihiro Okamoto1,3, Jun Takeya1,2 and Shun Watanabe1,3; 1The University of Tokyo, Japan; 2NIMS, Japan; 3JST PRESTO, Japan

Chemical doping in a conjugated polymer always involves redox reaction between a host polymer and guest dopant. Even though physics and chemistry in material science have been evolving rapidly, an efficiency of chemical doping is limited primarily by the redox potential of employed materials, which has been well described by Marcus theory. In contrast, we have successfully overcome this limitation by introducing anion exchange [1]. A thin film of poly[2,5-bis(3-tetradecylthiophen-2-yl)thieno[3,2-b]thiophene] (PBTTT) is doped by exposing it to solution of tetracyano-2,3,5,6-tetrafluorooquinodimethane (F4TCNQ). When a salt containing bis(trifluoromethane)sulfonamide (TFSI) anion is introduced to this system, the additional TFSI anion is instantaneously exchanged with the F4TCNQ radical anion that forms the intermediate ion-pair [PBTTT+ F4TCNQ●-]. Spontaneous anion exchange (from F4TCNQ●- to TFSI-) is confirmed comprehensively by UV-Vis-NIR, FTIR and ESR spectroscopies, where a lower limit of exchange efficiency is determined to be 98 %. Surprisingly, Hall measurements suggest that the efficient anion exchange increases the doping level up to almost one hole per monomer unit, which is three times higher than that of conventional F4TCNQ doping [2]. Promotion of chemical doping is also demonstrated with a weak acceptor tetracyanoquinodimethane (TCNQ). Even though the LUMO level of TCNQ (−4.5 eV) does not exceed the HOMO band edge of PBTTT (−4.8 eV), UV-Vis-NIR confirms a reasonably high doping level achieved by introducing anion exchange.

To examine the observed increase in doping level, one needs to consider equilibrium of doping reaction, where the forward reaction is charge transfer, and the reverse reaction is back-charge transfer. In a standard binary system, charge transfer takes place between neutral PBTTT and F4TCNQ, while back-charge transfer makes ionized [PBTTT+ F4TCNQ●-] back to the neutral state. In a steady state of equilibrium, these charge transfer and back-charge transfer occur at the same rate, where the doping level would not increase any more. Introduction of efficient anion exchange to this system converts [PBTTT+ F4TCNQ●-] to [PBTTT+ TFSI-], which results in suppression of back-charge transfer. Note that [PBTTT+ TFSI-] does not contribute to back-charge transfer because TFSI- is a stable closed-shell anion. Thus, efficient anion exchange biases the charge transfer equilibrium by suppressing back-charge transfer, so that the doping level increases.

Anion exchange doping provides a platform to explore material science in conjugated materials. In terms of charge transport property, the high doping level of PBTTT thin film results in Hall mobility of 2.0 cm² V⁻¹ s⁻¹ at room temperature and weak temperature dependence of it, which manifest that this system is close to onset metallicity. Another perspective would be creation of functional host-guest structures. One example here is that thermal stability is improved remarkably when a closed shell anion is introduced into polymeric semiconductors as a dopant. We believe that this study will be a benchmark for storage, transport and conversion of functional molecules within a solid-state of conjugated materials, which are the essential phenomena in broad fields of material science, e.g. catalytic activity, molecular recognition, and energy conversion.

Thermoelectric Performance of Carbon Nanotube Film and Its Composites Jiang Li and Mei Zhang; Florida State Univ, United States

Carbon nanotubes (CNTs) are expected as a high-performance thermoelectric material because of their one-dimensional nanostructure and their excellent electrical and mechanical properties. However, the thermoelectric performance is not as good as expected when they are assembled into a macroscale film. The main reason is the poor interconnections among CNTs in the film especially when the length of the CNTs is in micrometer scale. In this work, we used the special multiwalled CNTs, which have length in 1-2 mm and diameter less than 10 nm, and we employ polyacrylonitrile (PAN) as precursor to create crosslinks among CNTs after carbonization. The CNT films have improved conductivity and they are elastic and robust. For enhancing the thermoelectric performance, we further infiltrated PAN into the CNT network and investigated the effects of the PAN contents and its different status after stabilization and carbonization through thermal treatments. The results show that a maximum power factor of 13 µW/mK² was obtained from the CNT/PAN composite when the PAN content was 48% and thermally treated at 300 degree in air for 2 hours. A model was built to explain the phenomena.

High-Quality Textured Thermoelectric SnSe Thin Films for Quick Response Photothermoelectric Detection Yujia Zhong and Hongwei Zhu; Tsinghua University, China

Tin selenide (SnSe), a thermoelectric (TE) materials, has attracted much attention, since the record figure of merit (ZT=2.6) is discovered in SnSe single crystals (SC). Nevertheless, the practical application of SC is limited due to the high cost and extreme growth condition. With the development of flexible intergrated electronics, using flexible TE polycrystalline films to substitute rigid SC becomes a main trend. SnSe thin films, a flexible TE polycrystalline films, demonstrate potential high TE performance and low cost, which enable the thin films to be widely used in diverse applications. However, the lack of approach to synthesize scalable high-quality SnSe thin films constitute a main obstacle for their applications. Here, we report scalable high-quality SnSe polycrystalline thin films with strong (400) texture directly synthesized via chemical vapor deposition (CVD). Our SnSe thin films exhibit a ZT of 0.15 and power factor (PF) of 0.322 mWm⁻¹K⁻² at 550 K, demonstrating that TE performance of this SnSe thin films at low temperature region is at the SC level. Moreover, the SnSe thin films-based photothermoelectric (PTE) detectors illustrate a higher responsivity and speed than SnSe SC-based PTE detectors, which is resulted from small heating volume, small conductive heat flux and large dissipation content in the thin films. The high performance of PTE detectors demonstrates the superiority of TE thin films in a practical application. Based on the position sensitive PTE effect, in-plane laser positioning and tracking are further conducted when using the PTE detectors with two pairs of electrodes. We pave the way for fabrication and practical application of TE thin films.

High Thermoelectric Performance in n-Doped Silicon-Based Chalcogenide Si₂Te₃ Rinkle Juneja, Tribhuwan Pandey and Abhishek K. Singh; Indian Institute of Science, India

Silicon-based thermoelectric materials would be of great significance due to the huge dependence of electronic industry on silicon. Bulk silicon is not a good thermoelectric material due to its very high thermal conductivity, thereby limiting its thermoelectric efficiency. Nanostructuring and alloying are alternative solutions to reduce thermal conductivity, but the techniques involved are complex and costly. Recently, a silicon-based chalcogenide Si₂Te₃ has been experimentally synthesized. Si₂Te₃ exhibits layered structure, in which Te atoms form hexagonal sub-lattice and Si atoms can occupy any of the octahedral voids. Due to uncertainty in Si positions, previously unknown ground state structure of Si₂Te₃ was obtained using the Wyckoff positions of space group P-31c. The minimum energy configuration exhibits combination of desirable electronic and transport properties. In particular, n-doped Si₂Te₃ has an unprecedented figure of merit of 1.86 at 1000 K, which is comparable to some of the best state-of-the-art thermoelectric materials. Hence, n-doped Si₂Te₃ can be a long-sought silicon-based thermoelectric material which could be integrated to the existing electronic devices.

Goniopolar Thermoelectrics Joseph P. Heremans, Bin He, Yaxian Wang, Michael R. Scudder, Joshua E. Goldberger and Wolfgang Windl; The Ohio State University, United States

Goniopolar materials are metals and degenerate semiconductors with a thermopower that is n-type in one crystallographic direction, but p-type in another. This effect is due to a particular geometry of their Fermi surface [1], which must be concave and cannot be 1-simply connected in the Brillouin zone. Very interestingly, in some cases, the sign of the Hall effect is exactly the reverse of the sign of the Seebeck effect, which can again be explained by the topology of the Fermi surface. The same properties can arise in (pxn) materials [2], composites made from alternate p and n-type layers. They also arise in solids in which the Fermi surface consists of electron pockets and hole pockets. When single crystals of such materials are cut at a particular angle with respect to the axes that have positive and negative thermopower, a transverse thermopower arises, in the geometry a Nernst thermopower would appear, but in zero magnetic field. This can be used to design transverse thermoelectric power generators and transverse Ettingshausen-like coolers. In this talk, several members of this new genus of materials will be described, beyond the original materials (NaSn2As2) on which the effect was discovered [1].

8:30 AM EN14.01.02
Geometrically Defined Thermoelectricity in 2D Materials Achim Harzheim1, Charalambos Evangelis2, Jean Spicée2, Ed McCann2, Yuewen Sheng1, Jamie Warner1, Andrew Briggs1, Vladimir Falko3, Jan Mol1, Pascal Gehring4, and Oleg V. Kolosov5; 1University of Oxford, United Kingdom; 2Lancaster University, United Kingdom; 3University of Manchester, United Kingdom; 4Delft University of Technology, Netherlands

Classical view of thermoelectricity (TE) requires a junction of two differing conductors – two dissimilar metals, p and n doped semiconductors, etc. in order to create the electric potential when the junction is heated (Seebeck effect), or to cool/heat the junction depending on the direction of current flow (Peltier effect). With the efficiency of TE devices defined by both the electronic and heat transport properties of materials, contradictory requirements have to be satisfied, with nanostructuring offering additional “degrees of freedom” allowing to find optimal solutions.

Here we studied atomically flat 2D materials that include zero-gap semiconductor graphene (GR) and semiconducting transition metal dichalcogenides known for their extraordinary electronic and thermal properties. With relativistic carrier dynamics and exceptionally large mean-free path (MFP) of carriers in GR, combined with its highly anisotropic and environment dependent thermal conductance, one can expect unusual thermoelectric properties in such nanostructures. In order to study TE phenomena in these, we applied scanning thermal microscopy (SThM) that uses a sharp tip in point contact (few nm across) with the probed surface. SThM can
measure the local temperature of the heated sample or create a controlled local sample temperature rise, while measuring the resulting heat flow. We used e-beam lithography patterned GR devices of different geometry with attached electrodes that allow to either inject the current into the device, while mapping and measuring the local heat rise (Joule heating and Peltier effect) or to actively heat the SThM probe while providing nanoscale maps of the resulting “thermovoltage” (Seebeck effect). The latter method (we call it scanning thermal gate microscopy, or SThGM) developed for the first time in these experiments turned out to be very efficient in studying TE materials. We used high vacuum environment to eliminate spurious heat dissipation channels boosting accuracy and sensitivity down to mK range, and allowing measurements of samples down to cryogenic temperatures.

Using this methodology, we investigated TE phenomena in GR devices with varying geometry – starting with the simple bow-tie shape with the constriction of about 100 nm wide and 100 nm long connected to the triangular shaped areas expanding to the Au electrodes. While mapping and measuring Peltier cooling at the Au electrode – Gr interface (fully expected in the classical TE phenomena), we completely unexpectedly found that a much stronger Peltier cooling was observed around the constriction area. This phenomenon was confirmed by measuring the Seebeck thermovoltage map. This constriction had no dissimilar materials and we confirmed that no local doping was present by manipulating the back gate of the device to shifting the Dirac point, suggesting novel phenomenon of “geometrically” defined TE.

We then conducted a series of experiments on different geometries (multiple “necks, long constrictions, holes in the uniform ribbon) and varying current densities, comparing these with the MFP and heat flow models, for matching thermovoltage and cooling-heating measurements. These allowed to confirm that the new effect can be explained solely by the geometrical effect of the constriction on the MFP of the carriers in the GR layer. We also analyse experimental measurements of the effect for varying GR layer number, doping as well as nonlinear TE phenomena of “electron wind” effect observed at higher current densities when carrier drift velocity in 2D material becomes comparable with the carriers Fermi velocity.

In summary, we report the novel TE phenomena in 2D materials where geometry of the device alone can produce significant Peltier and Seebeck TE effects, offering new solutions for the efficient and compact TE devices. Additionally, a novel scanning thermal gate microscopy is presented allowing to very effectively study of TE phenomena in a broad range of nanostructures.

8:45 AM EN14.01.03
Enhanced Thermopower of Three-Dimensional Topological Insulators Yu S. Matsushita, Kakeru Ichimura, Khuong K. Hyunh and Katsumi Tanigaki; Tohoku University, Japan

Recent research on thermoelectrics (TE) focuses not only on phonon engineering but also on electronic engineering. Generally, metallic materials have low TE performance as can be explained by Mott relation, where the thermoelectric power (S) of metallic materials is related to the Fermi energy $E_F$ and carrier density $n$ depending on the dimension of the system. Consequently, a large number of carrier density $n$ in metallic materials gives a quite small value of $S$ in contrast to its large electrical conductivity $\sigma$, resulting in a very small value of power factor. Such a general conclusion, however, can be expected to be broken by introducing nonconventional electronic states such as the special surface states in topological materials. Dirac fermions existing on topological materials can be one of the candidates for non-trivial electronic systems, which attract much attention as the unique research platform in this decade. Three-dimensional topological insulators (3D-TIs) show intriguing gapless helical massless Dirac fermions on a two-dimensional (2D) surface of insulating bulk materials. The electronic band of Dirac fermions is characterized by a linear energy dispersion, which gives an extremely high carrier mobility that could enhance conductivity $\sigma$ without decreasing thermoelectric power to be compared with many conventional metals. This is because the thermopower in a 2D Dirac system is related to the carrier concentration $n$ with the special relation and can be different from the relation in the conventional metals, indicating a larger $S$ with the same value of $n$. Such a unique $n$ dependence of $S$ has been observed for graphene first in the past. In the case of 3D-TIs, however, the contribution from bulk carriers prevents such observations and discussions on the TE properties of topological surface Dirac states (TSDs) had been very limited and still ambiguous. In order to have clear understanding for thermoelectrics (TE) of 3D-TIs, it is essential to observe simultaneously the pure surface TE properties and the accurate band structure. Here, we demonstrate clear observations of both thermopower and quantum spin Hall effect (QSHE) using high quality single crystal flakes of 3D-TIs. According to the high bulk insulation of our 3D-TIs, we succeeded to observe clear QSHE of the TSDS at high temperatures and in the thickness of mm. Our high quality
3D-TIs enable one to determine accurate thermoelectric parameters. The details of band picture of surface states can be evaluated from both Shubnikov-de-Hass (SdH) oscillations and the QSHE. By employing the fine and accurate experimental data, we will discuss how the high efficient TE properties of 3D-TIs can be available.

9:00 AM EN14.01.04
High Thermoelectric Figure of Merit via Tunable Valley Convergence Coupled Low Thermal Conductivity in $A^\text{II}B^\text{IV}C^\text{V}$ Chalcopyrites Madhubanti Mukherjee, George Yumnam, Rinkle Juneja and Abhishek K. Singh; Indian Institute of Science, India

Development of efficient thermoelectric materials requires a designing approach that leads to excellent electronic and phononic transport properties. Tetragonal chalcopyrites materials have recently attracted significant attention in optoelectronic and photovoltaic applications. Using first principles density functional theory and semiclassical Boltzmann transport theory, we report unprecedented enhancement in electronic transport properties of chalcopyrites $A^\text{II}B^\text{IV}C^\text{V}_2$ (group II = Be, Mg, Zn, and Cd; group IV = Si, Ge, and Sn; and group V = P and As) via isoelectronic substitution. Multiple valleys in conduction bands, present in these compounds, are tuned to converge by substitution of group IV dopant. Additionally, this substitution improves the convergence of valence bands, which is found to have a direct correlation with the tetragonal distortion of these chalcopyrites. Furthermore, several chalcopyrite compounds with heavy elements such as Zn, Cd, and As possess low phonon group velocities and large Gruneisen parameters that lead to low lattice thermal conductivity. Combination of optimized electronic transport properties and low thermal conductivity results in maximum ZT of 1.67 in CdGeAs$_2$ at moderate n-type doping. The approach developed here to enhance the thermoelectric efficiency can be generalized to other class of materials.

9:15 AM EN14.01.05
Using Energy Filtering to Change the Thermoelectric Design Paradigm Seyed Aria Hosseini$^1$, Jackson R. Harter$^2$, Devin Coleman$^1$, Todd S. Palmer$^2$, Lorenzo Mangolini$^1$ and P. Alex Greaney$^1$; $^1$University of California, Riverside, United States; $^2$University of Oregon, United States

Complex Materials and Novel Theoretical Methods Researchers have recently developed processes for synthesizing monolithic Si with improved thermoelectric figure-of-merit, ZT. These materials obtain higher ZT through a finely controlled array of secondary phase inclusions. In this work we elucidate the role these particles play in two processes to increase ZT: (1) scattering of phonons to reduce thermal conductivity, and (2) energy selective scattering of electrons to increase the seebeck coefficient. For (1) Boltzmann transport simulations are used to predict the collective effect of the scattering mechanisms on thermal conductivity of different silicon samples and compared with equilibrium molecular dynamics counterpart. For (2) Fermi’s golden rule is used to compute electron scattering interactions with nanoparticles. There scattering rates are combined with electron-phonon and electron-impurity scattering rates using Mathessen’s method. The results are used to predict the electrical properties of the Si with different volume fraction of nanoparticles. We further present a semiclassical model of thermoelectric transport properties in the presence of energy selective electron scattering — electron energy filtering. The model is validated against a set of Si based thermoelectrics containing silicon carbide dispersoids. The model is extrapolated to explore how energy filtering can be used to enhance the thermoelectric figure of merit, ZT, in a wide range of materials. Counterintuitively, this model predicts that the highest ZTs can be achieved in the tails of the Fermi-dirac distribution of thermoelectrics doped to have high carrier concentration. Boltzmann transport simulations are used to predict the collective effect of the scattering mechanisms on thermal conductivity of different silicon samples. Together, these models present a new strategy for optimization of thermoelectrics that breaks materials engineers free from the traditional paradigm of engineering the fermi energy at the band edge.

Revealing the Intrinsic Electronic Structure of ZrNiSn Half-Heusler Thermoelectric Materials Chenguang Fu and Claudia Felser; Max Planck Institute for Chemical Physics of Solids, Germany

Half-Heusler compounds have recently been developed as the most promising high-temperature thermoelectric materials due to their excellent power factor. However, experimental investigations of their intrinsic electronic structures, underpinning the high power factor, are still rare. Herein, high-resolution angle-resolved photoemission spectroscopy, electrical and optical measurements, and first-principles calculations were performed to explore the intrinsic electronic structure of ZrNiSn, the archetypical n-type half-Heusler thermoelectric material. For the first time, the real bandgap of ZrNiSn was revealed as 0.5–0.6 eV using various methods, which are significantly larger.
than the values reported in previous literature. Additionally, a large anisotropic conduction band was directly identified to contribute to the high power factor. This successful observation of intrinsic electronic structure relies on the synthesized high-quality single crystals, which have much fewer Ni interstitial defects and negligible in-gap states. This work demonstrates the significance of processing-structure-property relationships in materials research and provides new insights to improve the thermoelectric performance of half-Heusler compounds.

**Thickness Dependent Magneto-Thermoelectric Effects in Co2MnGa Thin Films** Gyuhyeon Park1,2, Helena Reichlova3,4, Richard Schlitz3,4, Michaela Lammel1,4, Anastasios Markou5, Dominik Kriegner6, Claudia Felser4, Kornelius Nielsch1,2, Sebastian T. Goennenwein3,4, Andy Thomas1,4 and Nicolas Perez1; 1Leibniz-Institute for Solid State and Materials Research (IFW), Germany; 2Technische Universität Dresden, Germany; 3Institute für Festkörper- und Materialsphysic and Würzburg-Dresden Cluster of Excellence ct.qmat, Technische Universität Dresden, Germany; 4Center for Transport and Devices of Emergent Materials, Technische Universität Dresden, Germany; 5Max Planck Institute for Chemical Physics of Solids, Germany; 6Institute of Physics ASCR, v.v.i., Czechia

The anomalous Nernst effect (ANE), which is magneto-thermo-electronic transport, manifests itself experimentally as an anomalous transverse voltage perpendicular to both the heat current and magnetization.

We report a robust ANE in Co2MnGa thin films in the thickness series between 10 and 50 nm at 300 K. We further employ this thickness series to study the Mott relation and show that the anomalous Hall coefficient, which is thermoelectric counterpart of ANE, and the NANE measured in identical structures under equal conditions exhibit a similar dependency. Moreover, in selected samples, we measure all four transport coefficients – longitudinal and transversal resistivity, Seebeck and NANE – and we show that the values of measured and calculated Nernst coefficients and conductivity are comparable when assuming the validity of the Mott relation.

**Making Quantum Transport Visible in Thermoelectric Bi2Te3, Sb2Te3 and Bi2Se3 Nanoparticles** Gabi Schiering1, Sepideh Izadi1, Patrick Kawulok1, Lauritz Schnatmann1, Heiko Reith1, Manuel Loor2,1, Sarah Salloum2, Kornelius Nielsch1, Nicolas Perez Rodriguez and Stephan Schulz2; 1Leibniz-Institut IFW Dresden e.V., Germany; 2University of Duisburg-Essen, Germany

Bi2Te3, Sb2Te3, and Bi2Se3, are well established thermoelectric materials. To improve the thermoelectric performance of these materials, nanoparticles from a wet-chemical synthesis using metal-organic precursors and ionic liquids were synthesized as starting materials. By hot pressing these nanoparticles under inert conditions, record figure of merit ($zT$) values were demonstrated, for example of $zT=1.5$ at 470 K for Sb2Te3 nanoparticles from this synthesis. But these materials are also three-dimensional (3D) topological insulators (TI) exhibiting a bulk bandgap and highly conductive, robust, gapless surface states. Using the same nanoparticles, but slightly different compaction parameters, highly porous bulk materials were obtained. The high porosity and high interface density creates a situation in which surface transport from the topological states becomes visible in the transport properties at low temperatures. The high surface-to-volume ratio is hereby beneficial, because usually the transport properties of Bi2Te3, Sb2Te3, and Bi2Se3 are dominated by the bulk carriers. Using this nanoparticle-based materials’ design, the highly porous macroscopic sample features a carrier density of the surface states in a comparable order of magnitude as the bulk carrier density. Further, the sintered nanoparticles impose energetic barriers for the transport of bulk carriers at the interfaces (hopping transport), while the connected surfaces of the nanoparticles provide a 3D percolation path for surface carriers. This also helps to emphasis the topological transport properties. Within this
article, both the synthesis and nanoparticle processing as well as the transport properties of these combined thermoelectric and 3D TI samples will be discussed.

11:00 AM EN14.02.02
Thermoelectric Properties of SnSe—Improving Semiclassical Models Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Tin chalcogenides and specifically SnSe have recently gathered significant attention thanks to reports of record-high thermoelectric efficiency while devoid of toxic elements that might hinder commercial usage. The origin of the large thermoelectric figure of merit of SnSe, i.e. the ZT factor, is still subject of investigations, due to a number of interesting properties combined in this material. The large lattice anharmonicity is responsible for the low values of lattice thermal conductivity, whereas the presence of multiple valleys in the electronic band structure close to the chemical potential enhances the electrical transport characteristics. So far, theoretical modeling has mostly focused on describing the transport properties of SnSe using a semiclassical approach based on the Boltzmann transport equation. However, such model may not be sufficient to accurately describe the properties of this material. In this work, we study corrections to the Boltzmann transport equation, that can be derived more generally from many-body perturbation theory and parametrized using first-principles calculations. In particular, these corrections become more important for crystals with complex band structures (e.g. multi-valleys) and large temperatures, which routinely occur in thermoelectric materials, where electrons and holes are not a well-defined material excitations, and a description based on the density-matrix becomes necessary. We test these corrections in SnSe and show how they improve estimates of thermoelectric properties (by up to a factor 2), leading to an overall better agreement with experiments and providing a general path towards improved simulations of thermoelectric materials.

11:15 AM EN14.02.03
Thermoelectric Properties of Hexagonal Perovskite Chalcogenides with Low Thermal Conductivity Shanyuan Niu1, Sam Miller2, Joanna M. Guerrero1, Boyang Zhao1, Brent C. Melot1, G. Jeffrey Snyder2 and Jayakanth Ravichandran1; 1University of Southern California, United States; 2Northwestern University, United States

The ternary perovskite oxides with good stability and high power factor, epitomized by SrTiO3, have been studied for high temperature thermoelectrics. Their relatively large lattice thermal conductivity remains an obstacle towards achieving high thermoelectric figure of merit, ZT. Binary chalcogenides such as PbTe benefit significantly from reduction of lattice thermal conductivity due to heavy elements and give rise to several materials with record ZT values about 2. Ternary chalcogenides with perovskite and relates structures could potentially marry the attractive features of both materials systems. We have recently explored these semiconductors for optoelectronic applications.1,2 We chose the model system of BaTiS3 with a low bandgap and a hexagonal perovskite structure to study the thermoelectric properties. Low thermal conductivity around 0.6 W/mK, Seebeck coefficient of around 170 mV/K and electrical conductivity of about 1 W/cm were obtained at room temperature. Differential scanning calorimetry and thermogravimetric analysis indicate stability up to 1000K in air. The thermoelectric figure of merit was extracted as a function of temperature and a ZT value up to 0.03 was obtained at 700K. We attempted doping BaTiS3 with Nb and La, but no significant improvement on electrical conductivity was observed. More in-depth doping studies are needed to achieve higher ZT in these materials.

Simultaneous Increase in Seebeck Coefficient and Electrical Conductivity of BiCuSeO/Ca3Co4O9 Composites Emre Burak Yurdakul1,2, Murat Gunes3 and Ahmet Macit Ozenbas1; 1Orta Dogu Teknik University, Turkey; 2Aselsan, Turkey; 3Erzincan University, Turkey

In this work, we report a simultaneous increase in Seebeck coefficient and electrical conductivity, that results in increasing power factor, of Ca3Co4O9 (C-349) ceramic by forming a composite system together with another promising oxyselenide; BiCuSeO (BCSO). Composite engineering is a promising method to develop the existing properties of thermoelectric materials. The aim of this work is therefore to explore the unique thermoelectric properties of promising C-349 and BCSO oxides, then to investigate the new properties of their composites.
Pristine C-349 and BCSO were synthesized using sol-gel and solid-state reaction methods, respectively and mixed by several ball-milling steps followed by cold compaction. Bulk composites as pellets have been prepared and thermoelectric properties have been investigated. The electrical properties of samples were investigated by Hall effect measurements at room temperature. Lakeshore 7700A system was used with van der Pauw geometry between 0.15 and 1.5 T. Non-destructive measurements of the Seebeck coefficient and the electrical conductivity were carried out under vacuum in a temperature interval between 300 and 900 K using a lab-made system. As the BCSO content increased, the electrical conductivity and Seebeck coefficient were simultaneously enhanced. The highest power factor was obtained as 0.17 mW/mK² in the composite system that contains 5 wt % BCSO. This value represents nearly 41% improvement in the power factor of pristine C-349 at 900 K. The addition of BCSO phase causes a slight decrease in carrier concentration and at the same time creates more porous structure. Both consequences have a positive impact on Seebeck coefficient. The reason for enhancement in electrical conductivity is related with a high increase in electron mobility without significant decrease in carrier concentration. These results prove that composite engineering technology will provide a promising advantage in developing thermoelectric materials with higher efficiencies. However, most works carried out about composite engineering intend to reduce the thermal conductivity. Therefore, this work shows the potential of power factor enhancement of composite materials in order to produce highly efficient thermoelectric materials.

11:45 AM EN14.02.05
Oxide Thermoelectric Materials—Porous Influence Leilane R. Macario¹,², Edson R. Leite¹,³ and Holger Kleinke²; ¹National Center for Research in Energy and Materials, Brazil; ²University of Waterloo, Canada; ³Federal University of Sao Carlos, Brazil

As the concern about depletion of non-renewable resources is growing, waste heat harvesting has become one of the effective approaches for solving the energy shortage issue. Thermoelectric materials are promising candidates for solid-state energy generators for converting the huge amount of industry and automobile generated waste heat into electricity. The material’s performance is characterized by the figure of merit \( zT = S^2\sigma T/\kappa \), where \( S \) is the Seebeck coefficient, \( \sigma \) the electrical conductivity, \( T \) the absolute temperature, and \( \kappa \) the thermal conductivity of the material. Oxide thermoelectric materials have the advantages of low cost, environment-friendly manufacturing and chemical stability at high temperatures. However, oxides have been historically regarded as out of the question for good thermoelectric materials, because they are mostly poor conductors due to their high ionic nature and good heat conductors due to the light oxygen. Thus, alternatives such as presence of dopants, densification mechanisms, introduction of a second phase, and nanostructuring are considered to enhance the thermoelectric properties in oxides. The possibility of controlling the pores for optimization of materials properties motivates studies relating to the presence of dopants and densification mechanisms. Bi-layered pellets contain a layer of tin oxide doped with antimony, Sb-SnO₂, and a sintering additive, manganese oxide, MnO₂ allowed the production of materials with lower thermal conductivity and possible enhanced electrical conductivity. Thereby, these materials have the potential to improve the energy conversion and contribute to the expansion of new thermoelectric oxides materials.

Thermal Conductivities and Phonon Mean Free Paths of Silicon Germanium Nanowires of Different Lengths Gabriella Coloyan¹, Brandon P. Smith¹, Kevin D. Parrish², Feng Wen¹, Evan Fleming¹, Karalee Jarvis¹, Alan J. McGaughey², Emanuel Tutuc¹ and Li Shi¹,¹; ¹University of Texas at Austin, United States; ²Carnegie Mellon University, United States

Silicon germanium (SiGe) is a high-temperature thermoelectric material. Due to alloy scattering of short-wavelength phonons in SiGe, long-wavelength phonons make an important contribution to the lattice thermal conductivity of SiGe. The effects of nanostructures on suppressing the lattice thermal conductivity have been extensively studied for different materials including SiGe. However, the phonon mean free paths and lattice thermal conductivities of SiGe
bulk crystals and nanowires have remained one of the outstanding questions in the study of phonon transport and nanostructured thermoelectric materials due to inconsistent results obtained in previous experiments. Here we report multi-probe measurements of the intrinsic thermal conductivities of different segments of the same SiGe nanowires. Our measurement results reveal a weak length dependence of the thermal conductivity of the SiGe nanowires, and are in agreement with a Monte Carlo simulation of phonon transport in SiGe nanowires with diffuse surface.

2:00 PM EN14.03.02
Phonon Scattering Mechanism in Thermoelectric Material Revisited via Resonant X-Ray Dynamical Diffraction Adriana Valerio1, Marli d. Cantarino1, Fernando A. Garcia1, Claudio M. Remedios2, Guilherme Calligaris3, Stefan Kycia4 and Sergio L. Morelhao1,4; 1University of Sao Paulo, Brazil; 2Universidade Federal do Pará, Brazil; 3Brazilian Synchrotron Light Laboratory, Brazil; 4University of Guelph, Canada

Thermoelectric properties of the materials originate from thermal conduction by free charge carriers instead of by collective lattice vibrations (phonons). Understanding the scattering mechanism, or dissipation, of phonons allows the engineering of materials with higher coefficient of Seebeck [1], i.e. higher difference of electric potential created for a given thermal gradient. In skutterudite type of thermoelectric materials, dissipation of phonons are attributed to localized, low frequency and anharmonic vibrations of heavy ions of the lanthanide family introduced into the large voids of the crystalline structure. Since most of these materials can be synthesized in the form of high quality single crystals, we have the possibility of revisiting the phonon scattering mechanism through x-ray phase measurements via dynamic diffraction effects [2]. Structure factor phases are susceptible to the differences between the vibration amplitudes of the atoms (root mean square atomic displacements), or in other words, phase values are invariants with temperature only when all occupied sites of the unit cell have the same Debye-Waller factor.

Structure factor calculation in model structures revealed suitable Bragg reflections and x-ray energies to resolve the difference in atomic vibrations as a functions of temperature. It also revealed a giant resonant phase shift for the whole family of filled skutterudites RFep12 (R=Ce, La, Nd, Pr, Sm). By exploiting this resonant phase shift with synchrotron x-rays at different temperatures in CeFe4P12, we were able to demonstrated that rattling of Ce alone inside the icosahedral cage is not enough to explain phonon scattering and that the whole cage of 12 P is taking part of scattering mechanism.

2:15 PM EN14.03.03
Anharmonic Phonons and Electron-Phonon Coupling in Thermoelectrics SnSe and SnS Shan Yang1, Tyson Lanigan-Atkins1, Dipanshu Bansal1,2, Jennifer Niedziela3, Andrew May1, Tao Hong3, Georg Ehlers5, Songxue Chi3, Douglas Abernathy1 and Olivier Delaire1,1; 1Duke University, United States; 2Indian Institute of Technology Bombay, India; 3Oak Ridge National Laboratory, United States

Understanding electron-phonon and phonon-phonon interactions is critical for the design of new thermoelectric materials, in which the energy conversion efficiency is determined by the concurrent optimization of electrical and thermal conductivities. SnSe is a high-efficiency thermoelectric material, whose ultralow thermal conductivity originates predominantly from phonon anharmonicity [1,2], while SnS is of interest for both thermoelectric and photovoltaic applications. Previous inelastic neutron scattering (INS) measurements and first-principles simulations of SnSe identified the dramatic softening of TO (transverse optical) mode in the ambient Pnma phase, anisotropic dispersion of acoustic modes and velocities [2,3,4]. SnSe and SnS have similar crystal structures and electronic band structures below and above a second-order structural phase transition to a Cmcm phase at T=800K. Our INS measurements of SnS and SnSe extended previous studies to higher temperatures and directly revealed the condensation of a zone boundary TA (transverse acoustic) mode in Cmcm phase, which yields the Brillouin zone folding and re-emerges as the zone-center TO mode in Pnma. By including anharmonic
renormalization effects into the temperature-dependent force-constants, our first-principles calculations successfully reproduce the experimental phonon dispersions and the soft-mode condensation across the Cmcm-Pnma transition. The significant suppression of thermal conductivity near the phase transition temperature could be captured by including renormalized anisotropic group velocities into thermal conductivity calculations. Further, our ab initio molecular dynamics simulations could be used to understand electron-phonon coupling behaviors accounting for the response of SnSe and SnS under photo-excitation.

*Estimations of Thermal Conductivity and Thermoelectric Performance through Phase Transitions* Matthias T. Agne, Peter W. Voorhees and G. Jeffrey Snyder; Northwestern University, United States

The accurate characterization of thermal conductivity \( \kappa \), particularly at high temperature, is of paramount importance to many materials, thermoelectrics in particular. The ease and access of thermal diffusivity \( D \) measurements allows for the calculation of \( \kappa \) when the volumetric heat capacity, \( \rho c_p \), of the material is known. However, in the relation \( \kappa = \rho c_p D \), there is some confusion as to what value of \( c_p \) should be used in materials undergoing phase transformations. Herein, it is demonstrated that the Dulong-Petit estimate of \( c_p \) at high temperature is not appropriate for materials having phase transformations with kinetic timescales relevant to thermal transport. In these materials, there is an additional capacity to store heat in the material through the enthalpy of transformation \( \Delta H \). It is shown in a model Zn4Sb3 system that the decrease in \( D \) through the phase transition at 250 K is fully accounted for by the increase in \( c_p \). Importantly, \( \kappa \) changes smoothly through the phase transition. Consequently, reports of \( \kappa \) diverging through phase transitions have likely overlooked the effects of excess heat capacity on thermal properties measurements and overestimated the thermoelectric efficiency, \( zT \).

*Correction of Lattice Thermal Conductivity in Compounds with Electrically Resistive Grain Boundaries* Max Wood, Jimmy Kuo and G. Jeffrey Snyder; Northwestern University, United States

Nano structuring thermoelectric materials has long been a technique to scatter phonons and lower a material’s lattice thermal conductivity\(^1\). The lattice thermal conductivity of a material has historically been estimated by subtracting the electrical portion of thermal conductivity (calculated using the Weidman-Franz law) from the total thermal conductivity of a material (\( k_L = k - \sigma T \)). This method treats heat conducted by phonons and heat conducted by electrons as two separate and independent transport channels. While nano-structuring is known to scatter phonons, in some materials shrinking the grain size can have a detrimental effect on the electronic properties through additional grain boundary scattering\(^2\). Herein we discuss how this grain-boundary scattering can lead to underestimating the electronic thermal conductivity, which necessitates a correction term to our estimation of lattice thermal conductivity. We demonstrate this correction using experimental data on \( \text{Mg}_3\text{Sb}_2 \) and show examples in the literature of \( \text{CoSb}_3 \), \( \text{Bi}_2\text{Te}_3 \), and other materials that might have benefitted from using this type of correction.

Point Defects as Phonon Superscatterers Georg Madsen; Technische Universität Wien, Austria

Dopants play an important role in engineering the electronic properties of semiconductor materials. At the same time they can strongly influence the phonon scattering processes and thereby the thermal conductivity. We have recently shown how Boron point defects in 3C-SiC act as “superscatterers” and exhibit resonant phonon scattering which is one to two orders of magnitude higher than other defects.[1] The increased scattering leads to a thermal conductivity that is suppressed by one to two orders of magnitude.

In order to understand the physics behind and the factors causing resonance scattering, we explain the results with the help of a simple 1D mono-atomic linear chain.[2] We show that small lattice distortions emanating from two or more close energy minima in potential energy surface lead to very large perturbations of the interatomic force constants. Such a behavior is characterized by a peak in the trace of imaginary part of the T matrix (which is closely related to the scattering rates) and a reflection coefficient approaching unity.

The strong influence of the potential energy surface surrounding the defect atom on the thermal conductivity opens a new path to tailor thermal conductivities where required values range from very low in thermoelectric materials to very high in power electronics applications. Using doping of GaAs as an example[3], we show how the provided insights can be used to identify potential superscatters.

Finite Element Modelling of Optically Pumped Thermoreflectance David A. Lara Ramos¹,2,3, Kerry Maize⁴,4, Nicolas Perez¹, Gabi Schierning¹, Kornelius Nielsch¹,2 and Ali Shakouri⁴,4; ¹Leibniz Institute for Solid State and Materials Research, Germany; ²TU Dresden, Germany; ³Consejo Nacional de Ciencia y Tecnología (CONACyT), Mexico; ⁴Purdue University, United States

Thermoreflectance microscopy is a noninvasive optical technique that is capable of mapping 2D temperature fields of surfaces with high spatial and time resolution. State of the art thermoreflectance microscopy set-ups use electrical current to thermally excite the device or sample under study and so generate temperature differences. This technique is particularly useful for investigating hot spots in integrated circuitry leading to failure or premature fatigue of microelectronic components [1]. It is also a powerful tool for investigating thermal properties of materials [1, 2] and thermal characterization of micro thermoelectric devices [3]. All-optical pump probe thermoreflectance microscopy, which thermally excites the sample by a pump laser spot focused on the sample’s surface, has recently been proposed as a promising tool for investigating anisotropic thermal properties of thin film hetero structures [4]. The later research efforts motivates the technique’s further development, since thermoelectric materials often present anisotropic thermal transport properties whose experimental characterization is challenging, especially in thin films. In this work an all-optical pump probe thermoreflectance microscopy is used to study a series of thin film multilayers of TiN/AlScN deposited on MgO substrates [5] which present tunable anisotropy. The temperature distribution on the surface of the sample was then analyzed by the probe laser and correlated to finite element modelling (FEM) simulations. FEM allowed us to systematically analyze, using realistic parameters, the impact of various experimental factors that affect the result of measurements. We gained understanding about the required experimental conditions in order to extract cross plane and in plane thermal conductivity of the thin films. Using FEM, a measure of the sensitivity required by the experimental device was obtained.

Thermoelectric Materials with Large Anharmonic Phonons Katsumi Tanigaki1 and Jiazhen Wu2; 1Tohoku University, Japan; 2Tokyo Institute of Technology, Japan

Anomalous and nearly dispersionless phonons have recently been observed in many materials with a void (an inner space with large freedom of motion) inside a host cage containing a filler as the guest atom inside (usually called rattler), such as intermetallics, brownmillerite, skutterudite, pyrochlore and clathrate. The cage atoms are connected by covalent bonds, providing a robustly solid wall and a sufficient space for accommodating a guest atom. Since the guest atom in a cage is only weakly interacted with the surrounding atoms forming a cage, it can vibrate freely under a weakly-bound condition and shows an anomalous motion with low-energy excitation (ALE) and a large atomic displacement parameter (ADP). The rattling phonons of the ALE modes are scientifically important for: (1) large coupling with conduction electrons, giving rise to a significant modification of electron effective mass; (2) interactions with propagating phonons, leading to an enhancement of scattering probability of phonons and consequent low thermal conductivity which is useful for thermoelectric applications. ALE rattling phonons observed in cage materials have been both experimentally and theoretically investigated. The rattling phonon branches were shown to be optical-branch-like at around 5 meV, which was lower than the energies of the top of acoustic phonon branches, giving rise to ALE peaks in the phonon density of states (PDOS). The ALE vibration modes have also been detected and intensively discussed by Raman spectroscopy, optical conductivity, heat capacity (HC), and temperature dependent ADP obtained from crystallographic refinement of x-ray/neutron diffraction data. However, the origin of the low energy modes was still not perfectly clear. In the present paper, we address that van der Waals-type repulsive interactions between a guest atom and the atoms residing a host cage can be the origin of the ALE modes. The ALEs of three typical cage compounds of clathrates, skutterudites and pyrochlores have intensively been investigated. An exponential-form relationship between the force constant Fc and the free space derived based on the Morse-type van der Waals potential, gives very reasonable interpretations on ALEs. The Fc’s evaluated from the characteristic energies of the guest atoms are shown to vary exponentially as a function of the free space of guest atoms, being in good agreement with the unified relationship. By comparing the fitting parameters among clathrates, skutterudites, and pyrochlores, the features that specify each family of cage material are discussed. The anisotropic 3D van der Waals-type interactions significantly modify the physical properties of cage materials via phonon-phonon and electron-phonon interactions and play a very important role in thermoelectrics. The strategy of how to improve the figure of merits of these thermoelectric materials will be presented.

Effects of Structural Correlation on Phonon Transport in Random Composites and Bayesian Optimization Taishan Zhu, Giuseppe Romano and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Structural defects have become a primary driver for materials design in thermoelectrics and (opto-)electronics, but the understanding of correlated disorder and their effects on material properties is still incomplete. In this work, we theoretically study the effects of correlated disorder on lattice conduction, taking graphene-hexagonal boron nitride...
composites as our model system. While the kinetic theory suggests that the effective conductivity is independent of structural correlation, our non-equilibrium Green’s function analysis and Green-Kubo formalism implemented within molecular dynamics simulations both show a strong dependence on the correlation functional, which we propose as a new designing degree of freedom viewing all defects collectively. Among all functionals considered, we show that a hyperuniform distribution of defects leads to the highest conductivity, while the Cauchy and Dagum correlation functions give conductivities as low as amorphous limit. Our spectral analysis shows the preservation of long-wavelength modes in the former, while the latter approach the amorphous limit where phonon concepts are no longer invalid. Aiming at thermoelectric applications, we apply Bayesian learning techniques to minimize the thermal conductivity at a given defect density, which could be extended to thermoelectric optimization with constraints in electrical properties.

4:45 PM EN14.04.05
First Principles Investigation of Anomalous Pressure Dependent Thermal Conductivity of Chalcopyrites Loay A. Abdelhafiz; RWTH Aachen, Germany

The effect of compression on the thermal conductivity of CuGaS₂, CuInS₂, CuInTe₂, and AgInTe₂ chalcopyrites (space group I-42d) was studied at 300 K using phonon calculations. The lattice thermal conductivity (κₚ) was evaluated by solving the Boltzmann transport equation with harmonic and third-order force constants. Striking differences are obtained between the κₚ behavior of CuGaS₂, CuInS₂, CuInTe₂, and AgInTe₂ under compression. The κₚ value of CuGaS₂ always increases with pressure up to 9.5 GPa. A drastically different functional dependence is obtained as soon as heavier In is considered instead of Ga (BIII in AIBIIICVI₂). Under pressure up to 6 GPa, κₚ of CuInTe₂ decreases from 7.6 to 4.1 W m⁻¹ K⁻¹, which is anomalous. This is consistent with the experimental data [1,2], implying that important physics is captured within the methodology employed herein and structural modulations are not indispensable to drive the anomaly. By exchanging Te with lighter S (CVI in AIBIIICVI₂) and hence forming CuInS₂, κₚ increases up to 2 GPa, which is again a common behavior and equivalent to that of CuGaS₂. Upon a further pressure increase, κₚ begins to decrease and reaches a slightly lower value at 8 GPa than that at 0 GPa. To account for the effect of the transition metal constituent (Al in AIBIIICVI₂), Cu in CuInTe₂ is exchanged with heavier Ag. AgInTe₂ exhibits a significantly lower κₚ value and a steeper decrease in κₚ under pressure, reaching 0.2 W m⁻¹ K⁻¹ at 2.6 GPa.

Using the Slack model, Gui et al. [3] have showed that the Thermoelectric Figure of Merit for CuInCVI₂ (CVI = S, Se, and Te) uniformly increases at elevated temperatures up to 850 K. However, the effect of pressure on κ has not thoroughly been studied. Using the quasi-harmonic Debye model, Sharma et al. have evaluated electronic, thermal, and mechanical properties of AgInCVI₂ (CVI = S, Se, and Te) under pressure and reported a noticeable reduction in the Grüneisen parameter and volumetric thermal expansion coefficient as well as bulk modulus [4]. Since the Grüneisen parameter and volumetric thermal expansion coefficient can be related to κ, it appears that pressure effects on κ are considerable. This is consistent with an experimental study reporting a decrease in κ by 30% for CuInTe₂ under pressure up to 2.3 GPa [1]. Generally, κ should increase under compression [5]. This implies that the behavior of CuInTe₂ is anomalous. Two possible mechanisms have been proposed based on experiments: (i) anharmonic behavior of lattice vibrations [1] and (ii) structural modifications under high pressure (e.g. stacking faults) [2]. The underlying physics of the κ reduction under compression of CuInTe₂ and possibly other AIBIIICVI₂ compounds is not fully understood.

This can be understood based on the phonon dispersion curves. Softening of the acoustic phonon modes occurs for these anomalous chalcopyrites. This leads to the negative Grüneisen parameter and negative volumetric thermal expansion coefficient. The decrease in phonon frequency upon compression is suggested to be due to the phonon oscillations in the form of a rotational motion rather than compressive waves. The physical origin of the anomalous thermal conductivity is thus identified in this work and AgInTe₂ with a very low thermal conductivity of 0.2 W m⁻¹ K⁻¹ at 2.6 GPa is proposed to be a promising thermoelectric compound.

High and Low Thermal Conductivity Phase Boundary in SrTiO$_3$–SrNbO$_3$ Solid-Solution System Yuqiao Zhang$^1$, Hai Jun Cho$^1$, Kenyu Sugo$^1$, Masashi Mikami$^2$, Sungmin Woo$^3$, Myung-Chul Jung$^4$, Woosuck Shin$^2$, Woo Seok Choi$^2$, Myung Joon Han$^4$ and Hiromichi Ohta$^1$; $^1$Hokkaido University, Japan; $^2$National Institute of Advanced Industrial Science and Technology, Japan; $^3$Sungkyunkwan University, Korea (the Republic of); $^4$Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Electron-doped strontium titanate (SrTiO$_3$) is one of the candidate materials of thermoelectrics. In order to increase the carrier electron in SrTiO$_3$, usually, a part of Ti ions are substituted by Nb ions or a part of Sr ions are substituted by La ions. Although many researches on the electrical conductivity and thermopower of Nb or La-doped SrTiO$_3$ and Nb or La-doped SrTiO$_3$-based superlattices have been done thus far$^{[1,2]}$, there are only a few researches on the thermal conductivity because of the low solubility limit of dopant ions in SrTiO$_3$ bulk. Recently, we successfully fabricated SrTi$_{1-x}$Nb$_x$O$_3$ ($0 \leq x \leq 1$, STNO)$^{[1]}$ and Sr$_{1-x}$La$_x$TiO$_3$ ($0 \leq x \leq 1$, SLTO) full-range solid-solutions by PLD and found the anomalous behaviour of the electron transport properties. Since thermal conductivity is strongly correlated with the electron transport properties, we studied the thermal conductivity of the solid-solutions. Here we report high and low thermal conductivity phase boundary in SrTiO$_3$–SrNbO$_3$ solid-solution system. The $x$-dependent thermal conductivities ($\kappa$) of STNO and SLTO were measured by time-domain thermoreflectance (TDTR) method at room temperature. Steep increase in $\kappa$ was observed around $x \sim 0.5$ for STNO, suggesting the existence of a phase transition. However, in SLTO case, all the samples show a $\kappa$ at lower levels compared with SrTiO$_3$ single crystals, where no special behavior was observed. We attributed this special behavior to the polaron effect which only exists in STNO at $x \leq 0.5$ and SLTO and suppresses the $\kappa$. Furthermore, unlike the traditional alloy systems, SrNbO$_3$ with larger average atomic mass shows much higher $\kappa$ than SrTiO$_3$. According to the phonon dispersion calculations, the phonon transport of SrTiO$_3$ shows much more intense scattering between optical and acoustic branches than SrNbO$_3$, which is likely to suppress phonon mean free path for SrTiO$_3$. The Grüneisen parameters of SrTiO$_3$ were much higher than those of SrNbO$_3$, which also will reduce the phonon transport properties. Our findings revealed important role of polaron in heat transport for system with strong electron-phonon couplings, which will be a fundamental contribution to the current knowledge in heat transportation and may be utilized to develop new thermoelectric materials.

Enhanced Thermoelectric Efficiency in $n$-Type Ga-Doped PbTe via Asymmetrical Phase Boundary Mapping Ping-Yuan Deng$^1$, Yi-hui Du$^2$ and Hsin-Jay Wu$^3$; $^1$National Chiao Tung University, Taiwan; $^2$National Tsing Hua University, Taiwan

Lead-tellurides are important mid-temperature thermoelectric (TE) materials. Nevertheless, the moderate $zT$ of $n$-type PbTe limits the development of mid-temperature TE generator. Gallium (Ga) has been a successful $n$-type dopant for PbTe through contributing extrinsic carriers and optimizing the carrier concentration. In this study, the isothermal section of ternary Ga-Pb-Te is determined by various post-annealed alloys. In particular, the single-phase PbTe region could only tolerate a very small amount of Ga, and that single-phase region shows an asymmetrical homogeneity in the ternary Ga-Pb-Te. The combination between TE properties and phase diagram provided a better understanding in the dopant capability, which makes it serves as a crucial guideline for searching the high-efficient alloys where the compositional regions are seldom being explored before. With an as-determined isothermal section in hand as a map, the selective Ga-doped PbTe alloys are grown through the Bridgman method. In the temperature range of 550 K-673 K, an average $z$Tave value $\sim1.21$ (peak $zT$ $\sim1.5$) could be achieved in the Ga-PbTe alloy with the existence of nano-scale strain field.
Thermoelectric (TE) materials convert energy from waste heat into electricity and have been used, e.g., to charge batteries and for refrigeration. Thermoelectric properties are characterized by a figure of merit ($ZT$), $ZT = S^2 \sigma T/k$. $S$ is the Seebeck coefficient, $k$ the thermal conductivity, $\sigma$ the electrical conductivity, and $T$ temperature. This investigation reports respective properties of lead ruthenate Pb$_2$Ru$_2$O$_{6.5}$ and some derivatives. Lead ruthenate has a defect pyrochlore crystal structure. Molar fractions of Ru have been substituted by Pb, using the formula of Pb$_{2+y}$Ru$_{2-y}$O$_{6.5}$ with $y$ increasing from 0 to 0.9. All samples were prepared by solid-state synthesis and characterized by XRF, X-ray diffraction, SEM/EDX, for composition, structure and phase content. Thermal conductivity, electrical conductivity, the Seebeck coefficient and the $ZT$ values will be reported as a function of temperature (room temperature to 300°C) and stoichiometry.

Bulk Nanostructured Calcium Cobalt Oxide Ceramics—A Step towards Significant Enhancement in Thermoelectric Power Factor

Here, the calcium carbonate (CaCO$_3$) and cobalt oxide (Co$_3$O$_4$) in stoichiometric ratio of 3:4:9 for Ca, Co, and O are mixed using high energy ball milling (HEBM), processed for optimized time duration of 48 h followed by drying on hot plate, and calcined at 1123 K for 6 h to achieve Ca$_3$Co$_4$O$_9$ (CCO) powders. The resulting as-synthesized CCO powder was further ball-milled for 2, 6, 12, and 24 h and the FESEM images indicates of nanostructure formation after HEBM for 24 h. The hot-pressed pellets (HPPs) of bulk and nano-powders of CCO are prepared by placing the respective powders in a graphite die, heating the die to 1173 K inside a vacuum chamber, and applying a continuous pressure of 200 MPa for 15-20 mins. These processing parameters (pressure and temperature) are optimized to obtain pure, fully dense (99.2 ± 0.5%), and thermally stable pellets. The microscopic, crystallographic, thermal, and spectroscopic analysis suggest samples processed with longer HEBM time require less time for calcination during synthesis of highly pure crystalline phases of CCO.

The X-ray diffraction (XRD) patterns of all the CCO powders shows the signature (002) plane at ~16.5° along with other peaks and is in well-correlation with JCPDS #00-023-0110 assigned for CCO, consisting of alternate stacking sub-systems of rock-salt-type [Ca$_2$CoO$_3$] layers sandwiched between two hexagonal [CoO$_2$] layers along c-axis. However, XRD signals from both the pellets, B-HPP and N-HPP show peaks for (00$l$) crystallographic planes of CCO. The disappearance of other diffraction (hk$l$) planes corresponding to CCO crystal structure could be attributed to recrystallization and formation of textured growth due to simultaneous application of high temperature and pressure. The degree of orientation of crystallographic planes in the HPPs is evaluated by calculating the Lotgering factor (LF) for the perfectly oriented HPP samples (B-HPP and N-HPP) and their respective randomly oriented CCO powders. The estimated value of LF=1 supports the appearance of ideally aligned (00$l$) crystallographic planes of CCO and indicates achievement of texturing in B-HPP and N-HPP and further confirmed through FESEM.

The significant improvement of ~11 times in PF at 770 K for bulk nanostructured CCO (64.2 $10^{-3}$ Wm$^{-1}$K$^{-2}$) ceramics compared to the HPPs of as-synthesized CCO microstructures (5.8 $10^{-3}$ Wm$^{-1}$K$^{-2}$) is attributed to the enhancement in $S$ triggered due to oxygen vacancies and structural deformations developed during HP process along with introduction of enlarged interface area at grain boundaries. This concept of structural modulation could be adopted for understanding the TE properties in other nanostructured materials as well. The currently prepared bulk nanostructured CCO could be further utilised commercially for mass scale production.
Quantification of Uncertainty in the Lattice Thermal Conductivity of Thermoelectric Materials from a First-Principles Prediction Method

Jiwon Kang1, Semi Bang2 and Daehyun Wee1; 1Ewha Womans University, Korea (the Republic of); 2Samsung Electro-Mechanics, Korea (the Republic of)

Phonon transports in thermoelectric materials are affected by various different factors. One of these factors is the electron-phonon coupling phenomenon, which serves as a scattering source not only to charge carriers but also to heat-conducting phonons, especially in highly-doped thermoelectric materials.

We propose a relatively simple numerical method for estimating lattice thermal conductivity, including the effect of the electron-phonon coupling phenomenon, and present statistical approaches for quantifying the uncertainty in the predicted values. The method employs a formulation similar to that of the EPA (electron-phonon averaged) method. The electron-phonon coupling matrix elements, which are explicitly dependent on the momentum of charge carriers and that of scattering phonons, are approximated as a function of two energies only. At the same time, the energy levels of the involved electron bands are averaged over the Brillouin zone. These simplifications enable us to estimate the effect of the electron-phonon coupling phenomenon in phonon transports. We also demonstrate that the quantification of uncertainty in the predicted values can also be carried out by using statistical techniques like Gaussian process regression (GPR) and empirical bootstrapping, within our proposed method.

EN14.05.07

Effect of Heavy Doping of Aliovalent Cations on Structure and Thermoelectric Properties of NiO-Based Epitaxial Thin Films

Akifumi Matsuda1, Yoshiharu Shinozaki2, Okkyun Seo3, Osami Sakata2, Satoru Kaneko3, Yoshisato Kimura1 and Mamoru Yoshimoto1; 1Tokyo Institute of Technology, Japan; 2National Institute for Materials Science, Japan; 3Kanagawa Institute of Industrial Science and Technology, Japan

Thermoelectric oxide semiconductor thin films contribute to development of conversion devices due to their thermal and chemical stability in a wide temperature range, and property modification derived by to quantum effect[1]. Nickel oxide (NiO) thin films with rocksalt-type crystal structure has also been researched as an p-type semiconductor for thermoelectric sensors, though layered cobalt oxides have acquired interests for the thermoelectric conversion[2,3]. The p-type conductivity of NiO thin films has been modified by doping heterovalent cations such as Li+ (~10 atm%), and by epitaxial synthesis which improves the carrier mobility owing to structural consistency[4]. Reduction of the epitaxy temperature contributes to development of multilayered thermoelectric devices by surface and interfacial flatness, and homogeneous crystallites boundary as phonon scattering sites. Furthermore, low-temperature epitaxial growth allows extraordinarily high doping ratio because of the suppressed re-evaporation and phase segregation, which results in generation of charge carriers associated with local strain. In this study, epitaxial NiO thin films heavily doped with monovalent or trivalent ions, e.g. M=Li and Fe, were grown as Ni1-xMxO (0≤x≤0.7) solid-solution oxide semiconductor at room-temperature, and the effect of dopant ratio on local structure and thermoelectric properties were investigated.

The thin films were grown on atomically stepped α-Al2O3 (0001) substrates by laser molecular beam epitaxy (Laser-MBE) technique equipped with KrF excimer laser (κ=248 nm, d=20 ns, E~1.5 J/cm2) and NiO–Li2O or NiO–Fe2O3 targets. The growth took place in ultra-high vacuum to 10−3 Pa of O2 at room-temperature. As a result, the epitaxial growth of both Ni1-xLi,xO (111) and Ni1-xFe,xO (111) thin films with ultra-flat surface well reflecting morphology of the substrates was obtained. The remained rocksalt-type crystal structure of NiO and expansion of d$_{111}$-spacing along the increased doping ratio up to x=0.5 suggested substitution of Ni2+ with the dopants. The epitaxial thin films demonstrated semiconducting behavior at low-temperature (15—293 K), that electric resistivity decreased along the raised doping ratio (0≤x≤0.6) for either dopants of Li and Fe. The electric conductivity of Ni1-xLi,xO and Ni1-xFe,xO epitaxial thin films at room-temperature were ~3.3×102 Sm−1and ~5.3×101 Sm−1, which properties improved to ~5.0×103 Sm−1 and ~2.9×103 Sm−1 at 493 K, respectively. The Ni1-xLi,xO film demonstrated thermoelectric power factor of ~16 μWm−1K−2 at relatively low-temperature of 593 K, and the Ni1-xFe,xO film revealed negative thermopower which indicated n-type conduction above 493 K. Further detailed structural analyses, and effect of dopant species and ratio on the thermoelectric properties would also be presented.

EN14.05.08

High Temperature Structural and Thermoelectric Study of Argyrodite Ag$_8$GeSe$_6$ Xingchen Shen1,2, Jian He2
Argyrodites with a general chemical formula of \( A_8BX_6 \) (\( A = \text{Cu, Ag}; B = \text{Si, Ge, Sn}; \) and \( X = \text{S, Se, and Te} \)) are known for the intimate interplay among mobile ions, electrons, and phonons, which yields rich material physics and materials chemistry phenomena. In particular, the coexistence of fast ionic conduction and promising thermoelectric performance in \( \text{Ag}_8\text{GeTe}_6, \text{Ag}_8\text{SnSe}_6, \text{Ag}_8\text{SiTe}_6, \text{Ag}_8\text{SiSe}_6, \text{Cu}_8\text{GeSe}_6 \) at high temperatures ushered us to their chemical neighbor \( \text{Ag}_8\text{GeSe}_6 \), whose high temperature crystal structure and thermoelectric properties are not yet reported. In this work, we have employed a growth-from-the-melt technique followed by hot pressing to prepare polycrystalline \( \text{Ag}_8\text{GeSe}_6 \) samples, on which the crystal structure, micro-morphology, compositional analysis, UV-vis absorption, specific heat, speed of sound, and thermoelectric properties were characterized as a function of the Se-deficiency ratio and temperature. We found \((i)\) the crystal structure of \( \text{Ag}_8\text{GeSe}_6 \) evolved from orthorhombic at room temperature to face center cubic above 410 K, with a region of phase separations in between; \((ii)\) like other Argyrodite 816 phases, \( \text{Ag}_8\text{GeSe}_6 \) exhibited ultralow thermal conductivities over a wide temperature range as the phonon mean free path was down to the order of inter-atomic spacing; and \((iii)\) Varying Se deficiency effectively optimized the carrier concentration and power factor, a figure of merit \( zT \) value \( \approx 0.55 \) was achieved at 923 K in \( \text{Ag}_8\text{GeSe}_{5.88} \). These results not only fill a knowledge gap of \( \text{Ag}_8\text{GeSe}_6 \) but also contribute to a comprehensive understanding of 816 phase Argyrodites at large.

EN14.05.09
Dual Role of the Copper Layer to Integrate Electric and Thermal Transport in BiCuSeO
Bin Wei, Yingcai Zhu, Yongheng Li and Jiawang Hong; Beijing Institute of Technology, China

Reducing the lattice thermal conductivity without simultaneously decreasing the charge transport is a challenge to design high-performance thermoelectric materials. The rattling motion of fillers in cage structures has been verified to effectively reduce the lattice thermal conductivity recently. Here, we propose a rattling motion in layered structures to reduce the lattice thermal conductivity without suppressing the charge transport in a leading thermoelectric material---\( \text{BiCuSeO} \) (BCSO). Using a combination of inelastic x-ray scattering (IXS), inelastic neutron scattering (INS) measurements and first-principles calculations, we identify a Cu-dominated rattling mode, reflected as a low lying flat optic band in BCSO. The present results provide new evidence to clarify the origin of the intrinsic ultralow thermal conductivity of BCSO and pave a path for designing high-performance thermoelectric materials.

EN14.05.10
Dynamic Ag\(^+\)-Intercalation with AgSnSe\(_2\) Nanoprecipitates in Cl-Doped Polycrystalline SnSe\(_2\) toward Ultra-High Thermoelectric Performance
Lei Miao and Chengyan Liu; Guilin University of Electronic Technology, China

Recently, thermoelectric lead-free selenides have attracted great attention due to their earth-abundant, low-cost and environment-friendly characteristics. Here we report a new strategy to simultaneously enhance the electronic transport properties and reduce the thermal conductivity of polycrystalline SnSe\(_2\). By combining weak van der Waals bonding with the mobile behavior of Ag\(^+\) ions, the carrier concentration is optimized over a wide temperature range, which can be attributed to the dynamic Ag\(^+\)-intercalation into the van der Waals gap from the Ag\(^+\) ion reservoir AgSnSe\(_2\). On account of additional electrical bridges between interlayers contributed by the intercalated Ag\(^+\) ions and weak anisotropy, an exciting high power factor of up to 7.46 mW cm\(^{-1}\)K\(^{-2}\) at 789 K is achieved along the pressing direction. In addition, the thermal conductivity is simultaneously reduced to 0.57 W m\(^{-1}\)K\(^{-1}\) at 789 K, owing to numerous line defects, phase interfaces, twin boundaries, dislocation and intercalated atomic layers generated after Ag introduction, as well as the anharmonic vibration of Ag\(^+\) ions. As a result, a record peak \( ZT \) of 1.03 at 789 K is realized along the pressing direction, which is 1.6 times larger than the highest reported value (0.63) of polycrystalline SnSe\(_2\) and even comparable to that of p-type polycrystalline SnSe. This study opens a new way to achieve ultra-high thermoelectric performance, especially in layered materials.

The Thermoelectric Properties of Scandium Sesquitelluride
Dean Cheikh\(^1\), Kathleen Lee\(^1\), Wanyue Peng\(^2\), Alexandra Zevalkink\(^2\), Jean-Pierre Fleurial\(^1\) and Sabah Bux\(^1\); \(^1\)Jet Propulsion Laboratory, United States; \(^2\)Michigan State University, United States
Thermoelectric generators (TEG) are solid state heat engines which convert thermal energy to electrical energy. The efficiency of thermoelectric materials is related to Carnot efficiency and a material’s ability to convert heat into electricity. Thermoelectric efficiency is defined by the dimensionless thermoelectric figure-of-merit, $zT$, where $zT = (S^2/\rho\kappa)T$ where low electrical resistivity ($\rho$), high Seebeck coefficient ($S$) and low total thermal conductivity ($\kappa$) are essential for a good thermoelectric materials. Rare earth (RE) tellurides have been studied extensively for use as high-temperature thermoelectric materials, with lanthanum and praseodymium tellurides ($La_{3-x}Te_4$ and $Pr_{3-x}Te_4$) having $zT^*$s = 1.1 and 1.7 at 1273 K, respectively, with optimized carrier concentrations. The high-performance of these compounds warrants further investigation of additional RE tellurides.

While not part of the lanthanide series, scandium is classified as a RE element due to its chemical similarity to other elements of the lanthanide series. However, previous studies of scandium sesquitelluride ($Sc_{2}Te_{3}$) were limited to structural analysis, with the electronic and thermal properties remaining a mystery. In this study, we used a mechanochemical approach to synthesize $Sc_{2}Te_{3}$ and formed compacted pellets using spark plasma sintering (SPS). The thermoelectric properties were then measured from room-temperature to 1100 K. It was found to have a high power factor ($S^2/\rho$) at low temperature and a low $\kappa$, leading to a $zT = 0.3$ from 500 – 750 K. Additionally, temperature-dependent resonant ultrasound spectroscopy was utilized to measure the temperature dependent elastic constants and thermal expansion of $Sc_{2}Te_{3}$.

**High Efficient Thermoelectric pn-Junction Device Based on Bismuth Telluride and Molybdenum Disulfide Films**

Gilbert Kogo, Sangram K. Pradhan, Bo Xiao, Messaoud Bahoura and Makhes K. Behera; Norfolk State University, United States

Layered structure Bi$_2$Te$_3$ and MoS$_2$ thin films were successfully deposited on different substrates using radio-frequency magnetron sputtering technique. Structural, morphological and thermoelectric transport properties of Bi$_2$Te$_3$ and MoS$_2$ thin films have been investigated systematically to fabricate high-efficient thermal energy harvesting TE device. Magnitude of Seebeck coefficient of Bi$_2$Te$_3$ decreases with increase in film thickness. Bi$_2$Te$_3$ grown at 350 °C for 10 minutes which is approximately 120 nm display a maximum value of -126 $\mu$VK$^{-1}$ at 435 K. The performance shows strong temperature dependence when the films were deposited at 300 °C, 350 and 400 °C. Power factor increase from 0.91X10$^{-3}$W/mK$^2$ at 300 K to about 1.4x10$^{-3}$W/mK$^2$ at 350 K. MoS$_2$ films shows positive Seebeck coefficient values. The open-circuit voltage of the pn-junction TEG device increases with increase in $\Delta T$ to about 0.13 V at $\Delta T= 120$ °C. We demonstrated high efficient pn-junction thermoelectric generator device for waste heat recovery applications.

**EN14.05.13**

**Study of Conventional Sintered Cu$_{2-x}$Se Thermoelectric Material via Copper-Vacancy Engineering**

Zhiming Geng$^1$, Dongliang Shi$^1$, Kwok Ho Lam$^1$ and G. Jeffrey Snyder$^2$; $^1$The Hong Kong Polytechnic University, Hong Kong; $^2$Northwestern University, United States

As the featured material of the superionic thermoelectric (TE) material family, copper-chalcogenide Cu$_{2-x}$Se is attracting growing research interest for its excellent TE performance derived from the satisfactory power factor and the ultra-low thermal conductivity induced by the superionic effect. Various efforts have been made and proved to be effective to further enhance the TE performance for Cu$_{2-x}$Se. However, this material is still far from the application stage, which is mainly due to concerns regarding control of the properties and the costly complex fabrication technology. Here we report a scalable pathway to achieve high-performance and tunable Cu$_{2-x}$Se, utilizing conventional sintering technology and copper (Cu)-vacancy engineering with an effective mass model. The figure of merit $zT$ is a competitive value of 1.0 at 800 K for the optimized binary Cu$_{2-x}$Se, based on the precise modeling prediction and Cu-vacancy engineering. The changes in TE properties of Cu$_{2-x}$Se under heating-cooling cycle tests are also revealed. Our work offers the referable method along with the decent parent material for further enhancement of TE performance, paving a possible route for the application and industrialization of Cu$_{2-x}$Se TE materials.

**EN14.05.14**

**Soluble Sb$_2$Te$_3$ Molecular Precursor for Solution Processing of High-Performance Thermoelectric Thin Film**

Seungki Jo$^1$, Sun Hwa Park$^2$, Seung Hwae Heo$^1$ and Jae Sung Son$^1$; $^1$Ulsan National Institute of Science and
The recent interest in portable and wearable electronics lead flexible thin film thermoelectrics to be regarded as promising candidates for the power supply of self-powered systems. Herein, we report a cost-effective solution process to fabricate flexible Sb\textsubscript{2}Te\textsubscript{3} thermoelectric thin films using molecular Sb\textsubscript{2}Te\textsubscript{3} precursors, synthesized by the reduction of Sb\textsubscript{2}Te\textsubscript{3} powder in ethylenediamine and ethanedithiol with superhydride. This synthetic route decreases the size of the Sb\textsubscript{2}Te\textsubscript{3} precursor to the molecular level, thereby dramatically improving the uniformity and continuity of the thin film. Furthermore, thermally stable FePt nanoparticles are homogeneously embedded in the Sb\textsubscript{2}Te\textsubscript{3} thin film by using the mixed ink solution. The fabricated Sb\textsubscript{2}Te\textsubscript{3} thin films on flexible polyimide substrates exhibit a power factor of of \( \sim 8.5 \, \mu \text{W cm}^{-1} \, \text{K}^2 \) at 423 K. Moreover, such thermoelectric performances of thin films are well preserved during 1000 bending cycles. The current study offers considerable potential for a cost-effective manufacturing for high-performance flexible thin film devices.

**EN14.05.15**

Temperature-Dependent Thermoelectric Properties of Directly Deposited Chalcogenide Films

Jose Recatala Gomez\textsuperscript{1,2}, Hong Kuan Ng\textsuperscript{1,3}, Pawan Kumar\textsuperscript{4}, Ady Suwardi\textsuperscript{1}, Iris Nandhakumar\textsuperscript{2}, M. S. M. Saifullah\textsuperscript{1} and Kedar Hippalgaonkar\textsuperscript{1}; \textsuperscript{1}Institute of Materials Research and Engineering, Singapore; \textsuperscript{2}University of Southampton, United Kingdom; \textsuperscript{3}National University of Singapore, Singapore

Thermoelectric (TE) materials can directly convert heat into electricity. The leading commercialized thermoelectric materials are mainly tellurium (Te) based, despite Te being extremely scarce in the Earth crust as well as highly toxic. Among them, bismuth telluride (Bi\textsubscript{2}Te\textsubscript{3}) based materials show the best efficiencies for near room temperature applications.

First, we measure electrochemically deposited Bi\textsubscript{2}Te\textsubscript{3} films and show that a parallel circuit measurement technique is accurate to measure their temperature dependent Seebeck and electrical conductivity. This is in-line with expected properties for grain sizes and doping levels typical in electrochemical deposition. Next, in order to explore cheaper and less toxic alternative chalcogenide materials, we then perform direct nanoscale patterning of Bi\textsubscript{2}Se\textsubscript{3} using a spin-coatable and electron beam sensitive bismuth selenide resist, tris(N,N-diisobutyl-N’-(benzoylselenoureato))bismuth(III), without the lift-off or etching step. Subsequently, we perform temperature dependent TE characterization. The room temperature electrical resistivity of the film is measured by four probe I-V and is equal to 3400 \( \Omega \) cm. This large value of resistivity is attributed to the pristine nature of the Bi\textsubscript{2}Se\textsubscript{3} as well as to its low thickness (10 nm, as determined by Atomic Force Microscopy). Optimization of the film’s geometry as well as chlorine (Cl) and hafnium (Hf) doping of the Bi\textsubscript{2}Se\textsubscript{3} are ongoing in order to obtain films with enhanced TE performance.

**EN14.05.16**

Rapid Stoichiometry Control in Cu\textsubscript{2}Se Thin Films for Room Temperature Power Factor Improvement

Michael R. Scimeca, Nan Chen and Ayaskanta Sahu; New York University, Tandon School of Engineering, United States

Cu\textsubscript{2}Se thin films provide a promising route to relatively safe, sustainable and solution processable flexible thermoelectric (TE) modules in contrast to more expensive and toxic materials currently on the market such as Bi\textsubscript{2}Te\textsubscript{3}. Cu\textsubscript{2}Se is known in the thermoelectric community for its high performance at high temperature and has recently attracted attention from its large theoretically predicted figure of merit at room temperature. If the performance can be optimized at room temperature, flexible Cu\textsubscript{2}Se thin films will be the material of choice to utilize in TE modules for powering miniature electronics and sensors, which has been an increasingly popular and rapidly expanding market. Unfortunately, one of the main limitations encountered so far in Cu\textsubscript{2}Se thin films is that the carrier concentrations are not optimized for TE operation after solution processing. In this work, we conduct a comprehensive study of the structural, optical and TE properties of Cu\textsubscript{2}Se thin films and demonstrate that non-optimized carrier concentrations in these films lead to observations of poor performance at room temperature. Through a simple soaking procedure in a Cu\textsuperscript{2+} ion solution for only a few minutes, we demonstrate a 200-300\% increase in power factor. This soaking process pushes the carrier concentration of the Cu\textsubscript{2}Se thin film towards its optimal value for TE operation and marks the highest TE performance for any solution processable Cu\textsubscript{2}Se thin film at room temperature thus far.

**EN14.05.17**
Development of High Quality Na0.5CoO2 Thick Film for a Planar-Shape Thermoelectric Device Akihiro Tsuruta1, Miki Tanaka1, Masashi Mikami1, Yoshiaki Kinemuchi1, Woosuck Shin1, Yoshitake Masuda1 and Ichiro Terasaki2; 1AIST, Japan; 2Nagoya University, Japan

In our project, we are developing a planar-shape mW-class thermoelectric device with thick film thermoelectric materials for the advanced utilization of thermal energy by the recovery of abundant low-temperature and small-scale waste heat. We chose oxides as the thermoelectric material in favor of the high stability and low toxicity, and in particular Na0.5CoO2 as the p-type thermoelectric material. The Na0.5CoO2 thick film was formed by screen printing technique on an alumina substrate, but the simple printing and sintering process caused serious cracking and peeling from the substrate. We have developed the process to obtain a crack-free Na0.5CoO2 thick film with good adhesion to the substrate and its thermoelectric properties have been investigated.

The low chemical reactivity of Na0.5CoO2 and alumina made direct adhesion of the thick film to the substrate difficult. Therefore, we adopted the CuO interlayer to achieve good adhesion. Furthermore, we have found that the slight Co-Cu substitution in Na0.5CoO2 further improves the adhesion of the thick film to the interlayer. On the other hand, NaCl, which have been used as a flux for synthesizing of Na0.5CoO2 crystal, was mixed in Na0.5CoO2 in order to avoid the crack formation during sintering. Since the liquid phase NaCl promoted the sintering of the Na0.5CoO2 thick film, the film was densified and the cracks was removed. Through these developments, the thermoelectric power factor of the Na0.5CoO2 thick film reached 0.30 mW/K²m equivalent to the sintered body (0.31 mW/K²m). We will discuss the mixing effect of NaCl on morphology and properties of Na0.5CoO2 thick film at the presentation.

This work was financially supported by the Future Pioneering Program, "Thermal Management Materials and Technology," commissioned by the New Energy and Industrial Technology Development Organization (NEDO) of Japan.

EN14.05.18
Engineered Porosity and Thermoelectric Properties in Porous SnSeS Nanosheet Hyun Ju, Hyunwoo Oh, Kwanwoo Kim, Jaehyun Wie, Youjin Kim and Jooheon Kim; Chung-Ang University, Korea (the Republic of)

IV-VI group Tin (Sn) chalcogenide-based nanomaterials (SnSe, SnS, and SnTe) have intensive interest in various research fields because of the unique characteristics distinct from the bulk counterparts. The introduction of a number of pores into the nanomaterials can manipulate their electrical and thermal transport characteristics of a material, which is considered as a promising strategy to improve the transport properties. Herein, we report on that the successful fabrication and optimization of porous SnSeS-based nanosheets and their thermoelectric enhancement. Two-dimensional SnSe0.8S0.2 (SnSeS) nanocrystals are chemically exfoliated from the layered bulk structure through a Li-intercalation and an exfoliation process. A large number of pores are successfully introduced into the SnSeS nanosheets through a solution-phase chemical transformation procedure, and the porosity of the materials can be optimized with different reaction time, resulting in the effective reduction of the thermal conductivity and the enhanced thermoelectric performance. The incorporation of nano and porous structure can boost the research advances regarding nano and porous materials and high-performance thermoelectrics.

EN14.05.19
Improving the Transport Properties of Bi2Te3-xSe_x Alloys by Enhancing the Preferred Orientation via Melt-Spinning Method Omer Meroz and Yaniv Gelbstein; Ben Gurion University of the Negev, Israel

Thermoelectric devices fit power generation applications by converting excess heat, either directly from solar energy or as a byproduct of fuel burn, into electricity. A thermoelectric device is made of both n-type and p-type semiconductors. Bismuth–telluride-based alloys are of great importance not only as the best thermoelectric materials with the maximal ZT values close to unity near room temperature, but also due to the potential for further performance improvement.

The performance of thermoelectric devices is assessed by the dimensionless figure of merit ZT of the material, defined as $ZT = \alpha^2\sigma T/k$, where $\alpha$, $\sigma$, $k$ and $T$ are the Seebeck coefficient, the electrical and thermal conductivities, and the absolute temperature, respectively. The thermal conductivity is a combination of thermal conductivity via electrons, $\kappa_e$, and via phonons, $\kappa_l$. The main difficulty in improvement of the efficiency of a thermoelectric device is due to the complex relation between $\sigma$, $\alpha$ and $k$.

In this study Bi2Te2.4Se0.6 alloys were prepared and examined. The synthesis process included melting ingots via rocking furnace, melt spinning with two different wheel RPMs and hot pressing under optimal conditions. The
samples were characterized in the direction parallel and perpendicular to the pressing direction. The anisotropic properties of the material were maintained throughout the process and a high ZT of 1.06 was achieved at ~65°C.

**EN14.05.20**
**Microstructural Engineering of Sn-Te Eutectic/Near-Eutectic Thermoelectric Alloys** Sireesha P and Shanmukha Kiran Aramanda; Indian Institute of Science Bangalore, India

Conversion of dissipated heat into electricity is the basic principle of thermoelectricity. It has a wide variety of applications in the areas such as automobile engineering, refrigerating coolants, satellite etc. In search of such materials, thermoelectrics has given wide scope to complex materials like Tellurides, Clathrates, Zintl compounds, Half Heusler alloys, Si-Ge, Skutterudite etc. The defining factor for thermoelectric materials is ZT, thermoelectric figure of merit. This attributes to the power factor (P=σS², σ-electrical conductivity S-Seebeck coefficient) enhancement and thermal conductivity reduction. Bandgap tuning, carrier concentration are a few ways to improve power factor whereas, in parallel, grain size reduction, point defects, dislocations are key ways to thermal conductivity reduction. These can be achieved experimentally through microstructural engineering and processing. The issues existing with available thermoelectric materials are associated with the stability of performance for a long range of temperatures. Fine tuning of the microstructure is the key factor in overcoming thermal stability issues.

Currently, we are exploring a program of microstructure-transport properties correlation of newly processed thermoelectric alloys by fine-tuning the eutectic microstructure. In this current work, we have synthesized a set of thermoelectric alloys which are eutectic and near-eutectic compositions in Sn-Te system. The microstructure of these alloys shows microstructure consisting of SnTe and Te phases. We varied the morphology, orientation, fraction, spacing of the eutectic phases (SnTe and Te) using different processing conditions. Variations of transport properties with respect to different processing conditions have also been studied. Third component additions with various at% to Eutectic microstructure has been studied. To these alloys, the effect of **Directional solidification** has been studied and has improved TE properties significantly.

The elemental distribution mapping and the compositional analysis using electron probe microanalysis (WDS), demonstrates that the matrix is rich in tellurium and the continuous phase has the composition of Sn50Te50 (at%). Transport properties of the current alloy are attractive in terms of standard thermoelectric material. Further elemental additions have enhanced properties. They were directionally solidified at various speeds and TE properties were studied with microstructural modification. The detailed microstructure-transport properties correlation will be presented.

**Defect Formation Mechanism in Thermoelectric SnSe Structure Employing Atomic-Resolution Transmission Electron Microscope** YongKyu Lee¹², Sung-Pyo Cho¹² and In Chung¹²; ¹Institute for Basic Science, Korea (the Republic of); ²Seoul National University, Korea (the Republic of); ³National Center for Inter-University Research Facilities, Seoul National University, Korea (the Republic of)

Exceptionally high thermoelectric figure of merit $ZT$ of $-2.6$ at $923$ K for p-type and $-2.8$ at $773$ K for n-type were reported in the single crystalline form of SnSe along the crystallographic b-axis and a-axis respectively. Due to its undesirable mechanical properties and strict demands of crystal growth conditions, its polycrystalline counterparts have been extensively investigated as an alternative. However, polycrystalline SnSe has poor thermoelectric performances with higher total thermal conductivity than single crystals.

Defects such as point defects, nanoprecipitates and dislocations can significantly affect charge and phonon transport behavior. Accordingly, defect engineering has been a proven tool to control charge-carrier and thermal transport properties of thermoelectric materials. However, its formation mechanism at the atomic level has not been fully understood. In this presentation, we synthesized new SnSe materials involving a high degree of vacancy to induce
dense dislocations in the SnSe matrix. We traced the formation of atomic defects and edge dislocations with respect to annealing temperature at near the phase transition temperature employing spherical aberration corrected transmission electron microscope.

As a result of induced defect structure in SnSe, the resulting polycrystalline samples exhibit remarkably high power factor with a maximum of 6.3 μW cm⁻¹K⁻² at 800 K and substantially suppressed thermal conductivity. They synergistically contribute to remarkably high thermoelectric figure of merit over 2.0 at 800 K.

EN14.05.22
Dual-Beam Pulsed Laser Deposition of Diamond-like Carbon Added Bi-Sb-Te Based Nanocomposite Films with Enhanced Thermoelectric Performance Cheng-Chao Liu, Chih-Chuan Su, Po-Hung Chen and Chun-Hua Chen; National Chiao Tung University, Taiwan

The introduction of heterogeneous dopants could not only selectively improve intrinsically-poor specific properties of the base materials but potentially break the physically coupled thermoelectric properties due to the created various functional interfaces for further enhancing the overall thermoelectric figure of merit (ZT) [1]. In this work, a series of novel heterogeneous nanocomposite films comprising amorphous carbon materials (a-C) and BiₓSb₂ₓTe₃ (BST) were successfully deposited on SiO₂/Si substrates using a dual-beam pulsed-laser deposition system. BST and pyrolytic carbon targets were individually ablated for fabricating the a-C/BST films with different a-C contents (0~20 wt%). The highest Seebeck coefficient of the a-C/BST film (4 wt% a-C) was found to approach 650 μVK⁻¹ which is over three times higher than that for intrinsic BST. According to Pisarenko plot, the significantly enhanced Seebeck coefficient originated from the a-C/BST hetero-interfaces induced energy filtering effect. Besides, the significantly suppressed thermal transport as evidenced by micro-Raman and thermal diffusivity characterizations reasonably came from the grain refining of BST and the intrinsically low thermal conductivity of a-C. To further adjust the preferential orientation and interfacial structure, the laser energy ratio for providing the highest Seebeck coefficient was maintained for film preparation with a higher deposition temperature of 450 °C and 500 °C. It was found that preferential orientation gradually shifted from (015) to (00l) with temperature increasing. Besides, the TEM images attested high-density and strongly oriented twin bands almost across the whole BST flake-like structure, clearly indicate the potential for scattering multi-wavelength phonons and further decreasing the thermal conductivity, without substantially interfering the carrier transportation. An enhanced Seebeck coefficient of 620 μVK⁻¹ and the corresponding power factor of ~40 μWcm⁻¹K⁻² obtained from the a-C/BST film prepared at 450 °C (4 wt% a-C) are comparable to or higher than previously reported values of BST or Bi-Sb-Te-based nanocomposites.

EN14.05.23
A Descriptive Model of Thermoelectric Transport in a Resonant System of PbSe Doped with Tl Zhenyu Pan and Heng Wang; Illinois Institute of Technology, United States

Thermoelectric properties are governed by classic Boltzmann transport equations. This often sets limits for how much each material can be optimized for thermoelectric application. The resonant effect from dopants in certain systems presents one of a few successful strategies to work outside this classic limit. Using PbSe co-doped with Tl and Na as a platform, we have presented a method to describe the influence of resonant levels on thermoelectric properties at room temperature and above. We showed (and modeled) the impact of resonant levels on the Seebeck coefficient and mobility at different temperatures, which, especially for mobility, has not been shown before. In general, resonant dopants are not always beneficial for thermoelectric properties overall. This is because the enhanced Seebeck coefficient comes at the price of mobility reduction. Three parameters, namely the resonant level position E_res, the width of resonant levels G, and the percentage of participating resonant levels H, determine the observed transport properties. Among them E_res is crucial in deciding whether the resonant levels are beneficial (in terms of peak zT). Resonant levels could increase zT if E_res is inside the band but very close to the band edge. Our model also confirmed that it is possible to achieve moderate improvement of performance with resonant levels in systems similar to PbSe. This work could help the rational use of resonant levels to their full potential for thermoelectric materials.

EN14.05.24
Lead-Free Hybrid Perovskite Thin Film for Thermoelectric Applications Luyao Zheng, Yifan Li, Jiahua Zhu
In this work, we have investigated the thermoelectric properties of formamidinium tin iodide (FASnI3), lead-free hybrid perovskite, in terms of electrical conductivity, Seebeck coefficient and thermal conductivity. By doping with small amount of 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ), both electrical conductivity and Seebeck coefficient of solution-processed FASnI3 thin film are substantially improved, resulting in enhancement on overall thermoelectric performance. The optimal FASnI thin film with 0.05 mg/mL of F4-TCNQ doping exhibits higher electron/hole mobilities and lower trap densities with finely modified thin film morphology by F4-TCNQ. An ultralow thermal conductivity (~0.45 W m⁻¹ K⁻¹) is found in FASnI3 thin film by estimation based on quantitative scanning thermal microscopy (SThM). The thermoelectric figure of merit, value, of optimal FASnI3 thin film is enhanced to be 0.085 at room temperature, which is almost 10 times of pristine FASnI3. Our findings open a door for realizing room-temperature-operated thermoelectric applications by low-cost processing of less-toxic hybrid perovskite materials.

EN14.05.25
Thermoelectric Properties of All-Inorganic Perovskite Semiconductor CsSnBr₃

Yingyue Zhang, Jiangchao Qian and Qixi Mi; ShanghaiTech University, China

Thermoelectric materials have consistently been the focus of research efforts for energy conversion and harvesting. In recent years, organic-inorganic hybrid perovskite materials started to draw attention for thermoelectric applications, thanks to their low thermal conductivity and high Seebeck coefficient. Compared with the organic-inorganic hybrid perovskite materials, especially lead-based perovskites, the all-inorganic perovskite CsSnBr₃ is advantageous for its low toxicity, relative thermal stability, and higher electrical conductivity. In this work, we grew cubic CsSnBr₃ single crystals about 8 mm in size from ethylene glycol solutions, and measured its electrical conductivity to be ~64 S/m and p-type carrier concentration to be 10¹⁷–10¹⁸ cm⁻³ at room temperature. Its Seebeck coefficient increases steadily from ~400 μV/K at 325 K to ~700 μV/K at 575 K, while its thermal conductivity drops from 0.50 to 0.25 W/mK in the same temperature range. In summary, the highest figure-of-merit ZT that we recorded for single-crystal CsSnBr₃ is ~0.067 at 572 K, with a power factor (PF) of ~34 μW/(mK²). The electrical conductivity as well as ZT value can be further enhanced by heavy doping or replacing Br by I in CsSnBr₃.

SESSION EN14.06: Zintl Thermoelectrics

Structural Complexity and High Thermoelectric Performance of the Zintl Phase: Yb₂₁Mn₂Sb₁₈

Allan He¹, Sabah Bux², Davide Donadio¹ and Susan M. Kauzlarich¹; ¹University of California, Davis, United States; ²Jet Propulsion Laboratory, United States

The family of ternary Zintl phases with the 21-4-18 composition has several different structure types and has been explored for their electronic and magnetic properties. Yb₂₁Mn₂Sb₁₈ adds a new composition to this class of Zintl phases, crystallizing in the alpha-Ca₂₁Mn₄Sb₁₈ structure type (monoclinic, space group C2/c). The expected low thermal conductivity, due to the large primitive unit cell, and potentially high Seebeck, because of the significant number of states at the Fermi level, make this phase of interest for its thermoelectric properties. The complex crystal structure has been studied through synchrotron powder x-ray diffraction, single crystal x-ray diffraction and pair distribution function analysis using time-of-flight neutron diffraction that reveal positional disorder on several sites. The electrical and thermal transport properties show that the high efficiency of Yb₂₁Mn₂Sb₁₈ results from its large Seebeck coefficient (~290 μV/K at 650K) and extremely low thermal conductivity (~0.5 W/(mK) at room temperature). The optimum hole carrier concentration was tuned according to a single parabolic band model through Na doping which has improved ZT over all temperature ranges compared to the parent compound yielding a maximum ZT ≈ 0.8 at 800K, fairly high performance in the mid-to-high temperature regime. Electronic structure
Intermetallic compound of Mg$_2$Si and its solid solutions are promising thermoelectric materials since they exhibit high thermoelectric performance and consist of eco-friendly elements. In these materials, two types of Mg-related point defects (Mg vacancies and interstitial Mg atoms), as well as dopant elements, have significant influence on the carrier concentration \( n \) and resulting thermoelectric properties \[1\]. For example, Mg vacancies compensate the carrier from the dopant in heavily Sb-doped Mg$_2$Si (Mg$_{2-x}$Si$_x$Sb$_y$) \[2\], where a decrease in the Mg content of 0.01 corresponds to a decrease in \( n \) of ca. \( 3 \times 10^{20} \text{ cm}^{-3} \). While the carrier concentration is very sensitive to the Mg content, its precise control has not been achieved because of the high vapor pressure of Mg.

Here, we have developed a new approach, Mg-pressure-controlled annealing \[3,4\], to achieve the precise control of the Mg content for ternary and quaternary Mg$_2$Si-based materials (Mg$_{2-x}$Si$_x$Sb$_y$ and Mg$_{2-x}$Si$_x$Sb$_y$)$_{1-x}$Sn$_x$). Annealing under low and high Mg partial pressures (0.1 and 10 Pa) leads to low and high carrier concentrations (e.g. \( 1.4 \times 10^{20} \text{ and } 6.3 \times 10^{20} \text{ cm}^{-3} \) for Mg$_{2-x}$Si$_{0.90}$Sb$_{0.10}$, respectively). The change in \( n \) is reversible and attributed to an equilibrium reaction, where the Mg vacancies in the sample are partly filled by Mg atoms in the gas phase. In addition, annealing under an intermediate Mg partial pressure (2 Pa) results in an intermediate value of \( n \) (e.g. \( 4.1 \times 10^{20} \text{ cm}^{-3} \) for Mg$_{2-x}$Si$_{0.90}$Sb$_{0.10}$), suggesting that the Mg content in Mg$_2$Si-based materials can be tailored via the Mg-pressure-controlled annealing.

The variable range of \( n \) (\( \Delta n \)) due to the Mg non-stoichiometry in Mg$_{2-x}$Si$_x$Sb$_y$ depends on the Sb content and the maximum \( \Delta n \) of \( 4.9 \times 10^{20} \text{ cm}^{-3} \) is obtained at \( x = 0.10 \). The same \( x \)-dependence of \( \Delta n \) is also observed for the quaternary compound Mg$_{2-x}$Si$_x$Sb$_y$(Si$_{0.5}$Sn$_{0.5}$)$_{1-x}$Sb$_y$, where \( \Delta n \) at \( x = 0.10 \) is \( 3.5 \times 10^{20} \text{ cm}^{-3} \). In the case of Mg$_{2-x}$Si$_x$Sb$_y$(Si$_{0.5}$Sn$_{0.5}$)$_{1-x}$Sb$_y$, the high value of \( n \) due to Mg-rich composition suppresses the bipolar diffusion, which decreases the Seebeck coefficient and increases the thermal conductivity, at high temperatures. Owing to the suppression of the bipolar diffusion, Mg$_{2-x}$Si$_x$Sb$_y$(Si$_{0.5}$Sn$_{0.5}$)$_{1-x}$Sb$_y$ shows \( zT \) value of 0.9 at 773 K at Mg-rich composition whereas \( zT \) value of 0.6 is obtained at Mg-poor composition.

Evidence for Pronounced Influence of Guest Atoms on Anharmonicity in Intermetallic Clathrates Matt Beekman$^1$, James Kaduk$^{2,3}$, Winnie Wong-Ng$^4$, Antti Karttunen$^5$ and George S. Nolas$^6$; $^1$California Polytechnic State University, United States; $^2$Illinois Institute of Technology, United States; $^3$North Central College, United States; $^4$National Institute of Standards and Technology, United States; $^5$Aalto University, Finland; $^6$University of South Florida, United States

The detailed understanding of the mechanism(s) responsible for the very low and sometimes even glass-like lattice thermal conductivity in thermoelectric clathrates continues to develop. Of particular interest is the role of the guest atoms and the unique features of the structure of these materials. Despite a wide variety of novel mechanisms proposed over the past two decades to explain the unusual low temperature thermal transport, more recent theoretical and experimental analyses have suggested that phonon-phonon scattering, e.g. 3-phonon Umklapp-like processes, plays an important role in producing the low lattice thermal conductivity in select clathrate compositions, especially at elevated temperatures. We have shown this is supported by the application of a simple model due to Slack, which shows the lattice thermal conductivity values above the Debye temperature can be predicted relatively well assuming only 3-phonon scattering processes involving acoustic phonons, for a large number of clathrate compositions. Furthermore, our studies of thermal expansion using temperature dependent powder and single crystal X-ray diffraction from 20 K to 500 K on Na$_3$Si$_{136}$ clathrates with variable guest content (0 < \( x < 24 \)) reveal the mode averaged Grüneisen parameter increases dramatically by more than a factor of 2 as the guest content increases from...
0 to 100% filling, indicating the guest atoms have a pronounced effect on the anharmonicity of the interatomic interactions. Taken together, all of these results confirm the important role the guest atoms play in significantly influencing the lattice dynamics in these materials, and that anharmonic phonon-phonon scattering may play a leading role in the thermal transport and thermoelectric performance in the clathrates in the temperature range of interest for thermoelectric applications.

Development of High Performance Complex Zintl Phases for Thermoelectric Space Power Generation Applications Sabah Bux¹, Giacomo Cerretti¹, Trinh Vo¹, David Uhl¹, Paul Von Allmen¹, Susan M. Kauzlarich² and Jean-Pierre Fleurial¹; ¹Jet Propulsion Laboratory, United States; ²University of California, Davis, United States

Since the 1960s, the state-of-the-art power systems for space applications has typically been based up on either SiGe alloys or PbTe. Although reliable and robust, the thermal to electric conversion efficiency of these systems remains fairly low at only 6.5% with an average thermoelectric figure of merit of about 0.55. A factor of 2 improvements in the thermoelectric conversion efficiency is needed to support future space missions. In recent years, complex Zintl phases such as n-type La₃₄Te₄ and p-type Yb₁₄MnSb₁₁ have emerged as new high efficiency, high temperature thermoelectric materials with peak ZTs of 1.2 at 1275K. The high performance of these materials is attributed to their combination of favorable characteristics such as: semi-metallic behavior due to small band gaps, low glass-like lattice thermal conductivity values due to structural complexity and reasonably large Seebeck values near their peak operating temperatures. However, significant enhancements in material systems such as the Yb₁₄MnSb₁₁ have remained stagnant since its initial discovery in 2010. We will present an overview of recent research efforts at JPL and UC Davis collaborators on thermoelectric properties of new 14-1-11 formulations phases as well their suitability for advanced TE devices.

9:15 AM EN14.06.06
Compositing in Yb₁₄MnSb₁₁ as an Effective Strategy to Improve Thermoelectric Transport Giacomo Cerretti, Sabah Bux and Jean-Pierre Fleurial; NASA Jet Propulsion Laboratory, United States

Composite materials are conceptualized with the intent of obtaining a final material with improved characteristics. In thermoelectrics this has been achieved for organic-inorganic composites where conducting materials embedded in polymeric matrixes improved the thermoelectric properties. A completely different situation is the combination of two inorganic compounds. Although according to several studies a thermoelectric composite cannot have better properties than its constituents, a study from Bergman and Fel (1999) proved that the enhancement of the figure of merit of a composite material is possible under specific conditions. The purpose of this work is to show the effect of Co inclusions on the electronic and thermal property of Yb₁₄MnSb₁₁. Yb₁₄MnSb₁₁, with a zT of about 1.2 at 1200 K, is already the most performing p-type material for high temperature thermoelectric applications. Our intent is to further increase its thermoelectric performance by decoupling the electronic transport properties (σ, S). Even though cobalt is characterized by a metallic electrical conductivity, it shows a relatively high Seebeck coefficient (S ≈ -25 μV/K at 1100 K). Therefore, cobalt inclusions are expected to provide a boost to the electrical conductivity, while affecting only marginally S. At the same time, if the inclusion size can be kept in the nm-μm range, inclusions can act as active phonon scattering centers and hence reduce the lattice thermal conductivity. To verify the validity of our assumptions, we synthesized four samples with different inclusion density (0, 2, 5, 10 vol%). The samples have been chemically, electrically, and thermally characterized and the obtained results will be shown and compared with the baseline of the Jet Propulsion Laboratory for the Yb₁₄MnSb₁₁ ATEC (Advanced ThermoElectric Converter). In the end, the sample with 5vol% cobalt inclusions is the one that showed the best thermoelectric properties achieving a peak zT of 1.6 at 1250K.

9:30 AM EN14.06.07
Enhanced Thermoelectric Performance of Yb Filled CoSb₃ Due to Type-I Clathrates Addition Keshav P. Dabral, Kalpna Rajput and Satish Vitta; Indian Institute of Technology Bombay, India

Filled skutterudites such as Yb-Co₄Sb₁₂ have a high potential for medium temperature thermoelectric energy conversion due to their high power factor. Their high thermal conductivity, however, limits large scale practical application. In order to enhance both power factor and figure-of-merit of Yb filled Co₄Sb₁₂, type-I clathrates and modified type-I clathrates Ba₉Al₁₆Si₃₀ and (DyBa)₉Al₁₆Si₃₀ which also exhibits open cage structure have been added.
The skutterudite and clathrates were synthesized separately by vacuum alloying, and the mixed materials were obtained by hot pressing the requisite amount of powders at 873 K for 10 min and 60 MPa. All the materials, Yb$_{0.3}$Co$_4$Sb$_{12}$, (Ba$_{9}$Al$_{16}$Si$_{30}$)$_x$(Yb$_{0.3}$Co$_4$Sb$_{12}$)$_{100-x}$ and (Ba$_{7.5}$Dy$_{0.5}$Al$_{16}$Si$_{30}$)$_y$(Yb$_{0.4}$Co$_4$Sb$_{12}$)$_{100-y}$ with $x = 2.4$ and $y = 1.2$ wt.% respectively, exhibit a single phase X-ray diffraction pattern corresponding to the skutterudite phase. The X-ray diffraction peaks corresponding to the clathrates are extremely weak due to the small amount present in these materials. All the materials exhibit a negative Seebeck coefficient indicating electrons to be the major charge carriers. The materials with 1 wt.% Dy-modified clathrates addition has the highest Seebeck coefficient at all temperatures and has a peak value of 210 $\mu$V K$^{-1}$ at ~725 K, 15 % higher than Yb$_{0.3}$Co$_4$Sb$_{12}$. The electrical conductivity of this material is lowest compared to other materials, 1150 S cm$^{-1}$ at room temperature, which decreases to ~ 700 S cm$^{-1}$ at 750 K. The high value of Seebeck coefficient coupled with good electrical conductivity results in good power factor of 3.2 mW K$^{-2}$, 25 % increase compared to single filled skutterudite at 650 K. The power factor for $T > 650$ K decreases due to the onset of bipolar conduction. The thermal conductivity of this composite, however, does not decrease significantly compared to Yb$_{0.3}$Co$_4$Sb$_{12}$ indicating that the interfaces between Yb$_{0.3}$Co$_4$Sb$_{12}$ and Ba$_{7.5}$Dy$_{0.5}$Al$_{16}$Si$_{30}$ are band matched for charge transport as well as phonon transport. The figure-of-merit of $y = 1$ wt.% material reaches a value of ~ 0.85 compared to 0.7 for Yb$_{0.3}$Co$_4$Sb$_{12}$ at ~ 750 K, an increase of 20 %.

First-Principles Simulation of Mg$_3$Bi$_2$ Thermoelectric Properties Qian Xu$^1$, Weishu Liu$^2$ and Gang Chen$^1$; $^1$Massachusetts Institute of Technology, United States; $^2$Southern University of Science and Technology, China

Mg$_3$Sb$_2$-Mg$_3$Bi$_2$ alloy is recently found to have high performance n-type thermoelectric (TE) properties for low-grade waste heat recovery near room temperature. It rivals current best thermoelectric materials (e.g. Bi$_2$Te$_3$-Bi$_2$Se$_3$ alloy) for thermoelectric performance in the temperature range of 0°C to 250°C and features a higher fracture toughness and lower cost. While previous first-principles studies on Mg$_3$Sb$_2$ and Mg$_3$Bi$_2$ have revealed their complex electronic band structures, the effect of alloying, particularly on the electron transport properties has not been thoroughly understood. In this study, we perform first-principles calculations on Mg$_3$Bi$_2$ to investigate the major scattering mechanisms for both electrons and phonons in this system. Our results can provide guidelines for the design of better materials for low-temperature thermoelectrics.

On the Dopability of Semiconductors and the Governing Materials Properties Vladan Stevanovic; Colorado School of Mines, United States

To be practical, semiconductors need to be doped; in thermoelectric applications to nearly degenerate levels. However, many materials are not dopable at all, especially those with wide band gaps, while many other exhibit strong preference toward either p- or n-type conductivity, but not both. These doping bottlenecks and doping tendencies are well known but our present understanding of these phenomena is fairly qualitative and phenomenological. In this talk I will describe our recent work dedicated to advancing our understanding of the intrinsic materials properties that govern dopability of semiconductors. This we do by developing an analytic (model) description of the defect formation in semiconductors which allows formulation of rigorous design principles. Our approach, which builds upon the semiconductor defect theory applied to a suitably devised (tight-binding) model system, reveals analytic relationships between intrinsic materials properties and semiconductor dopability, and elucidates the role of previously suggested heuristic descriptors such as the absolute band edge positions and/or the branch point energy. We validate our model against the present state-of-the-art defect calculations as well as experimental data on a number of classic binary semiconductors. Finally, I will discuss the
model extension to more complex chemistries and its utility in large-scale material searches.

11:00 AM EN14.07.02
First-Principles Study of Thermal Conductivity and Thermoelectricity in Magnetic Half-Heusler Alloys
Fumiyuki Ishii, Akihiro Hori, Susumu Minami and Mineo Saito; Kanazawa University, Japan

The thermoelectric effect that is drawing attention from the viewpoint of energy saving is typically the Seebeck effect in which an electromotive force is generated in the same direction as the thermal gradient. In magnetic materials, there is also an anomalous Nernst effect that generates an electromotive force in the direction perpendicular to the thermal gradient due to spontaneous magnetization, and has recently been attracting attention for the improvement of energy conversion efficiency[1]. In each effect, it is important to examine the contribution of thermal conductivity in evaluating the thermoelectric figure of merit ZT that represents the performance of the material. Since the thermal conductivity can be described for each electron and lattice, in this research, we theoretically computed both electronic and lattice thermal conductivity, and then evaluated ZT.

Theoretical analysis of lattice thermal conductivity is conducted by Boltzmann transport theory with relaxation time approximation. In order to do this, it is necessary to determine the inharmonic atomic force constant exactly, and an accurate analysis is carried out by first-principles calculations based on density functional theory. As computational codes, OpenMX[2] is used as a density functional calculation, and ALAMODE[3] is used as a lattice thermal conductivity calculation.

The half-Heusler compounds are ternary compounds, have composition formula of XYZ, and are expected as thermoelectric materials that exhibit high power factor in a medium temperature range of about 600 to 1000 K. In this study, we analyzed thermoelectricity and thermal conductivity of ferromagnetic half-metallic half-Heusler MnCoSb[4]. We evaluated the ZT for the Seebeck and anomalous Nernst effect. We will discuss carrier and temperature dependence of ZT.

11:15 AM *EN14.07.03
Predicting Thermoelectric Transport from First-Principles Electron-Phonon Dynamics Boris Kozinsky1 and Geory Samsonidze2; 1Harvard University, United States; 2Bosch, United States

We develop and investigate fast automated first-principles methods for computing electronic and thermal transport properties of complex semiconductors and low-dimensional quantum materials, without empirically fitted parameters. Using these electron-phonon averaged (EPA) methods we performed screening and discovered new thermoelectric alloy compositions with leading performance and stability. The computational approaches achieve good predictive accuracy and transferability while greatly reducing complexity and computation cost compared to the existing methods. The first-principles calculations of the electron-phonon coupling demonstrate that the energy dependence of the electron relaxation time varies significantly with chemical composition and carrier concentration, suggesting that it is necessary to go beyond the commonly used approximations to screen and optimize materials' composition, carrier concentration, and microstructure. The new methods are verified using high accuracy computations and validated with experimental data before applying it to screen and discover promising compositions in the space of half-Heusler alloys. We discuss the universality of the Wiedemann-Franz law and deviations from it in semiconductors, computing the Lorenz number from first principles.

11:45 AM EN14.07.04
High-Throughput Prediction of Anisotropic Transport Properties and Thermoelectric Performance Prashun Gorai, Robert W. McKinney, Eric S. Toberer and Vladan Stevanovic; Colorado School of Mines, United States

Anisotropic electronic and thermal transport properties can be harnessed to enhance the thermoelectric (TE) performance of materials. There is also a growing interest in exploring the functionality of single crystals, especially of materials with layered motifs, for thermoelectrics. Layered materials often exhibit anisotropic transport properties. Therefore, it is crucial to account for the anisotropy in transport properties in computational searches for TE materials. Traditional computational approaches are expensive and not amenable to high-throughput searches. In
this work, we build upon our intuition from prior semi-empirical models to create a new anisotropic model of carrier mobility by utilizing the elastic stiffness and the conductivity effective mass tensors. Similarly, we extend our prior semi-empirical lattice thermal conductivity model to account for anisotropy by calculating the speed of sound tensor. By combining the models for anisotropic mobility and lattice thermal conductivity, we predict the anisotropic TE performance quantified by the thermoelectric quality factor. We apply these models to predict the TE performance of a large number of layered materials (>2000) and identify candidates with predicted high performance.

SESSION EN14.08: Heusler Thermoelectrics
Session Chair: Sabah Bux
Tuesday Afternoon, December 3, 2019

1:30 PM *EN14.08.01
Magnetic Topological Materials Claudia Felser, Kaustuv Manna and Chenguang Fu; Max Planck Institute, Germany

Topology, a mathematical concept, recently became a hot and truly transdisciplinary topic in condensed matter physics, solid state chemistry and materials science. In magnetic materials the Berry curvature and the classical anomalous Hall and the anomalous Nernst effect helps to identify potentially interesting candidates. As a consequence, the magnetic Heusler compounds have already been identified as Weyl semimetals: for example, Co2YZ, Mn3Sn and Co3Sn2S2. The Anomalous Hall angle also helps to identify materials in which a QAHE should be possible in thin films.

2:00 PM EN14.08.02
Anomalous Reduction of Lattice Thermal Conductivity in Half-Heusler ZrCoSb Ran He1, Zhenhui Liu1,2, Nicolas Perez1, Ulrike Wolff1, Andrei Sotnikov1, Kornelius Nielsch1,2 and Gabi Schiering1; 1Leibniz-Institut für Festkörper- und Werkstoffforschung, Germany; 2Technical University Dresden, Germany

The reduction of lattice thermal conductivity (κ_L) can be realized by introducing large mass contrast through atomic substitution within pristine compounds. Such process are usually termed as “point-defect scattering” and has been proved effective in the improvement of thermoelectric figure-of-merit (zT). Recently we synthesized two sets of half-Heusler compounds: ZrCoSb1-xSnx and Zr1-yTiyCoSb, and compared their lattice thermal conductivity with respect to the substitution level. Contrary to the general conception that larger mass difference are more effective in phonon scattering, we find a much lower κ_L in compounds with Sn substitution at the Sb site than the ones with Ti substitution at the Zr site. The origin of phonon scattering in the Sn-containing compounds will be discussed in great detail based on transport property measurement and microstructure characterization. Our work propose a novel strategy for increasing phonon scattering without large mass contrast so that a high carrier mobility can be preserved.

2:15 PM EN14.08.03
Ultrahigh Intrinsic Thermoelectric Performance, Phase Stability and Defect Energetics of Full-Heusler Compounds Junsoo Park1, Yi Xia2, Anubhav Jain1 and Vidvuds Ozolins3; 1Lawrence Berkeley National Laboratory, United States; 2Northwestern University, United States; 3Yale University, United States

This study shows that ultrahigh bulk thermoelectric performance across all temperatures is physically possible and within reach, and also that pocket multiplicity can hurt at high temperatures when the pockets have disparate scattering rates. Using state-of-the-art ab initio approaches to explicitly treat electron-phonon and phonon-phonon scattering for accurate electronic and phonon transport, we predict that full-Heusler Sr2BiAu and Sr2SbAu are theoretically capable of delivering ultrahigh n-type thermoelectric performance at cryogenic-to-high temperatures: zT=0.3-5.1 at 100-800 K. The feature critical to such high performance is a set of dispersive conduction band pockets, at the L-point in addition to those along Γ-X, for a total of ten. Relative to Ba2BiAu, the additional L-pockets significantly increase the power factor at low temperatures, generating as high as 10 mW m⁻¹ K⁻² at 200 K.
However at high temperatures, because the less dispersive L-states experience much heavier scattering, their existence damages the overall electron lifetime, mobility, and hence the power factor. The dominant intrinsic defect at play in these compounds is Bi/Sb$_{au}$ antisites, which limit their n-dopabilite. Nevertheless, Sr$_2$SbAu potentially has both a large enough stability region and high enough Sb$_{au}$ formation energies to retain some chance at experimental realization as a high-performance thermoelectric.

2:30 PM EN14.08.04
TaIrGe—A p-Type Half-Heusler with Ultra Low Lattice Thermal Conductivity and the Possibility of High ZT
Kieran B. Spooner, Benjamin A. Williamson, Alex M. Ganose, John Buckeridge and David O. Scanlon; University College London, United Kingdom

Thermoelectrics are unique materials which can transform heat into electricity and vice versa. They have applications ranging from renewable energy generation to heating and cooling units. Thus far, however, thermoelectric efficiency remains low, in part because of the contradictory requirements of high electrical conductivity and high Seebeck coefficient coupled with low thermal conductivity. Most TE materials possess small band gaps. A transparent TE that can operate near room temperature was discovered in 2014 [1], and the first inorganic one in 2017. [2,3] The discovery of a high performance transparent, room temperature TE would open up new fields of research in a range of novel applications such as smart windows (or screens) with energy harvesting, cooling and thermal sensing functionalities. Using density functional theory (DFT) with hybrid functionals we have screened the novel p-type transparent half-Heusler TaIrGe [4] for its thermoelectric ability. We will demonstrate that TaIrGe possesses an ultra-low lattice thermal conductivity and has the potential to yield the highest ZT ever for a transparent TE.

2:45 PM EN14.08.05
Thermoelectric Properties of Half-Heusler TaFeSb
Natalya Fedorova, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Half-Heusler alloys are among the most promising candidates for applications in thermoelectric power generators, since they are thermally and mechanically robust, do not contain toxic elements and exhibit some of the largest ZT values among bulk systems. In particular, exceptionally high ZT values (1.52 at 973 K) have been recently reported from the experimental measurements of transport properties of TaFeSb-based compounds, following up on theoretical predictions. However, the microscopic origin of such high ZT values in these systems is still not fully understood. In this work we use ab initio calculations to investigate the transport properties of TaFeSb in terms of semiclassical Boltzmann transport equation, beyond the constant relaxation time approximation. We take into account the effects due to electron-phonon interaction by calculating corresponding scattering rates using Wannier-Fourier interpolation of electron-phonon matrix elements as well as the recently developed electron-phonon averaged approximation. We discuss the likely mechanisms of high ZT in TaFeSb-based systems and possible ways to further improvement of these materials.

3:30 PM *EN14.09.01
Accelerating the Discovery of Thermoelectric Materials through High-Throughput Synthesis and
Characterization Eric S. Toberer; Colorado School of Mines, United States

Over the last decade, significant effort has been devoted to creating computational predictive frameworks for predicting the thermoelectric performance of materials. Such efforts shine light into reciprocal space, where we often have less chemical intuition, and thus enable the accelerated down-selection of candidate materials. Computational predictions, interrogated by experiment, has revealed new classes of thermoelectric materials, thereby validating this approach as a key tool in the search for thermoelectric materials. However, we now face a new problem: We have more predicted candidates than experimental bandwidth to test these candidates. Further, the expansion of thermoelectric training sets for machine learning remains quite slow. As such, our current efforts are focused on developing the infrastructure to accelerate synthesis and characterization of thermoelectric materials by x50 without significant sacrifices in material or data quality. These efforts are inspired by developments over the last three decades in combinatorial thin film growth, but are focused instead on bulk materials. Efforts to develop high throughput weighing, milling, consolidation, and transport measurements will be discussed in the context of pnictide and chalcogenide thermoelectric materials.

4:00 PM EN14.09.02
Carrier and Thermal Transport in Hierarchically Engineered Superlattice Structures and Their Comparison to Single-Period Superlattices Rama Venkatasubramanian1, Jonathan Pierce1, Meiyong Himmtann1, Geza Dezsi1, John Gaskins2 and Patrick E. Hopkins2; 1Johns Hopkins Applied Physics Lab, United States; 2University of Virginia, United States

In the past, we have developed thin-film P-type Bi2Te3/Sb2Te3 single period superlattice structures [1] with ZT ~2.4 at 300K and N-type Bi2Te3/Bi2Te3-xSex structures, with more modest ZT ~0.7-0.8. These thin-film superlattices have been utilized to demonstrate extraordinarily large (>1000 W/cm2K) heat-pumping in microelectronic devices [2]. There is a need to advance the ZT of N-type materials, in particular, as well as optimize both the P- and N-type materials for the temperature range of 300K to 100K to enable solid state cryogenic cooling devices. In this presentation, we will describe the concept of hierarchically engineered superlattices in thin-film thermoelectrics to improve the ZT of both P-type and N-type materials, to values approaching ~3 and ~2, respectively. We will present the electrical conductivity, Seebeck coefficient and thermal conductivity data in these materials in the 300K-100K range. Additionally, we will delineate the advantages of hierarchically engineered superlattices, as compared to conventional single-period superlattices, for designing efficient cooling down to cryogenic temperatures. The electrical transport of these hierarchically engineered superlattices has been studied by Hall-effect from 300K-77K. Parabolic band is assumed with energy dispersion relation of \( E = \frac{0.5}{h} \left( \frac{h}{2p} \right)^2 k^2 / m^* \) and carrier velocity \( \sim \left( \frac{h}{2p} \right) k / m^* \), with a relaxation time \( \tau (E,T) = \tau_0 (E/kT)^{-1/2} \). This model of transport data suggests that the scattering is dominated by optical phonons \( (T^{-1/2}) \) and less of acoustic phonons \( (T^{-3/2}) \); the hierarchical structuring seems to result in more optical phonon and less acoustic phonon carrier scattering than superlattices, consistent with lower \( K_{\text{attenu}} \) seen with hierarchically engineered nanostructures. The thermal conductivity measurements carried out by time domain thermo reflectance, between 300K and 100K, also indicates the benefit for scattering of a range of heat-conducting phonon wavelengths in such hierarchically engineered superlattices. The ZT advancements obtained with these hierarchically engineered superlattices will be presented along with cooling device advancements.

4:15 PM EN14.09.03
Development of a Full In-Plane zT-Characterization Platform for Electrodeposited Materials Vida Barati1, Javier García2, Kevin Geishendorf3, Lauritz Schnatmann1, Michaela Lammel1, Alexander Kunzmann1, Nicholas Perez Rodriguez1, Guodong Li3, Gabi Schierning1, Jens Freudenberger1, Kornelius Nielsch1 and Heiko Reith1; 1Leibniz Institute for Solid State and Material Research, Germany; 2University of Oviedo, Spain; 3Institute of Physics, China

Thermoelectric (TE) energy harvesting or Peltier cooling devices will be prospectively used in a broad range of applications from industry to consumer products. Successful optimization of the TE figure of merit, \( i.e., zT \), is a key enabler for the introduction of these devices to application. While \( zT \) of bulk materials is accessible by a variety of well-established measurement set-ups that are commercially available, exact determination of \( zT \) for thin and thick films remains a great challenge. This is especially true for thick films grown by the electroplating technique, which is favored for the fabrication of many micro TE devices. In this method the TE material is deposited onto an
electrically conductive seed layer. Such layer causes an in-plane short-circuit that makes the determination of transport coefficients almost impossible. Here, we develop a platform for full in-plane zT characterization of TE materials produced by electroplating technique, eliminating the impact of the electrically conducting seed layer. Such characterization is enabled by using a suspended TE material within a transport device which is prepared by photolithography and etching processes. This full in-plane zT characterization provides an inevitable milestone for a materials optimization under realistic conditions in a micro TE device. In addition, a comparative study is performed between an electrochemical deposited Co75Ni25 film and a bulk ingot with identical composition. The validation of the thermal conductivity measurement is done by Comsol simulation and analytic approach using heat transfer equation with specific boundary conditions dedicated to experimental setup.

4:30 PM EN14.09.04
Tackling Seebeck Coefficient Measurement Challenges with AC Technique Zhenyu Pan1, Fan Yang2, Jeffrey Urban3 and Heng Wang1; 1Illinois Institute of Technology, United States; 2Stevens Institute of Technology, United States; 3Lawrence Berkeley National Laboratory, United States

Seebeck coefficient (S) is the ratio of open circuit voltage generated per unit degree of temperature difference across a semiconductor. It is of essential importance to thermoelectric materials. In a broader context, S is a fundamental transport parameter. It can be used to extract various information including carrier type, position of Fermi level, effective mass, scattering mechanism, even the complex shape of electronic bands. Seebeck coefficient measurements on typical semiconductors are routinely done in labs with fairly simple requirement on methodology and hardware. However, at extreme cases, reliable measurement of a small voltage of 100 nV to 1 mV can be very challenging. We present here an AC measurement technique which has several advantages over DC methods. The first is the ability to measure high impedance samples: We demonstrate the successful measurement of S on a halide perovskite CH3NH3PbI3 film, with resistance over 100Gohms, can be determined whereas DC signal is totally obscured by random voltage fluctuations. The second, when a sample is inhomogeneous like often seen in lightly doped semiconductors, the AC method with a little modification can measure both the average S between the two points and the difference. In contrast, DC measurement under the same condition will only yield non-linear voltage behavior. Lastly, the great accuracy of phase sensitive detection allows the use of very small temperature gradients, for instance, DT = 0.1°C, revealing true S at a given temperature, which is useful when studying material behavior close to a phase transition.

4:45 PM EN14.09.05
Effects of Structural Phase Transition on Thermoelectric Performance in Lithium-Intercalated Molybdenum Disulfide (LixMoS2) Hong Kuan Ng1,2, Anas I. Abutaha1, Damien Voiry1, Ivan Verzhbitskiy2, Yongqing Cai4, Gang Zhang4, Yi Liu2, Jing Wu2, Manish Chhowalla1, Goki Eda2 and Kedar Hippalgaonkar1; 1Institute of Materials Research and Engineering, Singapore; 2National University of Singapore, Singapore; 3University of Montpelier, France; 4Institute of High Performance Computing, Singapore; 4University of Cambridge, United Kingdom

Layered transition metal dichalcogenides (TMDCs) intercalated with alkali metals exhibit mixed metallic and semiconducting phases with variable fractions. Thermoelectric properties of such mixed-phase structure are of great interest because of the potential energy filtering effect, which can enhance Seebeck coefficient and thermoelectric performance due to the alteration of energy-dependent scattering. The thermoelectric properties of mixed-phase LixMoS2 are studied as a function of its phase composition tuned by in-situ thermally driven deintercalation. We find that the sign of Seebeck coefficient changes from positive to negative during initial reduction of the 1T/1T’ phase fraction, indicating crossover from p- to n-type carrier conduction. These anomalous changes in Seebeck coefficient, which cannot be simply explained by the effect of deintercalation-induced reduction in carrier density, can be attributed to the hybrid electronic property of the mixed-phase LixMoS2. Our work shows that careful phase engineering is a promising route toward achieving thermoelectric performance in TMDCs.
EN14.10.01
Thermoelectric Properties of Two-Dimensional Materials Beyond the Confinement Effect
Nguyen Tuan Hung, Ahmad R.T. Nugraha and Riichiro Saito; Tohoku University, Japan

Thermoelectric research has been significantly activated during the past two decades by the quantum confinement effect, a characteristic of low-dimensional (1D & 2D) materials, thanks to the pioneering work by Hicks and Dresselhaus [1]. The confinement effect leads to an enhancement of the density of states at the Fermi energy, which enhances thermoelectric power factor (PF) of low-dimensional materials. In particular, for 2D material, the PF is enhanced only when the thickness of the material is smaller than the thermal de Broglie wavelength [2]. 2D semiconductors naturally satisfy this condition so that they are a good candidate for thermoelectricity. However, the thermoelectric performance of 2D semiconductors still needs to be improved for industrial applications because of large thermal conductivity. In this work, we propose two possible strategies to improve the thermoelectric performance of the 2D materials beyond the confinement effect. Firstly, we show that the thermoelectric performance of the 2D semiconductors can be improved by the band convergence, in which some distinct valleys become degenerate in energy [3]. This technique is possible to realize, for example, by applying mechanical strain in monolayer InSe [3,4]. Further, we show that the nonparabolic Kane bands and large anharmonicity of phonons could lead to better thermoelectric performance of the 2D tetracyamides [5].

EN14.10.02
Development of A Method for Quick and Rough Estimation of Electron-Defect Interactions in Thermoelectric Materials Based on Gaussian Process Regression
Minkyung Han¹, Semi Bang² and Daehyun Wee¹; ¹Ewha Womans University, Korea (the Republic of); ²Samsung Electro-Mechanics, Korea (the Republic of)

It is well known that the thermoelectric properties of materials are critically affected by the scattering due to impurities. Empirical or semi-empirical formulations like the effective-mass theory are typically being used for studying impurity scattering, and a fully ab initio study of the phenomenon remains a rather difficult task even today. Only a few detailed ab initio studies have been reported for relatively simple materials. Application of these ab initio methodologies to realistic, complex thermoelectric materials is still far from realistic. In this presentation, a method for quick and rough estimation of electron-defect interactions in thermoelectric materials is proposed. The method is based on Gaussian process regression (GPR), which is a statistical procedure used widely in machine learning communities. By using the GPR procedure, relatively coarse observations of electron-defect interaction coefficients in the Brillouin zone can be effectively interpolated in an appropriate energy window, whose results can be further utilized to estimate the scattering rate due to impurities. A numerical example to demonstrate the feasibility of our proposed method is also provided.

Intrinsic and Extrinsic Point-Defects in Thermoelectrics NbFeSb—Experimental and Calculational Studies
Yefan Tian¹, Joseph H. Ross¹, Lan Huang¹, Tahir Cagin¹, Hantian Zhu², Wuyang Ren² and Zhifeng Ren²; ¹Texas A&M University, United States; ²University of Houston, United States

The half-Heusler NbFeSb-based semiconductors have been of considerable interest due to their excellent thermoelectric performance, especially an enhanced power factor [1]. For enhanced performance, various substitutional elements can be incorporated, with Ti substitution, in particular, providing outstanding performance as a p-type material. However, intrinsic and extrinsic defects play an important role in adjusting the carrier concentrations and mobilities. To better understand the inherent defects in these materials and then improve the thermoelectricity, we used experimental and computational methods to study NbFeSb-based semiconductors.

To investigate the defects in NbFeSb-based semiconductors, we have performed XRD, ⁹⁵Nb NMR, and magnetic
measurements on pure NbFeSb and a series of Ti-substituted (Nb, Ti)FeSb samples with different substitution levels. Magnetic measurements combined with an observed Schottky anomaly and changes in the NMR line width indicate the presence of a 0.2% concentrated native magnetic defect in stoichiometric NbFeSb sample [2]. For Ti-substituted samples, the breaking of the 18-electron rule leads to heavily p-type materials. A small but consistently increasing paramagnetic defect density is observed with the increase of titanium substitution concentrations revealing the existence of additional Ti-induced paramagnetic defects. Also, with Ti substitution, the $^{95}$Nb NMR spectra show progressive increases in Knight shift providing a measure of band-edge carrier densities, and we have also mapped changes in the NMR line shapes to local carrier density distributions connected to different local configurations.

To further identify the origin of the defects in NbFeSb, DFT calculations have been utilized. In this work, we applied the pyCDT package [3] on p-type half-Heusler thermoelectric NbFeSb, combined with DFT calculations. The Fe(Nb) antisite is identified as an important n-type defect, and this defect was also identified to match the magnetic signature seen in undoped samples in NMR and magnetic measurements. In addition, we identified the Fe interstitial and Nb vacancy as other important native defects, and we discuss their relation to the observed NMR shift behavior. The iron interstitial is identified as an n-type native defect with relatively low formation energy, even though Ti-substituted NbFeSb forms as nearly a line compound, with very little interstitial formation. This stands in contrast to the end member of the series, TiFe$_{1+x}$Sb, in which a significant number of interstitials form spontaneously to balance the 18-electron rule. In addition, we discuss different local configurations in Ti-substituted alloys and their effect on the transport behavior.

**Prospects for Thermoelectric and Current Rectification Devices Using Electron Waveguides** Sathwik Bharadwaj and L. R. Ram-Mohan; Worcester Polytechnic Institute, United States

There have been several attempts in literature to provide a variational formalism for solving quantum transport problems. However, the asymptotic boundary conditions used in such methods do not take the evanescent modes into account, which is crucial for applications in meso- and nano-scale devices. We develop a novel method based on sources and absorbers to study quantum transport in confined geometries in the presence of defects [1]. This method overcomes the limitations of the currently prevalent approaches to provide a complete non-asymptotic variational description for quantum transport in meso- and nano-scale systems. We apply this method to study electron transport in disordered waveguides, and examine the impact of evanescent modes in enhancing the Seebeck coefficient and power factor beyond the earlier proposed limits. We also discuss a new way of fabricating current rectifiers using tapered electron waveguides [2].

References:
Here, we present the peculiar behavior of both electrical conductivity and Seebeck coefficient, which show a constant value along wide range of temperature, in Na- and Ag-doped PbTe. This temperature-robust electronic transport properties yield a broad plateau in power factor, while thermal conductivity keeps decrease as temperature increases. As a result, sharp increase of thermoelectric figure of merit ($\zeta F$) is achieved. This unconventional thermoelectric property is mainly attributed to the re-dissolution of the Na segregated at the grain boundary. Segregated Na can be incorporated into the lattice at the high temperature, increasing hole concentration significantly. As the optimum hole concentration in p-type PbTe shows monotonic increase as temperature increases, inducing segregation at low temperature and re-dissolution at high temperature can be an effective strategy to keep up with it.

It is further founded that Ag promotes the solubility drop of the incorporated Na, leading to the temperature-robust transport property even at the lower Na doping concentration. Formation of Ag$_x$ defect induces a huge lattice strain on the already shrunk Na-doped PbTe, thus phase separation between Na and PbTe lattice occurs. Microstructure analysis using SEM and TEM reveals that the segregated Na indeed exists at the grain boundary, and the defective structures such as dislocation and precipitation are uniformly distributed through the lattice.

**Lattice Thermal Conductivity of α-, β- and γ-graphyne—Molecular Dynamics and Boltzmann Transport Study**  
Minkyu Park, Mehmet E. Kilic, Seungchul Kim and Kwang-Ryeol Lee; Korea Institute of Science and Technology, Korea (the Republic of)

Graphyne is one of the two-dimensional carbon allotrope and consisting of $sp$ and $sp^2$ hydridized carbon atoms. Herewith we investigate the lattice thermal conductivities of α-, β- and γ-graphyne by perform large-scale non-equilibrium molecular dynamics simulations and solve linearized phonon Boltzmann transport equation. Up to the length of 1.5 μm along the heat transport direction is investigated, at which the converging behavior is found. The previous molecular dynamics simulations have been only limited up to few hundred nanometer scale in length, which may result in a large discrepancy with the experiments. Based on the results, the intrinsic macroscopic lattice thermal conductivities of α-, β- and γ-graphyne is evaluated to be 24.7, 23.8 and 42.0 W/m-K at room temperature. The previous theoretical studies with about few hundred length of graphyne are suggested here to have still ballistic thermal transport components and can give a smaller value than the macroscopic thermal conductivity of graphyne. We also calculate lattice thermal conductivity, mode-dependent phonon relaxation times, group velocities and dispersions based on density functional perturbation theory and linearized phonon Boltzmann transport equation. The calculated results are consistent with molecular dynamics calculation results, and we found that number of acetylene linkages in graphyne play significant roles on lattice thermal conductivities.

**Expansion of Ba and Ca Solubility Limit into SrSi$_2$ Thin Film and Their Thermoelectric Properties**  
Kodai Aoyama$^1$, Takao Shimizu$^1$, Hideto Kuramochi$^2$, Masami Mesuda$^2$, Ryoo Akiike$^2$, Ide Keisuke$^1$, Takayoshi Katase$^1$, Toshio Kamiya$^1$, Yoshisato Kimura$^1$ and Hiroshi Funakubo$^1$; $^1$Tokyo Institute of Technology, Japan; $^2$TOSOH Corporation, Japan

Silicide-based materials, such as Mg$_2$Si and MnSi$_{1.73}$, attract attention as promising candidate for thermoelectric materials because they have advantages such as high compatibility with Si process and good thermoelectric properties. SrSi$_2$ (α phase) is also a promising candidate as a thermoelectric material because it consists of abundant nontoxic elements and a good thermoelectric power factor ($S^2\rho^{-1}$) over 1 mWm$^{-1}$K$^{-2}$ near the room temperature. It is reported that the thermoelectric performance is improved by substituting Ca or Ba for Sr. In this study; we prepared (Ca$_{x}$Sr$_{1-x}$)Si$_2$ and (Ba$_{x}$Sr$_{1-x}$)Si$_2$ thin films on insulating substrates and measured their thermoelectric properties. Films are deposited at nonequilibrium condition that possible to increase the solubility limit of Ba and Ca into α phase. This larger solubility of Ba and Ca expects to improve the thermoelectric properties of α phase. (Ca$_{x}$Sr$_{1-x}$)Si$_2$ and (Ba$_{x}$Sr$_{1-x}$)Si$_2$ thin films were deposited on (001) Al$_2$O$_3$ substrates at various deposition temperatures by using co-sputtering method. Constituent phases strongly depended on the deposition temperature and film composition. At 700 ℃, the single phase of α phase was observed up to 26% of Ba/(Ba+Sr) ratio, while main phase of BaSi$_2$ structure phase (stable phase of BaSi$_2$) was observed over 30%. When the deposition temperature decreased to 650 ℃, the Ba/(Ba+Sr) ratio of main phase of α phase expanded to 30% and BaSi$_2$ structure phase was observed over 35%. Note that this solubility limit was larger than that of reported value of the powder. Linear relationship between the lattice parameter and the Ba/(Ba+Sr) ratio in the film was observed for the films deposited at both temperatures. This result
shows that the Ba soluble for Sr site of α-phase and its solubility limit increased as the deposited temperature decreased. When the deposition temperature further decreased to 600 °C, the metastable phase with CaSi2 structure became a main constituent phase up to 30% of Ba/(Ba+Sr) ratio and α phase was hardly observed. In case of (Ca,Sr1-x)Si2 films, the CaSi2 structure phase was the main phase except for the film with 6% of Ca/(Ca+Sr) ratio for the film deposited at 700 °C that consist of α phase. This shows that the solubility limit of Ba in α phase is larger than Ca. However, α phase was hardly observed at 600 °C. Power factor of α-phase was beyond 700 mW m⁻¹ K⁻² at room temperature and was not strongly dependent on the film composition. This value is larger than (111) one-axis-oriented Mg₂Si films prepared by the same deposition process, maximum 130 mW m⁻¹ K⁻² at 300 °C. The present result shows that α-phase of MₓSr₁₋ₓSi₂ (M = Ca, Ba) is one of the promising candidates as thin film thermoelectric materials.

EN14.10.10
Optimization of Degreasing-Sintering Process for Mg₂Si/PLA Mixture and Influences of Additive Amount of Al on Sintered Density and Thermoelectric Performance of Mg₂Si Fabricated by the Optimized Process
Takashi Itoh and Takumi Nakano; Nagoya University, Japan

Fused deposition modeling (FDM) type of 3D printing is widely used for manufacturing complex shaped polymer products. Recently, the metal/polymer composite products can be made by 3D printer using metal/polymer composite filament. Now, we are planning to develop a new manufacturing process of the thermoelectric (TE) elements or modules by combining the FDM type of 3D printing and the degreasing-sintering process. In this work, we focused on the degreasing-sintering process of the mixture of Mg₂Si and polyactic acid (PLA) powders. Mg₂Si compound powder was synthesized by a liquid-solid phase reaction (LSPR) method. Mixture powder of Mg₂Si, Al and PLA was pressed and heated in a pulse discharge sintering (PDS) chamber under a vacuum in various degreasing conditions. Following the degreasing, the sintering of Mg₂Si was carried out in the same PDS chamber at various starting sintering temperatures. Sintered density, Seebeck coefficient and electrical resistivity of the consolidated Mg₂Si were measured and power factor as TE performance was estimated from the TE properties. The optimum conditions of degreasing-sintering process maximizing the sintered density and the TE performance of Al-doped Mg₂Si were investigated. Furthermore, influences of additive amount of Al on the sintered density and the TE performance of Mg₂Si fabricated by the optimized degreasing-sintering process were investigated.

EN14.10.11
Quasiperiodic Branches in the Thermoelectricity of Nanowires
Vicenta Sanchez, Fernando Sanchez, Carlos Amador-Bedolla and Chumin Wang; Universidad Nacional Autonoma de Mexico, Mexico

Huge energy demand and pollution constitute two major problems of modern society. A large amount of normally wasted heat is present in many places around us, from human and animal bodies, natural thermal springs, combustion engines, up to numerous friction sources. The solid-state thermoelectric devices allow a direct conversion of heat into electricity without harmful contamination and those based on nanowires have demonstrated to be a promising route to reach a high thermoelectric efficiency [1,2]. Furthermore, branches attached to a nanowire may significantly modify the transport of excitations along it due to the wave interference [3]. In this work, we study the thermoelectric properties of thin nanowires with quasiperiodically placed branches by means of a real-space renormalization plus convolution method developed for the Kubo-Greenwood formula, in which tight-binding and Born models are respectively used for the calculation of electrical and lattice thermal conductivities [4]. The results show a substantial growth of the thermoelectric figure of merit (ZT) induced by the long-range quasiperiodic disorder, because it diminishes the thermal conduction of long wavelength acoustic phonons being such phonons usually not altered by local defects neither impurities [5]. A remarkable reduction of the thermal conduction can be further achieved by using low sound velocity materials [6].

This work has been partially supported by UNAM-IN115519, UNAM-IN106317 and CONACyT-252943. Computations were performed at Miztli of DGTIC, UNAM.

Characterization of Magnesium Silicide Stannide Powder for Use in Selective Laser Melting
Rachel Gray and Saniya LeBlanc; The George Washington University, United States

The aim of this study was to establish the feasibility of using magnesium silicide stannide ($\text{Mg}_2\text{Si}_{0.4}\text{Sn}_{0.6}$) powder in the selective laser melting process to produce thermoelectric generators (TEGs). $\text{Mg}_2\text{Si}_{0.4}\text{Sn}_{0.6}$ powder is a thermoelectric material optimal for high temperature applications and shows potential for use in TEGs. Currently TEGs are being manufactured using bulk material processing with multiple integration and assembly steps. Leading to decreased product efficiency, high manufacturing costs, and offering little flexibility in device geometry. Selective laser melting (SLM) an additive manufacturing technique, on the other hand, could provide a unique solution to these manufacturing challenges. However, current additive manufacturing techniques exist only for limited materials- namely polymers, ceramics, and metals- which do not include semiconductors (like thermoelectric materials). As well as require specific starting powder characteristics: desired particle size distribution, and high levels of circularity and convexity. Powder parameters such as convexity, circularity, and particle size distribution not only effect the flowability through the selective laser melting process but also the density of the final thermoelectric device. With a higher density, thermoelectric generators are more efficient and resilient to internal fractures.

Powder morphology and particle size distribution were analyzed through optical microscopy and the image analysis software FIJI. The ability to spread was assessed across 100 μm and 500 μm thick grooves using two rolling techniques, as well as a blade. Flowability was examined through the measurements of, angle of repose, angle of spatula, and compressibility. Each of these measurements follows the United States Pharmacopeia flowability standards. The results of these measurements show the potential for $\text{Mg}_2\text{Si}_{0.4}\text{Sn}_{0.6}$ to be integrated into SLM and paves the way for future studies looking to use $\text{Mg}_2\text{Si}_{0.4}\text{Sn}_{0.6}$ in thermoelectric devices.

EN14.10.13
Investigation of Three-Dimensional Thermoelectric Nanomaterials
David Osenberg$^{1,2}$, Laetitia Philippe$^{1,2}$, Stefano Mischler$^2$ and Johann Michler$^1$; $^1$Swiss Federal Laboratories for Materials Science and Technology, Switzerland; $^2$École Polytechnique Fédérale de Lausanne, Switzerland

Thermoelectric energy conversion is of great interest since most processes produce waste heat. Thus much effort has been devoted to enhancing the comparatively low conversion efficiency. Sufficient evidence has been provided that nanostructuring can enhance the thermoelectric conversion efficiency through size effects on the thermoelectric transport. These include phonon boundary scattering at grain boundaries, surfaces or interfaces within heterostructures, quantum confinement effects and modification of the phonon dispersion. While some of these effects have been investigated in simple low-dimensional systems, three-dimensional nanostructured materials are not as well understood, even though they are more relevant with regard to applications. Moreover most of the demonstrated enhancements of the figure of merit are due to a decrease of the lattice thermal conductivity, exploiting quantum confinement has been difficult, mostly due to strict requirements with regard to feature sizes.

In this work we apply electrochemical methods together with colloidal crystal lithography to tackle these problems, since this allows the fabrication of nanostructured and yet well-defined periodic materials. This facilitates relating the thermoelectric to structural properties and thus more accurate quantification of size effects. Additionally electroplating allows the growth of heterostructures by making use of the potential dependence of the composition in binary systems, in our case Bi-Te, which is expected to lead to enhanced phonon scattering due to the large acoustic mismatch and improved electrical properties (thermopower and mobility). The structural and thermoelectric characterization of the obtained materials is carried out both in- and cross-plane and numeric and analytic modelling is used to determine the material properties and quantify size effects.

EN14.10.14
Complex Mixed Anion Oxypnictides as Novel Thermoelectrics
Maud Einhorn, David O. Scanlon and Benjamin A. Williamson; University College London, United Kingdom
Thermoelectric materials, capable of directly and reversibly converting thermal energy into electricity, present a promising direction for renewable energy conversion.[1] The effectiveness of a thermoelectric material is measured using the dimensionless figure of merit $ZT$, with the world record set at 2.6 for single-crystal SnSe along the through-plane direction.[2] Realising reasonable conversion efficiencies generally requires high electrical conductivity and low thermal conductivity, with the maximum $ZT$ of a material often limited by the strong correlation between these properties.

Despite efforts to find promising thermoelectrics containing earth abundant and non-toxic elements, bismuth telluride (Bi$_2$Te$_3$) and lead chalcogenides remain the champion materials, with the performance of oxide thermoelectrics generally lagging behind the efficiencies achieved by chalcogenide-based materials.[3] Oxides generally present properties valuable for thermoelectric applications, including low cost, thermal and chemical stability and environmental benignity, but broadly thermoelectric performance has been hindered by the inherent high lattice thermal conductivities.[4] However significant progress has been made through novel materials with complex crystal structures which possess lower lattice thermal conductivities than usually seen in oxides.

In this study, we calculate the electronic band structures and corresponding $ZT$s of a range of novel mixed-anion quaternary oxypnictides using hybrid density functional theory, including spin-orbit effects. We have identified that LaZnOP and YZnOP possess promising properties for thermoelectric applications, including low intrinsic lattice thermal conductivities predicted from third order lattice dynamics calculations, and low charge carrier effective masses. In addition, we have examined the intrinsic defect chemistry of LaZnOP, to predict optimal carrier concentrations and an insight into ideal growth conditions for maximized performance. We conclude that these materials possess $ZT$’s greater than many existing oxide thermoelectric materials, and have the potential to perform as high-performance thermoelectric components.

**EN14.10.15**
**Analytical and Numerical Characterization of a Hybrid Thermophotovoltaic Coupled with a Thermoelectric Generator (HTPV-TEG) and a Microchannels-Based Cooling System** Pablo Araya, Jose Lincoleo, Tomas Salinger, Mario A. Di Capua and Amador M. Guzman; Universidad Catolica de Chile, Chile

A thermophotovoltaic (TPV) mounted on a thermoelectric generating (TEG) conceptual device is modeled analytically and numerically with the final goal developing a Hybrid Thermophotovoltaic (HTPV-TEG) system that offers improvements on efficiencies obtained with standard Thermophotovoltaic devices. The HTPV-TEG shall use inexpensive and simple components such as commercial photovoltaic cells and absorber/emitters, thermoelectric modules, and a microchannel-based cooling device. Special attention is given to the selection of specific absorber/emitter components, placed between a radiative heat source and a receiving Photovoltaic Cell (PVC). The goal is to predict the temperatures that will be reached by the absorbing/emitting element, the lower PVC and the TEG stacked under a controlled heat concentrating device. The objective is to determine heat input and resulting surface temperatures that will be reached under steady state conditions. Conduction, convection and radiative heat transfer will be present in the device. The resulting power generated by the PVC and TEG will be used to determine the overall device efficiency. Heat transfer simulations of conduction, natural convection and radiation of the device are performed using Computational Fluid Dynamics software in order to predict temperatures that will be reached by the test device as a function of input power, before its actual construction. Simulations allow for the selection of appropriate components and results are compared to studies by other authors. Preliminary results show that at 410 K a maximum theoretical improvement in efficiency of 7% can be obtained. These results are compared to studies conducted by others. HTPV-TEG improved efficiency therefore exceeds the performance of common solar photovoltaic cells, and TPV devices, and may be used for applications in the housing, agriculture and mining sectors, that do not necessarily require solar radiation.
Persistent, Single-Polarity Energy Harvesting from Ambient Thermal Fluctuations Using a Thermal Resonance Device with Thermal Diodes

Ge Zhang, Anton Cottrill, Michael Strano and Volodymyr Koman; Massachusetts Institute of Technology, United States

There is a pressing need for durable energy harvesting techniques that are not limited by intermittency, and capable of persistent and continuous operation over extended periods of time in a variety of environments. Our laboratory has identified ambient thermal fluctuations of various frequencies as potentially abundant, ubiquitous sources of such energy. We have developed a type of novel devices called thermal resonator for transient thermal energy harvesting, tested them in various environments and are working on integrating them with energy storage systems.\(^1\) \(^2\) In this work, we present a mathematical theory for the operation and design of a thermal resonator interfaced with optimized thermal diodes that we show is capable of much higher productivity than previous possible. This work is a significant advance over resonators that we have previously introduced using high thermal effusivity materials for a dual polarity electrical output from input temperature fluctuations. Herein, we outline the optimal design of a thermal resonance device incorporating optimal thermal diodes on its external boundaries with the environment, and we show that such a configuration is able to produce single polarity electrical generation drastically exceeding the performance of previous thermal resonators by a factor of 5. We also characterize additional thermal fluctuations in the environment, expanding the scope of resonator application. Lastly, we analyze the capability of thermal diodes available in the literature to realize such an enhancement in thermal resonance performance, and we conclude that current thermal diodes in existence could produce approximately a factor of 2 improvement in thermal resonator performance. This work points out the significant role of thermal diodes in ambient energy harvesting, and outlines important directions for next generation thermal diodes, independent of advances in thermoelectric or pyroelectric materials.

Development and Application of an Interatomic Potential to Model Thermal Conductance at GaAs-Ge Interface

Spencer Wyant and Asegun Henry; Massachusetts Institute of Technology, United States

Understanding the thermal conductance of solid-solid interfaces is important for applications like the thermal management of nanoelectronic devices and the engineering of novel thermoelectric materials. An ideal method to investigate interfacial thermal conductance with minimal assumptions is to explicitly model the atomistic interactions and their subsequent dynamics in a molecular dynamics simulation. However, prior attempts to perform such simulations often describe atomistic interactions using simple but unrealistic classical potentials that are not explicitly fit to capture thermal properties at an interface. An ideal interatomic potential used for this application would be able to replicate the interatomic force constants (IFCs) obtained from first-principles density functional theory calculations, remain stable at high temperatures, and would be quick to evaluate so as to enable large simulations over long time scales. Systems with heterointerfaces are especially challenging, as there are three distinct sets of IFCs: two for the different bulk regions surrounding the interface and one for the interface itself. We explore this challenge by developing an interatomic potential for a GaAs-Ge interface, a model III-V/IV heterointerface with minimal lattice mismatch. Our potential directly incorporates a Taylor expansion of the energy landscape of the different regions of our system. Comparisons are made with recent machine-learning inspired potentials, especially with respect to training data size and evaluation speed. Using this potential, the interface conductance modal analysis (ICMA) method is then applied to study the modal contributions to thermal conductance at the Ge-GaAs interface.

Improvement of Low-Temperature zT in MgSb\(_2\)-MgBi\(_2\) Solid Solution via Mg-Vapor Annealing

Max Wood, Jimmy Kuo, Kazuki Imasato and G. Jeffrey Snyder; Northwestern University, United States
The thermoelectric community strives to find new materials with better performance by looking for higher peak $zT$s. However, in real devices it is often more important to have a high average $zT$ over a broad range of temperatures in order to maximize the devices Carnot efficiency. Mg$_3$Sb$_2$-Mg$_3$Bi$_2$ alloys have recently garnered renewed attention due to their high performance at mid-range temperatures ($zT \approx 1.5$ at 700K). While having a relatively high performance at 700K, these materials suffer from grain boundary resistance at lower temperatures leading to an overall lousy performance at room temperature$^1$. Synthesis and optimization process to mitigate these grain boundary effects have been limited due to the loss of Mg, which hinders a sample's n-type dopability$^2$. Herein we demonstrate that a Mg vapor anneal can preserve a sample's n-type dopability, while allowing us to grow the grains within our material. We show that with different processing steps we can change the room temp performance of Mg$_3$Sb$_{1.49}$Bi$_{0.5}$Te$_{0.01}$ from $zT = 0.2$ to $zT = 0.8$.

Wearable Thermoelectric Generator Harvesting Body Heat and Solar Energy Simultaneously for High Performance

Kyoung Jin Choi, Myeong Hoon Jeong and Sung Bum Kang; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Recently, wearable and sustainable self-powering technologies have become increasingly important due to the development of wearable electronics such as sensors, health monitoring, and smart gears. Renewable energy sources include solar light, mechanical motion, thermal energy, and can be developed in the form of solar cells, piezoelectric and thermoelectric generators (TEGs), respectively. Among these, the wearable TEGs (WTEGs) operating based on the temperature gradient between the body and ambient temperature have generated significant amount of interest because the body heat can be used at any time and stable with time unlike other renewable energy sources. WTEGs are fabricated either by printing TE inks directly onto flexible substrates, or by embedding rigid TE legs, made small enough not to compromise the flexibility, in flexible matrixes. Chen et al. synthesized printable thick-film TE ink by mixing Bi$_2$Te$_3$ and Sb$_2$Te$_3$ powders with epoxy resin and fabricated TE legs using a dispenser printing on a polyimide (PI) substrate. On the other hand, Wang et al. reported a vertical-type WTEG using BiTe-based rigid TE pellets embedded in polydimethylsiloxane (PDMS) between the top and bottom PI thin films. The WTEG, composed of 52 pairs of p-n legs, generated an open-circuit voltage ($V_{OC}$) of 37.2 mV and output power ($V_{OUT}$) density of 16.7 $\mu$W cm$^{-2}$ at a $\Delta T$ of 50 °C. Suarez et al. enhanced the flexibility of a WTEG by replacing stiff electrodes with eutectic gallium-indium (EGaIn) liquid metal interconnects and filling the empty space between TE legs with PDMS in a commercial BiTe-based TE modules. These WTEGs exhibited relatively high TE material performances, because they were fabricated based on proven inorganic materials such as Bi$_2$Te$_3$ and Sb$_2$Te$_3$. However, a limit in temperature difference is observed when the body heat is used as a heat source. When the ambient temperature, at which the TEGs are driven, is in the range of 15 to 25 °C, the $\Delta T$ values of the body-heat-based WTEGs are only 1.5 – 4.1 °C. Previously, we first demonstrated a wearable solar TEG (WSTEG) with a solar absorber in WTEG and reported a high $\Delta T$ of 33.4 °C. The TE legs were fabricated by dispenser-printing a BiTe-based ink, prepared by dissolving mechanically alloyed BiTe powders and Sb$_2$Te$_3$ sintering additive in glycerol. However, despite the high temperature difference, high power density was not obtained due to low thermoelectric properties of Printed TE leg compared to the rigid TE legs. Herein, we proposed a dual-mode wearable thermoelectric that can obtain both body heat and solar energy by placing a solar absorber on the bottom surface of a bulk TEG. The WTEG can improve the temperature difference compared to conventional TEGs using only the body heat. In addition, a PDMS was filled between the rigid TE legs obtaining both flexibility and high value of power density.

Fabrication of Highly-Efficient Nanoscale Multilayered Thin-Film Based Integrated Thermoelectric Devices

Joevonte Kimbrough, Aalandria Henderson, Abigayle Glenn, Sam Chance, Samuel Banks, Broanna Rodgers, Zhigang Xiao and Lauren Williams; Alabama A&M University, United States

In this research, we report the growth of nanoscale multilayered thermoelectric thin films and fabrication of integrated thermoelectric devices for high-efficiency energy conversion and solid-state cooling. Nanoscale multilayered thin films such as Sb/Sb$_2$Te$_3$ and Te/Bi$_2$Te$_3$ thin films were grown using the e-beam evaporation with DC bias on the substrate. The multilayered films were prepared to have 150 to 300 layers, where each layer was
about 5 nm thick. The effects of DC substrate bias on the growth of films such as the crystalline structures in the films were studied. Integrated thermoelectric devices with a high density of thermoelectric elements were fabricated with the nanoscale multilayered thin films using the clean room-based microfabrication techniques such as UV lithography. X-ray diffraction and reflection and high-resolution tunneling electron micrograph (HR-TEM) were used to analyzed the e-beam-grown nanoscale multilayered thin films. SEM was used to image and analyze the fabricated devices. The thermoelectric characteristics of the fabricated devices such as the open-circuit voltage and output power were measured and analyzed. The effects of cooling and annealing on the nanoscale multilayered thin films and the integrated thermoelectric devices were studied. Highly-efficient thermoelectric thin-film materials and integrated devices will be demonstrated and reported.

EN14.10.22
Tuning Phonon Scattering by Interlayer Coupling Ben Xu; Tsinghua University, China

Interlayer interaction can introduce profound effects on thermal conductivity, which is strongly dependent on the properties of the coupling itself. Here we develop a model showing the ratio between the high-order and harmonic terms plays the dominate role in the phonon scattering behavior and demonstrated this relationship by carrying out comparison between the layered materials MoS2 and PtS2, using first principles calculation and solving phonon Boltzmann transportation equations. Moreover, series of materials with BiCuSeO structure are also analyzed, where geometry factor was constructed to indicate the delicate variance of the interlayer distance of these structure. These understanding can be used as guidelines for designing materials of particular phonon properties, for example low thermal conductivity.

EN14.10.23
A Time-Dependent Modeling and Characterization of a Concentrated Photovoltaic-Thermoelectric Hybrid System Cooled by a Microchannel Heat Sink Mario A. Di Capua; Pontificia Universidad Catolica de Chile, Chile

Photovoltaic electrical energy has experimented a significant increase in the last decade motivated mostly for the reduction of the PVC costs, the emergence of new PVC technology and increase amount of new large projects, particularly in areas with large levels of irradiance. However, despite the above factors, the worldwide electricity generated by photovoltaic technologies continue being low compared to other renewable technologies such as the ones based on water, biomass, and wind and with traditional fossil-based technologies. One of the main reasons that can explain this low participation is the low conversion efficiency of traditional PV technologies, which ranges from 10% to 25%. This low participation has pushed to developer and researchers to create novel and more efficient photovoltaic technologies that combine multi-junction solar cells with high solar concentration to achieve a conversion efficiency equivalent to 40%. By using a concentrated photovoltaic (CPV) system, it is possible to reduce the use of expensive and not easy disposable semiconductor materials. However, since only a fraction of the concentrated direct normal irradiance (DNI) is converted into electricity, a cooling system is completely necessary to avoid solar cell overheating, which reduces the solar cell efficiency and accelerates the solar cell degradation. Additionally, we consider integrating a thermoelectric generator (TEG) to produce extra electrical energy by mean of Seebeck and Peltier effect that can convert part of the solar cell heat into electricity. Several researchers have proposed and evaluated the use of microchannel heat sinks as a cooling system solution for CPVs, due to its high thermal performance at low Reynolds numbers and small heat transfer area, low weight, and its possible incorporation to the solar cell system structure ((Leonardo Micheli et al. 2013, M Di Capua H et al. 2018, Radwan et al. 2019).

The present work seeks to evaluate a CPV-TEG hybrid system cooled by a microchannel heat sink (MCHS) under variable DNI, ambient temperature, and wind velocity by developing an analytical model that is numerically simulated and solved. A time-dependent thermodynamic model has been developed to analyze the behavior of the CPV-TEG-MCHS system considering both, clear and cloudy day. The principal objective of our current work is to evaluate the thermal inertia of the hybrid system under variable surrounding conditions, as well as the coolant flow rate that allows achieving the maximum conversion efficiency and safe solar cell temperature. The system evaluated is composed of a concentration photovoltaic system that uses a Fresnel lens to concentrate the solar radiation over a multi-junction (GaInP/GeAs/Ge) solar cell with a concentration factor equivalent to 1000x. In the bottom solar cell face, a TEG is integrated ann an MCHS with several microchannels of Wc and Hc, the width and height, respectively, in a parallel flow configuration is incorporated in the cold side of the TEG. The considered PV cell areas in the analyzes are 3x3 mm2 and 10x10 mm2. The MCHS material is copper and the coolant is deionized
demineralized single phase water.

**Thermal Characterization and Modeling of Silicon Nanowires with Nickel Silicide Nanoinclusions** Laia Ferrer-Argemi and Jaeho Lee; University of California, Irvine, United States

Efficient silicon-based thermoelectric materials compatible with the existing electronic and photovoltaic technologies would provide excellent energy harvesting opportunities. Although the high bulk thermal conductivity of silicon has been successfully reduced during the past decade through nanostructures such as nanowires, nanograins, and nanomeshes, the fundamental mechanisms that reduce the thermal conductivity through nanometer-sized inclusions of other materials still require further investigation. Here, we report the thermal conductivity of silicon nanowires with epitaxial nickel silicide nanoinclusions (Si-NiSi$_2$ NWs) and develop a model to explain the observed thermal conductivity trend. We synthesize silicon nanowires using metal-assisted chemical etching and deposit nickel nanoparticles on their surface with electroless deposition. Annealing the nanowires allows the nickel to diffuse into the silicon, resulting in silicon nanowires embedded with metallic nickel silicide nanoinclusions grown in the diffusion plane [1 1 1], which results in diamond or rectangular-shaped inclusions. We measure the thermal conductivity of single nanowires using suspended micro-membranes in a cryo-chamber from 40 to 300 K in high vacuum. We report the thermal conductivity of two Si-NiSi$_2$ NWs with 30% inclusion density and diameters of 120 and 170 nm, respectively, which increases with temperature and saturates at 150 K with ~15 Wm$^{-1}$K$^{-1}$ with little difference between both wires. The consistent thermal conductivity among Si-NiSi$_2$ NWs wires with the same inclusion density differs from the reports on the thermal conductivity of silicon nanowires synthesized using metal-assisted chemical etching depending on their surface roughness, which can have large variability even within the same batch. This indicates that the nanoinclusions consistently decrease the phonon mean free path and dominate thermal transport. To better understand the underlying mechanisms that maximize the thermal conductivity reduction through diamond and rectangular nanoinclusions, we integrate Monte Carlo ray-tracing simulations with the kinetic theory and Landauer formalism, including the Diffuse Mismatch Model to calculate the thermal boundary resistance and the two-temperature model to estimate the electron-phonon coupling. We demonstrate that by incorporating nanoinclusions into a film with high interfacial density, the matrix phonon mean free path and the film’s thermal conductivity can be minimized without compromising the electrical properties. Additionally, metal/silicon junctions produce chemically stable Schottky barriers at the nanoinclusion interface that can filter low energy electrons and increase the Seebeck coefficient without damaging the electrical conductivity. The results of this work expand the understanding of transport phenomena in complex nanoengineered materials and open promising optimization paths for silicon-based thermoelectric materials.
This talk will discuss our recent work to simulate electron and phonon thermoelectric transport in complex materials and across interfaces based on the density-functional theory and atomic Green’s function. One example of the complex material is Mg2Sb3, which has been recently reported to have high figure of merit. We compare the charge defect scattering due to different dopants using first principle calculation and find weak impact of defect on mobility. Instead, the intrinsic carrier-phonon scattering is the major scattering mechanism. Only specific polar optical phonon modes make dominant contribution to the scattering rates, which we attribute to the atomic structure and electrostatic interactions in Mg2Sb3. For transport across interfaces, an important question to ask is if electron and phonon scatterings conserve lateral momentum, i.e., if they experience specular or diffuse scattering, in the presence of interfacial atomic mixing. We employ atomic Green’s function to simulate electron and phonon transmission across interfaces for SiGe interface with mode-by-mode resolution. We find the angular dependent interfacial transport for electron and phonon are behaving differently, which provides new opportunities for optimizing thermoelectric performance. This work is supported by DARPA MATRIX program (Grant No. HR0011-16-2-0041).

Amorphous-Like Thermal Conductivity in Crystalline Solids Saikat Mukhopadhyay and Thomas Reinecke; U.S. Naval Research Laboratory, United States

Thermoelectric materials (TEs) could play an important role in future energy management through environmentally sound cooling and power generation, e.g., converting waste heat into electricity. Efficient TEs inhibit the propagation of heat (low thermal conductivity, $\kappa$) but conduct electricity well (high power factor, PF). Although $\kappa$ in a given material can be reduced via alloying and nanostructuring, identifying materials with intrinsically low $\kappa$ is still needed. It has already been known that soft phonon modes due to weakly bonded atoms and $s^2$ lone-pair electron are common to materials with low-$\kappa$. Here, we predict a series of new materials which are weakly bonded systems with same constituent elements but different stoichiometry either with $s^2$ lone-pair electron or high mass density. Due to giant phonon anharmonicity and low phonon group velocities, they offer extremely low $\kappa$ (0.3-0.6 W/mK) at 300K approaching to those found in the amorphous/disordered regime. In addition to low-$\kappa$, high Seebeck coefficients and electrical conductivities in these materials may provide a new opportunity for designing high-efficiency thermoelectrics at room temperature.

New Horizons in Thermoelectric Materials—Inorganic-Organic Hybrids and Machine Learning for Inorganic Crystals Kedar Hippalgaonkar1,2; 1Nanyang Technological University, Singapore; 2Institute of Materials Research and Engineering, Singapore

For the next revolution in thermoelectrics, development of new physics as well as new materials needs to go hand-in-hand. In this talk, I will introduce new perspectives such as correlated electron physics, wave effects in phonons as well as opportunities for new inorganic-organic (hybrid) materials1. Then, I will introduce specifically the case of CuTe:PEDOT thin films and using this as a test case, describe the design principles for creating the next generation of hybrid materials2. In addition, I will describe how data-driven approaches can augment our knowledge: used in conjunction with the right material and transport descriptors, these can prove prescient in predicting new TE materials. I will end with a specific example of how we’ve used a Crystal Graph Convolutional Neural Network (CG-CNN) with training data from Materials Project to learn about TE properties. In addition, we use high-throughput, high-fidelity DFT calculations with the Electron Phonon Averaging (EPA) approximation to calculate carrier relaxation times, we propose that the transport effective mass remains an effective single descriptor that can guide inorganic TE material screening.

Thermoelectric Transport Descriptors in Data-Driven Thermoelectric Screening Ady Suwardi1, Deng Tianqi2, Daniil Bash1, Hong Kuan Ng1, Jose Recatala Gomez1, D V M. Repaka1, Pawan Kumar1, Anas I. Abutaha1, Michael Sullivan2, Shuo-Wang Yang2 and Kedar Hippalgaonkar1; 1IMRE, Singapore; 2Institute of High Performance Computing, Singapore

With the maturity of sophisticated, high throughput computational tools and the advent of machine learning applications in materials science, identifying the appropriate fundamental level descriptors has never been more relevant and pressing in data-driven materials discovery domain. In this work, we first present the inertial effective mass as an important descriptor in thermoelectric transport. The conclusion was obtained by analyzing data from 1617 compounds of all crystal structures mined from the materialsproject.org. Data was analyzed using polycrystalline averaging Seebeck, effective mass, as well as electrical conductivity. In addition, constant relaxation time approximation was used in all data analysis, which is known not to necessarily reflect experimentally measured compounds.

Subsequently, we present a state-of-the-art approach of using electron-phonon averaging (EPA) to obtain contribution of all possible scattering mechanisms to the relaxation time and challenge the initial assumption of constant relaxation time. More interestingly, we sought to evaluate the veracity of insights and conclusions drawn under constant relaxation time approximation from the EPA point of view and indeed confirm that effective mass is an important descriptor. Further insights gained from analysis of scattering times provide us additional insight towards prediction of new thermoelectric compounds.

Thickness-Dependent Thermal Conductivity of Titanium Trisulfide Nanoribbon Chao Wu1, Chenhan Liu1, Yongkang Wang1, Juekuan Yang1, Qingyu Yan2 and Yunfei Chen1; 1Southeast University, China; 2School of Materials Science and Engineering, Singapore

The two-dimensional layered materials with interlayer van der Waals (vdWs) bonding such as graphene have attracted tremendous interests in scientific community. Recently, layered materials composed of transition metal trichalcogenides with strong in-plane anisotropy, which show unusual properties based on theory, have been successfully synthesized so that their properties can be explored through experiment. For instance, due to theoretically calculated ZT value (3.1) of monolayer titanium trisulfide along $y$ direction at moderate carrier concentration, layered titanium trisulfide nanoribbons with intralayer covalent bonding and interlayer vdWs bonding burst extensive research, which inspires us to investigate the lattice thermal conductivity of the nanoribbon and the size effects on the thermal conductivity because lowering the thermal conductivity can increase the ZT value significantly. In order to better understand the thermal transport in the titanium trisulfide nanoribbon, the theoretical calculation combined with the experiment are adopted. Through solving the phonon Boltzmann transport equation (implemented in ShengBTE package) with the first-principles second- and third-order force constant (implemented in VASP package), the thermal properties of titanium trisulfide are obtained. The calculation results reveal that the thermal conductivity monotonously decreases with the number of titanium trisulfide layers increasing from one to three and displays a strong in-plane anisotropy as the temperature range from 40 to 500 K. For example, the thermal conductivity along $y$ direction is 2.7 times larger than $x$ direction at room temperature. Compared to layered graphite, due to the weaker interlayer coupling strength, the out-of-plane thermal conductivity (around 1.1 W/m-K) at the room temperature is 5 times lower.

Based on the results of theoretical calculation, we synthesized the titanium trisulfide nanoribbons with different thicknesses and measured the thermal conductivity using a suspended micro-thermometry from 20 to 300 K. The experimental results show that the in-plane thermal conductivity of titanium trisulfide nanoribbons decreases monotonously as the thickness increases, which is same as the theoretical calculation. Interestingly, the thermal conductivity keeps decreasing as the thickness is smaller than 272 nm, which is quite different from multi-layer graphene. In detail, the thermal conductivity decreases rapidly as the thickness is below 60 nm and becomes slowly beyond 150 nm. Due to the computational cost, 4 layers or thicker titanium trisulfide cannot be calculated. The giant layer thickness dependent in-plane thermal conductivity is surprising and confusing. We speculated that this phenomenon may stem from weak interlayer coupling strength and unique atomic structure, which needs further investigation.

Design and Engineering of Flexible Thermoelectric Devices G. Jeffrey Snyder; Northwestern University, United States

Thermoelectric semiconductors directly convert heat into electricity. These solid-state devices have been used reliably in space for over 40 years without maintenance. Temperature gradients and heat flow are omnipresent in natural and human-made settings and offer the opportunity to scavenge energy from the environment recovering waste heat from industry or replacing the need for batteries in remote sensor networks or mobile devices. Particularly attractive is the ability to generate electricity from body heat that could power medical devices or implants, personal wireless networks or other consumer devices. This talk will discuss the design principles for thermoelectric generators using a generalized electrical transport model combined with an effective thermal conductivity approach [1, 2]. Such design principles provide good estimates of the power that could be produced and the size and complexity of the thermoelectric generator that would be required. In addition these design principles can guide the search and optimization new thermoelectric materials. In organic and polymer semiconductors the optimum doping is identified and the peak $zT$ for a given class of materials can be determined. Also, a complete system design shows the misconception that power factor rather than $zT$ should be optimized for a TE generator. The power factor misconception also leads to misleading strategies for optimization and discovery of new TE materials. The materials requirements for flexibility, leading to a flexibility figure-of-merit will be discussed.

Thermoelectric Transport at Organic-Silicon Interface Mona Zebbarjadi, Naiming Liu, Md Golam Rosul and Tianhui Zhu; University of Virginia, United States

Nanopatterned holey silicon materials follow the concept of “phonon glass and electron crystal” and possess potential for thermoelectric device applications as it is also compatible with the well-developed Si-based industry. We fabricate a boron-implanted holey Si thin-film device, and study the thermoelectric transport properties. A novel method to measure in-plane thermal conductivity of thin film materials using thermal reflectance imaging is successfully conducted. Subsequently, we fabricate a hybrid F4TCNQ-silicon, which utilizes a non-destructive doping mechanism by charge transfer at the heterointerface. We conduct transport measurements and validate that organic F4TCNQ molecules effectively p-type dope the Si surface, resulting in power factor enhancement. Outcomes of this study serve as proof of concept in designing 3D hybrid structures with closely packed interfaces towards an efficient thermoelectric device, using organic-inorganic transfer doping mechanism.

11:15 AM EN14.12.03/EN13.04.03
Tuning the Thermoelectric Performance of Hybrid Polymer/Nanoparticle Composites Katherine A. Mazzio1, Danny Kojda1, Jens Niederhausen1, Britta Ryll1, Anyssa L. Derj2, Johannes Frisch1, Klaus Habicht1 and Simone Raoux1,3; 1Helmholtz-Zentrum Berlin, Germany; 2Université Paris Sciences et Lettres (PSL), France; 3Humboldt-Universität zu Berlin, Germany

Hybrid materials consisting of inorganic nanostructures embedded in conducting polymer matrices have emerged as promising systems for room temperature thermoelectric applications. They are attractive due to their intrinsic low thermal conductivities, the ability to engineer interfaces for energy filtering effects and phonon scattering, and their ability to take advantage of high-throughput and solution processable manufacturing. Most polymer and hybrid...
materials reported in the literature have been p-type, owing to difficulties in n-type doping of conducting polymers in conjunction with the nature of the applied nanocrystals. This has resulted in a strong drive to develop new n-type materials, since both are necessary for module development. Here we explore our recent developments in the synthesis chalcogenide nanowires encapsulated in poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) that are used as templates for the synthesis of Ag$_{2-x}$E (where E=Te, Se) via topotactic chemical transformation processes. This synthetic method allows us to engineer the composition of our hybrids, whereby we are able to directly influence the thermoelectric properties, including the production of both p-type and n-type materials from the same parent material. We detail the structural and morphological development of our materials with changing stoichiometry during aqueous based synthesis via X-Ray diffraction (XRD), X-Ray photoelectron spectroscopy (XPS), and transmission electron microscopy (TEM) and relate this to their thermoelectric performance. We take the example of one of our n-type Ag$_{2}$Te/PEDOT:PSS hybrid materials and further manipulate its performance via post-deposition (de)doping schemes, whereby the PEDOT:PSS is reduced by treatment with Tetrakis(dimethylamino)ethylene (TDAE). This process is followed by UV-Vis spectroscopy and electron paramagnetic resonance spectroscopy (EPR) to detail how this (de)doping process effects the charge carrying species. Control of the competing charge carrier concentration allows further improvement in the n-type hybrid device performance.

11:30 AM EN14.12.04/EN13.04.04
Flexible Cellulose Fiber-Based Hierarchical Porous Bismuth Telluride for High-Performance Thermoelectrics and Energy Harvesting Device Kaiping Tai, Qun Jin and Yang Zhao; Institute of Metal Research, China

Porous modification is general approach to endowing the rigid inorganic thermoelectric (TE) materials with considerable flexibility, however, by which the TE performances are severely sacrificed. Thus, there remains a struggling against the trade-off between the TE properties and flexibility. Herein, we develop a novel strategy to combine the Bi$_2$Te$_3$ thick film with the ubiquitous cellulose-fiber (CF) print-paper via unbalanced magnetron sputtering technique (ACS Appl. Mater. Interfaces 10, 1743, 2018). The Bi$_2$Te$_3$/CF TE composites with tailorable shapes and dimensions were successfully obtained by our approach, which have reasonable internal resistance as components of TE devices with in-plane configurations. Owing to the hierarchical nano-micro porous microstructures and the excellent fraction resistance of the Bi$_2$Te$_3$/CFs constructions, the prepared TE composites with Bi$_2$Te$_3$ nominal deposition thickness of tens of micrometers exhibit mechanically reliable flexibility, of which the bending deformation radius could be as small as a few millimeters. Meanwhile, the thermal conductivity was remarkably reduced, due to the phonon-nanopore scattering effects. Enhanced Seebeck coefficients were observed comparing with the dense films and the power factors of ~250 to 400 μW/mK$^2$ were obtained for the composites from room temperature (RT) to 473 K, which can be further improved by optimizing the carrier concentrations. As a result, the TE figure of merit, ZT, is as high as ~0.38 at 473K.

Moreover, Fig. 1 depicts the photograph, structure, and working principle diagram of the flexible TE device consisting of 12 pairs of p- and n-type legs integrated on the double sides of CF paper sheet employing a laser beam micro-cutting system, which displays great potential as flexible TE device for thermal energy harvesting. When the light bulb works for about a few minutes, the temperature of the central side rises quickly, the temperature difference between the center and periphery is about 50 K from the infrared image, and the TE device generates an output voltage of 0.144 V. This kind of flexible TE device can realize the collection and recovery of heat energy in daily life to power flexible electronics, such as wearable devices and environmental monitors, which also promotes the development of paper-based and thin-film electronics.

11:45 AM EN14.12.05/EN13.04.05
Creep Behavior of Thermoelectric Materials Muath M. Al-Malki$^{1,2}$, Qinyi Qiu$^3$, Tiejun Zhu$^3$, G. Jeffrey Snyder$^1$ and David Dunand$^1$; $^1$Northwestern University, United States; $^2$King Fahd University of Petroleum and Minerals, Saudi Arabia; $^3$Zhejiang University, China

Since the 1960’s, NASA has implemented Radioisotope Thermoelectric Generators (RTGs) to supply energy for many of its satellites and space probes. Similar generators for industrial and automotive waste heat recovery have been proposed and many new thermoelectric generator materials have been investigated. Nonetheless, mechanical integrity for the full operational life of the thermoelectric modules, which can extend to decades, has not been given much consideration in such applications. Among many contributors, clamping forces, vibrational stresses, and thermally-induced mismatch stresses may combine to give stress levels high enough to deform the thermoelectric
module by creep, thus diminishing its useful lifetime. To date, few thermoelectric materials have been tested for
creep, including Bi$_2$Te$_3$, PbTe, Mg$_{0.96}$Al$_{0.04}$Si$_{0.97}$Bi$_{0.03}$, and TAGS-85.

In the present talk, we show the case of the compressive creep deformation behavior of two thermoelectric
materials; half-Heusler n-type Hf$_{0.3}$Zr$_{0.7}$NiSn$_{0.98}$Sb$_{0.02}$ and n-type skutterudite (Yb-CoSb$_3$) alloys, at 500-705 °C.
When subjected to uniaxial compressive stresses at 600°C, the n-type half-Heusler alloy Hf$_{0.3}$Zr$_{0.7}$NiSn$_{0.98}$Sb$_{0.02}$
exhibits Newtonian flow, consistent with diffusional creep of its fine-grain (1-7 μm) microstructure achieved via
spark-plasma sintering of powders. In addition to its promising thermoelectric performance at high temperatures,
this alloy sustains very high compressive stresses at 600°C (from 21 to 359 MPa, for ~ 23 days) without
macroscopic failure. However, the brittle nature of the alloy leads to the formation of numerous cracks at such high
stresses, which in turn deteriorate the thermoelectric performance. A more realistic creep stress range (15-46 MPa,
for ~ 4 days) preserves the high thermoelectric figure of merit $zT$. Among thermoelectric materials mechanically
creep-tested to date, the ZrNiSn-based Half Heusler alloy has the highest creep resistance. On the other side, the n-
type skutterudite (Yb-CoSb$_3$) alloy showed acceptable creep resistance under protected environment.

Given their high melting temperature, stiffness, and creep resistance, half-Heusler alloys appear uniquely suited for
long-term thermoelectric applications where high stresses and temperatures are present.

Advanced Materials and Their Infusion into Efficient Thermoelectric Power Generation Systems Jean-Pierre
Fleurial and Sabah Bux; California Institute of Technology, United States

Thermoelectric power sources have consistently demonstrated their extraordinary reliability and longevity for deep
space missions as well as terrestrial applications where unattended operation in remote locations is required. The
discovery of new, more efficient materials, and the development of practical, robust elements and device
technologies are the key to improving existing space power system performance and versatility and expanding the
use of thermoelectrics into efficient, cost-effective terrestrial applications using medium to high grade heat sources.
We present an overview of NASA-funded collaborative research efforts to identify advanced bulk thermoelectric
materials, capable of quadrupling current state-of-practice average $ZT$ values over the available operating
temperature range of 1275 K to 475 K, through the exploration of structurally complex compounds allowing for a
wide range of chemical tuning and the possibility of forming stable nano- and micro-scale composites. Materials-
and device-level experimental performance validation accomplished to date, technical challenges, progress and
plans for technology infusion into future thermoelectric power systems are discussed.

2:00 PM EN14.13.02/EN13.05.02
Understanding Thermoelectric Devices at the Micro Scale Nicolas Perez, David A. Lara Ramos, Vida Barati,
Javier Garcia, Heiko Reith, Guodong Li, Gabi Schierning and Kornelius Nielsch; IFW Dresden, Germany

Energy harvesting and thermal management are required for applications in the internet-of-things, autarkic sensors,
or highly integrated electronic devices. Thermoelectric generators and coolers are promising technologies for
localized energy harvesting and thermal management. These devices are currently well optimized for near-room
temperature operation at the macroscopic scale. However, the high integration density of today’s most significant
applications requires an increasing degree of miniaturization. Using finite element calculations, we gained insight on
the design guidelines for micro thermoelectric devices with realistic material properties, and with concurring size
and geometry constraints [1]. Understanding the interplay between thermal and electrical heat fluxes at the micro
scale allowed our group to fabricate micro thermoelectric devices for thermal management, efficient enough that can
be integrated in electronic packages [2]. Our relevant findings about the design of micro thermoelectric devices will
be presented.
The detection of temperature and dynamics of working fluids, including water, is important for experimental and industrial applications, such as detection of precise changes in fluid environment, monitoring of drainage or cooling water at factory facilities, micro/nano flow analysis. However, due to the spatial limitations or complex geometry of fluid channel interfaces, it is important to accurately detect multiple parameters that are optimally integrated into the operating platform. Also, many fluid sensors necessarily disrupt the natural flow within the platform, and even though the installation of the sensing device should not affect the intrinsic properties of the target element in fluid applications. In this work, we develop a flexible, attachable dual-output sensor for fluid temperature and transfer dynamics based on structural design of thermoelectric materials (SDTM). The SDTM flexible substrates using PET was developed to detect real-time changes in temperature and peak voltage reflecting fluid dynamics. Simple sputtering deposition of Bi2Te3 through a patterning mask has allowed the fabrication of dual-power sensors which do not affect the fluid flow shape. When the working fluid contacts the surface, thermoelectric structure pattern induces continuous double thermal wave and time interval without disturbing the natural flow of working fluid. The raw voltage signal induced by thermal gradient wave provides the magnitude of the first peak voltage and the duration between the two peaks, which show the real time temperature and the moving velocity of the working fluid. Furthermore, as a demonstration of an expandable platform using SDTM, a scalable sensor array comprising multiple SDTMs was fabricated as a large-area device for sensing a fluid temperature flow dynamic sensing device. Its performance with respect to sensing the fluctuation of working fluid temperature and kinematics was verified using a 4 × 4 SDTM array. As a result, the new methodology using SDTM can contribute to the development of entirely new technologies for next-generation sensors that require advanced features such as multi-element detection and a variety of integrated flexible and removable features.

Thermoelectric Cooling Using a New p-Type Material Zhifeng Ren; University of Houston, United States

Bi2Te3-based p-type Bi0.5Sb1.5Te3 and n-type Bi2Te2.7Se3 have been the only materials used for thermoelectric cooling for decades. Even though the progress on advancing the thermoelectric figure-of-merit (ZT) has been significant especially the materials with peak ZT at high temperatures, materials with high enough ZT around room temperature are very rare. Up to now, in addition to Bi2Te3-based ones, the only reported is p-type MgAgSb with ZT of ~0.8 at room temperature. There is no report on any n-type material exhibiting ZT similar to that of the n-type Bi2Te2.7Se3. In this talk, I will present a new n-type material that has a ZT of ~0.7 at room temperature, which is comparable to that of n-type Bi2Te2.7Se3. The cooling performance of a unicouple consisting of the new n-type material and the p-type Bi0.5Sb1.5Te3 is also in par with the commercial legs consisting of the p-type Bi0.5Sb1.5Te3 and n-type Bi2Te2.7Se3.

4:00 PM EN14.14.02/EN13.06.02
Modeling the Temperature Dependent Seebeck Coefficient of Metastable Amorphous Ge2Sb2Te5 and Impacts of Thermoelectric Effects on the Operation of Phase Change Memory Devices Jake Scoggin, Noah Del Coro,
Thermoelectric effects play a significant role in phase change memory (PCM) and Ovonic threshold switch (OTS) devices used as access devices in PCM cells [1]. Typical PCM cells are two-terminal nanometer-scale resistive memory devices which can be reversibly switched between a low-resistance crystalline and a high-resistance amorphous state via nanosecond electrical pulses. Amorphization in PCM devices is achieved by self-heating the phase change material, typically a chalcogenide, close to its melting temperature, followed by a sudden quench. Crystallization is achieved by self-heating the phase change material above its glass-transition temperature. OTS devices typically use amorphous chalcogenides that do not crystallize during normal device operation. The local current densities in PCM and OTS devices can reach $10^8$ A / cm$^2$, giving rise to local temperatures in excess of 900 K and thermal gradients as high as 50 K / nm; hence, Peltier effects at material interfaces and Thomson heating within the active area are substantial. Accurate modeling of thermoelectric effects requires knowledge of temperature dependent electrical resistivity and Seebeck coefficients of these materials. These parameters can be measured at low temperatures on as-deposited amorphous films [2]. However, melt-quenched amorphous materials’ parameters tend to differ from as-deposited films, and PCM materials rapidly crystallize at higher temperatures. High-speed metastable electrical resistivity measurements can be performed on nanoscale devices using electrical pulses to uniformly amorphize devices up to approximately 200 nm in diameter [3], but larger devices tend to form current filaments and hence do not amorphize uniformly. On the other hand, measurement of the Seebeck coefficient ($S$), which is vital to understanding thermoelectric effects, is very difficult at small scales.

In this work, we model the Seebeck coefficient for metastable amorphous Ge$_2$Sb$_2$Te$_5$ (aGST) based on high-speed experimental results [3] and an energy band diagram proposed by Muneer et al. [4] from 300-850 K [3], [5], and we analyze thermoelectric effects in PCM cells using finite element phase change device simulations [6]–[9]. We calculate the electron and hole Seebeck contributions $S_e$ and $S_h$ in metastable aGST with the band diagram in [4] and find that $S_h$ is similar in both magnitude and slope to $S$ measurements on as-deposited aGST thin films in 300-400 K range [5], [10], consistent with the unipolar conduction assumed when deriving the band gap in [4]. We use $S_h$ as the Seebeck coefficient in metastable aGST and simulate reset and set operations in a PCM double mushroom cell and find that the Seebeck differential between crystalline and amorphous GST results in significant heating/cooling at amorphous-crystalline junctions during both crystallization (set) and melting (reset).

4:15 PM *EN14.14.03/EN13.06.03*

Flexible Thermoelectric Materials by Organic Intercalation of Two-Dimensional Layered Compounds

Chunlei Wan¹, Kunihioto Koumoto² and Kun Zhang³; ¹Tsinghua University, China; ²Nagoya Industrial Science Research Institute, Japan

Flexible materials with high thermoelectric performance have attracted growing interest recently. By intercalating organic molecules into the van der Waals gap of inorganic two dimensional layered compounds, we developed a large family of thermoelectric materials with excellent mechanical flexibility. The inorganic and organic monolayers are alternatively stacked to form an inorganic/organic superlattice, in which the high electronic transport properties of the inorganic component has been maintained and the thermal conductivity was dramatically suppressed by the organic components, finally resulting in boosted ZT value. We have demonstrated this idea in several two dimensional host materials, including TiS$_2$, Bi$_2$Se$_3$ and TaS$_2$, etc. The abundant choice of the organic
molecules also brings new opportunities to optimize the thermoelectric performance, such as the dielectric screening effect and the quantum confinement effect. We finally developed a solution-processed strategy to fabricate large area flexible thermoelectric foil based on this inorganic/organic superlattice, which enables easy integration into energy-harvesting electronic devices.

4:45 PM  EN14.14.04/EN13.06.04
Diffusion Behaviors of Bonding Interface of Bi–Te Based Thermoelectric Materials with Ni/Au Barrier Fabricated by Different Deposition Processes  Ekubaru Yusufu1, Tohru Sugahara1, Michio Okajima2, Shutaro Nambu2 and Katsuaki Suganuma1; 1The Institute of Scientific and Industrial Research, Osaka University, Japan; 2E-ThermoGentek Co., Ltd., Japan

Recently, our group developed a Bi–Te-based TEG device by using conventional semiconductor packaging technology. In that device, Ni/Au was used as the diffusion barrier, and Sn–Ag-based solder was used as the bonding material. Although Bi–Te-based TE materials can be used up to approximately 300°C, the maximum operating temperature of the device was limited to approximately 150°C owing to the low melting point of the Sn–Ag-based solder (~150°C) that bonds Bi–Te-based TE materials and Cu electrodes. Therefore, in order to apply higher temperature differences to the device, in this study, we attempted to develop a bonding interface resistant to heat up to 250°C. Ni/Au was retained as the diffusion barrier layer, but Ag paste was chosen as the bonding material, instead of the Sn–Ag-based solder, because it has many advantages such as high-temperature stability (melting point ~ 960°C), printability, low electrical resistivity, high thermal conductivity (150 Wm⁻¹K⁻¹), and a temperature requirement of less than 300°C for sintering-bonding. The Ni/Au diffusion barrier layer was prepared using two different deposition processes, sputtering and electroplating, and the element diffusion behaviors of these two bonding interfaces at 250°C were investigated.

In the bonded sample with sputtered Ni/Au, the Cu electrode diffused violently into the chip and formed a Cu–Te-rich phase. On the other hand, in the bonded sample with electroplated Ni/Au, the diffusion of Cu was blocked, but a NiTe phase formed on the chip side. The above results demonstrate that, with sputtered Ni/Au, grain-boundary diffusion is predominant and Cu electrodes diffused along the grain boundaries, while with electroplated Ni/Au, self-diffusion is predominant because of the instability of the monocrystalline–amorphous phase. These results suggest that the highly crystalline Ni layer, which has dense grain boundaries and no pores, is a highly effective diffusion barrier.

SESSION EN15.01: Chemical Sensors for Advanced Energy Systems
Session Chairs: Pu-Xian Gao and Paul Ohodnicki
Monday Morning, December 2, 2019
Sheraton, 3rd Floor, Commonwealth
Perovskite metal oxides have been studied thoroughly in the literature as electrode materials for solid oxide fuel cells, which necessitate stability at high-temperature and in chemically harsh environments. The stability of the perovskite crystal structure under high concentrations of dopants allows for a great deal of versatility in material design, due to the unique electrical, magnetic, and optical properties exhibited by materials within this family. The incorporation of metallic nanoparticles into metal oxide thin films has also been previously demonstrated as a method for introducing a strong, surface-sensitive optical absorption, which can be tracked for harsh environment sensing on the optical fiber platform.

In this work, the gas and temperature sensing properties will be presented for several perovskite oxide thin films (i.e., LST, LSM, LSF, LSC) incorporated with gold nanoparticles, measured under both oxidizing and reducing conditions at high temperature (up to 800 C). On their own, the optical absorption spectrum of these perovskite oxide films is governed by oxygen-defect sensitive interband transitions, in some cases extending into the visible and NIR, and the free-carrier absorption characteristic of other conducting metal oxides. Using modeling and in-situ optical transmission measurements at high temperature, the interaction between the nanoparticle localized surface-plasmon resonance (LSPR) and the unique properties of the individual host films will be examined. The sensing response is further studied using principal component analysis (PCA) to demonstrate improved sensing discrimination of several parameters of interest (i.e., temperature and gas concentration). The combined versatility of the perovskite oxide class of materials and LSPR-based sensing will be discussed as a tool for developing optical sensors able to provide “electronic nose”-like discrimination, suitable for harsh environment.

Differentiating Multiple Gas Analytes Using a Single Nano-Array Sensor

Commonly adopted resistive-type chemical sensors are based on metal oxide semiconductors, which usually display significant cross-sensitivities for different gaseous analytes, resulting in a low selectivity.1 By collecting sensing signals from a number of different individual sensors, so called a sensor array, the selectivity could be remarkably enhanced.2 However, complex and costly fabrication protocol is usually associated with integration of such an sensor array, limiting their applications , especially upon operation under extreme environments. Specifically, the complexity is due to the increased number of dissimilar sensor devices in need of complex electrical wiring, contacts, as well as electrodes, which may dramatically increase the risk of potential system malfunction. Besides, the bulky size and shortened service life resulted from complex circuitry may increase the cost of deployment, operation, and maintenance. In this study, a new pattern-recognition strategy has been developed based on correlation of resistance-metric mode and impedance-metric mode for differentiation of multiple gas analytes using a single ZnO nanorod array (nano-array) gas sensor. Uniform ZnO nano-arrays were grown on silicon substrate using a microwave-assisted hydrothermal synthesis method. The characteristic signature for the target analyte is successfully extracted by incorporating the resistive response and frequency-dependent dielectric response via global Electrochemical Impedance Spectroscopy (EIS). Targeting differentiation of three different oxidative gases, i.e., NOx, SO2 and O2, a database was established using the sensitivities characterized from three sensing data sets from resistance-metric mode, real part and imaginary part of the impedance-metric mode. These three oxidative gas analytes have been successfully differentiated through a principal component analysis (PCA) practice. Linear and non-linear decision boundaries have been computationally built for pattern recognition and analytes quantification utilizing machine neural network training. A facile user interface (UI) for recognition of unknown gas analyte has been developed using the MATLAB codes, with the error of analyte concentration achieved as low as 2%. The identification of test analytes beyond the available training data sets could be accomplished using a deep learning training-set; the error of corresponding concentration prediction is around 4.5%. In addition to the single analyte analysis, the on-board interrogation could be achieved towards gas mixture (i.e. NO and NO2) through correlation between the electrical and electrochemical responses. According to the in-situ DRIFTS spectra, no mutual interaction occurs between the NO and NO2 in the co-adsorption scenario. As such, a pair of equations could be derived between gas mixture responses and components’ concentration on the basis of charge carrier concentration. Facilitated by a graphical method, the detailed concentration of component gas could be quantified using the measured responses of NOx mixture in the bimodular sensing on such a single nano-array sensor platform.

Oxygen Diffusion in Functional Ultrathin Materials Generated by Atomic Layer Deposition for Gas Sensing Applications (FunALD) Hartmut Finger¹, Dorothee Dietz², Anna M. Knauß², Jupe Andreas², Holger Kappert³ and Tim Huelser¹; ¹Institute of Energy and Environmental Technology e.V., Germany; ²Fraunhofer Institute for Microelectronic Circuits and Systems IMS, Germany

Air quality sensors and sensors in measuring systems detect toxic and explosive gases and warn against the escape of hazardous pollutants. Today's sensors have a comparatively low sensitivity and a large cross-sensitivity for many applications with high power consumption and high costs. Actually, established nano-techniques use nanoparticles or nanowires that are processed at high temperatures separately from the substrate. Subsequently, these particles are suspended in liquids and applied to electrodes - the electrodes are arranged on the CMOS surfaces. However, the established nano-techniques provide only disordered structures. In addition, there are problems in the reproducibility of production.

"FunALD" is now taking a significant step further: the nano-electrodes are not produced by applying nanoparticles, but based on the ALD method (Atomic Layer Deposition). Ultrathin single and multiple layers with a layer thickness of less than 50 nm are deposited monolayer after monolayer. With the ALD method, layers with exact thicknesses and tunable electrical properties can be deposited. Ultrasensitive self-supporting nanowires, made of metal oxide and produced in a sacrificial layer process, are used as the sensing component.

As a first step we investigated the oxygen diffusion within tin oxide as sensing material. The sensor was heated up from room temperature to 313 K to evaporate surface water from the sensor surface. Resistance measurements reveal an increase of conductivity by a factor of about 10 during this process. After that process, the temperature was cycled between 313 K and 353 K and the resistance was measured. Within this temperature range an increase of conductivity with increasing temperature is observed as it is expected for a semi conducting material. An activation energy of 58 meV has been calculated from an Arrhenius representation and linear regression of the data for the charge carrier transport process. The oxygen diffusion capability of the sensing material was tested under N₂ atmosphere at 428 K. For this purpose the sensitivity $S = R_{N₂}/R_0$ was measured for 50 minutes, where $R_{N₂}$ represents the resistance in dry N₂ and $R_0$ the initial value. In dry N₂, the resistance decreased reversibly by 1–2 orders of magnitude and this decrease can be attributed to increased electronic conduction associated with loss of O₂ on reducing oxygen partial pressure $pO₂$ in the surrounding atmosphere. $S$ remains constant after 40 minutes, which can be attributed to a saturation of oxygen loss within the tin oxide. An immediate change of resistance was observed by introducing 400 ppm O₂ into the measurement chamber, which reveals an extremely fast increase of resistance by about 15 % with 5 s. Finally, ALD processed tin oxide shows a remarkable high, reversible loss of oxygen, in N₂ and air at temperatures of 428 K and the changes can be attributed to sample surfaces effects, at least on short timescales.

Polymers Coated Palladium Sensors for H₂ Detection—Insights from First-Principles Calculations Lucy Cusinato and Anders Hellman; Chalmers University of Technology, Sweden

Hydrogen-powered vehicles are part of a more global answer in order to develop a sustainable society. However, like with other energy sources, safety issues are crucial, and because of the high flammability of hydrogen gas, efficient hydrogen sensors are needed. Hydrogen sensors meeting performance targets for use in hydrogen-powered vehicles are scarce, and a lot of effort has been invested in material design to improve the sensitivity and response time of such sensors. Palladium-based materials have been known for long for their capacity to easily form hydride phases, making them good candidates for hydrogen sensing applications. Those rely on two fundamental features of metallic palladium: the ability to dissolve hydrogen to form stable hydride and the possibility to easily release the stored hydrogen. More than a bare protective layer, polymer coating of palladium nanoparticles has been shown to enhance sensing
behavior. Using DFT, we shed light on how this phenomenon can be explained. We propose a large scope model for this system, going from the modelling of H₂ diffusion in a polymer matrix to the study of subsurface hydrogen diffusion in palladium hydride via the comprehension of the processes occurring at the polymer-metal interface. In order to do this, the effect of several polymer coating on H₂ adsorption/desorption as well as subsurface diffusion is considered. Rationalization on how and why the polymers affect the metal NP is proposed. The diffusion of H₂ molecules in polymer environment is studied as to take into account a realistic medium for those nanoparticles. Finally, the challenging task of properly describing the metal NP-polymer interface is addressed in order to be able to give an as complete and as accurate as possible view of the whole phenomenon.

Nanoparticle Chemisorption Printing of Silver Nanocolloid—Underlying Mechanism and Sensing Application Tatsuo Hasegawa; Univ of Tokyo, Japan

Silver nanocolloid (or nanoink), a dense suspension of ligand-encapsulated silver nanoparticles, is an important material for printing-based device production technologies. Here we present and discuss a groundbreaking printing technique that takes advantage of the unique nature of specific silver nanoinks that show self-sintering characteristics [1]. The technique, which we call as surface photo-reactive nanometal printing (SuPR-NaP), is based on chemisorption effect of silver nanoparticles on activated patterned perfluoro-polymer surfaces. The technique is extremely simple, only composed of two-step processes: fabrication of a patterned activated surface by masked vacuum ultraviolet (VUV) irradiation of the perfluoro-polymer (Cytop) layer surface, and then blade coating to expose the silver nanoinks on the surface for a short period of time at ambient conditions. Eventually, it allows easy, high-speed, and large-area manufacturing of ultrafine metal wiring with a minimum line width of 800 nm that is conductive without any post-heating treatment, and strongly adheres on substrate surfaces. These features are in striking contrast to the conventional printing technique which usually suffer from the limitations of the physisorption phenomena of the fluidic ink. The technique is applicable to the production of flexible and transparent touch screen sensor sheet composed of printed ultrafine metal mesh.

We found that the technique is possible only with a class of silver nanoinks, obtained by thermal decomposition of oxalate-bridging silver alkyl-amine complexes [2]. The peculiar nature of these nanoinks is that the high dispersion stability is preserved for several months at room temperature, whereas the silver nanoparticles are readily self-fused with each other, if the metal nanoinks are dried out, eventually exhibiting metallic conductivity at room temperature. Based on the confocal dynamic light scattering study, we recently demonstrated that these silver nanoinks are composed of a unique balance of ligand formulation and dispersant composition, and that the unique balance enables the rapid silver nanoparticle chemisorption [3,4]

Harsh Environment Compatible Multivariable Chemical Sensors Michael Carpenter¹, Nora M. Houlihan¹ and Radislav A. Potyrailo²; ¹SUNY Polytechnic Institute, United States; ²GE Global Research, United States

Monitoring the levels of combustion gases such as H₂, CO and NO, within high temperature (>300°C) environments requires multivariable sensing materials with demonstrated stability and resilience. Au nanoparticles (AuNPs) have shown potential in plasmonic gas sensing applications due to their catalytic activity, redox stability, and plasmonics sensitivity to changes in its surrounding environment. Encapsulation of the AuNPs in a variety of 2D metal oxide thin films enables both the sensitive and selective detection of target gases within a multivariable sensing array or a single sensing element system design. Au nanorods (AuNRs) embedded in metal oxides allows for the plasmonically active wavelength region to range from the visible to the NIR through variation of the AuNR aspect ratio. Furthermore, AuNRs can be designed to have both the transverse and longitudinal dipole modes as well as multipole plasmon modes for extended multivariable sensing applications within a single array element. Recent multivariable sensor platforms which utilizes Morpho butterfly wing dimensionality for bio-inspired inorganic 3D structures will also be detailed. Functionality and performance parameters of metal-metal oxide thin film coatings on 3D structures will be compared with 2D thin films within the framework of general sensor design as well as their
application for the oxygen free detection of steam reforming gases.

**11:00 AM EN15.01.07**  
**Selective Sensing of Formaldehyde in Indoor Air**  
A. T. Güntner, S. Abegg and Sotiris E. Pratsinis; ETH Zürich, Switzerland

A major challenge in environmental sensing is the detection of trace-level pollutants (e.g. carcinogenic formaldehyde\(^1\)) in complex gas mixtures. Devices based on chemo-resistive gas sensors would offer sufficient sensitivity and low detection limit down to ppb, _but lack selectivity_. Here, we present a highly sensitive, selective and compact sensor array for real-time quantification of formaldehyde at realistic conditions\(^2\). This array consists of four nanostructured and highly porous Pt-, Si-, Pd- and Ti-doped SnO\(_2\) sensing films directly deposited onto silicon wafer-based microsubstrates by flame spray pyrolysis (FSP). The constituent sensors offer stable responses and detection of formaldehyde down to 5 ppb (signal-to-noise ratio > 30) at breath-realistic 90% relative humidity. Each dopant induces different analyte selectivity enabling selective detection of formaldehyde in 2- and 4-analyte mixtures by multivariate linear regression. In simulated breath (FA with higher acetone, NH\(_3\) and ethanol concentrations), formaldehyde is detected with an average error ≤ 9 ppb using the present array.

In a next step, this can be improved further when combining the sensors with highly selective _zeolite membranes_ pre-separating gas mixtures\(^3\). Zeolites - broadly applied in catalysis and gas separation - effectively separate molecules based on kinetic diameter, sorption and diffusion characteristics\(^4\). Therefore, zeolite membranes are suitable filters for gas sensors removing undesired species from indoor air. As proof-of-concept, a zeolite MFI/Al\(_2\)O\(_3\) membrane is placed upstream a highly sensitive but weakly selective Pd-doped SnO\(_2\) sensor. Their combination exhibits exceptiona selectivity (>100) for formaldehyde down to 30 ppb at 90% relative humidity, outperforming state-of-the-art detectors by more than an order of magnitude. This novel concept is readily extendable to other tracers, as manifold combinations of _widely tunable_ microporous membranes and gas sensor types can be realized in the modular sensing device. This could enable a new class of highly sensitive and selective environmental monitors.

---

vehicle operation. Unfortunately, ammonia is one of the byproducts of reduction of NOx during the process, which is often referred to in the industry as "ammonia slip". Released ammonia participates in the oxidation of SO2 into SO3, which reacts with atmospheric water vapor to form sulfuric acid fumes, and also forms ammonium sulfate which can clog flue lines and filters. In this work, we report on the development of a one-time electronic ammonia fuse. Formic and citric acids were reacted with ammonium vanadate precursor to synthesize vanadium oxides. Powder X-ray diffraction (PXRD) confirmed the formation of the orthorhombic and monoclinic crystal structure of V2O5 and VO2 respectively. Energy dispersive x-ray analysis (EDX) confirms the purity of the samples. Using transmission electron microscopy (TEM), we inferred that the average diameter of vanadium oxides particles was in the range of 90-120 nm and some small size particles ~70-90nm are also observed. Chemical composition of the synthesized vanadium oxides was confirmed using Raman spectroscopy. V2O5 shows Raman shift at 993 cm−1, 698 cm−1, 478 cm−1 and 404 cm−1 which can be attributed to the V=O bonding, stretching modes of triple-bonded oxygen, stretching mode of V−O−V, and bending vibrations of the V−O bonds respectively. VO2 show a weak hump at 224 cm−1 which can be attributed to motions of V, highlighting the phase transition of monoclinic phase to rutile phase. Commercial silicon dioxide wafers (University Wafers) were cleaned (RCA) and a bottom metal stack was deposited using DC sputtering (Cr) and RF sputtering (Au). Using the synthesized VxOy (x=1,2, and y= 2, 5) species, a film of the oxide was deposited using spin-coating. Top contact (Ag) was deposited using thermal evaporation to complete a metal insulator metal structure. Current-voltage (IV) characterization of devices (Keithley 4200-SCS) showed an on/off ratio of 102 and less than 101 respectively for V2O5 and VO2. On exposing these devices to ammonia solution (boiling point 24°C) by introducing 5-10 µl of ammonia (30%) solution at 60-70°C, the IV characteristic of the device started exhibiting a distorted waveform, without any retention, possibly due to the effect of the corrosive ammonia. We are at present establishing the minimal exposure level of ammonia to achieve the destruction of the device. In deployment, the exhaust from the catalytic converter would be monitored by this sensor to provide feedback to the automotive control to reduce ammonia emissions from the vehicle.

11:45 AM EN15.01.10
Facile Conversion of Zn5(CO3)2(OH)6 to ZnO Induced by Ca(OH)2 to Form CaO-ZnO—Role of Active Nanointerfaces in Selective CO2 Gas Detection
Shravanti S. Joshi1,2,3; 1G.S. Mandal's Marathwada Institute of Technology, India; 2CSIR Indian Institute of Chemical Technology, India; 3RMIT University, Australia

Environmental pollution as a result of rapid urbanization and industrialization and its indirect effect on global warming, climate change, and ocean acidification has been of increasing scientific concern worldwide over the past few decades. Carbon dioxide (CO2) is one of the many such toxic pollutants that contribute to environmental pollution, thus stimulating extensive research and concerted efforts for its detection, monitoring, capture, and storage. However, the development of metal oxide semiconductor (MOS) based heterostructures with controlled structural motifs such as a large number of active nanointerfaces for low temperature (sub 200°C) CO2 sensing applications continues to be an alluring task. Herein, we report on the highly selective CO2 sensing performance of CaO-ZnO heterostructures achieved using an elegant strategy of calcium hydroxide (Ca(OH)2) mediated transformation of zinc hydroxide carbonate (Zn5(CO3)2(OH)6) to zinc oxide (ZnO) at 50°C. FE-SEM analysis of zinc hydroxide carbonate powder revealed hierarchical microspheres (referred here as ZMS) with diameters of 3–8 μm, primarily composed of numerous thin sheets (thickness ~10 nm) interleaved to form floral architectures. Feasibility of the synthetic route was probed by comparing CO2 sensing characteristics of CaO-ZnO heterostructures achieved at 50° C for 12 h with the ones obtained by heat treatment at 600°C for 2 h and referred to as Ca-ZMS and CaO-ZnO, respectively.

Case 1: Synthesis of Ca-ZMS hierarchical heterostructures
Briefly, ca. 67 mg of as-synthesized ZMS was added to 40 ml of water in a beaker and sonicated for 60 min. To this solution, 33 mg of Ca(OH)2 was added to the prepared solution containing 100 mg/40 mL Ca-Zn-C-O-H complex mixture. The calculated amount of Ca(OH)2 varied based on weight percentages. The complex mixture solution was then continuously stirred for 12 h followed by drying overnight at 50°C using a hotplate and will be referred to as “R-Ca-ZMS” (where R = Ca(OH)2 concentration in wt.%).

Case 2: Synthesis of Ca-ZnO hierarchical heterostructures
Ca-Zn-C-O-H complex mixture (100 mg/40 mL) was sonicated for 30 mins followed by centrifuging and drying overnight at 70°C in an ambient air atmosphere using a furnace. Subsequently, the dried Ca-Zn-C-O-H mixture was weighed (20 mg) and calcined at 600°C for 2 h in a muffle furnace under air atmosphere and post-calcination will be referred to as “R-CaO-ZnO” (where R = Ca(OH)2 concentration in wt.% added before the calcination). Calcination
at high temperature was deemed necessary to completely convert Zn$_5$(CO$_3$)$_2$(OH)$_6$ to ZnO and Ca(OH)$_2$ to CaO with an increased adhesion among the singularities.

Pure ZnO, Zn$_5$(CO$_3$)$_2$(OH)$_6$, Ca(OH)$_2$ and CaO microsensors exhibited low sensitivity (≤20%) towards 500 ppm of CO$_2$, whereas the CaO-ZnO heterostructures from both the cases exhibited significant sensitivity (from 26 to 91%) towards CO$_2$ concentration in the 100-10000 ppm range, respectively, when operated at 150°C. In this study, 25Ca-ZMS heterostructures exhibited promising sensitivity of 77% and a superior selectivity of 98%, while 25CaO-ZnO heterostructures revealed lower sensitivity of 59% and selectivity of 87% upon exposure to CO$_2$ gas (500 ppm). The gas sensing mechanism in dry and humid conditions underlying the high selectivity in presence of 6 analyte gases that commonly coexist with CO$_2$ (such as methane, ethanol, hexane, H$_2$, CO, NO$_2$, SO$_2$ etc) and faster kinetics (response and recovery times of 230 s and 280 s to 100 ppm) compared to control samples as well as to the ones reported in the literature is detailed. Improved performance is attributed to the low-temperature synthesis route which results in a gas-accessible hierarchical morphology. Additionally, the high CO$_2$ adsorption capacity of CaO combined with the compatibility of CaO-ZnO in forming highly active $n$-$n$ nanointerfaces is a promising step towards developing a precise and cost-effective CO$_2$ gas microsensor.

SESSION EN15.02: Environmental Energy Detection and Utilization

1:30 PM *EN15.02.01
Terahertz Spectroscopy and Microscopy for Non-Destructive Optoelectronic Characterisation of Advanced Functional Nanomaterials Jessica L. Boland; University of Manchester, United Kingdom

The terahertz frequency range (0.1-10THz) provides the perfect probe for investigating electronic processes within these nanomaterials. The energy range of terahertz radiation extends over the energies of several typical quasiparticles, such as free electrons and holes, plasmons, magnons and polarons, and can stimulate collective excitations, such as optical phonons. Terahertz spectroscopy therefore forms a powerful, non-contact, non-destructive technique for measuring electrical conductivity in advanced functional nanomaterials.

In this talk, I will demonstrate how terahertz spectroscopy can reveal the ultrafast carrier dynamics of an ensemble of semiconductor nanowires on ultrafast (<1ps) timescales, allowing characterisation of photoconductivity lifetimes, mobility and doping levels1,2. This technique will directly be applied to InAsSb nanowires to demonstrate the effects of alloying on optoelectronic properties and elucidate the scattering mechanisms governing their carrier transport. I will show that these nanowires have a record-holding electron mobility due to a reduction in defect density and impurity scattering, making them promising candidates for MIR photodetectors and thermoelectric devices3. Following this, I will also introduce near-field THz microscopy, which allows direct imaging of key optoelectronic properties on nanometre length scales with surface sensitivity, as well as direct electrical probing within a device architecture4,5. I will present recent results on topological insulator thin films, highlighting the capability of this technique. Finally, I will show how these techniques can be used to develop novel THz devices based on semiconductor nanowires: single-nanowire THz detectors6,7 and THz modulators8. These devices are promising candidates for active components in THz imaging devices, shrinking down current THz technologies down by 3 orders of magnitude accelerating the development of nanoscale/microscale THz sensing systems.

2:00 PM  EN15.02.02
Radio Frequency Organic Field-Effect Transistors on Plastic Substrates Bianca Passarella1,2 and Mario Caironi2; 1Politecnico di Milano, Italy; 2Istituto Italiano di Tecnologia, Italy

–The organic electronic field is nowadays collecting increasing interest by both the scientific and industrial world. Compared to the inorganic counterparts, Organic Thin Film Transistors (OTFT), show some important advantages such as flexibility and stretchability but, most importantly, the compatibility with low-cost high-throughput printing-based manufacturing: all these advantages are mainly due to the use of Organic Semiconductors (OSCs). 

OSCs’ properties like, for example, solution processability and easy molecular structure’s tailoring, open a wide range of applications that could not be covered by traditional electronic devices, such as into the medical field with biocompatible sensors, into the consumable electronic field with flexible and infrangible screens, into the wearable electronics field, or into the smart tags and distributed sensors fields. 

On the other side, the stability of these materials and the overall performances of the Organic Field Effect Transistors (OFETs), mainly in terms of operational speed, should be improved. The figure of merit widely adapted to evaluate the operational speed of a single transistor is called Transition Frequency (\(f_t\)) and is defined as the frequency at which the current gain of a transistor, in short circuit condition, is equal to 1. At the state of the art, the highest \(f_t\) measured on planar OFET made by techniques compatible to large-printing is 20 MHz\(^1\), while on a vertical transistor is 40MHz\(^2\). In this contest, the aim of this work is to overcome this limit, bringing the transistors to operational frequencies in the order of hundreds of MHz or of the GHz, keeping the flexibility requirements.

In this landscape, to maintain flexibility and guarantee good performances together, bottom-contacts top-gate OFETs have been fabricated, mainly on flexible and very thin substrates of Polyethylene Naphthalate (PEN) (around 100μm thin and a rms roughness around 50nm) by means of several different techniques: lithography and laser sintering has been used to make bottom contacts, bar coating and/or spin coating have been used to deposit the organic semiconductor and the dielectric layers, thermal evaporation or inkjet printing have been used to deposit the gate electrode. Once the lithography process and the laser sintering have been optimized on plastic substrate, different kind of organic semiconductors and dielectric materials have been used. For example, among the n–type semiconductor, the poly \{N,N’– bis (2–octyldodecyl) – 1,4,5,8 – naphthalene dicarboximide – 2.6 – diyl]–alt–5,5’– (2,2’–bithiophene)} ((P(NDI2OD–T2)) has been optimized and tested on short channel devices, obtaining a directly measured transition frequency of 11MHz. Among the p–type semiconductor materials, optimizations have been carried out on the diketopyrrolopyrrolethieno [3,2–b] thiophene copolymer (DPP–T–TT), obtaining a directly measured transition frequency of 22MHz. This represents an important result because it is the best frequency achieved until now on flexible substrate (with respect to the 14MHz obtained by Perinot et al.\(^3\)).

Germanium Nanowire Based Bolometer for Mid-IR Sensing Maximilian G. Bartmann, Masiar Sistani, Juergen Smoliner and Alois Lugstein; Technische Universität Wien, Austria

With the ever-growing number of applications demanding photodetectors in the Mid-IR, ranging from astronomy, pollution monitoring and fire sensing to healthcare, security and automotive, thermal photodetectors especially bolometers gained significant research interest over the last years. Per definition, a bolometer consists of an absorptive element, which is connected to a thermal reservoir through a thermal link and a thermometer. Any radiation, which is incident on the absorptive element, will raise its temperature above that of the reservoir.
proportional to the radiation intensity. Quasi 1D germanium (Ge) nanowires (NWs), embedded between two electrical contacts are perfect building blocks for bolometers according to the above definitions. They have an extremely small thermal mass, and in addition, the same highly temperature dependent electrical resistance as bulk Ge-bolometers, which are already used since decades. Here we present a Mid-IR sensing device based on an individual aluminum (Al) contacted Ge NW on a 40 nm thick Si₃N₄ membrane. By using a thermally induced exchange reaction between the polycrystalline Al contact pads and a single crystalline Ge NW, the length and thus the thermal mass of the NW can be tuned. The resulting self-aligned single crystalline Al leads provide a highly effective heat link to the surrounding macroscopic Al metallization, which acts as the thermal reservoir. The final quasi 1D monolithic NW heterostructure thus resembles an ultrascaled Ge NW segment contacted to crystalline Al leads with atomically sharp interfaces. An electrically contacted multi-layer graphene (MLG) flake placed on the opposite side, acts as the absorber and as an electrostatic gate controlling the Fermi level and thus the intrinsic resistivity of the Ge NW. The heat generated in the absorbing MLG flake is transferred via the ultrathin Si₃N₄ membrane to the NW thus controlling the temperature dependent electrical transport in the diffusive as well as quasiballistic/ballistic for ultrascaled devices with Ge NW length down to 20 nm. In a detailed analysis we investigated the temperature dependence and transient response as well as the the influence of surface traps defining the overall functionality of the bolometer device.

2:30 PM EN15.02.04
A Humidity-Resistance, Super-Durable Triboelectric Nanogenerator from a Fluorinated Polymer Sponge for Efficiently Harvesting Biomechanical Energy Zehua Peng; City University of Hong Kong, Hong Kong

Wearable electronics are becoming increasingly significant owing to their widespread and far-reaching applications in the forthcoming Internet of Things (IoTs) era, including but not limited to health monitoring, motion tracking, and interactive entertainment. The rapid development and potential market of wearable technologies make it urgent to strategically re-aligning currently predominant power supplies, i.e. batteries, considering the limitations in terms of regular recharging and replacing, size and weight, as well as environmental pollution. In this regard, alternative energy supplying technology with the merits of sustainable, maintenance-free, and eco-friendly is highly desired. Triboelectric nanogenerators (TENGs) are proven to be efficient, simple, and environmentally friendly to generate power by daily human motion. Nevertheless, it remains a challenge to improve its unsatisfactory performance under the humid condition that obstructs the practical wearable applications, e.g. being integrated into clothes or shoes, since sweating is inevitable for the body to release excessive heat routinely.

In this work, we report a fluorinated polymer sponge-based TENG (FPS-TENG), which is capable of addressing the moisture-sensing issue benefiting from intrinsic hydrophobicity of the sponge structure and chemical introduction of hydrophobic terminated functional groups, achieving a relatively stable output performance over a wide range of ambient humidity. Concurrently, the FPS-TENG is super durable even under heavy abrasion (simulated via wearing away 1mm-thickness surface layer), indicating the capability in long-term operation under harsh conditions. Specifically, the FPS-TENG is primarily assembled with electropositive copper electrodes and a critical electronegative component, i.e. polydimethylsiloxane (PDMS) based functionalized polymer sponge (FPS), which is suitable for wearable applications for its excellent shock absorption and comfortability due to the elastic property. Under a relative humidity of 40%, the open-circuit (OC) voltage, volume current density, and transfer volume charge density can reach 181 V, 0.55 A/m³, and 17.5 mC/m³ by the FPS-TENG treated at 95°C for 60min during the fluorinated process, respectively, corresponding to a volume power density of 60 W/m³, providing up to 364 % increase compared with those of pristine PDMS sponge-based TENGs (PPS-TENGs) and pristine PDMS film-based TENGs (PPF-TENGs). With the remarkable humidity resistance of FPS-TENGs, 60% electrical output is reserved from 20% RH to 85% RH, comparing to only 10% for PPF-TENGs, demonstrating the feasibility of FPS-TENGs to be applied in potential wearable applications. Last but not least, quasi-bulk-phase functionalization brings about dramatic improvement in working stability and durability than surface functionalization, by which the improvement would vanish once the functionalized surface is worn away. Herein, the enhanced performance of FPSs from functionalization is certified to degrade by only 10% after wearing away 1mm-thickness surface layer. Additionally, the FPS-TENG charges a 50μF capacitor from zero to 5 V within 10min and successfully lights up a LED panel through tapping by hands.

Reduced Transition Temperature in Low Powered Potential Smart Window Coatings Based on Al:ZnO and VO₂ Multi-Layered Structure Grown Using Pulsed Laser Deposition Makhes K. Behera, Sangram K. Pradhan
and Messaoud Bahoura; Norfolk State University, United States

In the modern world of an impending energy crisis, energy saving low powered devices will become a commodity of necessity to help prevent the total depletion of the present natural resources. One of the major chunks of energy being used in today’s world is the HVAC systems installed all around, accounting for ~ 10% of the total energy generated in the United States. Low powered smart window devices are a viable alternative to help saving this major part of the energy generated. In this regard, researchers all around the globe have been working on being able to tune the Metal-to-Insulator Transition (MIT) properties in VO₂ thin films, which, because of the MIT property is a potential candidate for smart window coating applications. In this work, we report successful fabrication of VO₂ thin films despite their highly metastable nature using pulsed laser deposition by systematic optimization of the deposition and annealing oxygen partial pressures. The as-grown films were able to demonstrate a transition temperature of ~ 64 °C, approximately 4-6 °C lower than the reported transition temperature for bulk VO₂. Moreover, in this work we were able to successfully fabricate a potential smart window device structure using aluminum doped zinc oxide (Al:ZnO) thin films as a resistive heating layer which has an added advantage of being transparent. Using a conventional VO₂/Al:ZnO structure resulted in certain degradation to the properties of the films, such as decrease in the magnitude of the MIT as well as a total loss of the Joule heating in the Al:ZnO films. The fabricated device using a modified structure was able to display the MIT transition successfully, all while maintaining the Joule heating effect in the Al:ZnO thin films and the magnitude and sharpness of the MIT in the VO₂ thin films along with reducing the transition temperature of the films to ~ 60 °C, approximately 10 °C lower than bulk VO₂. The results shown in this work demonstrate the structural, electrical and optical properties of all the fabricated films as well as the multi-layered films proving the effectiveness of the films to serve as a potential standalone smart window device. In addition, the results will open up doors to incorporate different structures to the multi-layered film in order to improve the performance of the device.

Piezoelectret for Wearable Healthcare Sensor Jun Zhou; Huazhong University of Science & Technology, China

Wearable electronics for detecting physiological and biomechanical signals of human body are key sensors for healthcare. The vision of non-invasive, automated personalized healthcare is a new and fast-growing multidisciplinary research area. To make the sensors work independently and sustainably, self-powered sensors that can extract energy from human body motions is particularly desirable. In this talk, i’ll present our research progress on the fabrication of piezoelectret for wearable healthcare sensor. For an integrated sensor device based on a piezoelectret film, continuous reliable heartbeat and respiration information is successfully detected and transmitted to a mobile phone. The study promisingly has great influence for professional motion detecting, touch screens, artificial intelligence, mobile healthcare, and wearable electronics.

Multidirectional, Small-Scale Human Motion Detection by Directionally-Aligning Carbon Nanotube-PDMS Conductive Films with Enhanced Sensitivity as Wearable Strain Sensors

Mehmet Tas, Mark Baker and Vlad Stolojan; University of Surrey, United Kingdom

Recent interest in the fields of human motion monitoring, electronic skin and human-machine interface technology demand strain sensors with high stretchability/compressibility ($\varepsilon > 50\%$), high sensitivity (or gauge factor ($GF > 100$)) and long-lasting electromechanical compliance. However, current metal and semiconductor-based strain sensors have very low ($\varepsilon < 5\%$) stretchability and low sensitivity ($GF < 2$) indicating that a new generation of strain sensors are required where the stretchability is not sacrificed for high-sensitivity. We propose a simple one-step, low cost fabrication of mechanically compliant, physically robust metallic carbon nanotube (CNT, grown via photo thermal vapour deposition method)- polydimethylsiloxane (PDMS) strain sensors. The process allows the alignment of CNTs within the PDMS elastomer permitting directional sensing. Aligning CNTs horizontally (HA-CNTs) on the substrate before embedding in the PDMS reduces the number of CNT junctions as well as introduces scale-like features on the CNT film perpendicular to the tensile strain direction, resulting in improved sensitivity compared to vertically aligned CNT (VA-CNT)-PDMS strain sensors under tension. The CNT alignment combined with the scale-like features with CNTs bridging-over modulate the electron conduction pathway affecting the electrical sensitivity. Resulting GF are 316.1 for HA-CNT-PDMS and 140.9 for VA-CNT-PDMS sensors under 50 % tensile strains. We further show that these sensors behave differently under compressive strains. VA-CNT-PDMS show more sensitivity to small-scale deformation than HA-CNT-PDMS due to the CNT orientation and the continuous morphology of the film demonstrating that the sensing ability can be improved by aligning the CNTs in certain directions. Furthermore, mechanical robustness and electromechanical durability are tested for over 6000 cycles up to 50 % tensile and compressive strains with good frequency response with negligible hysteresis. Finally, both sensors can detect human motion induced mechanical deformations multidirectionally, both at large and small-scale such as swallowing, frowning, wrist and finger bending with ability to distinguish the motions with reaction and recovery times as low as 130 ms and 240 ms, respectively. These sensors could help people with severe disabilities and limited movement to translate small muscle movements into electrical signals that can be developed into gestures/new alphabet to help communication.

Solution Based Infrared Sensing Using Deep Silicon Carbide Gratings

Thomas G. Folland1, Guanyu Lu1, Autumn Bruncz1, Joshua R. Nolen1, Marko Tadjer2 and Josh Caldwell1; 1Vanderbilt University, United States; 2U.S. Naval Research Laboratory, United States

Infrared spectroscopy is a versatile tool for the identification of trace levels of various volatile chemicals which act as common pollutants. However, for applications in environmental monitoring, trace quantities of a target analyte need to be detected to make a practically useful sensor, which can be difficult using simple transmission geometries. One of the routes to enhancing the sensitivity of infrared spectroscopy is to exploit the surface enhancement of the electric field at the surface of certain materials. This is called surface enhanced infrared absorption (SEIRA) spectroscopy, and typically exploits surface polaritons which form at the surface of certain materials. Surface polaritons form when light couples to coherently oscillating charges in a material, most commonly electrons (surface plasmon polaritons, SPPs) or phonons (surface phonon polaritons, SPhPs). This type of wave can be excited in nanostructured optical antennas, which support a series of resonant modes at a sense of defined frequency. To realize SEIRA using surface polaritons the analyte is typically coated onto the antenna which supports the SPP or SPhP mode. As a consequence, one of the challenges in realizing practical SEIRA is achieving an excellent coating over the optical antennas in order to get a predictable and reproducible response. One appealing route to achieving repeatable SEIRA results is to perform measurements directly within a liquid environment. This gives a consistent overlap between the analyte and the polaritonic material, and provides compatibility with microfluidic applications. Here we fabricate deep gratings (up to 24 $\mu$m depth) of 4H-SiC, in order to perform SEIRA within liquid environments. Our gratings support SPhP modes in the spectral region between ~792 and 972 cm$^{-1}$, coincident with the frequencies of spectral signatures of fluorocarbon pollutants. Resonant modes exhibit strong absorption of incident infrared light (>80%) and high Q factors (>90). This is due to the formation of waveguide type modes in-between the grating teeth, with strong electric field enhancement. This provides an ideal platform for SEIRA, as the high Q factor provides excellent chemical selectivity for individual chemical bonds. After characterizing our sample in air, we then characterize our gratings when submerged in a range
of solvents, including water, isopropyl alcohol, acetone and toluene. We find that resonant modes are still supported in these different environments, despite infrared absorption from the medium itself. We then assess the possibility of performing SEIRA on a target molecule with an absorption band in this frequency range. Our results suggest that deep gratings offer a versatile platform for SEIRA, which could be tuned using a range of different materials to target specific molecules.

Multi-Axis Joystick Position Tracking Using Crack-Based Strain Sensor and Machine Learning Seongjin Yang1, Seong Kyung Hong1, Seong Jin Cho2 and Geunbae Lim1; 1POSTECH, Korea (the Republic of); 2Chungnam National University, Korea (the Republic of)

Recently research on sense of touch has been carried out in a great deal of research, and research is being conducted to detect hand movement and body movement as well as accurate implementation of strength and touch. In order to realize this, modern science not only measures and utilizes motion of one axis or independent two axes, but also detecting the motion of three or more axes to measure human motion more accurately. Therefore, it is necessary to measure the movement as well as the feedback of the device.

Strain sensors, especially flexible sensors, can be attached to the surface of a moving object or any type of object to measure the deformation of the object, so that various types of elastic strain sensors can be developed in a variety of materials and structures. As part of this research trend, we have recently developed a sensor that is very flexible but sensitive, cost-effective, has a wide measurement range and is highly applicable. With this method, our noble strain sensors can measure up to 150% strain and have fast response, good linearity, repeatability, etc.

In general, however, polymers used in strain sensors have defects due to material limitations such as mullins effect. When the strain is restored after stretching in one direction, the mechanical response of the strain-stress curve varies with the maximum load, which is a fundamental limitation of the polymer-based sensor. In order to solve this problem, the resistance information received from the high-precision strain sensor can be used to learn the position of the current polymer according to the previous resistance change using machine learning. In this way, even if the mechanical characteristics and the resistance information change depending on the maximum load, it is possible to compensate for the more accurate position tracking.

In the case of the strain sensor developed in this way, when the device is attached to a specially manufactured device, the accurate movement of the device can be predicted according to the deformation of the device. In addition, learning algorithms can be used to learn and feedback on the exact position of the polymer. This approach allows precise motion measurement by attaching a stretchable strain sensor to a multi-axis deformable joystick. This is expected to play a useful role in medical surgical robots and virtual reality, which require precise movement.
material which has better stability and proper conductivity in reducing atmosphere and evaluated the hydrogen sensing performance in material and optical points of view. Based on the obtained sensitivity results, distributed sensor tests have been performed to check the feasibility in the final applications such as solid oxide fuel cells.

**Electrical Sensing of Methane Oxidation with Ultrathin Films of Transition Metal Oxide Nanosheets** Yoshiaki Ishihara¹, Ryo Nouchi¹,² and Wataru Sugimoto³,³; ¹Osaka Prefecture University, Japan; ²Japan Science and Technology Agency, Japan; ³Shinshu University, Japan

A change in an electrical resistance is a facile platform for monitoring chemical reactions. However, a reaction-induced change in resistance is usually masked by a high bulk conductivity of the sensing layer. Therefore, an ultrathin sensing layer is desired to enhance the surface sensitivity. In this study, an atomically thin film of transition metal oxide nanosheets was employed as the sensing layer to monitor surface chemical reactions. Oxides of transition metals such as iridium and ruthenium are known to possess a hydrocarbon oxidation activity. A change in an electrical resistance was clearly observed upon methane exposure, which is ascribable to an electron transfer process associated with the oxidation of methane molecules adsorbed on the nanosheets.

**Theoretical Study of the Geometrical and Optoelectronic properties of VO₂ and Mg-VO₂** Arpita Varadwaj and Takashi Miyake; National Institute of Advanced Industrial Science and Technology (AIST), Japan

This study examined the geometrical, charge density topologies, electronic band structures, optical and dynamical properties VO₂ and its Mg-substituted species in the rutile and monoclinic phases using density functional theory implemented in VASP.[¹] It was found that the strongly constrained and appropriately normed meta-GGA functional SCAN[²] could correctly predict the insulating and metallic behaviors of these materials, in appreciable agreement with the photoemission data.[³] In particular, it was found that the singly-substituted Mg atom in VO₂ promotes significant widening of the band gap in both the phases, which is not only consistent with experiment but also explains the enhanced optics of the Mg-VO₂. Substitution of Mg in VO₂ did not contribute directly to either the conduction band or the valence band extrema, which were primarily due to the orbital contributions from the constituent V and O atoms. Although the GGA functionals, such as PBE and PBEsol, provided erroneous density of states and electronic band structures for the low-temperature phase of these materials, these were efficient in revealing the dielectric properties of both VO₂ and Mg-VO₂ in the near infrared to the visible region. From phonon band structure analyses, it was found that VO₂ in both phases is dynamically stable, but this is not so for Mg-doped VO₂.

Gate-Voltage Control of the Persistent Photoconductivity Effect (PPC) in SnO₂ Nanobelts

Emilson R. Viana¹,², Geraldo M. Ribeiro³, Alfredo G. de Oliveira² and Juan C. Gonzalez²; ¹Universidade Tecnológica Federal do Paraná, Brazil; ²Universidade Federal de Minas Gerais, Brazil

The persistent photoconductivity (PPC) effect was studied in individual tin oxide (SnO₂) nanobelts as a function of temperature and gate-voltage, in air, helium, and vacuum atmospheres, and low temperature. Photoluminescence measurements were carried out to study the optical transitions and to determine the acceptor/donors levels and their best representation inside the band gap. Under ultraviolet (UV) illumination and at temperatures in the range of 200–400 K, we observed a fast and strong enhancement of the photoconductivity, and the maximum value of the photocurrent induced increases as the temperature or the oxygen concentration decreases. By turning off the UV illumination, the induced photocurrent decays with lifetimes up to several hours. The photoconductivity and the PPC results were explained by adsorption and desorption of molecular oxygen at the surface of the SnO₂ nanobelts. On the basis of the temperature dependence of the PPC decay, an activation energy of 230 meV was found, which corresponds to the energy necessary for thermal ionization of free holes from acceptor levels to the valence band, in agreement with the photoluminescence results presented. The molecular-oxygen recombination with holes is the origin of the PPC effect in metal oxide semiconductors, so that the PPC effect is not related to the oxygen vacancies, as commonly presented in the literature [1]. Was also observed that the gate-voltage V_G can control the maximum value of the photocurrent induced up to 10⁴.

EN15.03.05
Metal-to-Insulator Transition Induced by UV Illumination in a Single SnO₂ Nanobelt

Emilson R. Viana¹,², Geraldo M. Ribeiro³, Alfredo G. de Oliveira² and Juan C. Gonzalez²; ¹Universidade Tecnológica Federal do Paraná, Brazil; ²Universidade Federal de Minas Gerais, Brazil

An individual tin oxide (SnO₂) nanobelt was connected in a back-gate field-effect transistor (FET) configuration and the conductivity of the nanobelt was measured at different temperatures from 400 K to 4 K, in darkness and under UV illumination. In darkness, the SnO₂ nanobelts showed semiconductor behavior for the whole temperature range measured. However, when subjected to UV illumination the photoinduced carriers were high enough to lead to a metal-to-insulator transition (MIT), near room temperature, at T_MIT = 240 K. By measuring the current I_ds versus gate-voltage V_G curves, and considering the electrostatic properties of a non-ideal conductor, for the SnO₂ nanobelt on top of a gate-oxide substrate, we estimated the capacitance per unit length, the mobility and the density of carriers. In darkness, the density was estimated to be 5–10 × 10¹⁸ cm⁻³, in agreement with our previously reported result (Phys. Status Solid. RRL 6, 262-264 (2012)). However, under UV illumination the density of carriers was estimated to be 0.2–3.8 × 10¹⁹ cm⁻³ near T_MIT, which exceeded the critical Mott density estimated to be 2.8 × 10¹⁹ cm⁻³ above 240 K. These results showed that the electrical properties of the SnO₂ nanobelts can be drastically modified and easily tuned from semiconducting to metallic states as a function of temperature and light.

Controlled Growth of Layered Double Hydroxide and its Optoelectronic Applications

Chan Woo Jeon¹, Sang Seok Lee¹, SungJong Yoo² and Il Kyu Park¹; ¹Seoul National University of Science and Technology, Korea (the Republic of); ²Korea Institute of Science and Technology, Korea (the Republic of)

People living in modern society in the 21st century live in a place where fire does not go out 24 hours a day. These lights are sometimes helpful to people, but sometimes there are lights that cause discomfort to humans, such as light pollution. Thus, as important as the generation of light is the detection of light. The range of applications of photodetectors is very diverse. Photodetectors are also used for image sensors, missile defense, daily UV detection, environmental pollution monitoring, and optical communication. Light sensing materials have various band gaps and various structures. Among them, we used a Layered Double Hydroxides (LDHs) material that is easy to synthesize and environmentally friendly. The general formula of a LDH is [M(II)₁₋ₓM(III)ₓ(OH)₂]⁺[(Aⁿ⁻ₓ/n°yH₂O)⁻], where M(II) and M(III) are divalent and trivalent metal cations, respectively, and Aⁿ⁻ is an exchangeable n-valent anion, such as CO₃²⁻, Cl⁻, NO₃⁻, and CH₃COO⁻. In this study, we fabricated the photodetector using a material that grows in a scroll structure. The ZnAl-LDH nanosheet scrolls exhibit highly resistive semiconducting properties with
a band gap of 3.2 eV and work function of 3.64 eV. The photodetector grown in a scroll structure has shown a performance suitable for fabricating flexible and reliable devices.

Anisotropic Dielectric Properties of Cs-Doped Tungsten Oxide Nanoparticles Studied by Electron Energy-Loss Spectroscopy
Keisuke Machida¹,², Kenji Adachi¹, Yohei Sato² and Masami Terauchi²; ¹Sumitomo Metal Mining Co., Ltd., Japan; ²Tohoku University, Japan

Selective and wide near-infrared (NIR) absorption property realized by Cs-doped hexagonal tungsten bronze (Cs-HTB) in the form of nanoparticulate dispersion has been applied to various industrial use such as solar control windows, optical filters for imaging units, agricultural heat-shading sheet, photothermal conversion materials, and others. However, the understanding of the NIR absorption mechanism of Cs-HTB nanoparticles has been still controversial among preceding studies. In our recent report, optical absorption spectra of Cs-HTB nanoparticles were analyzed with a conclusion that the crucial factors determining the optical absorption property are the anisotropic dielectric property derived from the hexagonal crystal structure and the alteration in dielectric property of nanoparticles. In this study, high energy-resolution electron energy-loss spectroscopy (EELS) electron microscope was applied to measure the anisotropic dielectric properties of coarse and nano-sized Cs-HTB particles, and also examine the possibility of alteration in dielectric property.

A mixture of cesium carbonate and tungstic acid was calcinated under reductive atmosphere to synthesize coarse Cs-HTB powders of mm size. The powder was mixed with propylene glycol monomethylether and a dispersing agent, followed by bead-milling to be pulverized into nanoscale size.

For the coarse particles, EELS spectra with momentum transfer vectors ($q$) along with a- and c-axes of hexagonal structure, which reflect each component of dielectric tensor, have been measured. Those EELS spectra showed plasmon peaks at 1.2 eV and 1.8 eV respectively, whose energies are close to reported values obtained by an optical measurement on bulk Cs-HTB. By using anisotropic dielectric functions derived from those spectra of coarse particles, an optical extinction coefficient was calculated based on Mie’s scattering theory. However, the calculated extinction coefficient did not reproduce the optical absorption curve of nanoparticles well even though the size and shape effects were included, which suggested the alteration in the dielectric property of nanoparticles.

For the nanoparticle measurement, different EELS spectra were obtained depending on probe positions just outside a nanoparticle facing different surface orientations. Such a dependence on probe positions should reflect each dominant component of dielectric tensor. EELS spectra obtained along a- or c-axes showed plasmon peaks at different energies of around 0.8 and 1.2 eV, respectively. Those anisotropic plasmon peak energies were smaller than those energies determined of μm-sized Cs-HTB particles, which provides evidence of the alteration in dielectric properties from bulk sample to pulverized nanoparticles. It was also confirmed that energy positions of the plasmon peaks varied within the ranges of 0.6-1.1 eV for a-axis and 0.9-1.5 eV for c-axis among nanoparticles. These various plasmon energies should be due to the different degree of dielectric alterations and/or the shape effect of individual nanoparticles.

Morpho-Butterfly Inspired Gas Sensors for High Temperature Applications
Nora M. Houlihan¹, Radislav A. Potyrailo² and Michael Carpenter¹; ¹SUNY Polytechnic Institute, United States; ²GE Global Research, United States

It is well known that Morpho butterflies get their intense shimmering colors from the ordered, nanostructured arrays on their wings. Using these butterflies as inspiration, we are developing optical sensors with three-dimensional (3D) nanostructures using a conventional cost-effective fabrication process of photolithography and chemical etching. These 3D nanostructures are built with vertical ridges that support several horizontal lamella. These nanostructures are coated with materials designed to be sensitive to specific gases such as hydrogen or carbon monoxide. The concentrations of these gases can be measured through changes in the intensity of the reflected light at different wavelengths upon interactions of the 3D nanostructures with analyte gases.

Development of these new sensing paradigms are needed since mature analytical techniques, including vibrational spectroscopy, are currently used because of the need of accurate quantitation of these gases. The use of these techniques is unavoidable because existing sensors have several prominent limitations such as poor dynamic range, poor stability, slow response time, and inability to accurately detect one or several gases of interest in the presence of numerous interferences and contaminants. Therefore, in the present study Au nanoparticles embedded within cerium oxide thin films have been deposited on 3D nanostructures and are evaluated for the sensitive, stable and selective detection of hydrogen and carbon monoxide, at elevated temperatures.
The future of these sensors is to simultaneously detect multiple gases, such as for solid oxide fuel cell applications where numerous gases are present (such as hydrogen, carbon monoxide, carbon dioxide, methane, and water). These sensors will be used to complement existing analytical instruments in situations when multi-point or distributed measurements are needed and as such sensors with demonstrated stability, selectivity and sensitivity will ensure a series of parallel measurements for enhanced system control.

EN15.03.09

A Self-Powered Smart Rotation Movement Sensing System with a Triboelectric Nanogenerator Roller-Bearing Daehwan Choi, Taehoon Sung and Jang-Yeon Kwon; Yonsei University, Korea (the Republic of)

Triboelectric nanogenerators (TENGs) technology have been one of several candidates for energy harvesting. TENGs can convert external mechanical energy into electrical energy without other electrical power source. The invented TENG technology has rapidly developed with various approaches such as energy harvesting, mechanical/chemical sensors, self-powered systems, etc. Measuring the rotating motion in mechanical motions is one of common and essential technology in industrial and manufacturing systems. We believe that our triboelectric sensors provide high potential in terms of applicability. It shows that it can be used in many ways from a point of industry, not simply from a device. Through this, we have enhanced capability of self-powered triboelectric mechanical sensors.

In this work, we have roller-bearing structure applied to triboelectric sensors. Herein a simply fabricated, cost-effective, triboelectric sensor with a roller-bearing structure which is composed of rollers and electrode is presented. By integrating the structure of bearing and TENG technology, our triboelectric bearings would be applied to a variety of mechanical areas, particularly those involving mechanical movement. Based on the triboelectric effect, this smart bearing generates the output electrical signals in response to rotation movement or displacement of an object mounted with the bearing. Notably, our self-powered bearing exhibits high output performance, compared to other TENG based on the structure of bearing, of 45 V (open-circuit voltage) and 6 μA (short-circuit current) at a rotation rate of 400 r/min. Using the output signals of the smart bearing, the angular velocity and position as well as damage in the components can be continuously monitored. Furthermore, the smart bearing shows the sensing capabilities of various angle movements. We showed that our smart bearing mounted to the steering wheel can be utilized as an energy harvester, a rotation direction detector, and a driving style sensing system at the same time. This work greatly expands the applicability of triboelectric nanogenerators as self-powered sensing systems.

Effect of Loading rGO on Room Temperature NO2 Sensing Performance of CuO Nanochains Jyoti Jyoti and Ghanshyam D. Varma; IIT Roorkee, India

The synergistic effects among different nanomaterial induces new physical and chemical properties of the composite materials which can be applied for advanced applications. In the present work, CuO nanochain structure was fabricated via wet chemical method. Composite films of CuO/ graphene oxide (GO) with different ratio of CuO and GO were synthesised by drop casting method on glass substrate, where GO in the CuO/GO films was reduced by the thermal reduction treatment. The structures and morphologies of the CuO nanostructure and composite films were investigated by X-ray diffraction (XRD), field-emission electron scanning microscopy (FESEM), transmission electron microscopy (TEM), Raman spectroscopy and X-ray photoelectron spectroscopy (XPS). XRD patterns revealed the presence of reduced graphene oxide (rGO) sheets in the CuO nanochains by showing a broad peak of rGO along with the peaks indexed to monoclinic CuO. FESEM and TEM images of CuO nanostructure exhibited nanoparticles arranged to form chain like structure. High resolution transmission electron microscope (HRTEM) image CuO nanochains displayed the lattice fringes of spacing 0.232 nm that correspond to (111) crystalline plane of the monoclinic CuO. Selected area electron diffraction (SAED) pattern showed several concentric diffraction rings masked by spots, thus, indicating the polycrystalline nature of the nanochains. FESEM image of the composite films showed well dispersed CuO nanochains affixed onto the rGO sheets. Furthermore, XPS spectroscopy confirmed Cu to be present in Cu2+ state. The study on the gas sensing properties of CuO at room temperature (RT~25 °C) was carried out by loading different amount of rGO in the CuO nanochain sample. A maximum sensor response value of 29.1% for 20 ppm NO2 was obtained for the optimized material ratio of CuO and rGO (4:1) which was almost four times of the sensor with ratio of CuO and rGO (1:3). Furthermore, the optimal CuO/rGO film sensor exhibited fast response rate and excellent reversibility within the detection range of 5–100 ppm NO2. Moreover, the sensor showed good repeatability when tested over five repeated cycles of 20 ppm NO2 at RT. The
presence of local p-n heterojunctions between rGO sheets and nanochain structure of CuO was attributed to the enhanced sensor response. The present study suggest that GO addition would be an effective approach for developing RT NO2 sensors based on CuO.

**Composition and Optical Properties of Ordered Arrays of Ag Nanorods in a Polymer Matrix**

Dmitrii V. Panov, Tatyana V. Murzina, Alexander R. Pomozov and Dmitry L. Zagorskiy; 1National Research University Higher School of Economics, Russian Federation; 2Lomonosov Moscow State University, Russian Federation; 3Center of Crystallography and Photonics of RAS, Russian Federation

Optics of metal-dielectric composites reveals variety of new effects: surface plasmon excitation, related resonant enhancement of the electromagnetic field through multiple optical antennas, poles and nearly zero values of the dielectric coefficient (epsilon near zero, ENZ), etc. Of great interest are so called hyperbolic metamaterials, which got this name from the hyperbolic dispersion low that is realized due to the uniaxial anisotropy of a nanostructured metal-dielectric composite medium. We suggest and implement one of the ways for the composition of the hyperbolic medium based on Ag and ferromagnetic metals incorporated in the pores of the nuclear filters. The main goal was the search of the proper design of the structure for the realization of the hyperbolic dispersion.

Metal-polymer composites (arrays of nanowires (NWs) embedded in a polymer matrix) were obtained and investigated. Two types of samples were grown: pure silver NWs and silver NWs with a short layer of iron on top. NWs were obtained by galvanic deposition into the pores of etched-track matrix (track membranes with pore diameter - 30-100 nm, pore length - 12 μm, pore density 1.5*10⁹, JINR, Dubna). The filling of the pores was carried out by the two-bath technique. Two solutions were used: silver iodide (AgCl - 20 g/l; KI – 300 g/l) and ferrous sulphate (FeSO₄ * 7H₂O – 120 g/l; H₃BO₃ - 45 g/l; SDS and C₆H₈O₆). The deposition potentials were 400 mV for silver and 1200 mV for iron; the dependence of the current on time was recorded. SEM investigation of obtained NWs confirmed the calculated length: for silver part it was 500 - 3500 nm, while for iron part (cap on the silver NW) it was 100 nm.

We performed the modelling of the optical spectra of the composed samples using the analytical expressions for the Maxwell Garnett anisotropic effective medium. It was found that for all types of structures should reveal strong absorption close to 400 nm wavelength due to the local plasmon excitations, and a deep valley in the red-IR wavelength at oblique incidence associated with ENZ spectral point. In particular, for the arrays of Ag NWs (L=3 mcm, diameter-70 nm) the ENZ point corresponds to the wavelength of 1450 nm. The theoretical predictions are consistent with the experiment obtained via the transmission spectroscopy measurements, which proves high homogeneity of the structures, which can be used as hyperbolic media with properties tunable by varying the design of the NWs. We also composed similar structures consist in part of ferromagnetic metals (Ag/Fe NWs) which reveal specific magnetooptical (MO) spectral features, while their resonant behavior is controlled mostly by the geometry of Ag nanowires. The data obtained for Ag/Fe NWs are also presented and discussed. Such materials are rather perspective as MO media with tunable resonance behavior.

**Reaction Acceleration of Nanoporous High Purity Pd Film Formation by Dealloying of Al-Pd-N Film in pH-Controlled EDTA Solution**

Tomoya Nishi, Takuji Ube, Takashi Ishiguro and Syuya Hasegawa; Tokyo University of Science, Japan

Palladium (Pd) is expected material as one of hydrogen gas detection and/or hydrogen storage material. Furthermore, by forming the nanoporous (NP) structure, the specific surface area is increased, and improvement in sensitivity can be expected. In our previous study, we succeeded in the preparation of NP-Pd films by dealloying of Al-Pd alloy films using chelating solution of citric acid [1]. However, there were problems, that is slow reaction rate and residual Al (about 13 at%) in the film after dealloying. In this study, using ethylene-diamine-tetraacetic-acid (EDTA) as dealloying agent instead of citric acid speeds up the dealloying reaction. Furthermore, in order to increase the purity of Pd after dealloying the nitrogen-containing Al-Pd alloy (Al-Pd-N) film was used as the mother alloy film.
These 70-nm-thick Al_{0.82-Pd}_{0.18} or Al_{0.82-Pd}_{0.18-N} mother alloy films were prepared by the rf-sputtering method in the ambient gas of pure Ar or in the mixture gas of Ar and N\textsubscript{2}. The pH value was controlled to optimize the chelating ability of EDTA to Al ions in solution. EDTA dissociates four ionic states, i.e., EDTA\textsuperscript{-}, EDTA\textsuperscript{2-}, EDTA\textsuperscript{3-}, and EDTA\textsuperscript{4-} by increasing pH value from 4 to 10 by adding sodium carbonate (Na\textsubscript{2}CO\textsubscript{3}).

The dealloying process was performed at 368K and at the same time, in-situ observation of light transmittance change was performed to evaluate the dealloying rate. The membrane structure of dealloyed film was also evaluated by using SEM and STEM.

When the pH value of the EDTA solution was increased from 4 to 10, the ionization of EDTA proceeded, and the dealloying reaction saturation time (T\textsubscript{s}) of the Al_{0.82-Pd}_{0.18} mother alloy film was reduced to 1/33 from about 4000s to 120s. Furthermore, the T\textsubscript{s} was reduced to 40s by dealloying the nitrogen-containing Al-Pd-N film in EDTA solution at pH=10 instead of the Al-Pd alloy film without containing nitrogen. As a result, the T\textsubscript{s} was reduced to 1/100, and the composition of the NP-Pd film was purified to 99.5 at%Pd.

Preparation Nanopatterned Graphene (NPG) Structure for Gas Sensing Duyoung Choi, Myeonghoon Kim and Siwhan Lee; Korea Institute of Industrial Technology, Korea (the Republic of)

First, Thin anodized aluminum oxide nano-mask was prepared by facile self-assembly technique without using polymer buffer layer, which was utilized as direct-contact template for oxygen plasma etch to produce near periodic, small-neck-width NPG. This work also demonstrates that our direct-contact, self-assembled mask lithography is a pathway for low-cost, high throughput, large scale nanomanufacturing of graphene nano devices. The average neck width on graphene after controlled etching time is 25.0 ± 4.3 nm. It is expected that a neck width reducing process, such as utilizing a controlled oxygen plasma etch, could be utilized, which can lead to a substantially reduced neck width.

By using the fabrication of large-scale NPG network, its applications for gas sensing are reported. NPG network shows significantly enhanced sensitivity to ammonia gas compared to pristine graphene. The detection sensitivity of the nanoscale NPG network is even further improved by decorating NPG network with palladium (Pd) nanoparticles, which shows a relative resistance response of 65 % to 50 ppm of ammonia in nitrogen at room temperature as well as good reversibility in air.

EN15.03.14
Effect of Yb Doping on Piezoelectric Properties and Crystal Structure of AlN Piezo Thin Film Masato Uehara\textsuperscript{1}, Yuki Amano\textsuperscript{2}, Sri Ayu Anggraini\textsuperscript{1}, Kenji Hirata\textsuperscript{1}, Hiroshi Yamada\textsuperscript{1} and Morito Akiyama\textsuperscript{1,2}; \textsuperscript{1}National Institute of Advanced Industrial Science and Technology, Japan; \textsuperscript{2}Kyushu University, Japan

Piezoelectric functional material is an vital for microelectromechanical systems (MEMS) such as physical sensor, energy harvester, ultrasonic transducer for fingerprint and resonator for radio frequency. Aluminum nitride (AlN) is a piezoelectric material. Because this material has good properties such as sensor sensitivity, thermal stability and elastic modulus, we can use in harsh environments such as industrial plants and geothermal power generators as well as cars and smartphones. Additionally, it was revealed that a doping scandium (Sc) significantly increases the piezo response of AlN. This finding made the doped AlN a candidate for advanced MEMS device applications but Sc is an expensive element for the industry. In this study, we investigated the effect of Yb doping into AlN piezo thin film as an alternative for Sc. The Yb doped AlN YbxAl\textsubscript{1-x}N films were prepared on the silicon substrates by a radio frequency co-sputtering. The concentration of Yb, x was controlled by the cathode power. The prepared films had a column texture less than 100 nm in diameter. The piezoelectric coefficient increased by Yb doping. The coefficient reached to about twice that of AlN at x= 0.33. Because the rate of increase at concentrations below 0.1 was comparable to that of Sc doping, Yb can replace Sc in this concentration region. However, Yb could not be doped as much as Sc. Although Sc can be doped at 0.4 or more and the film shows giant piezo response, Yb did not exhibit piezoelectric response at 0.37 or more. The decrease of piezo response would be caused by a phase transition. In case of Sc doping, it is known that the crystal structure changes from wurtzite (polar phase) to rock salt (non-polar phase). In this study, the lattice constant changed continuously until the Yb concentration of X = 0.37. However, the change in lattice constants was discontinuous above x= 0.4 according to the conventional XRD analysis. This result would indicate the phase transition. We analyzed the crystal structure of prepared films in detail by a wide area X-
To cope with surging demand for highly sensitive, responsive, long term stability and selective Volatile Organic Compounds (VOCs) and Humidity Sensor’s in IoT applications, requires the development and exploration of innovative materials which can be considered as stepping stone in next generation sensing applications.\textsuperscript{1} Gas sensors with high sensitivity and selectivity at room temperature have been expected for practical applications. But the limitations of conventional metal oxide based sensing materials and their unstable outputs caused by ambient environment or harsh conditions, significantly restrict their practical applications.\textsuperscript{2}

Here in this study, we are exploring a heptazine based microporous polymer sensor for ammonia detection at room temperature and ambient conditions. The chemiresistive sensor performance was investigated for ammonia over a wide concentration range (1-200 ppm) and in the presence of relative humidity range (23-85 %RH). The presence of active sites (C=N and NH groups) and porous network of heptazine gas sensor enables enhanced response (16.6 @ 70 %RH & 47 @ 84 %RH) towards 50 ppm of ammonia with response and recovery times of 65 and 9s, respectively. The electron withdrawing nature of heptazine enables better selectivity towards ammonia over other VOC analytes.

Therefore, we believe that the developed sensing material presents an excellent opportunity for the development of high performance, portable, easy-to-use device for disease diagnosis via breath analysis and environment monitoring in ambient conditions.

Thin films of Pb(ZrxTi1-x)O3 have been most widely used for piezoelectric sensors and gyro applications due to their large piezoelectricity. These films have been also investigated for the vibration energy harvesters. In particular, the giant electromechanical response is obtained at the Zr/(Zr+Ti) ratio near the so-called morphotropic phase boundary, MPB. Most of studies have been only focused on the relationship between the crystal structure of the as-deposited films and the piezoelectric response. However, studies on the relationship between the crystal structure during the poling process and the piezoelectric response are very limited. Because the piezoelectric response is considered to accompany the crystal structural change under applying an electric field. Thus, it is crucial to investigate the change of crystal structure via the poling process and under applying an electric field after the poling.

In the present study, we investigated the change of crystal structure by the poling process and under applying an electric filed using a micro-beam XRD study. The measurements were performed for \{100\}-one-axis -oriented Pb(Zr,Ti\textsubscript{1-a})O\textsubscript{3} films with 1.5 µm in thickness and near MPB composition. The crystal structures and their change by these treatments strongly depended on the Zr/(Zr+Ti) ratio of the films. Films with Zr/(Zr+Ti)=0.65 changed from (100)-oriented rhombohedral phase to (001)-oriented tetragonal one by the poling process. Furthermore, Zr-rich films with Zr/(Zr+Ti) = 0.67 changed from (100)-oriented rhombohedral phase to (001)-oriented tetragonal one only under an electric field. The present results suggest the change from (100)-oriented rhombohedral to (001)-oriented tetragonal phases by not only the poling process but also under applying an electric field. This study provided fundamental insights on the crystal structure change with an electric field for Pb(Zr,Ti)O\textsubscript{3} films with composition near phase boundary.
Vanadium dioxide has been intensively explored as a viable material for numerous applications such as smart windows coatings and miniaturised optoelectronic devices and a great progress has been achieved on laboratory-scale. To realise its commercialisation, industrially-viable synthetic techniques are highly required for large-area thin films that meet commercial demands. DC reactive sputtering is such a robust technique which offers high quality large-area thin films on large-scale with controllable stoichiometry and composition for various applications in optoelectronic and energy harvesting devices. Herein, we report synthesis, characterization and IR photoresponse properties of 150.8 nm thick VO$_2$(M1) thin films synthesized by DC reactive sputtering. Phase purity was confirmed by XRD and Raman spectroscopic studies. Morphological and microstructural analysis by atomic force microscope (AFM), field emission scanning electron microscope (FESEM) and transmission electron microscope (TEM) revealed the polycrystalline nature of the nanosized films with rms roughness value of 8.69 nm. Electrical characterization showed a first order transition of the films with a resistance change of more than two orders of magnitude and a TCR of -1.24 % K$^{-1}$ at 30 °C. The fabricated IR photodetector based on VO$_2$(M1) thin films exhibited high photoresponse properties with excellent stability and reproducibility in the ambient conditions with a sensitivity of 1775 %, responsivity of 40.09 mA/W, quantum efficiency of 4.67 % and detectivity of 7.07 X 10$^{11}$ Jones upon illumination with a 1064 nm laser having a power density of 250 mW/cm$^2$ at 5 V bias voltage.

Ag-Pt Core-Shell Nanowires with Enhanced Environmental Stability

Serkan Koylan$^{1}$, Sensu Tunca$^{1}$, Melih Ogeday Cickek$^{1}$, Dongkwan Kim$^{2}$, Seunghwan Ko$^{2}$ and Husnu E. Unalan$^{1,1}$, $^{1}$Middle East Technical University, Turkey; $^{2}$Seoul National University, Korea (the Republic of)

Silver nanowire (Ag NW) networks hold great potential to replace commercial transparent conducting oxides due to their superior properties in conjunction with their competitive cost, availability and flexibility. However, there are still challenges to overcome for the wide scale utilization of Ag NWs in devices due to oxidation/sulfidation of nanowires depending on the operating conditions, which leads to loss in performance. Here we develop a solution based strategy to deposit a thin platinum (Pt) shell layer to improve environmental stability of the Ag NWs. Ag NWs were synthesized by polyol method [1] and coated with a thin conformal Pt layer. In a typical coating process, ascorbic acid was used as the reducing agent, polyvinylpyrrolidone (PVP) was used for the directional growth, surface of Ag NWs acted as nucleation sites for Pt ions and deionized water was used as the solvent. Fabricated core-shell nanowires were then deposited onto glass substrates in the form of networks via spray coating. Environmental stability of the core-shell nanowire networks was monitored under different relative humidity conditions (43, 75 and 85%) and compared to that of bare Ag NWs. In order to further evaluate their stability and simulate organic electronics fabrication conditions, both electrodes were kept at 75 °C for 120 hours and 150 °C for 24 hours. Finally, hydrogen peroxide stability of core-shell nanowire networks was tested and compared to that of bare Ag NW networks. All in all, this highly effective and simple strategy to improve the stability of Ag NWs will certainly open new avenues for their large scale utilization in various optoelectronic devices. The applicability of the fabricated highly stable networks has been demonstrated both in resistive and capacitive touch screens and capacitive sensors are fabricated.

Systematic Study on Helium Induced Nanostructure Formation of 5th Period Transition Metals for Gas Sensor Application

Kazuki Yuzawa, Kenya Uehata, Issei Hirai, Kenzo Ibano, Heun Tae Lee and Yoshio Ueda; Osaka University, Japan

Helium(He) plasma exposure to various metals with low irradiation energy and high ion fluence greatly changes the surface structure of the metals. Among them, the unique structure induced on tungsten (W) is called tungsten nanostructure or fuzz because it has a fluff-like shape [1]. Since this fluff-like fibrous structure (fuzz) has a nano-order sized and complicated structure, its surface area is greatly increased compared with flat surfaces. Therefore, application of fuzz to various gas sensors is very attractive. In particular, with regard to an ethanol gas sensor, an experiment was conducted for a molybdenum (Mo) layer deposited on a quartz surface, which was irradiated with...
He plasma to form fuzz [2]. By using this Mo fuzz, significant improvement in sensitivity of ethanol was confirmed and the possibility of application to various gas sensor was shown. Presently development of hydrogen gas sensor with W fuzz is in progress for future hydrogen based energy society.

For the gas sensor applications of the fuzz structure, it is necessary to produce nanostructures with larger surface area and durability. For this purpose, understanding of formation mechanisms controlling the thickness and length of the fuzz structure must be known. However, although a lot of experimental and simulation researches have been performed, there still remain many uncertainties in formation mechanisms and the detailed control methods of fuzz. So far, in order to elucidate the formation mechanism, various 6th period transition metals were irradiated with He plasma under various conditions [3]. In this work, fuzz structures were observed for several 6th period transition metals except tantalum (Ta) in the region where the normalized temperature $T/T_m$ is 0.3 or above ($T$: specimen temperature, $T_m$: melting temperature).

Based on the above mentioned research, He plasma irradiation to the 5th period metals have been also performed to systematically investigate the surface morphology changes and to acquire basic data for controlling fuzz structure. He plasma irradiation experiments have been conducted for zirconium (Zr), niobium (Nb), molybdenum (Mo), palladium (Pd), silver (Ag), and we found that thin fibers are formed in the region where the normalized temperature $T/T_m$ is 0.3 or above for all of these except for Nb. Similar tendency was observed for the same group elements such as tantalum (Ta) and Nb (5th group), and tungsten (W) and molybdenum (Mo) (6th group) [4]. A thick rod-like structure was formed for Nb and Ta, while fibrous structure (fuzz) was formed for W and Mo. In the presentation, experimental results on alloys with two metals which have different responses to He irradiation (e.g. Mo and Nd) are also shown, and the formation mechanism of fuzz will be discussed in detail.

**Microfabrication of Graphite by Oxygen Plasma Etching**  Jianwei Fu¹, Genki Hirobe², Yasushi Ishiguro² and Kazuyuki Takai¹,²; ¹Graduate School of Science and Engineering, Hosei University, Japan; ²Department of Chemical Science and Technology, Hosei University, Japan

Graphite has excellent properties, such as high strength, high thermal conductivity, and chemical stability. A variety of applications such as high performance batteries and heat dissipation materials for highly integrated electronic devices are expected for graphene as the next-generation materials. Recently, focusing on the high thermal conductivity of graphite in particular, investigations for the mechanism of phonon-scattering at crystalline domain interfaces have attracted attention. In this study, we tried to microfabricate nano-sized graphite by oxygen plasma etching process for highly oriented pyrolytic graphite (HOPG) in order to clarify the size-dependent thermal conductance of graphitic materials.

By an ICP plasma etching system (RIE-101iPH, Samco), a HOPG plate (10×10×3mm) was etched by using a copper / nickel-made metal mesh, a SiO₂ (285 nm) / Si plate and micro-patterned Au / Cr islands (1 µm circle) as masks, in the conditions of ICP power of 100 W, Bias power of 50 W, and process pressure of 0.05 Pa. AFM measurement was performed by using SPA400-DFM, Seiko Instruments Inc. with the Si cantilever. SEM images were acquired by using SU-8020, HITACHI High-Technologies in the condition of acceleration voltage of 15.0 kV. Both of copper and nickel mesh are deformed during etching process above 60 min. The longer etching time, the more significant deformation of the mask. On the other hand, SiO₂ (285 nm) / Si masks exhibit sufficient etching-proof nature. The etching rate gradually decreases as the etching time increases. It is known that a deposition layer is formed at etched step by the reattachment effect during plasma etching of graphite, where etching in the sample region just below the deposition layer is prevented [1]. This is why the etching rate becomes dropped in the initial etching process below 5 hours. By using micropatterned islands mask, well-aligned and uniform micro-fabricated graphite pattern is successfully obtained, where the horizontal size of the island was found to be slightly larger than that of the mask pattern.

**Elliptical Capacitive Pressure Sensor for High Pressure and Harsh Environment Deployment for Underwater Pressure Monitoring**  Rishabh B. Mishra and Aftab M. Hussain; International Institute of Information Technology (IITT) Hyderabad, India

Pressure is one of the most important process variables for wide area applications. Various principles used to design
pressure sensors include strain, piezoresistivity, piezoelectricity, capacitance and so on. Among these, capacitive pressure sensors have several advantages such as high measurement sensitivity, low temperature sensitivity, low power consumption and high stability. However, non-linearity of change in capacitance with respect to applied pressure is a major consideration in capacitive pressure sensors, thus necessitating the need for detailed modelling and analysis. An interesting characteristic of capacitive pressure sensors is insensitivity to harsh environments such as extreme temperature, strong chemicals and radiation. Further, for harsh environment applications, selection of materials with suitable properties is also very important. In literature, materials such as silicon nitride, silicon carbide, stainless steel, sapphire and diamond have been studied for applications in capacitive pressure sensors for harsh environment applications. In this work, we have designed and modelled capacitive pressure sensor membranes using composite membranes of silicon carbide and silicon nitride to reduce the dielectric constant while maintaining structural stability and manufacturability.

The basic capacitive pressure microsensor consists of two parallel plates, one is a movable diaphragm under applied pressure, and the other one is fixed. In this work, mathematical modelling of elliptical capacitive pressure sensors has been carried out. In order to perform mathematical modelling, the fourth order partial differential plate equation of clamped elliptical diaphragm was solved, following which the capacitance change was calculated using the area integral of the capacitance of the diaphragm. While developing the mathematical model, the small deflection Kirchhoff’s plate theory and pull-in phenomena were considered. To follow the small deflection theory, the deflection in diaphragm should be less than 1/10th of diaphragm thickness and the maximum deflection was limited to 1/3rd of the separation gap between plates to avoid pull-in phenomena. While performing the mathematical modelling of elliptical pressure sensor, the effect of electric field was ignored. We also performed finite element analysis (FEA) to validate the mathematical model. Various performance parameters of capacitive pressure sensors such as diaphragm deflection, capacitance variation, mechanical sensitivity, electrical sensitivity, non-linearity of sensor have been studied as a function of diaphragm physical dimensions, flexural rigidity, applied pressure and separation gap.

To compare various sensor designs, we designed the elliptical diaphragm using the same total area with different eccentricities. The designs were also compared with a circular shape diaphragm of the same area. The sensors were designed for measurement of pressure underwater in marine environments. After study of elliptical sensors of the same overlapping area between plates, it was found that the deflection decreases as the semi-major axis increases, which results in decrease in change in capacitance, which, in turn, reduces the mechanical and electrical sensitivity. However, the responses become more linear as eccentricity is increased. It was observed that circular diaphragm pressure sensor shows more deflection, capacitance change, mechanical and electrical sensitivity, however the repose is more nonlinear than the elliptical-shaped diaphragm. Hence, there is a trade-off between linearity and sensitivity. Thus, the ideal eccentricity for elliptical (circular) pressure sensors can be calculated based on the particular requirements of the application.

Effects of Hydrogen Molecule Adsorption and Defects on the Electronic Properties of Graphene

Yudai Shigehisa1, Yoshinori Obata1, Yasushi Ishiguro2 and Kazuyuki Takai1,2; 1Graduate School of Science and Engineering, Hosei University, Japan; 2Department of Chemical Science and Technology, Hosei University, Japan

Graphene is a two-dimensional material with a thickness of single atomic layer where carbon atoms are arranged into a honeycomb lattice. Molecular adsorption effects are significant in graphene because all of carbon atoms belong the surface, where the electronic properties are modulated by the interactions at the interface between graphene and other materials. Hydrogen molecule adsorption is one of the most important examples in terms of applications for the transistor devices accompanied with band gap opening technology and hydrogen storage materials. Meanwhile, introducing defects is one of the interesting strategies to give additional adsorption sites to graphene in view of enhancing the interactions between hydrogen molecule and graphene. In this study, we investigated carrier doping and scattering caused by hydrogen molecule adsorption and defects introduction into graphene by electric conductivity measurement and Raman spectroscopy.

A 4-terminal field effect transistor using single-layer graphene obtained by exfoliation of graphite (g-FET) was fabricated on SiO2/Si substrate. Time dependence of the electrical conductivity for the g-FET was measured after annealing in a vacuum chamber under hydrogen atmosphere (1 atm) at room temperature. For Raman spectroscopy, epitaxial graphene grown on SiC was used, where atomic vacancies were introduced by sputtering with Ar ion beam after pre-annealing, followed by exposed to ambient atmosphere and hydrogen molecule and atomic hydrogen,
respectively. The charge neutral point where the minimum conductivity appears in a g-FET exhibits no significant shift from 30 min after the hydrogen molecule adsorption up to 24 hr. This means little carrier doping occurs into graphene when hydrogen molecule adsorbed at 1 atm at room temperature. However, for a theoretical calculation, where hydrogenated atomic vacancies in graphene have a low energy barrier and little adsorption heat for additional hydrogen molecule [1]. Thus, we verified hydrogen molecule adsorption to defect-introduced graphene by Raman spectroscopy. The ratio of D-band to G-band in Raman spectroscopy is smaller for graphene with defects adsorbed by hydrogen molecule and atomic hydrogen than that exposed to ambient atmosphere containing oxygen. This might be explained by that holes are injected into graphene through oxygen-terminated defects and electrons are injected into graphene through hydrogen-terminated defects. The scattering probability of carriers at the defect site depends on the Fermi energy. Thus, D-band intensity which is related to carrier scattering processes in graphene is different between

Effect of MS₂ Layer on the Heating Effect of Al Doped ZnO Multilayer Transparent Heaters
Brandon A. Obasogie¹, Mamadou T. Mbaye¹, Jasmine Beckford¹, Laura Sweet², Sangram K. Pradhan¹ and Messaoud Bahoura¹;
¹Norfolk State University, United States; ²ODU, United States

In the last years, much effort has been dedicated to the development of high-performance transparent heaters (TFTFs) due to their versatile use in consumer electronics, automobiles, and smart windows. We successfully fabricated and studied the electrical, optical and thermal properties of Al:ZnO (AZO) / MS₂ multilayer thin film heaters by keeping the AZO layer fixed and varying the MoS₂ layer thickness. The multilayers (3 – 5 layers) of AZO and MS₂ films were grown at 200-400°C temperature range on glass, kapton, and silicon substrates using radio-frequency magnetron sputtering. The transparent heaters show a stable and reproducible heating effect with low consuming power (<10 V) as well as maintaining a high optical transparency higher than 75%. The temperature dependent resistivity behavior of the films was investigated using linear four probe measurement technique. The AZO films exhibit good electrical conductivity. These heaters offer an alternative to conventional and expensive ITO electrodes at a much lower cost. The potential applications are automobile window defrosters, foldable and wearable electronics, pain/injury therapy, smart windows, and low-cost power electronics.

Transition Metal (V, Nb and W) Doped TiO₂ Nanostructures for Chemiresistive Ozone Sensors
Ariadne C. Catto, Emerson dos Santos, Luis F. da Silva and Waldir J. Avansi; DF-UFSCar, Brazil

Chemiresistors based on metal oxide semiconducting (MOS) nanostructures have drawn researchers’ attention because of their several advantages related to gas sensor performance, such as stability, sensitivity, and reversibility [1]. Despite having wide-ranging applications, the gas-sensing performance of TiO₂ nanostructures, still needs to be better evaluated and TiO₂ in anatase phase has demonstrated interesting sensing properties related to gases such as CO, NO₂ or acetone [2-3]. Thereby, a facile and environmentally friendly synthesis approach for the production of MxTi₁−xO₂ (M=V, Nb and W) nanostructures was demonstrated via hydrothermal decomposition of their respective peroxy-complexes. The effect of metal ions addition on the structural, morphological and electronic properties of the as-prepared samples were investigated by X-ray diffraction (XRD), Raman Spectroscopy, UV-visible diffuse reflectance spectra (DRS), X-ray photoelectron spectroscopy (XPS), and electron microscopy techniques. XRD analysis confirm that all MxTi₁−xO₂ (M=V, Nb and W) samples presented only the TiO₂ anatase phase, despite the different amounts or metallic ions. Despite the different amount or metallic ions, scanning electron microscopy (SEM) shows that the increasing of metallic ions contents leads to a morphological evolution, from anisotropic to isotropic nanostructures, reducing their size (at around 5nm) as the surface area. From the studied samples, W doped
TiO₂ nanostructures presented interesting ozone (O₃) gas-sensing performance evidenced by their working temperature (below 200°C), sensor response, repeatability, as well as a good range of detection.

EN15.03.25
Electrical, Optical and Thermal Transport Properties of Oxygen Deficient Amorphous WOₓ (2.5 < x < 3) Films
Gowoon Kim¹, Hai Jun Cho¹, Yu-Miin Sheu² and Hiromichi Ohta¹; ¹Hokkaido University, Japan; ²National Chiao Tung University, Taiwan

Tungsten oxide (WOₓ) is attracting attention as an active material for many useful applications such as material for electrochromic device, electrode of Li-ion batteries, gas sensors and so on. Especially, amorphous tungsten oxide a-WOₓ films are essential material for advanced thin film devices, for example, the recently developed electrochromic transistor (ECT) because a-WOₓ films show clear electrochromism as well as flexibility, and it can be fabricated at room temperature (RT). One can expect that practical smart windows, which can store the information both electronically and visually utilizing the electrochromism of a-WOₓ. In order to improve the a-WOₓ-based ECT performance, fundamental physical properties of a-WOₓ are strongly required. Although the relationships between the electrical, optical and thermal properties and the chemical composition of crystalline WOₓ have been investigated, there is no systematic report in the case of a-WOₓ. Here we report the relationship between the valence state of W ion and the properties of oxygen deficient a-WOₓ thin films continuously against x.¹[1] We fabricated a-WOₓ films with various x ranging from 2.511 to 2.982 by the pulsed laser deposition technique and measured the electrical, optical, and thermal properties systematically. Although the +6 dominant films were electrical insulators with optical transparency in the visible region, we found that both optical transmissivity and electrical resistivity decreased drastically with increasing the +5 concentrations, which also enhances the thermal conductivity due to the fact that heat can be carried by additional conduction electrons. As the +4 states became dominant in the film, the resistivity slightly increased whereas the low transmission was maintained in the visible range. We believe that the results would provide useful information to improve recently developed a-WOₓ-based ECTs, which utilized reversible electrochromism of the active material to change the valence state of its transition metal ions, enabling the control of both the electrical conductance and visible transmission.

Resonant Inelastic X-ray Scattering Studies of Temperature-Varied Metal Insulator Transition in Vanadium Dioxide Nanoparticles
Emma Anquillare¹,², Dana Goodacre¹, Vedran Jovic³, Connor Gallagher¹, Xuefei Feng², Yi-Sheng Liu³, Feipeng Yang², Yang Har², Jinghua Guo², Linda Doerrer¹ and Kevin Smith¹; ¹Boston University, United States; ²Lawrence Berkeley National Laboratory, United States; ³University of Auckland, New Zealand

Monodisperse Vanadium Dioxide nanoparticles were synthesized using a hydrothermal method and characterized using Transmission Electron Microscopy and Synchrotron X-ray Diffraction. The particles were then studied using Soft X-ray Absorption (XAS) and Resonant Inelastic X-ray Scattering (RIXS) at both above and below the metal insulator transition, in order to reveal the extent of particle size and lattice effects on nano-scale sample bandstructure. For the first time to our knowledge, the XAS peak indicating the prominent presence of vanadium dimers in the low-temperature monoclinic phase has been identified as a stand-alone peak in VO₂ nanoparticles. Implications for extent of dimerization and the metal insulator transition will be discussed.

EN15.03.27
Substrate Dependent Active Channel Characteristics in Low-Temperature Polycrystalline Silicon Thin-Film Transistors
Dong Hyun Kim, Soohyun Kim, Jung Chun Kim and Jae Woo Lee; Korea University, Korea (the Republic of)

Nowadays, thin film transistor (TFT) are utilized in various display application like TV, mobile phone, car, etc. Backplane contains an array of TFTs which operate for switching the individual pixels on and off. It determines performance when it comes to resolution and power consumption. Active channels of TFTs include amorphous
silicon (a-Si), low-temperature polycrystalline silicon (LTPS) and indium gallium zinc oxide (IGZO). Especially, LTPS channel has an advantage of compatibility on a-Si fabrication processes.

In this study, we focus on electrical properties of LTPS TFT as a function of temperature in the range of 300 – 375 K. The characterization of LTPS TFTs fabricated on glass and plastic substrates is measured by using the semiconductor parameter analyzer (Keithley 4200) in vacuum chamber with thermal chuck. Electrical performances (Threshold voltage $V_{TH}$, Subthreshold swing $SS$, Effective mobility $\mu_{eff}$) of LTPS TFTs on glass and substrates are different. Although active channels have similar dimension, $V_{TH}$ $SS$ related to switching operation on plastic substrate ($1.44$ V/decade) is larger than glass substrate’s one ($0.60$ V/decade) at 300 K. $SS$ is explained by equation $SS=2.3nkT/q$, ($n = 1+(C_{dep}+C_{iT})/C_{ox}$). $C_{dep}$ is inverse proportional to temperature, also $C_{i}$ exponentially decreases according to increasing temperature. Compared to LTPS, single crystalline Si can be the ideal $60$ mV/decade at 300K because the effective $C_{dep}$ and $C_{i}$ are negligible. But, LTPS channel has many grains and grain boundaries which related to channel depletion capacitance and then glass and plastic substrates which have different interface quality are the cause of interface trap capacitance. It can affect $\mu_{eff}$ difference between glass ($75$ cm$^2$/Vs) and plastic ($59$ cm$^2$/Vs) substrates.

Ascending temperature in the range of 300 – 375 K, the characterization of LTPS TFTs on glass and plastic substrates get worse that $SS$ is proportional to temperature. Compared to extracted $SS$ and equation which applies the thermal dependency of depletion and interface capacitance, $C_{dep}$ of plastic substrate among grains is near 2 times larger ($0.33$ µF/cm$^2$) than one of glass substrate ($0.16$ µF/cm$^2$). It might describe that small grain size and large number of grain boundaries for plastic substrate affect depletion capacitance and lower effective mobility.

Meanwhile, glass substrate which has lower interface traps between gate oxide, active LTPS layer, and substrate than plastic substrate operates deeper and faster. Consequently, active LTPS channel layers on glass and plastic substrate have different physical factors like grain size, grain boundaries, and trap densities among another layers (gate oxide, substrate). It has been shown that these factors affect switching operation and driving performances of TFTs, respectively.

**Synthesis Pd-Au(Alloy)@ZnO Core-Shell Nanoparticles and Their Enhanced H$_2$ Gas Sensing Performance**

Yeon-Tae Yu, Ha-Nui Choi and Dong-Seok Kim; Chonbuk National University, Korea (the Republic of)

Among various Metal Oxide Semiconductor (MOS) gas sensor materials, ZnO is an n-type semiconductor, which has a band gap of 3.37eV, is recognized as a noticeable sensing material due to its chemical stability, its high electron mobility, and the variation of donor density. Typically, optimal working temperature of ZnO based gas sensors is above 300°C. However, ZnO has a problem in that it has no selectivity for target gases. Recently, as the hydrogen age comes, there is a growing interest in hydrogen gas sensors having selectivity to hydrogen gas.

In recent years, noble metal nanoparticles (NPs) have been used to improve the sensing properties of gas sensor. Among the various noble metal catalysts, palladium has excellent ability to adsorb hydrogen, so that it can increase the selectivity of the gas sensor to hydrogen gas when used as a catalyst. However, since palladium can be easily oxidized at a high temperature, when it is used as a catalyst of a gas sensor at a high operating temperature, it is oxidized so as to lose its function as a metallic catalyst. Therefore, palladium alloy needs to be considered as a catalyst. On the other hand, one of the new strategies for using noble metal NPs in MOS gas sensors is to design core-shell NPs. In the core-shell structure, the shell helps maintain the catalytic properties of the metal core.

In this study, Pd-Au alloy nanoparticles with different composition were synthesized to prevent oxidation of palladium. Subsequently, Pd-Au(alloy)@ZnO core-shell NPs were prepared using Au colloid, Zn(NO$_3$)$_2$ and ascorbic acid. To investigate the oxidation behavior of the Pd-Au alloy core, Pd-Au(alloy)@ZnO core shell nanoparticles were annealed at the range of 200 to 500°C. The synthesis of Pd-Au alloy nanoparticles was confirmed by using HRTEM, and the oxidation behavior of Pd-Au alloy core with different composition was observed through X-ray diffraction analysis. In addition, the gas sensing tests were performed at operating temperature of 200–500°C for various gases (H$_2$, CO, CH$_4$, C$_2$H$_6$O), and the composition effect of Pd-Au alloy on H$_2$ gas sensing response was investigated.

**Battery Intercalation Strategy for Material Synthesis, Energy Application and Mechanism Study** Zhiyuan Zeng; City University of Hong Kong, Hong Kong

In this talk, I will focus on Material Synthesis, Energy Application and Mechanism Study using Battery Intercalation Strategy. For material synthesis, I will discuss how to design battery intercalation “environments” to obtain a serials
of high quality single layer transition metal dichalcogenides (TMD) nanosheets (MoS$_2$, WS$_2$, TaS$_2$, TiS$_2$ and ZrS$_2$)-
the Li insertion can be monitored and finely controlled in the battery testing system, so that the galvanostatic
discharge is stopped at a proper Li content to avoid decomposition of the intercalated compounds; Moreover, the
battery intercalation strategy can be optimized and the controllable lithiation process can be extended to BN, NbSe$_2$,
WSe$_2$, Sb$_2$Se$_3$, Bi$_2$Te$_3$ and so on. The prepared noble metal-2D TMD composites are promising candidate for sensing
and hydrogen evolution reaction. For mechanism study, I am interested in failure mechanism study of
Lithium/Sodium Ion Batteries at nanometer scale utilizing imaging and spectroscopy protocols. With the self-
designed electrochemical liquid cell TEM, we can directly capture the dynamic electrochemical lithiation and
delithiation of electrode in a commercial LiPF$_6$/EC/DEC electrolyte, such as lithium metal dendritic growth,
electrolyte decomposition, and solid-electrolyte interface (SEI) formation. This technique opened a venue by which
looking inside the dynamic electrochemical reactions in real-time. Which render us to improve the electrode design
for reducing short circuit failure and improving the performance of lithium/sodium ion batteries.

Reticulate Dual Nanowire Aerogels for Multiple Applications Zhipeng Wang and Anyuan Cao; Peking
University, China

Nanowire aerogels (NWAs) possess an unusual conglomeration of many useful properties: lightweight, large surface
area, high electrical conductivity and low thermal conductivity. They have been used in many applications such as
electronics, energy generation/storage, thermal management, sensing, catalysis, etc. However, most synthesized
NWAs are composed of single component that may produce unsatisfactory aggregated performance in mechanical
strength, conductivity and electrochemistry. Therefore, it is hard to apply them in a multifunctional application.
To address this issue, we synthesized the reticulate dual-nanowire aerogels (rDNWAs) composed of FeS$_2$ nanowires
and carbon nanotubes (CNTs) via a simple solvothermal method. In the typical synthesis process, highly porous
CNT sponge was used as the matrix to allow the in-situ growth of nanowires and thus the two components densely
intertwined with each other to form the reticulate structure. This structure is versatile and TiO$_2$ based rDNWA was
also successfully fabricated by a similar process. The FeS$_2$ based rDNWA shows high porosity (> 98%), good
conductivity (0.65 S cm$^{-1}$), and excellent mechanical properties (maximum Young’s modulus: 1.32 MPa). Due to its
high compressibility, it can be used as the strain sensor. The sensor exhibits good sensitivity and enhanced stability
compared to the CNT matrix. Besides, it can be directly compacted to produce a high-performance free-standing
electrode for lithium ion batteries (LIBs) that exhibits high mass and areal specific capacities (10 mAh cm$^{-2}$
with the mass loading of 14.4 mg cm$^{-2}$). Further, the obtained TiO$_2$ based rDNWA shows not only similar properties and
applications but also some uniqueness. When applied as the electrode for the LIBs, it can be utilized to fabricate the
compressible LIB devices by controlling the voltage window to 1-3 V. The outstanding overall performance and
multiple applications of our hybrid aerogel are derived from the synergistic effect of intertwined two components
and the reticulate structure can be extended to fabricate more NWAs with novel multi-functional capabilities.

Transparent and Wearable Single-Electrode Triboelectric Nanogenerators for Self-Powered Touch and
Strain Sensors Using Electrospun AgNW/P(VDF-TrFE) Composite Nanofibers Seung-Rok Kim and Jin-Woo
Park; Yonsei University, Korea (the Republic of)

Healthcare monitoring devices assess the health status of a person by detecting the physiological signals such as
heartbeat, respiration rate, and temperature measured directly or in relation to the deformation and vibration of the
human body. Due to the needs for maintenance-free operation of wearable and wireless sensing units, the demand
for self-powered sensors is continuously growing. Using various kinds of nanogenerators that convert thermal,
mechanical or chemical energy into electricity, self-powered sensors can continuously measure physiological signals
of the body. Among these power-generators, triboelectric nanogenerators (TENGs) have attracted interest for
wearable sensing applications because they can scavenge energy from mechanical body motion with high energy conversion efficiency. There are four fundamental operation modes of TENG; vertical contact-separation, in-plane sliding, single-electrode, and free-standing operation mode. Compared with other paired-electrode modes, the single-electrode mode has a much simpler structure that does not need an auxiliary electrode on the surface. Hence, only the single-electrode mode TENG (SETENG) fulfills the energy harvesting conditions necessary for human-machine interfaces, such as touch panels, where human skin acts as the opposite triboelectric surface to the component surface of the TENG. In this work, we fabricated the SETENG using the electrospun silver nanowires (AgNWs)/P(VDF-TrFE) composite nanofibers (NFs). The inclusion of a small fraction of AgNWs in the NFs promoted the β-phase formation of P(VDF-TrFE), a higher surface charge density, and the output performances. The SETENG generated an output power density of up to 217 W/m² with repetitive contact and separation. To the best of our knowledge, this power density is one to two orders larger than that of other single-electrode-type TENGs (3.4 ~ 27 W/m²) reported by others. Conducting high-resolution X-ray diffraction (HR-XRD), Raman spectroscopy, Fourier transform infrared spectroscopy (FT-IR) and Kelvin probe force microscopy (KPFM) analyses, we could confirm that AgNWs create the β-phase and induce a much lower surface potential. Using highly efficient SETENG, we demonstrated a self-powered, transparent and wearable touch panel for a human-machine interface by arraying SETENG units as a touch sensing component. The SETENG array was connected to Arduino microcontroller for real-time communication using low-pass RC filters with 10 Mohm resistors and 10 nF capacitors for noise filtering. We could successfully type any text on the computer using the SETENG array. Additionally, we designed a self-powered strain sensor connecting SETENG with the strain sensor as a power source. Touching and detaching the SETENG, saturated open-circuit voltage signal by transferred charges was transformed by resistive transducer (the strain sensor). It showed the linearity with 16 gauge factor (GF) at 35% strain. It also had no hysteresis behavior up to 10% strain of and showed stable ε sensing performance during the repeated stretching test at ε of 10% for 10,000 cycles. Using self-powered strain sensor, we could successfully measure the strain on the finger without any power supply.

8:30 AM *EN15.04.03
Advances in Low Dimensional Metal Oxide Chemiresistive Sensors for Environmental Monitoring Oomman K. Varghese; University of Houston, United States

Recent developments in the areas of energy, environment and public health have made the role of chemical sensors more relevant than ever before. While efforts to increase process efficiency without environmental impact and new technologies emerging in the areas of energy conversion and storage demand development of reliable chemical sensors for process monitoring and safety, concerns over increasing pollutants in the environment and rapidly increasing mortality rates related to a wide range of diseases including cancer prompt their use in environment and health monitoring. Nevertheless, the concentrations of gases/vapors of interest are, in many of these cases, in the range of parts per million to trillion (ppm to ppt) levels and the environment is complex. Metal oxide semiconductor based chemical sensors are attractive for such applications because of their ability to detect a wide range of chemical species. These devices are generally low cost and fast responding and have the ability to operate in harsh environments. Inadequate sensitivity and selectivity are often problems with these sensors. Advent of new low dimensional metal oxides facilitated the development of sensors with unique functionalities. These materials offer high surface area and nanoscale features for improved receptor and transducer functions. As a result, highly selective sensors with ppm to ppt range detection ability can be developed using these materials. For example, we recently developed a zinc oxide nanomaterial based sensor that could detect parts per billion levels of certain volatile organic compounds (VOC) in air with reasonable selectivity. Such VOC sensors find applications in various areas including pollution monitoring and early diagnosis of diseases. This presentation will give an overview of the current status of the nanostructured oxides based chemiresistive sensor technology for environmental monitoring. The focus of discussion will be on trends in volatile organics detection technology.

Effect of Twinning on Nanowire Electromigration Lifetime Mohammad Waliullah and Rodrigo Bernal; The University of Texas at Dallas, United States

Electromigration is a critical failure mode in the semiconductor industry, and in the emerging fields of flexible and wearable electronics. This failure can be attributed to the diffusion of metallic atoms due to momentum transfer of electrons flowing through a metallic interconnect when voltage is applied. The diffusion eventually leads to formation of voids and hence a time-dependent increase of electrical resistance of the interconnect. Since it is a
diffusion process, the microstructure of the interconnect is one of the controlling factors of electromigration. Twin boundaries, in contrast to grain boundaries, can have the potential to reduce diffusion of atoms and consequentially improve electromigration performance. In flexible electronics, it is common to have twinned interconnects. Unfortunately, very few studies have been conducted about the diffusion performance of these interconnects. Even those studies consider a few twin boundaries in grain boundary diffusion. No literature is available about the collective effect of twin boundaries throughout the interconnect. Moreover, some of the studies said that twinning slows down the diffusion and hence void growth [1], [2] and some said that twinning does not necessarily hinder void growth [3]. Given these conflicting reports, there is clearly a need for a systematic study of the electromigration reliability of twinned interconnects.

In this work, we investigated electromigration failure of penta-twinned silver nanowires, with a nominal diameter of 100 nm and length ranging from 3 μm to 15 μm, to yield reliability estimates for nanowire-based flexible electronics. Samples were prepared by random deposition of nanowires on a substrate containing gold electrodes fabricated by photolithography. The nanowires were connected with the electrodes by e-beam lithography. The electrodes were then connected to a printed circuit board (PCB) through a wirebonding package. Under a fixed current density and temperature, the resistance was measured using 4-point measurement method so that it can be measured continuously without the influence of contact resistances. The currents were applied in an automated fashion to test a large number of nanowires. The failure criterion was set as 10% increase in resistance which is also widely used in the electronics industry. The median time to failure of nanowires was determined using Black’s equation. The experimental data not only provides a significant guideline about reliability of flexible electronics in terms of electromigration failure but also valuable information about diffusion parameters through twin boundaries. Comparison between the data obtained in this experiment and the published data for interconnects currently used in the electronics industry, depending on the variation in diameter and length, revealed promising prospect for twinned interconnects in the next generation electronic devices.

Nanoparticle-Based Chemiresistor Array for Classification of Tea Aromas Tuo Gao, Yongchen Wang, Chengwu Zhang, Jing Zhao, Ranjan Srivastava and Brian Willis; University of Connecticut, United States

As one of the world’s favorite beverages, teas have been consumed by many generations. Due to their high health benefits, it is important to understand the quality of teas. The objective is therefore finding an economic way to identify aromas of tea that can eventually help with the purpose of tea quality control. Conventionally, similar to wine products, a tea-tasting expert will tell how good a tea is. However, it is very expensive and subjective as there is no measurable parameter. For that reason, a more reliable and easy-to-operate alternative approach is desirable. Based on earlier success using organo-functionalized nanoparticles to differentiate volatile organic compounds, we continue to investigate the performance of gold nanoparticle chemiresitive sensor arrays using more complex analytes - tea samples.

In this work, we demonstrated a nanoparticle-based electronic nose system that separates 35 flavors of teas, ranging from black teas, green teas, and herbal teas. Four types of gold nanoparticles (AuNPs) with chemically diverse ligands were chosen as sensing elements. The functionalization includes DMAP (4-dimethylaminopyridine), ODA (octadecylamine), 3-MPA (3-mercaptopropionic acid), and 4-ATP (4-aminothiophenol). To assemble the electrodes, nanoparticle solutions were drop-cast on the active sensing region that consists of castellated microstructures with 2-μm gap. The sensor chip was designed with separated active sensing regions so that each AuNP can have 12 working sensors maximum. This allowed diversity as well as redundancy for sensing experiment. Fresh tea powders were added to a glass syringe and the dosing was completed by a syringe pump with controlled delivery speed. Dry nitrogen gas was used for purging. Sensing responses, expressed as ΔR/R0, were measured simultaneously for all sensors using a switch matrix/multimeter system. Raw data processing and statistical analysis were performed using
MATLAB to evaluate the performance of the chemiresistive electronic nose array.

Depending on flavors, sensing elements, and baseline resistance difference, $\Delta R/R_0$ of 1-20% were achieved. The resulting variation enables statistical analysis, such as principal component analysis (PCA), linear discriminant analysis (LDA), support vector machine (SVM), and random forest (RF). With five-fold cross validation, we have achieved 99% accuracy with LDA for all 35 flavors of teas. We also found that multi-particle assembly works better than using single type of particles. For example, by choosing two working sensors from each particle, we obtained $91.4 \pm 3.3\%$ accuracy for 13 black and green teas, and $88.6 \pm 3.7\%$ for 22 herbal teas. On the other hand, if we chose 8 sensors from each of the four particles, the classification accuracy dropped. This is a significant improvement (>10%) from single particle assembly. The results showed accurate classification of 35 flavors of teas and provided a promising approach to monitor the quality and grade of tea products. Moreover, by increasing the chemical variation in ligands, it is possible to select the ligand combination that gives the best overall performance.

Graphene Nanoresonators for Molecular Detection in Solvated and Complex Environments Maicol A. Ochoa$^{1,2}$ and Michael Zwolak$^2$; $^1$University of Maryland, United States; $^2$National Institute of Standards and Technology, United States

New nanoscale devices and protocols for molecular detection in aqueous environments at room temperature are desirable for their potential application in biomolecular analysis and in vivo cell studies. Due to their electromechanical properties, graphene and other 2D materials provide a platform for electromechanical sensing in noisy and complex environments. We have investigated this idea by analyzing representative tight-binding models and extended Huckel models for suspended graphene nanoribbons. In particular, we have derived analytic expressions for the current, the electromechanical susceptibility, and signal-to-noise ratio. These expressions reveal the relative importance of thermal fluctuations, strain, and geometric properties in the signal and electromechanical response. We find that as a result of the environmental fluctuations, electromechanical structures have an electron transmission function that follows a generalized Voigt profile, in close analogy to the inhomogeneous lineshapes found in spectroscopic and diffraction studies. These results allow us to formulate optimal sensing protocols in terms of detector parameters, and give the underlying mechanics and fundamental operational principles for the design of graphene-based nanoelectromechanical detectors.

9:45 AM EN15.04.07
A New Route of Developing Stable Super-Nernstian Performance pH Sensing IrO$_2$ Films with Nanoparticles Yi-Chieh Hsieh$^1$, Tzu-Ying Chan$^1$, Kuang-Chih Tso$^1$, Bo-Han Huang$^1$, Pu-Wei Wu$^1$, Pochun Chen$^2$ and Tsung-Eong Hsieh$^1$; $^1$National Chiao Tung University, Taiwan; $^2$National Taipei University of Technology, Taiwan

The pH sensing applications have been widely used in various fields, and its redox reaction is the determining mechanism of sensitivity. However, regular pH sensing materials are limited to a pH sensing slope under -59 mV/pH due to the Nernst equation. In contrast, the IrO$_2$ is known to reveal a super-Nernstian response, a characteristic slope as high as -88.7 mV/pH. In our recent work, we have developed a facile method to synthesize robust IrO$_2$ thin films via a bipolar pulsing processing combining electrophoresis and electro-flocculation of IrO$_2$ nanoparticles in a colloidal suspension. The synthesized IrO$_2$ thin film exhibits a pH sensing slope of -73.6 mV/pH, with impressive surface uniformity and strong adhesion to the substrate.

ZnFe$_2$O$_4$/TiO$_2$/Au@Pt Nanoarray Modified Paper-Based Biochip for Ultrasensitive Immunosensor Lina Zhang, Li Li, Yan Zhang, Hongmei Yang and Jinghua Yu; University of Jinan, China

A novel photoelectrochemical (PEC) immunosensor based on the ZnFe$_2$O$_4$/TiO$_2$/Au@Pt nanoarray functionalized paper working electrode (ZnFe$_2$O$_4$/TiO$_2$/Au@Pt-PWE) was developed and used for ultrasensitive detection of carcinoembryonic antigen (CEA). To achieve a boosted PEC response under visible light excitation, the ZnFe$_2$O$_4$ nanocrystals served as photosensitizer were grown in-situ on the surface of the paper fibers with modification of highly ordered TiO$_2$ nanotube arrays and Au@Pt alloy nanoparticles, which was further used as the 3D electron collector to boost the separation of the photogenerated electron-hole pair of the TiO$_2$ arrays. The probable PEC
promoting mechanism was investigated by Mott-Schottky tests, phosphorescence decay measurements as well as X-ray photoelectron spectroscopy analyses. The obtained ZnFe$_2$O$_4$/TiO$_2$/Au@Pt-PWE was explored as the immunosensor substrate for fixing biomolecules. By virtue of sandwich-like immunoreaction, ultra-sensitive quantification of CEA was obtained. Under the optimized experimental conditions, the developed sensor exhibited a fast response, a broad linear range, and low detection limit. This work may provide a universal method for preparing multifunctional paper-based electrode and offer an innovative platform for the highly sensitive antigen-analysis.

11:00 AM EN15.04.09
Bioinspired Nanosensors for Energy and Environmental Detection Wen Shang, Qingchen Shen, Zhen Luo, Jiaqing He, Lingye Zhou and Tao Deng; Shanghai Jiao Tong Univ, China

Prof. Wen Shang, Qingchen Shen, Zhen Luo, Jiaqing He, Lingye Zhou, Porf. Tao Deng

School of Materials Science and Engineering, Shanghai Jiao Tong University, Shanghai, China, 200240

With billions of years of nature evolution, biological systems have developed many elegant sensing structures with superior sensing performance. Inspired by such biological sensing systems, different man-made sensors have been designed and fabricated to match or surpass the performance of those biological counterparts. In this presentation I will discuss our effort in design, fabrication, and characterization of bioinspired nanostructured sensors for energy and environmental detection. In particular I will discuss the nanosensors for thermal energy detection. The detection of thermal energy is critical in many industrial applications, including the thermal energy distribution within both steam turbine and gas turbine, the thermal energy signal within the component of aerospace vehicles, and the thermal energy distribution within a solar-thermal energy conversion system (1). With the critical roles played by the thermal detection technologies in a growing range of applications, the need of portable and high performance thermal sensing systems drives up the technology development (2, 3). We explored an alternative thermal detection mechanism that is based on the desorption of vapor molecules from the butterfly-inspired nanosensor under the stimulation of incoming thermal radiation, and demonstrated the use of such stimulated desorption for both broadband and wavelength selective thermal radiation detection. This new detection mechanism enables more than an order of magnitude of improvement in both the response of relative reflectance and also the signal-to-noise ratio at the maximum heat-sink-free response speed. The stimulated desorption also provides the opportunity to achieve the wavelength selective thermal radiation detection due to the wavelength selective thermal absorption of the molecules. Based on the similar approach, a self-powered thermal radiation nanosensor that can convert thermal radiation into electric signals was also demonstrated. Besides the thermal energy detection, these bioinspired nanosensors can also be used for the detection of other environmental targets, including both vapor detection and noise detection (4, 5). Such detection approach thus offers a platform for a range of high performance sensing systems, including energy, environmental, chemical vapor, and biological sensing systems.

11:15 AM EN15.04.10
Light-Controlled Deformations of High-Aspect-Ratio Liquid Crystalline Elastomers Microstructures Michael M. Lerch1,1, Shucong Li1, Yuxing Yao1, James T. Waters2, Anna C. Balazs2 and Joanna Aizenberg1,1; 1Harvard University, United States; 2University of Pittsburgh, United States
Liquid crystalline elastomers (LCEs)\cite{1} are crosslinked polymeric systems with the ability to undergo temperature-dependent anisotropic shape changes. These changes are governed by the orientation of liquid crystal mesogens connected to the polymer backbone. The dynamic behavior of LCEs makes them interesting for actuators in soft robots and sensors.

Drawing inspiration from nature\cite{2,3} we can build materials with microstructures\cite{4,5} that can perform tasks for applications such as wetting, microfluidics, information processing and cargo transport, capture and release. When composed of LCEs, these arrays of microstructures can variously tilt, twist, stretch or contract upon heating depending on a director alignment encoded magnetically during fabrication.\cite{6} Upon incorporation of a molecular photoswitch (e.g., an azobenzene), they can be rendered light-responsive\cite{7} which further extends their range of deformations. Here, we use light-responsive microstructured LCE surfaces with unprecedented deformation behavior. In arrays of pillars of different geometry, reversible twisting of these pillars can be triggered with directionality governed by the angle of UV irradiation with respect to the director alignment. Achiral surfaces can thus be dynamically converted into surfaces with controlled chirality. Moreover, depending on the light intensity, deformation modes beyond twisting are accessible. This bioinspired LCE platform offers new modes of deformation, coupled motion, and energy conversion that may be interesting in contexts such as soft robotics and microfluidic devices.

**Fire Detection from Light Scattering** Georgios A. Kelesidis¹, Reza M. Kholghy¹, Joel Zuercher², Julian Robertz², Martin Allemann², Aleksandar Duric² and Sotiris E. Pratsinis¹; ¹ETH Zürich, Switzerland; ²Siemens AG, Switzerland

Early and reliable fire detection is essential to prevent thousands of human deaths and injuries every year in the US alone [1]. Modern fire (smoke) sensors detect the light scattered from carbonaceous particles (soot) emitted during open fires. Such particles have fractal-like structure formed by agglomeration and surface growth [2]. Yet, their optical properties are calculated typically by Rayleigh or Mie theories for spheres impeding their selective sensing among other airborne particles [3]. So, fire detectors are not selective enough for such particles producing false alarms costing up to 1 billion £/y in United Kingdom alone [4].

Here, carbonaceous agglomerate structure and light scattering are measured from premixed ethylene flames [5] and simulated by coupling Discrete Element Modeling (DEM) for surface growth and agglomeration with the Discrete Dipole Approximation (DDA) [6]. Using the Mie theory for spheres overestimates the measured particle mass up to 10 times. This results in 60 % larger differential light scattering cross-sections than those measured in premixed ethylene flames. In contrast, the DEM-derived particle structure and light scattering is in excellent agreement with those measured here in premixed flames. Thus, the DEM-DDA can be used to optimize the selective sensing of fire detectors.

Ultrasensitivity of Self-Powered Wireless Triboelectric Vibration Sensor for Operating in Underwater Environment Based on Surface Functionalization of Rice Husks

Sz-Nian Lai1,2,3, Chih-Kai Chang1, Cheng-Shiun Yang1, Chun-Wei Su2, Chyi-Ming Leu2, Ying-Hao Chu1, Pao-Wen Sha3 and Jyh Ming Wu1; 1National Tsing Hua University, Taiwan; 2Industrial Technology Research Institute, Taiwan; 3National Chiao Tung University, Taiwan

We demonstrate the self-powered wireless triboelectric vibration sensor as made from the naturally nanoporous SiO2 particles for allowing the detection of the vibrations and movement in the underwater environment. The nanoporous SiO2 particles are directly converted from rice husks (referred to as RH_SiO2), which exhibit strongly interacting surface hydroxyl groups. Through the enzymatic treatments, the surface potential of the RH_SiO2 can be modulated to obtain either an extremely low or strongly high electronegativity. Specifically, by adding fluorinated groups using fluoroalkylsilane (FOTS) treatment to obtain RH_SiO2-F, the charge density of the RH_SiO2-F triboelectric nanogenerator (TENG) can be enhanced ~ 56.67-fold as compared to the untreated RH_SiO2-TENG. The power density of the RH_SiO2-F TENG is increased from 0.077 mWm⁻² to 261 mWm⁻². The RH_SiO2-F particles are encapsulated in a quartz cube to fabricate a self-powered wireless sensor that can be stabilized for operating in water at various temperatures. The theoretical calculation further demonstrates that the triboelectric potential is dramatically established between the surface functionalized RH_SiO2-F particles and the quartz’s surface. With porous nature of rice husks covered with nano-Si is of a high functionality for designing a new-type TENG which has a great potential to apply in the environmental monitoring.

Scalably-Nanomanufactured 2D Tellurene for Ubiquitous Electronics and Sensors  Wenzhuo Wu; Purdue University, United States

The reliable production of atomically-thin crystals with tailored properties is essential for exploring new science and implementing novel technologies in the 2-D limit. However, ongoing efforts are limited by the vague potential in scaling-up, restrictions on growth substrates and conditions, small sizes, and instability of synthesized materials. In this talk, I will discuss our recent progress in the discovery and production of tellurene (2-D form of elemental tellurium) with an intriguing chiral-chain structure. The solution-synthesized tellurene crystals exhibit process-tunable thickness from a monolayer to tens of nanometers, lateral sizes ~ 100 nm, and can be transferred to designer substrates. I will further discuss our findings in 2-D tellurene’s material properties, as well as our efforts in the prototypical device explorations with the acquired fundamental understandings of tellurene’s properties. Our results show that the air-stable tellurene, as an emerging 2-D material, exhibits a plethora of intriguing physical properties appealing for applications in electronics, optoelectronics, energy, sensors, and quantum devices.

Beyond p-n Junctions—Flexoelectric Photo-Detection and Energy Harvesting in Bismuth Telluride Thin Films  Bruno Lorenzi1,2, Yoichiro Tsurimaki2, Akihiro Kobayashi3, Masayuki Takashiri3, Gang Chen2 and Svetlana Boriskina2; 1University of Milano-Bicocca, Italy; 2Massachusetts Institute of Technology, United States; 3Tokai University, Japan

Bulk photovoltaic (PV) effect has recently attracted an increasing interest for its potential in simplifying the structure of optical sensors and photovoltaic cells, and as a possible solution to overcome the Shockley – Queisser limit in the solar cell energy conversion efficiency. Until recently, the bulk PV effect has only been observed and
exploited in non-centrosymmetric materials, strongly limiting the range of possible applications.

A possible way to overcome this limitation comes from the so-called flexo-PV effect, in which a gradient strain is used to induce an internal polarization within the material, enabling the collection of photo-generated carriers also in centrosymmetric materials. In this context flexo-PV has already been demonstrated in many large and intermediate bandgap materials, including titanium dioxide, strontium titanate, and silicon under visible and ultraviolet light illumination.

Low bandgap materials, such as Bismuth Telluride (Bi$_2$Te$_3$) are sensitive to infrared (IR) light, opening opportunities for the implementation of the bulk PV effect to develop new types of IR sensors. However, a comprehensive theoretical and experimental analysis of the strain-induced flexo-PV effect in this kind of materials is still missing. Furthermore, the flexo-PV effect has been mainly demonstrated at the nanoscale, leaving doubts on its applicability in wider contexts and for macroscopic device footprints.

In this communication we present the experimental demonstration of flexo-PV effect in Bi$_2$Te$_3$ thin films, under different illuminations and conditions. Depositing Bi$_2$Te$_3$ thin films on flexible substrates, by magnetron sputtering, and developing ohmic contact and anti-reflective coating by e-beam evaporation, we were able to create a strain gradients in the material, and analyze its electrical response. We will show and discuss how the power output in our samples can be varied as a function of the applied strain, sample temperature, and illumination level at different wavelengths. Our results help to shed light on the relation between applied strain, material polarization, and the photon detector performance, and reveal new possible applications of the flexo-PV effect in low-gap materials under different illumination scenarios. The new flexo-electric photo-detectors can operate under real-life conditions, i.e., without cryogenic cooling and in the self-powered regime, and provide an opportunity to integrate energy-harvesting and conversion as well as environmental sensing capabilities on a single cheap, lightweight, and flexible platform.

**Novel Solvent Exchange Process of a Highly Conductive PEDOT:PSS by Ultrafiltration for Conformal Nano-coating on Micropyramids towards a Highly Sensitive and Stable Pressure Sensor**

Jung Joon Lee$^{1}$, Srinivas Gandla$^{1}$, Byeongjae Lim$^{2}$, Sun-ju Kang$^{1}$, Sunyoung Kim$^{2}$, Sunjong Lee$^{2}$ and Sunkook Kim$^{1}$; $^{1}$Sungkyunkwan University, Korea (the Republic of); $^{2}$Korea Institute of Industrial Technology, Korea (the Republic of)

Water, a solvent for a poly(3,4-ethylenedioxythiophene): poly(styrene sulfonate) (PEDOT:PSS) solution, was solvent-exchanged with various solvents by an ultrafiltration method, while PEDOT:PSS continuously remained in a wet state for stable redispersion without aggregation. Among the tested solvents, we demonstrated for the first time that PEDOT:PSS was successfully and stably dispersed in ethanol (EtOH) and ethylene glycol (EG) by the facile ultrafiltration method. Compared to water, the EtOH based PEDOT:PSS exhibited enhanced wettability over Polydimethylsiloxane (PDMS) substrates without any additional surface treatments, as measured by the contact angle measurements. The solvent exchange process (SEP) did not alter the conductivity of PEDOT:PSS from its pristine form, but increased the pH from 2.4 to 4.5 by removing the excess PSS. An exceptionally uniform with conformal nano-coating of EtOH-based PEDOT:PSS solution on PDMS pyramids resulted in a pressure sensor exhibiting very high sensitivity in the low-pressure regime (~21 kPa$^{-1}$, < 100 Pa), a fast response time (90 ms) with a maximum load of 1 kPa, and high mechanical stability over 10000 cycles. In addition, the pressure sensor functioned as a human pulse rate sensor that produced a precise pulse waveform with peaks clearly indicating incident, systolic, and diastolic pressure. Additionally, it exhibited excellent selective accuracy with little interference in a 4 x 4-pixel pressure mapping panel. We believe that the solvent-exchange process developed in this study provide the pressure sensor could deliver new opportunities in wearable electronic applications.

**Oligomers with Mechanical Bistability as a Promising Material for Nanosensing Elements**

Anastasia Markina$^{1,2}$ and Vladik Avetisov$^{1,2}$; $^{1}$N. N. Semenov Institute of Chemical Physics of the Russian Academy of Sciences, Russian Federation; $^{2}$Molecular Machine Corporation Ltd, Israel

Nanosystems capable of reversible transitions between two states in response to applied stimuli are attracting more and more attention given the pursuit of miniaturization of trigger-type and switch-type elements. These elements are key units of many functional nanodevices (e.g., molecular and macromolecular switches, single molecular sensors, molecular actuators, electric- and optoelectric devices, as well as logic gates). The desire to create nanometer-scale switching devices has motivated an active search for bi-state macromolecular systems allowing for sharp
conformational transitions in response to stimuli. Short oligomers possessing such mechanic-like characteristics are a promising platform for the design of nanodevices and molecular machines.

Using full-atomistic simulations, we demonstrate that oligomers of thermosensitive polymers, themselves only a few nanometers in size, possess conformational bistability, and react to power loads as non-linear mechanical systems. We establish the bifurcation effect, the hysteresis effect, spontaneous vibrations, as well as the stochastic resonances of these oligomers [1]. This study shows how such switching-like behavior of oligomers of thermosensitive polymers can be used in molecular nanosensing, in particular for single molecule detection.

Reversible Light-Induced Insulator-to-Metal Transition in Yttrium Oxy-Hydride Epitaxial Thin Films

Yuya Komatsu1, Ryota Shimizu1,2, Kazunori Nishio1, Masahiro Miyachi1, Markus Wilde1, Katsuyuki Fukutani1 and Taro Hitosugi1; 1Tokyo Institute of Technology, Japan; 2Japan Science and Technology Agency, Japan; 3The University of Tokyo, Japan

Yttrium oxy-hydride (YO\textsubscript{1-x}H\textsubscript{x}, cubic, \(a = 5.35\) Å) is a promising material for optoelectronics applications such as smart windows and optical sensors, because optical transparency and electrical resistance can be reversibly switched by sunlight irradiation [1]. It is reported that the resistance of YO\textsubscript{1-x}H\textsubscript{x} is reduced by one order of magnitude on irradiation of sunlight [1]; however, the resistance change is smaller than that of the commercially available CdS (three orders of magnitude). A possible reason of the small response in the resistance is their polycrystalline nature of YO\textsubscript{1-x}H\textsubscript{x} films deposited on glass substrates [1, 2].

In this study, we fabricated epitaxial YO\textsubscript{1-x}H\textsubscript{x} thin films, and investigated the influence of crystallinity on the photochromic response. We observed a sunlight-induced resistance decrease by three orders of magnitude, comparable to that of CdS, and finally achieved reversible light-induced insulator-to-metal transition using UV-laser irradiation.

Epitaxial thin films of YO\textsubscript{1-x}H\textsubscript{x} were deposited on single-crystalline yttria-stabilized zirconia (YSZ) (111) substrates using reactive magnetron sputtering (thickness: \(~150\) nm). We monitored the four-probe resistance of the YO\textsubscript{1-x}H\textsubscript{x} epitaxial thin films during the light irradiation using a solar simulator (intensity: 1 mW/mm\textsuperscript{2}) and a UV laser (wavelength: 375 nm, intensity: 15 mW/mm\textsuperscript{2}).

Irradiation of sunlight for 30 min. reduced the resistance in YO\textsubscript{1-x}H\textsubscript{x} epitaxial thin film by three orders of magnitude (2\times10\textsuperscript{8} W to 2\times10\textsuperscript{5} W). Furthermore, we found that the irradiation of UV-laser (more intense light) for 90 min. induced insulator-to-metal transition in YO\textsubscript{1-x}H\textsubscript{x} epitaxial thin films. The original four-probe resistance of as-grown YO\textsubscript{1-x}H\textsubscript{x} epitaxial thin film was \(~5\times10\textsuperscript{7} W\) (high resistance state). After the UV laser irradiation, the resistance sharply dropped accompanying color change, and finally reached 2\times10\textsuperscript{1} W (low resistance state). In this low resistance state, surprisingly, the temperature dependence was metallic in the range of 4 – 300 K. We next annealed the UV irradiated sample at 125°C for 2 h in 4%-H\textsubscript{2}/Ar gas atmosphere of 0.05 MPa. As a result, the optical transparency and the high resistance state recovered. We again irradiated UV-laser onto the YO\textsubscript{1-x}H\textsubscript{x} sample and confirmed the metallic behavior. These results demonstrate the reversible light-induced insulator-to-metal transition in YO\textsubscript{1-x}H\textsubscript{x} epitaxial thin films.

Free-Standing 2D Oxide Nanomaterials and Hybrids with Exotic Physical Properties

Xudong Wang; University of Wisconsin--Madison, United States

Two-dimensional (2D) nanomaterials, particularly when their thickness is just one or a few atomic layers, exhibit
physical properties dissimilar to those of their bulk counterparts and other forms of nanostructures. Nonetheless, 2D nanostructures so far have been largely limited to naturally layered materials, i.e. the van der Waals solids. A much larger and diverse portfolio of 2D materials including non-layered compounds are desirable to meet the specific requirements of individual components in various devices. We demonstrate that surfactant monolayers could serve as a soft template supporting the nucleation and growth of 2D nanomaterials in large area beyond the limitation of van der Waals solids. Through this approach, 1 to 2 nm thick, single-crystalline free-standing ZnO nanosheets with sizes up to tens of microns were synthesized at the water-air interface. This technique was denoted as Ionic Layer Epitaxy (ILE) – the first solution-based technique for growing large-area ultrathin nanosheets without the support of crystalline substrates. Mimicking the biomineralization processing by using mix charge surfactants led a successful synthesis of single-crystalline nanosheets from a broad range of functional oxide materials, including CoO, MnO₂, Bi₂O₃, etc. New physical properties emerged from the ultrathin geometry. For example, stable p-type conductivity was observed from the ZnO nanosheets as a result of electron depletion. High concentration of cation or oxygen vacancies could be controlled by the surfactant modulation, leading to superior magnetic property and memristive behavior. Substantially enhanced electrochemical catalytic performance was also discovered from multiple ultrathin oxide systems. In general, ILE vastly broadens the range of 2D nanomaterials from layered van der Waals solids to oxide ceramics, opening up opportunities for discoveries of exciting transport, magnetic, photonic, and catalytic properties.

van der Waals Epitaxy of Ferroelectric LiNbO₃ Thin Film Ru Jia and Jian Shi; Rensselaer Polytechnic Institute, United States

The superior ferroelectric and nonlinear property of LiNbO₃ makes it a popular and promising candidate for electro-optics, energy converter and memory devices. However, integration of LiNbO₃ on technologically important substrates has been a challenge. In this work, by pulsed laser deposition, we synthesize epitaxial LiNbO₃ thin films on muscovite mica through van der Waals epitaxy. We apply X-ray diffraction to characterize the impurity phase and optimize the growth condition. We reveal the in-plane epitaxy relation by pole figure/X-ray diffraction phi scan. We obtain freestanding LiNbO₃ thin films by mechanical exfoliation. Raman spectroscopy is used to confirm LiNbO₃ phase after transfer from muscovite mica. Ferroelectric and pyroelectric devices out of freestanding LiNbO₃ reveal giant polarization in film of a few tens of nanometers in thickness. Our work shows that van der Waals epitaxy may enable the feasibility of integrating high-quality LiNbO₃ onto semiconductor substrates such as Si, opening a window in pursing novel heterogenous devices and circuits.

Study of Charge Transfer in IGZO Phototransistor with Various Type of Quantum Dots Byoung-Hwa Kwon, Sooji Nam, Chul Woong Joo, Jae-Eun Pi, Sung Haeng Cho, Seong-Deok Ahn and Seung-Youl Kang; Electronics and Telecommunications Research Institute, Korea (the Republic of)

Amorphous oxide semiconductor based thin film transistors (TFTs) using quantum dots (QDs) have great potential for photosensors because they show high sensitivity to light and excellent electrical properties (field effect mobility and on/off ratio) [1]. In most studies, characteristic evaluation of QD-based oxide phototransistors is the effect of interest. However, the interface and the charge transfer between the oxides and the QDs are rarely reported. In this presentation, indium–gallium–zinc oxide (IGZO) TFTs with QDs are fabricated and characterized. We uses QDs with core and core/shell structures and with various surface ligands. In order to explore the change of electrical energy levels and chemical bonding between the IGZO and the QD according to different surface treatments, ultraviolet photoelectron spectroscopy (UPS) and X-ray photoelectron spectroscopy (XPS) measurement are carried out. Lastly, we perform time resolved photoluminescence (TRPL) measurement on the IGZO with various type of QDs to clarify the carrier transfer mechanism.

Acknowledgment

The excellent intrinsic properties of aligned nanofibers, such as carbon nanotubes (CNTs), and their ability to be easily formed into multifunctional 3D architectures motivates their use as shape-engineerable materials for a variety of commercial applications, such as batteries, chemical sensors for environmental monitoring, and energy harvesting devices. While controlling nanofiber adhesion to the growth substrate is essential for bulk-scale manufacturing, application-specific performance, and integration with advanced device platforms, limited experimental approaches and models to date have neglected to address the scaling of CNT array-substrate adhesion ($F_a$) with processing conditions, and a mechanistic understanding of this phenomenon is still unknown. In this work, we synthesize vertically aligned CNT arrays by chemical vapor deposition and combine experimental and modeling techniques to study a simple, post-growth annealing step we call 'cementation' and its effect on $F_a$ as a function of temperature ($T_c$) up to $1000^\circ$C. This process, which increases $F_a$ by two orders of magnitude ($\sim 0.5$–$50$ N/cm², as measured via uniform CNT array delamination from a flat growth substrate) enables the capillary densification of CNT arrays spanning three orders of magnitude in height (μm-mm scale) to create dense, patterned architectures whose geometries can be accurately predicted by elasto-capillary theory. Here, the non-monotonic scaling of $F_a$ with $T_c$ is quantified and modeled analytically based on contact mechanics theory and the atomic- and meso-scale evolution of CNT-catalyst-substrate interfaces. Extensive morphological, structural, and chemical characterization of the CNT arrays and CNT-substrate interfaces is performed via scanning and transmission electron microscopy, Raman spectroscopy, X-ray diffraction, and X-ray photoelectron spectroscopy. These results show that higher $T_c$ reduces the CNT-catalyst number density, graphitizes and stiffens the CNT roots to increase $F_a$, and alters the mechanical deformation mode during CNT-substrate separation, consistent with the model results. Using this approach, this work provides new insights into the interfacial interactions responsible for variable nanofiber-substrate adhesion and enables the creation of shape-tunable architectures for advanced sensors, energy devices, and emerging nanoscale technologies.
build a model between two forms of precursor alloys, ligament sizes and the resultant products. Finally, the electrochemical reactions within the NPC structures could be predicted and well-controlled.

**Analysis and Detection Based on Solid Nanopore/Channel**

Fan Xia; China University of Geosciences, China

Various types of transmembrane pores and ion channels in the range of 1-100 nm are found in each biological cell, playing crucial roles in various significant physiological activities such as maintaining cell osmotic balance and stabilizing cell volume. Inspired by this natural phenomenon, different biomimetic nanodevices (nanopore/channel) with different characteristics have emerged as an attractive and powerful platform and have been used for a wide range of applications. Generally, the principle of analysis applications based on solid nanopore/channel can be described as follows: molecules access or attach on the inner surface of a nanopore/channel, change the effective diameter of the nanopore/channel, or affect the charge transfer as well as the wettability of the inner surface of the nanopore/channel, leading to ionic current changes that can be detected.

**EN15.06.03**

**Non-Enzymatic Sensing of Glucose Based on Au Nanoparticles and TiO2 Modified Polyaniline**

Wan-Ting Chiu1, Tso-Fu Mark Chang2, Masato Sone2, Agnès Tixier-Mita1 and Hiroshi Toshiyoshi1; 1The University of Tokyo, Japan; 2Tokyo Institute of Technology, Japan

In this study, Au NPs and TiO2 integrated into PANI are synthesized by facile and time-saving electrochemistry techniques of low waste emission. The stability of Au NPs-TiO2/PANI, which superior than most of reported results, reached up to 70 days. The sensitivity and detection limit are 355.8 μA mM⁻¹ cm⁻² and 0.15 μM (S/N=3), respectively. It is also confirmed that Au NPs-TiO2/PANI performs high selectivity by the interference test. The current response of the developed Au NPs-TiO2/PANI electrodes were tested 5 times, and the relative standard deviation was obtained to be 1.30%, indicating a high reliability of the electrode preparation method. The evaluated results suggest the applicability of Au NPs-(0.05)TiO2/PANI electrode for glucose sensors. More than 285 million people worldwide are suffering from diabetes mellitus, which is a major public health problem today [1]. Therefore, accurate, fast, and reliable sensors for detecting glucose are attracting a great attention to prevent further development of diabetes mellitus. Electrochemical sensors are considered to be the most promising measure due to its good sensitivity, rapid response, outstanding selectivity, high reliability, portability, and user friendliness. Electrochemical glucose sensors are further divided into enzymatic and non-enzymatic types. Enzymatic sensors are considered to be less stable than non-enzymatic ones since its accuracy tend to fluctuate easily with temperature, humidity, pH, and toxic chemicals.

In the non-enzymatic glucose sensors, metals such as Pt, Pd, Au, Ag, Cu, Ni, CuO, NiO, and their derivatives are found to be intrinsically electroactive to the electrooxidation of glucose. Since the faradic current arising from the glucose oxidation can be enhanced by increasing the surface area, the aforementioned metals and metal oxides in nano scale have been considered as a promising candidate. In particular, Au is at the top of the list due to its high electrocatalytic activity and negative oxidation potential for the oxidation of glucose [2]. Oxides such as ZnO, CeO2, and TiO2 were utilized for achieving well distribution of nano-structure Au, since they have an effect to immobilize the Au nanoparticles (NPs) and impede the aggregation of Au NPs due to the anchoring effect. In this work, TiO2 was chosen to control the Au NPs due to its low cost, biocompatibility, and ease of modification. TiO2 also showed a great affinity to H2O and OH⁻, which is a critical factor for the oxidation of glucose in the aqueous solution. Electrooxidation of glucose, which is catalyzed by Au NPs, is benefited from the OH⁻ on the adjacent TiO2, and hence the current of electrooxidation of glucose is enhanced. Polyaniline (PANI), which is a common electrically conductive polymer, was utilized as a supporting material in this study, for its low cost, good stability, and good electrical conductivity [3]. Nano-materials (i.e. metal NPs and/or oxides) integrated with PANI enhanced the electrochemical properties, such as augmented amount of nano-materials loading on electrode, accelerated electron transfer, and homogeneous distribution of nano-materials. These improvements accordingly result in improved electrocatalytic activity to the oxidation of glucose.

It has been known that the fabrication process for the non-enzymatic glucose sensor is tedious and time-consuming. In this study, however, a facile and time-saving procedure to fabricate Au NPs-TiO2 decorated PANI was conducted. Furthermore, by virtue of the facile and time-saving procedure, little waste-solution emission was realized.

Infrared thermal imaging is a key technology used in night vision, surveillance, medical diagnosis, firefighting, as well as in the chemical, metallurgical and petroleum industry, where the monitoring of thermal processes is fundamental for correct and safe operation. A microbolometer measures the temperature changes through the change in the resistance of a thermosensor material as a result of the absorption of infrared radiation. The operation of the uncooled microbolometers is carried out at room temperature, which is convenient and advantageous for systems of smaller size, weight, power, and cost (SWPaC). Microbolometers are generally made of vanadium oxide (VOx) or amorphous silicon (a-Si:H), both types must meet the requirements of low resistivity to perform a coupling with the reading circuit and a large temperature coefficient of resistance (TCR). In addition, the material must have low electrical noise and, in order to reduce manufacturing costs, be compatible with standard integrated circuit (IC) fabrication processes. As a result of the current trend, it is evident that amorphous silicon is receiving a lot of attention in its application and improvement as the active sensing layer due to its compatibility with IC processes. However, it still has a high level of noise and electrical resistivity. By modifying the deposition parameters during the growth of a-Si:H, it can be turned into a nanostructured material. Hydrogenated polymorphous silicon-germanium (pm-Si$_x$Ge$_{1-x}$:H) is a material composed mainly of an amorphous matrix with embedded nanocrystals (approximately 2-5 nm) produced in the plasma cloud and incorporated during growth. These nanocrystals improve transport properties and resistance to radiation-induced degradation, which translates into better performance and long-term stability. Here we present the characterization of a pm-Si$_x$Ge$_{1-x}$:H alloy deposited by plasma enhanced chemical vapor deposition (PECVD) at 200 °C and the application of this in microbolometers. The material properties as surface roughness, TCR and resistivity have been investigated. Device performance having an area of 50x50 µm$^2$ was evaluated through responsivity and noise measurements.

Hierarchical nanoscale structure plays a vital role in achieving excellent property, which can successfully be used in preparing tailor-made materials for sensing applications. These hierarchical nanostructures can successfully be prepared with the help of structure directing agents (SDAs). This work reports the preparation of polyaniline (PANI) nanorods in the presence of anionic (sodium dodecyl sulfate, SDS) and nonionic surfactant (Pluronic F127) as the SDAs. We prepare a series of ternary composites with varying ratio of PANI and F127 for a given amount of SDS. The SDS and F127 play a pivotal role as SDAs in delivering a hierarchical nanostructure of PANI. Detailed characterization reveals that the in-situ polymerization of PANI confirms the formation of the well-disperse composite. The amphiphilic character of F127 facilitates the formation of a core-shell micellar structure, which in turn facilitates the polymerization of PANI in the core region. We have observed a composition based structure formation of the ternary composites. At the increasing amount of F127, the composite exhibits higher crystallinity (viz. less porosity) ensured via XRD and microscopy images. Among them the synthesized composite at the 1:1 ratio of PANI and F127 exhibits less porosity (viz., high crystallinity) explored by BET surface area measurements. The XRD analysis does not show a sharp peak, which signifies that the material acquires a polycrystalline structure, as revealed by HRTEM analysis. The polycrystalline nature of the nanorods facilitates the highest thermal stability, contributes significantly towards the enhanced electrochemical activity and thus, can successfully be used in sensing applications. The 1:1 material shows remarkably highest glucose sensitivity (~485.787 µA/cm² mM) compare to ternary composites under amperometric measurements. The sensor shows an excellent electrochemical performance within a range of 5 to 50 mM with a lower detection limit of ~3.202 µM.

Detection of Digitized Phase on Electromagnetic Wave by Nanomechanical Resonator and Influence of Temperature Keita Funayama$^{1,2}$, Hiroya Tanaka$^1$, Jun Hirotani$^2$, Keiichi Shimaoka$^1$, Yutaka Ohno$^{2,3}$ and Yukihiro Tadokoro$^1$; $^1$Toyota Central R&D Labs., Inc., Japan; $^2$Nagoya University, Japan
Nanomechanical resonator offers the possibility of an ultrasensitive detection of various physical quantities, with emerging applications including signal processing, biological detection and fundamental tests of quantum mechanics. By exploiting a vibration of nanoscale cantilever, electromagnetic wave has been reported to be detected even with a nanoscale detector. However, the detector cannot correct the whole energy of the wave due to its ultra-small size, which results in the failure of the detection. Here, to improve the detection performance, we introduce digital signal processing for nanomechanical systems.

We first suggested the nanomechanical phase detector, which consists of single carbon nanotube (CNT) cantilever\(^1\). Here, the digitized phase of the electromagnetic wave is to be detected. In the proposed detector, the tip of the CNT vibrates according to the phase. The amplitude of the vibration can be observed via field emission current; the oscillation of CNT varies the current, and the original phase information can be estimated by observing the current. Analytical investigation reveals an interesting point that the information is contained in two frequency components of the current. By introducing a simple signal processing that combines these components with optimum weights, our analysis shows that the detection performance is significantly enhanced.

One of the critical issues in the detector is the dependence on temperature. In traditional semiconductor physics, the current inherently depends on temperature, which affects on the detection performance. To analyze the influence of the temperature variation, a mathematical model of the mean and variance of the current was first derived based on experimental results\(^2\). The obtained mathematical expression shows that both the mean and variance exponentially increase with increasing temperature. Based on this result, the detection performance was also analyzed; as the increase of the temperature, the variance is significantly increased, and then the detection is likely to be failed. This analysis indicates that to secure the reliable detection, temperature should be kept low like room temperature.

Above results provide a novel framework of detecting the electromagnetic wave in nanomechanical systems. The operational condition regarding temperature was also derived. Notable point is that the digitized phase of the electromagnetic wave can be detected in the nanoscale detector. This indicates that digitally modulated signals, which are often used in digital communications, can be detected even with nanomechanical systems. This opens up a new paradigm to transfer digital data, which contributes to the forthcoming age with IoT and AI-based systems.

EN15.06.07

**Highly Sensitive and Transparent Polymer Thermistors Composed of Silver Fractal Dendrites and Polyacrylate**

Jongyoun Kim and Youngu Lee; DGIST, Korea (the Republic of)

Temperature is an important parameter that regulates chemical reactions of the environment and has been developed until recently for monitoring in various fields. Particularly, developing polymer positive temperature coefficient (PTC) thermistors is attracting much attention because they have several advantages including high sensitivity, flexibility, conformability, biocompatibility, and biodegradability. However, most polymer PTC thermistors including containing a high concentration of opaque filler materials still have issues such as low sensitivity, low optical transparency, and poor operational durability due to low electrical conductivity and inefficient hopping transport. Here, a highly sensitive, flexible, and transparent polymer thermistor based on silver fractal dendrites (AgFDs) and a polyacrylate (PA) matrix has been successfully demonstrated. AgFDs–PA composite films are prepared using a simple melt-mixing process for the AgFDs and molten PA. It exhibits a superior PTC effect (about \(10^6\text{~}10^7\) Ω) around body temperature because of the high electrical conductivity of the AgFDs and the quantum tunneling effect resulting from their unique structures. A flexible and transparent thermistor based on the AgFDs–PA composite shows excellent sensitivity, detection resolution, and fast sensing response through dramatic resistance changes in the human body temperature range. Moreover, it exhibits excellent optical transparency, mechanical flexibility, and operational durability. In addition, electrical impedance spectroscopy (EIS) analysis proved that the quantum tunneling effect amplified by the AgFD branch has a significant effect on the changes in resistance. Based on these characteristics, the thermistor was successfully demonstrated for real-time temperature monitoring of human body.

EN15.06.08

**Atomistic Molecular Dynamics Simulations of Nanomaterial Adhesion on Calcite Surface Defects in Deionized Water and Reservoir Fluids**

Hsieh Chen\(^1\), Shannon L. Eichmann\(^2\) and Nancy A. Burnham\(^3\); \(^1\)Aramco Services Company: Aramco Research Center-Boston, United States; \(^2\)Aramco Services Company: Aramco Research
Calcium carbonate (CaCO₃) is a widely important mineral that is found extensively in biological and geological systems. The interaction of water, ions, organic molecules, macromolecules, and nanomaterials with calcite surfaces controls a broad range of natural and industrial processes such as ion exchange, contaminant migration, enhanced oil recovery, biomineralization, and flocculation. Previously, an atomic force microscopy (AFM) study and molecular dynamics (MD) simulations demonstrated that carboxylate alkanethiols functionalized AFM tips (as surrogates for nanomaterials) showed mitigated adhesion to calcite surfaces in fluids with specific ions. The MD study also showed that calcite crystallography affected adhesion as a result of surface calcium ion exposure. Here, we extended the MD simulations to explore the effects of calcite surface defects. Specifically, we focused on four line and point defects on the calcite (104) surfaces: (1) acute step, (2) obtuse step, (3) Ca⁺² vacancy, and (4) CO₃²⁻ vacancy. In addition, we considered three fluids: (1) deionized water (DI), (2) seawater (SW; 0.7 M NaCl), and (3) brine (B; 1.28 M NaCl + 0.34 M CaCl₂), which the latter two are relevant in subsurface hydrocarbon reservoir applications. The simulation results showed that the calcite surface defects have the strongest effects on adhesion in DI compared to in SW and B, where in DI the adhesion were changed by -30% on obtuse step, -10% on Ca⁺² vacancy, and +25% on CO₃²⁻ vacancy. On the other hand, in SW and B the adhesion changed within ±10% in most cases. Interestingly, we observed an inversion of the adhesiveness of vacancies compared to no-defect surfaces in different fluids, where the Ca⁺² vacancies were less adhesive in DI but more adhesive in SW and B, and the CO₃²⁻ vacancies were more adhesive in DI but less adhesive in SW and B, due to counter ion accumulations on the vacancies. We believe the atomic-level understanding obtained in this work can be helpful for developing novel nanomaterials for subsurface applications and may further the understanding of wettability alteration mechanisms in ionic fluids.

EN15.06.11
Structural and Optical Properties of In-Doped ZnO Thin Films Prepared for Flexible and Transparent UV Photodetector Euije Jo, Dongwan Kim and Jae-Young Leem; Inje University, Korea (the Republic of)

Zinc oxide (ZnO) has attracted a great deal of interest because it has direct wide band gap of 3.37 eV at room temperature (RT) and large exciton binding energy of 60 meV, and these properties make ZnO a suitable material to fabricate a variety of optoelectronic devices, such as light-emitting diodes, laser diodes, optical communication, and solar cells. In addition, ZnO represents several other interesting advantages like high optical transparency in the visible region and high carrier mobility, so it can be applied as flexible and transparent UV photodetectors. But, ZnO has high electrical resistivity owing to its low carrier concentration induced by native donor defects, interstitial zinc, and oxygen vacancies which degrade the optical and electrical properties of ZnO thin films-based UV photodetector. Thus, many researchers have doped with group three elements such as aluminum, gallium, and indium acted as donor dopants for ZnO to reduce the electrical resistivity of ZnO thin films [1]. Particularly, the indium-doped ZnO (IZO) represents higher optical transmittance, better conductivity, and excellent surface roughness than the other dopants doped ZnO. IZO thin films can be synthesized by various techniques such as physical or chemical vapor deposition, pulsed laser deposition, atomic layer deposition, and sol-gel spin coating method. Among these methods, sol-gel spin coating method has some advantages including uniformity of thickness, controllability of composition, simplicity, and low cost [2]. However, since the sol-gel spin coated IZO thin films must be annealed at high temperature to crystallize the amorphous phase of IZO, the IZO thin films-based flexible and transparent UV photodetectors which utilize the polymeric substrate couldn’t have been fabricated by sol-gel spin coating method. Therefore, it is necessary to develop a new annealing method which prevents damage to polymeric substrate that are affected by high temperature during annealing process. In this study, we annealed the sol-gel spin-coated IZO thin films by using a novel method, synchronized heat and cool annealing (SHCA) method, which anneals thin films on top with IR heaters and simultaneously removes the high light energy transferred to polymeric substrate using cold plate. To investigate the effect of indium on the structural and optical properties of IZO thin films annealed by SHCA method, we measured the IZO thin films by using X-ray diffraction (XRD), and photoluminescence (PL). As a result of the measurement, in the XRD, IZO thin films showed the three diffraction peaks corresponding to ZnO (100), (002), and (101) plane, and the diffraction peak of ZnO (002) plane was red-shifted. For PL, the intensity of the near-band-edge and deep-level emissions for IZO thin films significantly increased, which indicates that carrier concentration and the number of defects in the ZnO lattice increased, respectively.

EN15.06.12
Gas Detection System Using Color Films by Chitin Based Colorimetric Thin-Film Effect Dong Jin Han and
Byung Yang Lee; Korea University, Korea (the Republic of)

By detecting gases, we can take early measures in keeping the safety and freshness of our life. So far, various types of highly sensitive and selective gas sensors have been reported using carbon nanotubes or nanowires as sensing materials. However, these previous reports have limits in their practical application due to the need of electrical power and high manufacturing cost. Here, we introduce a biomimetic colorimetric film that can be utilized for the detection of ethylene glycol. The film is fabricated by Chitin on a silicon surface by a thermal evaporation from a Chitin powder. The film enable to thin-film effect into stable color patterns. By controlling the evaporation times 1 to 3, the film thickness could be controlled from 50 to 180 nm, resulting in films with different colors in the visible range.

When the Ethylene glycol reacted with the amine groups on the Chitin-film by etherification, the films underwent both chemical and structural changes, resulting in color changes in sub-ppm concentrations.

We demonstrated that sensing data analysis interlocked with a phone camera and discriminant analysis algorithms can further discriminate gas concentration in air. We expect that our results will be utilized in providing a low-cost and low-power systems for the monitoring of gas.

EN15.06.13
Structural, Electrical, Optical and Thermal Properties of Gallium Doped Zinc Oxide (GZO) Thin Film for Transparent Heater Applications
Jasmine Beckford, Makhesh K. Behera, Kelsea Yarbrough, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

There is an increased interest in thin film transparent heaters (TFTH) for applications in optoelectronics, military, de-icing of airplane wings, defogging of windshields, and a plethora of domestic usages such as smart windows, defrosters in automobiles and many other applications. In this work we present the growth and characterization of one of the potential TFTHs, Gallium doped zinc oxide (GZO). GZO thin films were deposited by pulsed laser deposition (PLD) on transparent substrates such as glass and flexible polymer. Ga doped (5 atomic weight percentage) ZnO target was made in the laboratory using Ga2O3 and ZnO powder. GZO films with thickness 110 and 125 nm were deposited on glass and flexible polymer at substrate temperatures of 400°C and 120°C, respectively. Atomic force microscopy images reveal that the films are very smooth with excellent surface roughness (~1.18 nm). The temperature dependent resistivity measured was done using linear four probe measurement and the samples showed a very low sheet resistance value of about 2.6×10-4 Ω cm and also exhibited high optical transparency value of (>90%) from transmission data. GZO transparent heater also showed a stable and reproducible Joule heating effect and the temperature can reach easily 100°C by the application of low input (~8V) voltage. This research finding may be beneficial for the potential use of GZO as a transparent oxide material for possible applications in the emerging area of low-cost power electronics, and flexible and wearable optoelectronics devices.

Spectral Photosensitivity and Lifetime of Mg2Si Photodiodes for SWIR Sensor Application
Fumiya Takahashi, Yuutarou Fuse, Takeru Miyauchi and Haruhiko Udonou; Ibaraki University, Japan

Photodetectors in the short wavelength infrared region (SWIR: 0.9 to 2.5 μm) have attracted attention for use in environmental monitoring, night vision, automotive autonomous driving and also biological research. Recently, we thermally diffused Ag to an n-type Mg2Si substrate to fabricate a Mg2Si pn junction photodiode (PD), and succeeded in obtaining photosensitivity below a cutoff wavelength of about 2.1 μm. The lifetime of minority carrier is important to enhance the photosensitivity of PDs, but so far the lifetime of Mg2Si has not been investigated. In this paper, we measured the lifetime of Mg2Si pn junction PDs fabricated by the thermal diffusion method in the temperature range from 300 K to 77 K by the open circuit voltage method (OCVD) method. The observed voltage decay waveform which is a result of the time required for the minority carrier decay became longer with decreasing the temperature and reached maximum at about 160K. The minority carrier lifetimes determined from the OCVD measurements were 0.5 μs at 300 K, 5.3 μs at 160 K, and 3.8 μs at 77 K, respectively. Furthermore, the relationship between the measured minority carrier lifetime and the photosensitivity of the fabricated device was investigated.

Near Infrared Reflective Coatings for LiDAR Sensor with Optically Controlled Multilayers Youngseok Kim, Jin Hwan Kim, Hyunsang Park and Sangwon Seo; Korea Electronics Technology Institute, Korea (the Republic of); Kangnam Jevisco Co., LTD., Korea (the Republic of)

LiDAR sensors, a primary sensor used on AVs, utilize emitted light pulses, typically at 905nm, to remotely detect the location of objects. Incident light from the LiDAR sensor is both specularly reflected by the clearcoat and absorbed/reflected by pigments in the basecoat. Paint colors that reflect a greater amount of light at 905 nm are more easily detected by LiDAR. Thus, technologies to enhance paint reflectivity at 905 nm, while not affecting the appearance of the paint, are desirable. However, most black and dark tone cars are painted with paints based on carbon black pigment that exhibits very low reflectivity not only for the visible but the infrared light. Alternately, autonomous vehicles need to raise the laser power to detect the black vehicles, which is highly energy consuming. As the automotive market changes, the development of new black paint with high infrared reflectivity has become necessary.

Here, we design a dark-tone multilayer with low reflectivity at the visible wavelengths and high reflectivity at 905nm at the same time. Various oxide materials including Fe₂O₃, CuO, TiO₂, SiO₂, and Al₂O₃ are investigated, and the reflectivity is calculated as a function of the multilayer’s composition, the number of layers, and the layer thicknesses. We find an optimized multilayer and deposit the constituents by using sputtering on a glass substrate alternately. Finally, the measured reflectivity shows a good agreement with the simulation. We expect it can be materialized as a pearl pigment that is a plate type particle with tens of aspect ratio by depositing the oxide materials on pulverized substrate materials or by pulverizing the substrate with deposited materials.

Hybrid Cellulose Nanocrystal Nanocomposite-Based Biosensor for Detection of Uric Acid and Lactate Joseph Laws, Pedro Cortes, Eric Macdonald and Byung-Wook Park; Youngstown State University, United States

The advanced nanomaterials and fabrication methods for various biomarkers, including pH, glucose, uric acid, and lactate, are important to monitor the wound healing process. Numerous sensing techniques have been developed for effective wound monitoring. Cellulose nanocrystals (CNCs) have been attractive bio/nanomaterials, due to the high specific surface area and specific strength, hydrophilicity, biodegradability and surface functionalization. In this study, we have successfully developed hybrid CNC nanocomposite biosensors for detection of uric acid and lactate. The CNC and polypyrrole (Ppy) nanostructures were fabricated on the electrode by electropolymerization. Subsequently, the urease or lactate oxidase was immobilized on the CNC-Ppy modified electrode. The structural investigation was performed to examine the growing mechanism of the CNC-Ppy nanocomposite on the electrode surface using physical and chemical characterization methods, such as SEM, FTIR, EIS, and CV. The stability, reproducibility, repeatability, selectivity and linearity of the biosensor were investigated. The proposed biosensor exhibits high sensitivity and was fully selective. The developed hybrid nanocomposite biosensor is cost effective and the fabrication method is relatively simple, providing an excellent sensing platform for efficient electrochemical biosensing of uric acid and lactate.

A Scalable Solution-Processed Inorganic Passive Radiative Cooler for Tropical Regions Chongjia Lin, Yang Li and Baoling Huang; Hong Kong University of Science and Technology, Hong Kong

Air conditioning consumes a significant amount of electricity in summer, especially in humid tropical regions. Passive radiative cooling can radiate heat to the outer space through the infrared atmospheric window (8-13 um) without any energy consumption, providing an attractive approach for cooling buildings. Most of the state-of-the-art daytime radiative coolers show high solar reflection but high emission in the whole mid-infrared (mid-IR) regime (5-25 um) without good spectral selectivity beyond the atmospheric window, and their cooling performances under humid climates are limited. Besides, most of them adopt organic components that face aging issues when exposed to sunlight. In this study, we developed a solution-processed inorganic passive radiative cooler with high mid-IR emissivity, good mid-IR selectivity and high solar reflectivity. It illustrates a high solar reflectivity up to 98% and a high infrared emissivity of 90% within the 8-13um atmospheric window. Compared with the state-of-the-art passive coolers, it can achieve high cooling power in both mid-altitude (>85W/m²) and humid area (>25W/m²) and better cooling temperature (-7.6°C) in tropical areas, due to its good mid-IR selectivity. Its high cooling performance and excellent scalability render it promising for space cooling in humid tropical regions.
Domain Spacing versus Chain End Density Effect on Energy Storage Capacity of Lamellar Block Copolymer Film Capacitors

Maninderjeet Singh1, Mei Dong2, Saumlal Samant3, Monali Basutkar3, Michael Durstock4, David Tran2, Sushil Satija2, Karen L. Wooley2, Dharmaraj Raghavan6 and Alamgir Karim1; 1University of Houston, United States; 2Texas A&M University, United States; 3Intel Corporation, United States; 4Wright Patterson Air Force Base, United States; 6National Institute of Standards and Technology, United States; 1Howard University, United States

Designing next generation light-weight pulsed power sources hinges on understanding the factors influencing the performance of high energy density storage materials. We have demonstrated the use of Cold Zone Annealing with Soft Shear (CZA-SS) as a processing strategy to fabricate highly stratified lamellar block copolymer (L-BCP) films which results in ~50% enhancement in breakdown voltage ($E_{BD}$) or ~225% increase in stored energy density ($U$), compared to unordered as-cast films. Increasing L-BCP layer thickness, $d$ by increasing $M_w$ increases $E_{BD}$ but kinetics of ordering is challenging at high L-BCP $M_w$. Modestly high molecular weight films of amorphous L-BCP of PS-$b$-PMMA with layered morphology exhibited $U$ of 4.8 J/cm$^3$, comparable to the industry standard of semi-crystalline BOPP films of ~5 J/cm$^3$. Efforts continue to demonstrate the full potential of the method. Notably, $E_{BD}$ was found to increase linearly with $M_n$ of neat L-BCP and will be reported. Blending L-BCP with homopolymers or cyclics is an alternate approach to increase layer thickness. While blending increases L-BCP layer thickness, chain ends of linear homopolymers act as defect sites for promoting breakdown in the L-BCP polymer films, that may be avoided by addition of cyclic polymers. Neutron Reflectivity and X-ray scattering (GISAXS) measurements confirm stratified lamellar structure in blend systems for correlations to $E_{BD}$. Neutron reflectivity measurements show that the ‘wet brush regime’ swelling of L-BCP with cyclics and homopolymer are comparable while ‘dry brush regime’ swelling differ significantly. The breakdown strength of L-BCP swollen with cyclics will be reported. These findings can be vital in the selection of L-BCP for designing next generation high energy density, solid-state polymer capacitors for flexible electronics.

Nanoporous Silver for SERS Fabricated by Nucleation and Growth Control During Evaporation

Eunji Lee1, Jaeyeong Lee2, Jungi Min1, Woomi Kwon1, Hak Ki Yu2 and Sangwoo Ryu1; 1Kyonggi University, Korea (the Republic of); 2Ajou University, Korea (the Republic of)

Evaporation techniques for making dense metal films typically utilize a high vacuum process. Through the conversion of the idea of high-pressure evaporation, it was possible to create highly porous structure of silver by increasing background working pressure to a few Torr. In this evaporation process, opposite to the typical thermal evaporation, evaporated silver atoms encounter repeated collision with the surrounding Ar gas molecules and this causes homogeneous nucleation and growth of silver. The nucleation and growth are controlled by adjusting the working pressure, temperature, evaporation rate, etc., resulting in different morphology and porosity. The higher the pressure, the higher the porosity and the darker the structure becomes absorbing light more. As evidenced by SEM and TEM, the porous structure consists of aggregates of crystalline nanoparticles of silver ranging tens of nanometer to hundreds of nanometers. Especially, a lot of nano-sized gaps are found between the particles. These nanogaps can act as a hot-spots for surface-enhanced Raman spectroscopy (SERS). Using rhodamine-6G, we show these nanoporous structures of silver outperform commercial test substrates of SERS. This new approach of metal deposition can contribute to other areas that need high surface-to-volume ratio such as catalysts and gas sensors.

Cellulose Based Triboelectric Nanogenerator for Electronic Paper and Environmental Sensors

Inkyum Kim and Daewon Kim; Kyung Hee University, Korea (the Republic of)

With the development of internet of things (IoT), energy harvesting technologies are evolved to increase the operation time of small electronics without consuming more fossil fuels in recent years. In addition, natural materials have recently been attracting much attention due to their eco-friendly and abundant properties. Above all, cellulose, which plays a role of the primary cell wall of green plants, is the most abundant organic compound on earth. In this work, we investigate a cellulose nanofiber-based triboelectric nanogenerator (CN-TENG), which was developed to convert vertical moving energy into an electrical energy. The top and bottom parts of the CN-TENG consist of silver nanowires (AgNWs) and cellulose nanofiber (CNF), respectively. The electrical output of this CN-TENG was measured by contacting and separating with only two sheets of fabricated devices. The CN-TENG with a
higher pressure and increased number of passes in the homogenizer during fabrication from the suspension represents highest open-circuit voltage of 21 V and short-circuit current of 25 µA, respectively. AgNWs layer with the concentration of 0.1 wt% showed saturated electrical outputs. Scanning electron microscope (SEM), X-ray photoelectron spectroscopy (XPS), and atomic force microscopy (AFM) were utilized to analyze the components and surface morphology in order to investigate the correlation between the surface morphology and the electrical output. Additionally, a 693 mW/m² power density was observed at an external resistance of 10 MΩ. Moreover, this fabricated film shows the characteristics of foldable, writable, erasable This fabricated CN-TENG can be developed as a paper-based electrical energy generator for various applications such as e-paper.

EN15.06.21
The Depth Analysis to Enhance the Efficiency of Triboelectric Nanogenerator as a Wind Speed Sensor and Energy Harvester Hyoeunhee Roh and Daewon Kim; Kyung Hee University, Korea (the Republic of)

A triboelectric nanogenerator (TENG) can convert mechanical energies into electrical power with excellent conversion efficiency. TENGs can generate electrical energy based on contact-electrification and electrostatic induction. Among the various operating modes, a rotating-disk-based TENG harvesting wind energy is being studied extensively because it can produce high current. Deep analysis of the flow of the fluid is essential to improve the conversion efficiency of the TENG.

In this paper, the propeller TENG (P-TENG) was designed to demonstrate the relationship between TENG and fluid mechanics as a wind energy harvester and wind speed sensor. The P-TENG is mainly composed of three parts: a rotator (propeller) and a stator (electrode), and a main body. The P-TENG has the cylindrical structure—having a diameter of 8.8 cm and height of 3 cm—and an inlet and outlet on the side and top, respectively. The rotator (propeller) and main body were 3D-printed of acrylonitrile butadiene styrene (ABS). The ABS has outstanding resistance to chemicals, heat, and impact. When the wind energy is injected into the main body, it collided with the perpendicular plane of the propeller and cause the rotational motion.

The five factors (the pressure of the injected gas, the distance between the stator and rotator, the number of propeller wings, and the height and angle of the inlet) were changed to verifying the electrical characteristics of the disk-based TENG and to examine the gas flow within the P-TENG. The highly injected pressure of the fluid causes the higher rotating speed, as a result, it contributes to increasing the current. In this regard, the P-TENG can act as a wind speed sensor without an external power source. Also, the comprehensive analysis conducted based on these electrical output results. The COMSOL simulation was carried out to calculate the value of pressure to the propeller and the flow of fluid. The laminar flow was applied as physics condition and solved with the Navier–Stokes equations. The injected fluid was analyzed by dividing it into four flows in the vertical and horizontal directions and each flow influences the rotational motion in a way to improve or reduce.

Based on the comprehensive analysis, the optimized P-TENG consists of the 16-sector propeller, a low inlet height, a 60° inlet angle, and PTFE film with a nanostructured surface. Finally, the P-TENG can power 205 LEDs as well as a commercial stopwatch in real time, without any other power source. The P-TENG enabled Bluetooth transmission and reception and drove the sensing, processing, and data transmission of a commercial temperature and humidity sensor, so it can be used as a power source for a self-powered wireless sensor system. The investigation of P-TENG provides not only the possibility that using as a self-powered wind speed sensor and maximized energy conversion efficiency by optimizing the structure of the device based on depth analysis of the flow of fluid.

EN15.06.22
Anti-Kasha Effect of Graphite-ZnO Nanocomposite without Dropping Fluorescence Intensity in Water—A Cyanide Sensor Somrita Mondal; Calcutta University, India

Of late, carbon-based nanomaterials have been prevalent research topic owing to their potential application and especially excitation-dependent diverse fluorescence emissions. The later property can be tremendously useful in sensing, imaging, and photovoltaics. However, applications using this unique fluorescence property of carbon-based nanomaterials have not been explored so far, which may be due to a significant drop in fluorescence intensity in longer wavelength region after photoexcitation of the nanomaterials. In this paper, we report a simple aqueous synthesis of ZnO-graphite nanocomposite, which displayed unusual excitation dependent fluorescence emission violating the Kasha’s rule, without significant shrink in the fluorescence intensity at longer wavelength region. Moreover, the fluorescence intensity of the nanocomposite monotonically increased with the addition of cyanide ion of millimolar concentration. The fluorescence enhancement followed Langmuir binding isotherm, which enables quantitative detection of cyanide. The phenomenon of unique excitation-dependent emission along with
fluorescence enhancement in the presence of cyanide ion opens up a new avenue for the design of a multichannel array-based sensor to detect toxic and environmentally hazardous analytes.

A Study of Lifetime and Binding Energies of Excitons in Mn-Doped PbS Nanoparticles Grown in Solution
Gen Long1, El Mustapha Lotfi2, Elmustapha Feddi3 and Mostafa Sadoqi1; 1St. John's University, United States; 2Université Mohammed V de Rabat Maroc, Morocco; 3Mohammed V University, Morocco

Lead Sulfide (PbS) is a unique material system that is interesting for photovoltaic, thermoelectric, and sensing applications. In this work, we report a systematic study of syntheses of Manganese (Mn) doped lead sulfide (PbS) nanoparticles via varying growth temperature (50°C to 120°C), growth time (10min to 24hrs), with various precursors’ ratios (Mn : Pb). The synthesized nanoparticles (2~5nm) were characterized by UV-VIS absorption, XRD, EDS, TEM, XRD, etc. The lifetimes of emissions of doped nanoparticles measured by ultrafast spectroscopy were found to be affected by Mn concentration, ranging from 5ns to 100ns. The DOS of nanoparticles simulated by DFT method were also found to be dependent upon the doping concentration. The band gaps were found out to be not affected by the doping concentrations. Through tuning of doping concentration, the material properties of Mn-PbS nanoparticles can be modified based on specific applications.

EN15.06.25
Optical Properties of Mechano-Luminescence-Optoelectronic Composites for Vibration-Based Structural Health Monitoring
Alfred Mongare, Donghyeon Ryu, Willow Lindsey-Paek, John Huckabee and Nikolai Kalugin; New Mexico Tech, United States

Vibration-based structural health monitoring (SHM) systems allow to evaluate the state of the structure and the presence of damage. [1] For the detection of damage by sensing strains under vibrations without external electrical energy supply, multifunctional mechano-luminescence-optoelectronic (MLO) composites were suggested. [2] MLO composites use two transformative materials – vibration-sensitive light-emitting mechano-luminescent (ML) material, and photosensitive electrical-response generating material. [3] As a result, MLO composites generate direct current (DC) by harvesting mechanical energy from ambient vibrations in tested structures via the coupled two-step energy conversion mechanism (i.e., mechanical-radiant and radiant-electrical energy conversions). [4] The two functional constituents – ML copper-doped zinc sulfide (ZnS:Cu)-based elastomeric composites and mechano-optoelectronic (MO) poly(3-hexylthiophene) (P3HT)-based films – of the MLO composites are designed to selectively sense different modes of vibrations. [5] The MO P3HT-based thin films generate DC by utilizing light emitted from ML ZnS:Cu-based composites. Being combined together, our materials and devices represent a new class of self-powered and multi-modal sensor technology that can potentially enhance self-sustainability of, for example, unmanned aerial vehicles, or other remotely controlled mechanisms.

In our study, two functional constituents – ZnS:Cu-and P3HT-based composites – will be prepared and characterized. Optical spectra of ZnS:Cu and PDMS; ZnS:Cu-PDMS composites will be obtained using Raman, FTIR, and photoluminescence spectroscopies. Depending on the Cu doping concentration, the PL spectra of ZnS:Cu-PDMS have a maximum of emission in green (low doping concentration) or blue (higher Cu concentration). Composites with ZnS, which is co-doped with Cu and Mn, show orange luminescence. In addition, all tested samples demonstrate broad-range room temperature luminescent signals in the range of 0.86-0.84 eV, which seems to be attributed to optical transitions via AN, AS and PS centers of Cu2+ in ZnS. This indicates possibilities of the coexistence of different structural forms and different particle sizes of ZnS in the ML ZnS:Cu-PDMS composites. ML spectrum from different repetition loading frequencies and strains will be obtained. Luminescence from ZnS:Cu-PDMS was found to be sensitive to the strain and strain rate. The photodetection spectra of MO P3HT-based composites show a sensitivity peak around 590-600 nm (2-2.1 eV); the experiments with different light modulation frequencies reveal the dynamical limitations of this type of photodetector. Overall, simultaneous optical characterization of ML and MO constituents of MLO composites opens up possibilities for “fine tuning” of both ML and MO constituents for the achievement of maximal mutual compatibility and optimal performance of the entire multifunctional MLO composites.

We would like to thank NASA’s Space Grant College and Fellowship Program and NASA EPSCoR CAN (grant #: 80NSSC17M0050) for supporting this study.

CNTs can have the ability to act as compliant small-scale springs or as shock resistance micro-contactors. This work investigates the performance of vertically-aligned CNTs (VA-CNTs) as compliant, micro-contactors in electromechanical testing applications for testing at wafer-level chip-scale-packaging (WLCSP) and wafer-level-packaging (WLP). Fabricated on ohmic substrates, 500-μm-tall CNT-metal composite contact structures are electromechanically characterized. The probe design and architecture are scalable, allowing for the assembly of thousands of probes in short manufacturing times, with easy pitch control. We discuss the effects of the metallization morphology and thickness on the compliance and electro-mechanical response of the metal-CNT composite contacts. Pd-metallized CNT contactors show up to 25 μm of compliance, with contact resistance as low as 460mΩ (3.6 kΩ/mm) and network resistivity of 1.8 x10^{-5} U cm, after 25000 touchdowns, with 50 μm of over-travel; they form reproducible and repeatable contacts, with less than 5% contact resistance degradation. Failure mechanisms are studied in-situ and after cyclic testing and show that, for top-cap-and-side metallized contacts, the CNT-metal shell provides stiffness to the probe structure in the elastic region, whilst reducing the contact resistance. The stable low resistance achieved, the high repeatability and endurance of the manufactured probes make CNT micro-contactors a viable candidate for WLP and WLCSP testing. Furthermore we show the addressability of individual probes for an array with 200 μm pitch by utilising ink-jet printing after on-chip CNT-metal hybrid probe fabrication allowing to address 144 individual probes. The stable low resistance achieved, the high repeatability and endurance of the manufactured probes make CNT micro-contacts a viable candidate for WLP and WLCSP testing.

Designing and Structural, Optoelectronic Characterization of Nanocrystalline TiO2-Based Hybrids for Solar Devices Sagar D. Delekar, Ananta Dhodamani and Krantiveer More; Shivaji University, India

Herein, the different chemical strategies have been adopted for tuning the properties of nanocrystalline TiO2 so as to form the ternary hybrids and thereafter these hybrids have been tested for efficient solar-to-electrical conversions through photovoltaic measurements. Initially, nanocrystalline TiO2 have been anchored with the different systems such as dyad system, dye-quantum dot system, composites with carbon nanostructures sensitized through dye. Along with optical coverage for better absorption, the interconnectivity between the various components and their charge-transport properties of modified TiO2 for solar energy conversions have been studied in detail. In the dyad system, a supramolecular ruthenium (II) phthalocyanine (RuPc) with peryleneimide (PI) has been anchored on the surfaces of TiO2 and thereafter these TiO2-dyad sensitized solar cells have assembled in a bottom-up fashion. Upon photo-irradiation at air-mass (AM) 1.5, the dyad-based solar devices convert solar light to electricity of 2.1%; which is higher than that of individual dyes. In next strategies, the synthesized CdS quantum dots (QDs) have connected electrostatically to the surfaces of TiO2 nanoparticles (NPs) and thereafter, this binary hybrid heterojunction is further self-assembled physically with N719 dye to form ternary TiO2 NPs-CdS QDs-N719 photoelectrodes. These co-sensitization devices reported the solar energy conversion efficiency (η) up to 2.35 %. In addition, anatase TiO2 NPs is anchored on the surface of functionalized carbon nanostructures (MWCNTs or RGO); which is further sensitized with Ru(II) dyes for solar devices having efficiency reached to 6.21%. In another modification, Cr(III) as well as Mo(VI) ions are inserted into TiO2 host lattice and then their composites with CNs are further sensitized with dyes for boosting the solar energy conversions and reached up to 7.69 % of efficiency.

EN15.06.29
Surface Modification of Gold Nanorods to Enhance the Detection of Hg2+ John Crockett1, Luan Tianqi1,2 and Eli Doebler1; 1Western Washington University, United States; 2University of Georgia, United States

The abundance of mercury (II) in trace amounts throughout the ecosystem, combined with its ability to accrue in human tissue has motivated the need for highly sensitive and selective detection methods. Gold Nanorods (AuNR) have demonstrated a unique facility for the detection of mercury due to their plasmonic properties and the propensity for mercury and gold to form an amalgamation. Prevalent methods for the synthesis of AuNR’s utilize high concentrations of cetyl trimethylammonium bromide (CTAB) which forms a dense micelle bi-layer on the exterior of the AuNR’s. The sensitivity of AuNR’s to mercury has been shown to be extremely diminished with increasing concentration of CTAB, however reduction of CTAB concentration led to aggregation of the AuNR’s. CTAB was exchanged for polyethylene glycol thiol (PEG) as a capping agent on the AuNR’s resulting in much better stability and a significant increase in both sensitivity and selectivity for detection of mercury (II) over CTAB coated AuNR’s. The increased stability of PEG coated AuNR’s also allows for manipulation of the region of highest sensitivity to mercury (II) by changing the concentration of AuNR’s. It was also discovered that the sensitivity of PEG coated AuNR’s to mercury (II) could be as much as tripled with incubation of the PEG coated AuNR’s. This increased sensitivity has been attributed to the preferential removal of PEG from the tips of AuNR’s by the formation of a complex between PEG and mercury (II) which has a higher stability than the complex between gold and PEG.

EN15.06.31
Identifying Chemical Structure Responsible for the Reactivity of GO Regarding Oxidative Amine Coupling Reaction Kazuyuki Takai, Ryutaro Suzuki, Takuya Isaka, Kentaro Tajima and Tomoki Yamashina; Hosei University, Japan

Graphene oxide (GO) having oxygen-containing groups is expected as metal-free and environment-compatible catalyst. The research on GO catalyst progressed [1 - 3], although the detail mechanism for GO catalytic activity is not clear yet. Investigating Graphene Oxide (GO) properties before / after the catalytic reaction is a promising strategy for clarification of the mechanism for GO catalytic activity. Additionally, it is known that removing oxidative debris on GO by base-treatment is important factor to get the higher yield for the following catalytic reaction [1]. In this study, the principle for reactivity of GO is investigated by conducting the oxidative amine coupling reaction of benzylamine (1) to N-benzylimidobenzylamine (2) using baGO and thermally reduced one (rbaGO) as catalysts. baGO-Pristine was obtained by washing GO, synthesized by Hummers method, with NaOH. rbaGO was prepared by reducing baGO at 450C under Ar gas flow. After the reaction, the reaction media filtered for
removing the catalyst was characterized by GC-MS. After the 1st cycle reaction, the recovered catalyst was used as that for the 2nd cycle (baGO-1st cycle, rbaGO-1st cycle). The chemical structure of each catalyst after the reaction was evaluated by XPS (Al Ka), where it was washed with ethanol after the reaction. The atomic ratio O/C of catalyst much decreases after the reduction or 1st cycle reaction and rbaGO shows poor yield, suggesting roles of baGO / rbaGO not as catalyst but as oxidant. However, baGO-1st cycle exhibits the highest yield in spite of C1s spectrum and O/C similar to that of rbaGO and rbaGO-1st cycle, which also indicates no more reduction for rbaGO in the 1st cycle reaction. Taking these results and appearance of nitrogen content after the 1st cycle reaction into consideration, a different mechanism in the 2nd cycle reaction is suggested, where nitrogen incorporated into rbaGO / baGO in the 1st cycle reaction plays an important role for the reactivity. To clarify the most responsible functional groups in rbaGO / baGO for the higher catalytic reactivity in the 2nd cycle reaction, we have derived the amount of nitrogen-containing functional group per 100 mg in each GO sample for the 2nd cycle reaction. By plotting the amount of nitrogen-containing functional group and the GC-yield of the product, the correlation coefficient r is calculated for each functional groups. In particular, the GC-yield tends to increase as Graphitic N (correlation coefficient r = 0.94) and Oxidized N (correlation coefficient r = 0.87) increase. The important roles of those functional groups in the oxidation amine coupling reaction could be explained by the enhancement in the oxygen adsorption ability, which is important to produce O2*- species from ambient oxygen molecules for proceeding the oxidative coupling reaction.

Novel Highly Accurate and Sensitive Graphene-based Nanocomposite Electrochemical Sensor of Cilostazol Pharmaceutical Agent Mahmoud A. Saleh1, Manar M. Taha1, Nasaah Ahmed1, Mona Mohamed2 and Nageh K. Allam1; 1American University in Cairo, Egypt; 2National Organization for Drug Control and Research, Egypt

Cilostazol is a quinolone antiplatelet agent that contributes to vasodilatation. It can be used to relief the symptoms of intermittent claudication (decreased blood supply in the lower limps) that is attributed to ischemia. Also, it relieves the cramping pain that occurs during heavy exercises. Its main mode of action is the inhibition of both primary and secondary agglomeration of platelets, which is an important issue in drug monitoring. Herein, we report on the modification of carbon paste electrodes (CPE) with transition metal oxides (TMO), which showed a superior accuracy and sensitivity towards cilostazole than unmodified CPE. Characterization of the composite was done by scanning electron microscope (SEM), X-ray diffraction (XRD), Fourier transform Infrared (FTIR), Cyclic voltammetry (CV), and square wave voltammetry (SWV). Moreover, the addition of reduced graphene oxide as a composite material has increased the current and sensitivity of the CPE to cilostazole. The ratio of the graphene to TMO in the composite was optimized to achieve the maximum response. The electrochemical sensor showed high linearity, sensitivity, and very low limit of detection in both Britton Robinson Buffer (BRB) and spiked plasma and urine samples.

Crystal Facet Selective Photo-Induced Etching of GaN Nanostructures in Water Max Kraut, Florian Pantle, Julia Winnerl, Martin Hetzl, Felix Eckmann, Ian D. Sharp and Martin Stutzmann; Technische Universität München, Germany
GaN nanowire (NW)-based devices have gained increasing interest for applications in solar driven photocatalysis and sensing due to the intrinsically high surface-to-volume ratio, the excellent achievable crystal quality and possible electro-magnetic field enhancement within periodic array [1]. Many materials that are catalytically active and sensitive to environmental changes, suffer from insufficient stability under operational conditions. By investigating the accelerated corrosion of hexagonal, dodecagonal and round GaN NWs in deionized water under high intensity illumination, we find that the crystallographic c-plane facet is stable, while a- and m-plane are etched with rates up to 11 nm/min, depending on the applied light intensity and wavelength. We identify photo-excited holes that are driven to the NW surface by the upward band-bending present in not intentionally doped GaN as the driving force of this process. Consequently, structural defects decrease the etching rate by serving as recombination centers for photo-induced carriers, which is shown by low-temperature photoluminescence and scanning electron microscopy investigations. The gained fundamental insights allow the development of viable strategies for the stabilization of the nanostructures under light-driven reaction conditions and harsh environments, which include facet engineering, change of doping type and shell growth.

In the present work, we investigate routes towards a direct photo-electrochemical water-splitting and conversion of CO₂ into useful chemicals via the integration of a light absorber and boron-doped diamond electrodes as cathode and anode material. In such a system, silicon photoelectrode is responsible for the light absorption, charge carrier generation and separation (p-n junction), while BDD electrodes protect the Si surface from its inherent corrosion in an aqueous media.

Nanocrystalline BDD electrodes have been fabricated via microwave plasma-enhanced chemical vapour deposition process [3]. We show that nanocrystalline BDD layer (thickness of 150 - 300nm) deposited onto Si photoelectrode allows for photogenerated hole charge carrier transfer from the underlying Si towards the electrolyte solution to participate in water oxidation reaction. Addition of the water oxidation catalyts onto the BDD surface reduces the overpotential for the water oxidation. Nanocrystalline BDD electrodes of various thicknesses and electrical conductivity values have been investigated for the CO₂ reduction in water-based electrolytes to establish a relationship between the BDD layer structure/composition and the products observed from CO₂ conversion. This work has been supported by the Grant Agency of the Czech Republic (GACR) contract 19-09784Y.

Efficient 3D Printed Pseudocapacitive Electrodes with Ultrahigh MnO₂ Loading Bin Yao¹, Swetha Chandrasekaran², Marcus A. Worsley² and Yat Li¹; ¹University of California, Santa Cruz, United States; ²Lawrence Livermore National Laboratory, United States

Achieving excellent electrochemical performance of electrodes at high mass loading holds significant importance to energy storage. Pseudocapacitive materials such as manganese oxide (MnO₂) deposited on current collectors have achieved outstanding gravimetric capacitances, sometimes even close to their theoretical values. Yet, this is only achievable with very small mass loading of active material typically less than 1 mg cm⁻². Increasing mass loading often leads to drastic decay of capacitive performance due to sluggish ion diffusion in bulk material. In this talk, I will demonstrate a 3D printed macroporous graphene aerogel electrode with MnO₂ loading of 182.2 mg cm⁻², which achieves a record-high areal capacitance of 44.13 F cm⁻². The engineered porous structure allows efficient ion diffusion and therefore enables the ultrahigh mass loading of pseudocapacitive materials without sacrificing their gravimetric and volumetric capacitive performance. Most importantly, this 3D printed graphene aerogel/MnO₂ electrode can simultaneously achieve excellent capacitance normalized to the area, gravimetry, and volume, which is not possible for traditional electrodes. This work successfully validates the feasibility of printing practical pseudocapacitive electrodes, which might innovate the conventional layer-by-layer stacking fabrication process of commercial supercapacitors.

MnO₂/Multi-Walled CNT Electrodes for Supercapacitors Manufactured by Material Extrusion 3D Printing Yuqi Gao and Junjun Ding; New York State College of Ceramics at Alfred University, United States

The development of electrodes with high specific capacitance remains the main challenge for energy storage nowadays [1]. As an emerging technique, material extrusion 3D printing [2] provides an alternative pathway for designing and fabricating electrodes of supercapacitors by controlling the 3D macrostructures and nanocomposites.

In this work, MnO₂-nanoparticles and multi-walled CNT are mixed with polyvinylpyrrolidone (PVP) and deionized water as designed inks for desired rheological properties, which allow material extrusion from the nozzle. The inks are then used to print the nanocomposite electrodes layer by layer, followed by thermal treatment in the argon atmosphere. The ink composition is studied for the printability. PVP and deionized water tune the viscosity of the ink so that the ink can be printed fluently and completely, while multi-walled CNTs, served as conductive networks and interconnects in the nanocomposites for the high efficiency of electron delivery [3].

The 3D printed electrodes effectively integrate MnO₂ and multi-walled CNT, which achieves more abundant interactions caused by the higher loading of MnO₂ without the traditional binder of polyvinylidene fluoride (PVDF)
In addition, the stacking and alignment of MnO\textsubscript{2} and multi-walled CNT via material extrusion 3D printing provides the flexible tunable thickness \cite{5} of electrodes by controlling the printing layers (design and test one, two, four, eight layers with a 0.4 mm in diameter nozzle, respectively). This approach provides a promising way of manufacturing the needed electrodes in multiple aspects of size, shape, and dimension.

**Keywords:** MnO\textsubscript{2}/multi-walled CNT electrodes, supercapacitors, material extrusion 3D printing.

Assessment of MgZr\textsubscript{4}P\textsubscript{6}O\textsubscript{24} Composite Electrolyte for Fabricating Solid-State Mg-Sensor and Sensing Mg in Liquid Al

Mohammed Adamu and Girish M Kale; School of Chemical and Process Engineering, University of Leeds, United Kingdom

The potential solid-state electrolyte, MgZr\textsubscript{4}P\textsubscript{6}O\textsubscript{24} was synthesised by a modified sol-gel method. The structural, electrical and thermodynamic properties of this solid-state electrolyte were determined. DSC-TGA analysis indicated that pure dried xerogel powder when calcined at 800°C and 900°C, converts to single phase MgZr\textsubscript{4}P\textsubscript{6}O\textsubscript{24} nanopowder with good crystallinity. Pellets of 13-mm diameter and 3.8-mm thickness made by uniaxial compression were sintered at 1300°C for 24h. XRD and HR-TEM indicated that the crystalline phase is monoclinic having crystallite sizes of approximately 32nm and 40nm, after calcining at both temperatures, respectively, showing positive temperature effect on crystallite size. The sintered pellets were stable in the temperature range from 1000 to 1300°C, with minor extraneous peaks indicating traces of a coexistent second phase, Zr\textsubscript{2}(PO\textsubscript{4})\textsubscript{2}O at higher temperatures. Using electrochemical impedance spectroscopy, the electrical conductivity of MgZr\textsubscript{4}P\textsubscript{6}O\textsubscript{24} was determined as 7.23 x 10\textsuperscript{-3} Scm\textsuperscript{-1} at 725°C \cite{1}. MgZr\textsubscript{4}P\textsubscript{6}O\textsubscript{24} pellet was successfully employed for the design and fabrication of solid-state Mg-sensors for sensing Mg concentration in liquid Al at 700±5°C, with a biphasic powder mixture of MgCr\textsubscript{2}O\textsubscript{4}+Cr\textsubscript{2}O\textsubscript{3} as the ceramic reference electrode in air. A linear dependence of emf on logarithm of Mg concentration was obtained. Thermodynamic measurements using electrochemical method was deployed. The measured voltage of the sensor emf against the theoretical emf was achieved and compared, and an average transport number for Mg\textsuperscript{2+}-cation in the MgZr\textsubscript{4}P\textsubscript{6}O\textsubscript{24} solid-state electrolyte is approximately 0.85(±0.03) at 700±5°C, which is in agreement with an earlier study \cite{2}. The thermodynamic activity of Mg in liquid Al shows a negative deviation from the Raoult’s law. MgZr\textsubscript{4}P\textsubscript{6}O\textsubscript{24} solid-state electrolyte has useful applications in a stable, highly-sensitive, high-temperature electrochemical Mg-sensors during scrap metal recycling, refining and virgin metals alloying.

Electronic and diffusion properties of hydrogen in ZnO have been extensively studied, since efficient defect engineering is essential to fabricate electronic, ferroelectric, and optical devices [1-2]. We introduced the protons in ZnO from chemical doping and/or proton implantation. To investigate the properties, we employed $^1$H nuclear magnetic resonance (NMR) relaxometry, which is a powerful technique of atomic-scale access to probe ion hopping motion in solids. Herein, we unambiguously identify the proton species which were occupied at the surface or in the bulk of ZnO, from their distinct NMR relaxometry and resonance shifts. NMR relaxometry gives the activation barriers of interstitial H in the bulk to be 0.46 eV by means of the rotating-frame spin-lattice relaxation measurements. Besides, it turns out that correlated jump diffusion of the surface hydroxyl group of multiple lines at ~1 ppm indicates the presence of structural disorder at the ZnO surface [1]. Hence, $^1$H NMR relaxometry may shed light on identifying proton species and investigating proton dynamics in hydrogen-incorporated systems.

Study of Nano-Materials for Hydrogen Leak Detection Sensors Nicolas Javahiraly; University of Strasbourg, France
We present in this work the study of nano materials for hydrogen leak detection sensors. On example of a configuration that can be used is based on a original transducer layers deposited on the core of a multimode fiber optic. The reference transducer layer is a multilayer stack based on a silver, a silica and a palladium layer. The spectral modulation of the light transmitted by the fiber allows to detect hydrogen. The sensor is only sensitive to the Transverse Magnetic polarized light and the Transverse Electric polarized light can be used as a reference signal.

The multilayer thickness defines the sensor performances in terms of sensitivity, SNR and time response. The silica thickness tunes the resonant wavelength, the silver (or gold) supports the plasmon and the palladium detects the hydrogen gas in the environment.

This study synthesizes the sensors performances as a function of different parameters such as the sensitive materials, different thicknesses, numerical apertures…

**Nanocarbon Icing Sensor and Dew Point Hygrometer** Vladimir Samuilov; Stony Brook University, The State University of New York, United States

This research is devoted to the development of a totally novel platform of carbon nanomaterial icing sensors and dew point hygrometers and to the fundamental understanding of the adsorption of water molecules, the mechanisms of nucleation of liquid water and crystallization into solid ice at the molecular level and nano-scale.

Our sensor is a film of carbon nanomaterial. Water molecules adsorption and phase transition of the first order of water into ice can be precisely detected by measuring of this carbon nanotube or graphene oxide film resistance. Further applications of the icing sensor will help to detect and to prevent the ice building up on specific surfaces like airfoils in aerospace vehicles, and will helps to the development of the methods to mitigate or inhibit icing phenomena.

The sensitivity range of the nanocarbon dew hygrometer ($T_D$) (frost ($T_F$)) is extremely wide from as low as -90°C to higher than +30°C. The applications can include the standard ones, like dew point hygrometers and cryopreservation of cells and tissues, food processing, or ice-templating the morphology of materials, etc.

**Thermal Transport in Additively Manufactured Glassy Carbon Nanowires and Nanolattices** Shiva Farzinazar and Jaeho Lee; University of California Irvine, United States

Advanced additive manufacturing has enabled an unprecedented material design space that spans over a wide range of structures and properties. While the additively manufactured nanomaterials have demonstrated fascinating mechanical properties, their thermal properties, and potential capabilities of controlling heat transfer have received little attention. The controlled thermal properties of additively manufactured nanomaterials could lead to efficient sensing and control of various energy systems, and the understanding will contribute to the emerging field of thermal metamaterials. Here we use a combination of two-photon polymerization direct laser writing (TPP-DLW) and pyrolysis to create glassy carbon nanowires and nanolattices. The pyrolysis process induces a high-strain shrinkage up to 80% and allows the formation of glass carbon nanowires with an aspect ratio as large as 640, in which the nanowire length is in an average of 48 µm, and the diameter is in an average of 75 nm. The large aspect ratio allows characterization of the heat capacity as well as the thermal conductivity. We use an electrical resistance thermometry technique known as the 3ω method to simultaneously characterize the electrical conductivity, thermal conductivity, and heat capacity of the glassy carbon nanowires over a wide range of temperature. The electrical conductivity of the glassy carbon nanowires increases from 22740 S/m at room temperature to 27757 S/m at 748 K, and their thermal conductivity increases from 2.4 Wm⁻¹K⁻¹ at room temperature to 7.0 Wm⁻¹K⁻¹ at 748 K. The increase in electrical and thermal conductivities is attributed to an increasing rate in graphitization ratio as a function of temperature. We measured the volumetric heat capacity of 2.1×10⁶ J/m³K for glassy carbon nanowires as compared to the amorphous carbon which has a specific heat capacity of 1.8×10⁶ J/m³K. The glassy carbon nanowires also provide excellent thermal stability, high Young’s modulus (20-30 GPa), and low density (1.3-1.5 gcm⁻³), which would be useful for sensing and control systems in extreme environments. Furthermore, we use the same manufacturing and characterization methods to create glassy carbon nanolattices and control the porosity up to 99%. Our investigations show that thermal properties of nanolattices can range from that of bulk materials to nanowires and offer unique capabilities of decoupling mechanical and thermal properties. The outcomes of this work advance our understanding of size, shape, and temperature dependences of thermal transport in additively
manufactured nanomaterials, and these findings will guide future designs of sensing and control of various energy systems.

Unique Plasmonic Coupling at Nanojunction and Ultrafast Detection Nasrin Hooshmand and Mostafa El-Sayed; Georgia Institute of Technology, United States

Merging optics and nanotechnology has led to a remarkable fundamental insight into the interaction between light and matter at the nanoscale. The unique capacity of plasmonic nanostructures to concentrate electromagnetic fields, scatter electromagnetic radiation, makes them important in many scientific areas, including imaging, near field scanning optical microscopy, and chemical and biological sensing. Taking advantage of plasmonic nanoparticles especially those made of gold and silver is necessary to develop techniques to design responsive material with high sensitivity, selectivity, and high spectral resolution. Manipulation of the tight confinement of light across the gap of assembly of plasmonic nanoparticles could enable possibilities to achieve this idea. Plasmonic optical modes are very sensitive to the surrounding media, because of their electromagnetic field distribution around the particles. With considering a plasmonic nanoparticle as a thousand dipole points, when they are exposed to electromagnetic radiation, for nearby particles, dipole-dipole interaction has the most contribution in their plasmonic coupling. However, achieving even more tightly hot spots (confined fields) at the gap size of 2 nm or less requires to consider other multipole modes in the coupling phenomenon. This study develops new models of plasmonic equation that takes account the contribution of multipolar modes in the plasmonic coupling of pairs of silver nanoparticles at nanojunction separation. As the inter-dimer axis decreases, an increase in the plasmon dipolar and multipolar interaction takes place. It reveals that the plasmonic coupling depends on the density of the dipoles on the nanoparticle; as the dipole density increases, the average multipole density increases, resulting in higher dipole-multipole interactions. This research aims to design more sensitive optical sensors, which have many applications including single-molecule spectroscopy, biomedical and ultrafast optoelectronic applications.

Aligned, Suspended PVDF-TRFE Nanofibre Webs Fabricated by Dynamic Near-Field Electrospinning (dNFES) Patrick Stipp1,2, Wenyu Wang1 and Yan Yan Shery Huang1; 1University of Cambridge, United Kingdom; 2ETH Zürich, Switzerland

Most acoustic sensors are based on rigid Micro-Electro-Mechanical Systems and are optimised for high-frequency applications (>10k Hz). These systems often distort the airflow during measurement and require an additional output power source. Herein, we demonstrate a high performance, self-powered acoustic sensor platform. A dynamic Near-Field Electrospinning (dNFES) method is developed to fabricate suspended and interconnected sub-micro scale fibre webs. Permissive to flow, these interconnected and suspended sub-micro scale fibre webs can precisely imitate tiny variations triggered by the surrounding airflow motion. Electroactive Poly(vinylidene fluoride-co-trifluoroethylene) P(VDF-TRFE) copolymers are used as material to create the self-powered sensing ability of the fibre webs. Our dNFESFP process enables us to fabricate novel fibre webs to produce an acoustic sensing device in a one-step process. Due to the suspension and flexibility of the fibre webs, the acoustic sensing device shows particularly high sensitivity at most audible acoustic waves (between 200-5000 Hz). Furthermore, the dNFESFP process is an easy-to-use and stable technique that demonstrates a high reproducibility. Lastly, the process allows the tuning of fibre webs to optimise the sensitivity of the acoustic sensing device to the frequency range of interest.
MEMS-Type Gas Sensor of Pd-Loaded SnO2 for Ultra-High-Sensitive Detection in ppt Level
Kengo Shimano, Koichi Suematsu and Ken Watanabe; Kyushu University, Japan

Ultra-High-Sensitive gas detection in ppt level have been proposed by using pulse-heating of MEMS attached with Pd-loaded SnO2. My group reported three important factors, receptor, transducer functions and utility factor, for gas sensor material designs and their integration in 2003 and 2006, respectively. In 2014, the gas sensor using Pd-loaded SnO2 clusters based on the idea of the above integration could successfully detect toluene in ppb level. To enhance the sensor response more, we investigated the combination of utility factor and pulse-heating of MEMS. The MEMS-type gas sensors are repeatedly heated and allowed to cool by the application of voltage to the microheater; the target gas can penetrate into the interior of the sensing layer (Pd-loaded SnO2 clusters) during its unheated state. In 2018, we reported that such sensor responded to toluene in 0.1 ppb. In addition, the sensor response was found to increase by considering the oxygen adsorption state in the preheating and waiting-time before pulse-heating for measurement. The response of MEMS-type gas sensors showed a linearity to toluene concentration. It is found that the sensor response depends on the waiting-time between pre-heating and measure-heating. For example, in relationship of sensor response to gas concentration, the short waiting-time gave a steep slope, but the long waiting-time gave a gentle slope with lower detection limit. In the presentation, I will show the details as such Ultra-High Sensitive gas sensor.

Flexible Metal Oxide Nanowire Chemoresistors
Miriam Alvarado, Ernesto Gonzalez, Silvia DeLaFlor, Alfonso Romero, José Luis Ramirez and Eduard Llobet; Universitat Rovira i Virgili, Spain

New developments in consumer electronics, especially in the rapidly evolving field of wearable electronics require the use of different types of sensor devices. However, the use of gas sensors within this paradigm remains incipient, yet shows potential for developing wide spectrum of applications with enormous associated markets. Gas sensitive nanomaterials such as single crystalline (pure or metal loaded) metal oxide nanowires (NWs) will find commercial application provided they are produced employing scalable techniques that enable the mass production of high quality materials at affordable costs. Solution processing methods and additive fabrication techniques are seen as interesting enabling technologies for coupling nanomaterials to their application substrates. Here we show how metal oxide NWs can be integrated in flexible polymeric substrates for achieving chemoresistors employing either direct growth or transfer techniques. In addition, we discuss the results of careful studies on the reliability of the resulting flexible sensors having undergone stringent, automated bending tests.

Results:
The transducers for chemoresistive sensors were produced via the inkjet printing of silver or gold electrodes and heating elements on a Kapton substrate. The electrode area was then coated with mats of pure or Pd-loaded tungsten oxide NWs. Two approaches were used for integrating the nanomaterials on the transducers: 1) The direct growth of
the nanomaterial via a single step aerosol assisted chemical vapor deposition (AACVD) process, which was run at 380°C, for ten minutes. 2) The ex-situ growth of metal oxide nanowires via AACVD, ink preparation and screen-printing onto the flexible transducer. For the bending tests, an AGS-X 10 kN, Shimadzu universal testing machine was used. A compression force was exerted and the sample buckled achieving a maximum deflection. The loading speed of the crosshead displacement was high to reproduce the real situation of a sudden bending (i.e. buckling). Moreover, the curvature radii achieved (<4 mm) represent very harsh conditions, well beyond what can be expected to happen to a wearable during its normal operational life. When directly grown onto flexible substrates, NW coatings showed better adhesion than their screen-printed counterparts. However, the direct growth of Pd-loaded NWs onto silver electrodes suffered from delamination failures because Pd reacts with Ag during the AACVD process. This was solved by inkjet printing Au, instead of Ag tracks. For tungsten oxide NW sensors, the permanent increase in electrical resistance of the active layer after bending was small (about 3%). The sensitivity to hydrogen remained unchanged. The differences observed before and after the bending process, resulted mainly from cracks that developed both in the gas sensitive layer and tracks. Such cracks generate permanent changes in the electrical resistance of the active layer, and therefore, modify the baseline and sensor response. Also, during the bending tests, NWs may change orientation and their NW to NW distance, which possibly modifies the binding energy and charge transfer between the gas sensing layer and the target gas molecules, producing slight variations (positive or negative) in sensor response. However, our results show that it is possible to produce reliable, flexible chemoresistors employing scalable, additive fabrication. After 50 cycles under tensile strain, the response of the sensors remains almost unchanged, which means that the sensing properties of the material are preserved despite the bending. This demonstrates that WO3 chemoresistive sensors on flexible substrates can withstand different harsh mechanical conditions and afterwards still be usable. In particular, inkjet-printed gold electrodes demonstrated to withstand the AACVD growth process and the bending tests, which allowed us to obtain truly flexible sensors that remained functional after over 200 cycles of harsh bending.

9:15 AM EN16.01.03
Fabrication of Oxide Nano-Structured Sensor Device for Low-Molecule Gas Sensor Tohru Sugahara¹, Leila Alipour¹, Yukiko Hirose¹, Jun-ichi Nakamura², Hironobu Ono², Nobuyuki Harada² and Katsuaki Suganuma¹; ¹Osaka Univ, Japan; ²Nippon Shokubai Co. Ltd., Japan

Sensing with tenuous volatile organic compounds (VOC) gas which contain in human exhalation is important issue for next generation healthcare. In recent years, gas sensors are much attention research topics to use synthesis nano-materials and fabricate conventional device product process. In the previous study, MoO3 nanorod arrays growth on the silica substrate with fixed diameters of 10 nm but controllable length of 20 - 600 nm has been successfully synthesized by a simple solution metal organic decomposition (MOD) method. Here, we are demonstrating fabrication of some oxide nanostructure gas sensor device for VOC gas with a very simple printed coating process. The sensor devices are evaluated gas sensing properties such as sensitivity, responsivity through morphology of the oxide nanorod arrays with each EtOH, MeOH, IPA and ACE volatile gas in this study. The gas sensors show good response performance with quick response and recovery time, as well as various selectivity of each VOC gas at 573 K. The relationship between adsorption/desorption abilities and morphology of the nanorod arrays will be discussed in detail on the symposium.

9:30 AM EN16.01.04
Optimally Designing Self-Powered Hydrogen Gas Sensor Platform—Toward Outstanding Response, Durability and Humidity-Independence Hyeonghun Kim and Gun Young Jung; Gwangju Institute of Science and Technology, Korea (the Republic of)

Following a research trend for mobile sensors being miniaturized and consuming negligible power, a chemo-resistor consisting of semiconductor and metal catalyst has become a promising platform as a gas sensor. However, a requirement of the continuous power supply into the device limits the miniaturization of the entire sensing system owing to the demand of energy storage system bulkier than the main body of the sensor. Moreover, gradual deterioration of the sensor arisen from aggregation or surface contamination of the metal catalyst, and humidity-interference on the sensing performance remain as major barriers. Herein, we fabricated a self-powered H2 sensor based on Pd-decorated n-indium gallium zinc oxide (Pd-IGZO)/p-silicon (Si) photodiode operated under white light. To induce significant photocurrent change before and after an H2 exposure, a novel diode architecture consisting of finger-type electrodes interposed between the Pd-IGZO film and Si substrate were contrived. The device surface
was covered by zeolitic imidazolate framework-8 (ZIF-8) in which micropores not only enabled amplifying the photocurrent change by accumulating gas (H\textsubscript{2} or O\textsubscript{2}) molecules at the vicinity of the Pd surface but also prevent instability issues of the Pd nanoparticles mentioned above. The sensor exhibited remarkable sensing response of 1.57×10\textsuperscript{4} % at 1 % H\textsubscript{2} under white light at an irradiance of 5 mW cm\textsuperscript{-2} without external bias, a limit of detection of 35 ppm, and outstanding durability indicated as negligible change after 3 months. Besides, a self-powered humidity sensor with identical architecture to the H\textsubscript{2} sensor except the Pd was separately fabricated and exploited to correct the humidity-interference of the H\textsubscript{2} sensor, resulting in marking an accurate H\textsubscript{2} concentration even at ever-changing humidity. In conclusion, the dual sensing platform paves the way for resolving the main drawbacks of the traditional chemo-resistor.

**EN16.01.05**
Highly Selective and Sensitive Distinct Flower-Like ZnO Microstructure Based Gas Sensor with Optimized CTAB Concentration for Detection of NO\textsubscript{x} at Room Temperature

Srijita Nundy\textsuperscript{1} and Tae-yil Eom\textsuperscript{2};
\textsuperscript{1}Sungkyunkwan University, Korea (the Republic of); \textsuperscript{2}Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

Nitrogen oxides (NO\textsubscript{x}) is considered as toxic molecule giving harmful influences not only on the human body but also on the environment [1]. A highly selective and sensitive NO\textsubscript{x} gas sensor operating at room temperature (25 °C) based on flower-like ZnO (FZO) microstructures were successfully fabricated by a CTAB-assisted hydrothermal process at 90 °C. We report the hydrothermal synthesis of ZnO microstructures with a gradual increase of CTAB concentration forming nanorods (0M), nanorods assembled structure (0.001M) to flower-like (0.005M) and studied morphology dependent gas sensing behavior to NO\textsubscript{x} gas at low temperature (25 °C). The characterizations of the as-prepared samples were done in detail by using X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, photoluminescence (PL) spectroscopy and Brunauer-Emmett-Teller (BET). The gas sensing performance of sensors fabricated with as-prepared ZnO structures to various concentrations of NO\textsubscript{x}, ammonia, toluene, carbon monoxide, acetone, and ethanol, at various operation temperatures (25 to 150°C) was noted. A clear trend showing the effects of the morphology on the sensing behavior with temperature was demonstrated. The flower-like ZnO exhibited stability (up to 140 days) and excellent sensitivity with a high gas response of 29 which drops sharply with the increase of temperature and is highly selective towards 0.74 ppm of NO\textsubscript{x} at 25 °C without additional use of UV irradiation or doping materials such as Pt or Pd. The ZnO sample with 0.001M of CTAB shows a similar trend but with much lower sensitivities at low temperatures. For the sample without CTAB, the temperature behavior switches to a volcano-type one, in which the sensitivity is low at a low temperature and increases gradually with the temperature increasing. Thus, we proposed a possible reason for the evolution of overall characteristics by suggesting changing reactions between ZnO and reacting gases in various operating temperatures.

Selective Humidity Sensing at Ambient Temperature Using Individual Gallium Oxide Nanowires

Albert Romano-Rodriguez\textsuperscript{1,2}, Guillem Domenech-Gil\textsuperscript{1,2}, Irmina Peiró\textsuperscript{1}, Jan Romano-deGea\textsuperscript{3,4}, Elena López-Aymerich\textsuperscript{1,2}, Paolo Pellegrino\textsuperscript{1,2}, Christophe Serre\textsuperscript{1,2}, Mauricio Moreno\textsuperscript{1,2}, Sven Barth\textsuperscript{1}, Isabel Gràcia\textsuperscript{4} and Carles Cané\textsuperscript{4};
\textsuperscript{1}Universitat de Barcelona, Spain; \textsuperscript{2}Institute of Nanoscience and Nanotechnology (IN2UB), Spain; \textsuperscript{3}Physikalisches Institut, Goethe University, Germany; \textsuperscript{4}Institut de Microelectrònica de Barcelona-Centre Nacional de Microelectrónica, CSIC, Spain

Gallium oxide (β-Ga\textsubscript{2}O\textsubscript{3}) is a wide band gap semiconductor material used in the high power, high temperature and gas sensing fields. It is widely reported that Ga\textsubscript{2}O\textsubscript{3} in form of thin films is sensitive towards oxygen and reducing gases at temperatures above 600 °C. To decrease the working temperature and, consequently the power consumption, different modifications for its use as gas sensor have been introduced. The innovations proposed to overcome the material limitations concern surface functionalization, material doping or the increase of the surface-to-volume ratio using the nanowire (NW) morphology. In this work, single β-Ga\textsubscript{2}O\textsubscript{3} NWs grown via vapor-liquid-solid (VLS) mechanism are studied as gas sensors.

β-Ga\textsubscript{2}O\textsubscript{3} nanowires are fabricated via a metal-assisted VLS mechanism using carbothermal reduction and the synthetized NWs, after a structurally and optically characterization, are individually contacted using Focused Electron Beam Induced Deposition techniques for their use as gas sensors. The fabricated devices are tested towards
different concentrations of relevant gases in air quality monitoring, from ambient temperature and up to 200 °C, resulting in fast and reproducible responses towards water vapor at room temperature (25 °C), giving rise to a very low power consumption, in the range of nW.

Different features of the response towards moisture were studied, revealing similarities with carbon-based materials. Furthermore, the summarized response of the sensor, resembles an isotherm type V, typically from charcoal. As-grown β-Ga2O3 NWs were studied using Electron Energy Loss Spectroscopy, confirming the presence of a carbon layer at the surface of the nanowires forming a core-shell structure. The carbon layer, result of the growth process, is crucial to understand the sensing behaviour of the fabricated devices and should be considered in other gas sensing studies.

Synthesis and Enhanced Gas Sensing Performance of Conducting Polymer Functionalized In2O3 Flower-Like Nanostructures Hung-Chieh Lin, Wang W. Chien and Chun-Hua Chen; Department of Materials Science and Engineering, National Chiao Tung University, Taiwan

Human breath contains numerous volatile organic compounds (VOCs). Several studies have demonstrated a strong correlation between exhaled breath components and specific diseases. For instance, the acetone concentration in exhaled breath of diabetes is much higher than that of healthy people (~0.39 to 1.09 ppm). So accurate detection of specific VOCs in exhaled breath can thus provide essential information for the diagnosis of particular diseases. To develop highly sensitive gas sensors for detecting low concentrations of specific VOCs, a series of three-dimensionally assembled hierarchical oxides nanostructures with a high surface-to-volume ratio and porosity will be specially designed and synthesized as the base sensing materials. For further improving the selectivity while detecting specific VOCs, the synthesized three-dimensionally assembled hierarchical oxides nanostructures will be subsequently decorated with polymers with desired mass fractions and chemical procedures to form a novel organic-inorganic heterogeneous nanocomposite. The sensing performance, as well as the sensitivity of the fabricated organic-inorganic nanocomposite sensors, will be systematically characterized by a variety of VOCs for investigating the potential of diagnosis of diseases with the exhaled breath.

Up to date, we have successfully synthesized a series of porous three-dimensional metal oxides nanostructures having a high specific surface area by optimizing a variety of synthesis parameters. The underlying physical and chemical properties, as well as the critical parameters of spin and drop coating, are still under investigation for the subsequent decoration procedures. Also, we have designated and are modifying a unique gas sensing system which could safely, rapidly, and precisely create an atmosphere with single or multiple targeting gases for sensing characterizations. It was found that the prepared three-dimensionally assembled hierarchical oxides nanostructures, organic-inorganic heterogeneous nanocomposites exhibit similar tendency in selectivity for these target gases, and the addition of organic polymers improved the sensitivity of the three-dimensionally assembled hierarchical oxides nanostructures as our expectation.

11:00 AM EN16.01.08
Synthesis and Ozone Sensing Properties of Highly Stable Zinc Peroxide Thin Films Valmor R. Mastelaro, Maria I. Bernardi and Bruno S. de Lima; University of São Paulo, Brazil

Zinc peroxide (ZnO₂) is a semiconductor material with a wide band gap in the vicinity of 4.5 eV. Due to its oxidative capacity, this compound has been explored in various applications from medicine to photocatalysis. Its main application, however, is to be used as a precursor of zinc oxide (ZnO), a promising material for the semiconductor industry. Although several authors have reported the synthesis of ZnO₂ nanoparticles, little effort has been given to the deposition and growth of ZnO₂ thin films. Furthermore, several authors report that ZnO₂ nanoparticles decompose in ZnO and O₂ in temperatures higher than 230°C. Within this context, we present XRD, XPS, and SEM characterization of ZnO₂ thin films deposited by RF-magnetron sputtering with a reactive atmosphere of oxygen. Our results suggest that ZnO₂ thin films do not exhibit long-range order and are stable at temperatures as high as 500°C. The gas sensing properties of this material were also investigated by monitoring the electrical resistance of these films during exposure to ozone. Preliminary results show that when operating at 300°C the response (R₀₃/Rₐir) is higher than 500 for 40 ppb of O₃ with response time in the vicinity of 50 s.

In Situ X-Ray Spectroscopy to Identify the Tunable Surface Space Charge Layer as Origin for Oxygen
Sensing with Doped SrTiO$_3$ David N. Mueller$^1$, Michael Andrae$^1$, Misha Vorokhta$^2$, Filip Dvorak$^2$, Vladimir Matolin$^2$, Hendrik Bluhm$^3$, Regina Dittmann$^1$, Claus M. Schneider$^1$, Rainer Waser$^{1,4}$ and Felix Gunkel$^1$; 
$^1$Forschungszentrum Juelich, Germany; $^2$Charles University, Czechia; $^3$Lawrence Berkeley National Laboratory, United States; $^4$RWTH Aachen University, Germany

Many oxides of the perovskite structure not only exhibit fascinating properties originating from the bulk defect chemistry, but also show intricate behaviour at the solid/gas or solid/liquid interface leading to applications such as resistive gas sensing.$^1$

One particular example is donor doped SrTiO$_3$ (STO), which shows gas sensing behaviour similar to Taguchi type materials,$^2$ albeit at higher temperatures. This is usually explained by the formation of a space charge layer, however the underlying mechanisms and defect chemistry are yet to be fully understood: The space charge layer may either be formed by charged adsorbate molecules on the surface, or by defect chemical rearrangements at the surface in the form of Sr vacancies as observed in the bulk defect chemical model.$^3,4$

As the space charge region extends only a few nanometres form the surface into the bulk, this state is virtually impossible to quench in order to access it with conventional ultra-high vacuum spectroscopic techniques. With the advent of near ambient pressure X-ray photoelectron spectroscopy (NAP-XPS), this shortcoming is alleviated, allowing us to access the surface electronic and ionic structure of any material under conditions close to technologically relevant ones, often times requiring high temperatures and gas pressures far from UHV.

Lab- and Synchrotron-based NAP-XPS conducted on n-SrTiO$_3$ thin films under applied thermodynamic bias ($T$, $p_{O_2}$) reveals the presence of a variable surface potential and a corresponding negative surface charge.$^5$ $p_{O_2}$-dependent surface potential profiles were mapped by spectroscopic depth profiling, revealing an electron depletion layer present at the surface of n-SrTiO$_3$ thin films in both nominally reducing (ultra-high vacuum) and oxidizing conditions. Sr Core level XPS indicated Sr vacancy formation in the perovskite by SrO precipitation as the governing process, resulting in a resistance change at the surface. Depth resolved spectra furthermore revealed that a reversible conversion of the charge-neutral strontium oxide surface termination into strontium oxide clusters upon oxidation takes places, rendering the mechanism of resistive gas sensing in STO more complex as nanoscopic morphology changes also need to be considered.$^7$

Effect of Nanostructuring of Cu$_2$O Films on Detection Properties of Chemical Gas Sensors Jan Lancok$^1$, Misha Vorokhta$^2$, Martin Vondracek$^1$, Jiri Bulir$^1$, Michal Novotny$^1$, Premysl Fitol$^1$, Jan Vlcek$^3$, Jakub Cizek$^2$ and Martin Vrnata$^3$; $^1$Institute of Physics CAS, Czechia; $^2$Faculty of Mathematics and Physics, Charles University, Czechia; $^3$University of Chemistry and Technology Prague, Czechia

Copper oxide Cu$_2$O is an important and well known p-type transition metal oxide semiconductor material which has the advantages of direct band gap 2.1 eV at 300 K, a high absorption coefficient in the visible spectral range. This material has already been employed in the fabrication of electronic devices, thanks to its low cost, non-toxicity and fairly good carrier mobility. For example Cu$_2$O has been used in thin photovoltaic devices, resistive switching, transistors, gas sensors or catalyzers.

In our work the either epitaxial Cu$_2$O (110), Cu$_2$O(100) or nanocrystalline Cu2O films has been fabricated by Pulsed Laser Deposition on MgO(100), MgO(110) and fused silica substrates, respectively. The oxygen pressure in the chamber was varied between 10$^{-5}$ Pa and 1 Pa, while the substrate temperature was held between 200 and 750 °C.
The crystalline quality and out-of-plane orientation of the films were characterised by means of X-ray diffractometers. The epitaxial single crystalline films were fabricated on MgO substrate at substrate temperature above 500 °C, contrary on amorphous substrates (fused silica, alumina) the films were polycrystalline. The surface morphology was characterised by Atomic Force Microscopy. The role of the deposition conditions on crystalline structures and following to structural properties were examined in detail by XPS, SEM and TEM. The attention was focused also on determination of defect especially cooper and oxygen vacancies by means of Electron Paramagnetic Resonance and Positron Annihilation Spectroscopy. Because we focused on utilization of the Cu2O films as gas sensors, the powerful technique near ambient pressure photoelectron spectroscopy (NAP-XPS) was carried out to investigation of surfaces composition in the presence of gasses and vapours such as ethanol, hydrogen, NO2 and acetaldehyde. The idea was to observe the reaction of species on the surface of Cu2O while exposed to atmosphere as a function of temperature as well as in-situ- resistivity measurements. The following chemical responses of the films on the gasses mentioned above were measured at the same condition as NA-XPS.

Toxic Methanol Detection by Handheld Filter–Sensor Device Jan van den Broek, S. Abegg, Sotiris E. Pratsinis and A. T. Güntner; ETH Zürich, Switzerland

Methanol is poisonous when ingested or inhaled, resulting in devastating consequences including organ failure, blindness and death.1 This is a potential hazard as methanol is commonly used as solvent and feedstock in laboratories and chemical plant, but increasingly also as alternative fuel.2 Also, alcoholic beverages adulterated with methanol are a threat, commonly leading to poisoning outbreaks in developing countries with hundreds of victims. While chemical sensors, such as nanostructured metal-oxides, are portable, inexpensive and can detect alcohols down to ppb concentrations,3 they cannot differentiate methanol from ethanol and other interferants.4 To improve selectivity between ethanol and methanol, sensor can be combined with filters.5 Here, we present a detector capable to selectively detect methanol in the presence of high ethanol background. It consists of a filter placed upstream of a highly sensitive, but non-specific Pd-doped SnO2 microsensor. The filter is a small packed bed (150 mg) of an adsorbent that separates analytes based on their chemical interaction. After passing the filter, analytes are detected by the sensor consisting of a highly porous network of Pd-doped SnO2 nanoparticles fabricated by flame spray pyrolysis (FSP).6 The resulting methanol detector can selectively detect methanol without interference of simultaneous ethanol and other interferants. In specific, methanol is detected within 2 min in a large concentration range from 1–1,000 ppm at ambient 50% RH. The detection of methanol is thereby independent of the interfering ethanol concentration up to 95% relative saturation (~60,000 ppm). As a proof-of-concept, the detector was tested on methanol-spiked breath samples and rum where it could reliably detect and quantify toxic methanol concentrations. It shows thus great promise for detection of toxic methanol concentrations in ambient air or in the headspace of beverages, as well as for fast screening of methanol poisoning from breath.

Advanced Materials—Challenges and Opportunities for Gas Sensing Performances Sandrine Bernardini; Aix Marseille Univ, Université de Toulon, CNRS, France
Advanced materials have a huge potential of providing sensing data on air quality environment and individual health. The need for low-cost sensor used continuously to monitor air quality around people has sharply growing up with human activities and world industrialization. Nowadays, environment and health concerns drive the sensor market. Chromatography, optical, and spectroscopy approaches are accurate methods to obtain sensing data however they are generally expensive and non embedded equipment. Metal OXide (MOX) materials offer an alternative way to develop miniaturized resistive gas sensors with repeatable, reliable and reproducible sensing results. Since the fifties, it is well-known that the material conductivity changes with the adsorption or the desorption of a gas on a metal oxide surface. It has been proved first with Zinc Oxide (ZnO) thin layer in 1962 [1]. Then, tin oxide (SnO2) and ZnO have been demonstrated to be good gas-sensing materials for several gases such as O3, NO2, NH3, CO, and ethanol.

This talk will present the work being carried out in Microsensors and Instrumentation group in the Institute of Materials Microelectronic Nanoscience of Provence (IM2NP) at Aix-Marseille University (France). The design and the conception of the transducer is one of an important aspect. In 2013, a new design patterned in our group allows us to integrate heaters and reach low powered operation as low as 25mW [2]. Furthermore, the measurement metrology needs to be taken account. Recently, studies on the chamber design based on microfluidic simulations lead to improve our measurement reliability [3]. Concerning the sensing layer, MOX material synthesis is one of the key challenge to control the morphologies and the sensing performances. Hydrothermal and microwave hydrothermal synthesizes have been used to prepare metal oxide nanoparticles and will be presented. The deposition method plays also a major part in the sensing layer properties. Technics from solid target like Radio Frequency sputtering and from solution like spin coating or ultrasonic spray will be discuss. Repeatability, fast response and recovery times have been demonstrated. Thanks to a high surface/volume ratio, the nanostructuration for MOX like SnO2 and ZnO improves the sensing properties at temperatures around 200 or 300°C depending on the target gases. Due to the optical properties of these materials, our studies demonstrate that these temperatures are reduced to room temperature by considering sensing activity under continuous light activation [4]. However, selectivity is still challenging with MOX materials. The combination of several sensors based on different nanomaterials is one possible way to overcome this lack of selectivity. By changing the heterojunction composition and the light wavelength, the gas sensing properties have been enhanced and a selectivity have been reached. Access to toxic gaseous detection by such resistive micro-sensors and multi-sensors is promising for applications in individual environmental monitoring devices.

Direct Integration of Multifunctional Nanowire and Nanofiber Networks on Sensor Platforms for Selective Gas Detection David Graf1, Aida Jamil1, Albert Queraltó2, Thomas Fischer1, Isabel Gessner1 and Sanjay Mathur1;
1University of Cologne, Germany; 2Institut de Ciencia de Materials de Barcelona, Spain

The high surface-to-volume ratio as well as the typically high crystallinity and directional charge carrier transport of metal oxide NWs are beneficial for the use in chemo-resistive gas sensors. Semiconducting n-type SnO2 nanowire networks have been site-selective deposited on gas sensor platforms by chemical vapor deposition approach based on a catalyst-mediated vapor-liquid-solid (VLS) growth mechanism. Compared to classical screen-printed SnO2 sensors showed the direct integrated nanowire network superior sensing performance in terms of sensitivity and response time. The selective detection of target gas molecules in complex gaseous composition or high humidity is quite challenging. We improved the lack of selectivity toward gaseous species through surface decoration with metal oxides (VO2) and noble metals (Rh) nanoparticles by a second CVD step. For this approach, we developed tailored volatile molecular precursors based on bidentate heteroarylalkenolate and enaminonate ligands. An enhanced gas detection capability under high humidity was achieved by deploying hydrophilic zeolite microcrystals embedded in nanofiber meshes on top of the sensing material. Moreover, we fabricate ternary metal oxide (BiFeO3, LaFeO3 and Sn2Nd2O7) nanofibers meshes by electrospinning, which exhibit excellent selective and sensitive sensing characteristics. High-resolution transmission electron microscopy in conjugation with 3D tomographic analysis confirmed an interwoven network of hollow and porous (surface) LaFeO3 nanofibers. Owing to their high surface area and p-type behavior, the nanofiber meshes showed...
high chemoselectivity toward reducing toxic gases (SO2, H2S) that could be reproducibly detected at very low concentrations (< 1 ppm) well below the threshold values for occupational safety and health. In contrast, pyrochlore Sn2Nd2O7 nanofibers showed a highly selective detection towards Hydrogen (H2). The interdependence between structure, porosity and surface chemistry were evaluated in detail to achieve a high-detection performance.

Sputtered Metal Oxide Semiconductor n-p Heterojunctions for Volatile Organic Compound Sensing Andrea Fasoli1, Giulio Tilde2, Lisa Thornquist1, Krystelle Lionti1, Linda Sundberg1 and Luisa Bozano1; 1IBM Almaden Research Center, United States; 2Politecnico di Torino, Italy; 3San Jose State University, United States

Metal Oxide Semiconductors (MOS) have been the subject of decades of investigation directed towards integrating them in multi-sensorial electronic-nose systems1. Despite tremendous research efforts, a key limitation persisting to date is the lack of diversity in response to analytes, especially among the materials that reached the stage of commercialization. By and large represented by n-type MOS, predominantly doped SnO2, the materials comprising this limited set show high output correlation upon exposure to many gaseous species. Interestingly, it has been shown2,3 that the formation of a heterojunction between n- and p-type MOS can be leveraged to enhance and tune sensing performance. Thanks to the differentiation in surface interactions and charge transport mechanism, such materials combination gives access to a different range of gas selectivities and can mitigate the deleterious effect of humidity on sensitivity, as well as improve the sensor recovery time. It remains to be seen, however, whether highly-reproducible and cost-effective manufacturing processes can be developed to realize the untapped potential of this new class of sensing materials.

Here, we report on the fabrication and characterization of SnO2/NiO n-p heterojunctions thin films and analyze their response to Volatile Organic Compounds (VOCs) at sub-ppm concentrations. Films of varying thickness (20 – 200 nm) are deposited by conventional magnetron sputtering and subject to different annealing protocols. We show that in optimal processing conditions, the response of the films to VOCs can be greatly increased and its dependence on temperature, typically described in the context of a Diffusion-Reaction model, altered. In addition, we show that p-type NiO layers of given thickness can trigger a reversal in the response pattern of ultra-thin n-type SnO2 underlayers. The chemophysical and transport mechanisms leading to the emergence of such behavior are discussed.

Our results pave the way for the practical realization of n-p heterojunction MOS sensors of orthogonal response to VOCs compared to their n-type counterpart, thus expanding the range of functionalities of electronic noses.

2:30 PM EN16.02.04
Evaluation of Surface Responsivity of a Tin Dioxide Thin Film for the Highly Sensitive Gas Sensing Reo Kometani1, Ryotaro Ueki2, Penekwong Khennat1, Kenta Yoshihara1, Shinji Kunori2, Katsuya Ikeda2, Kazuyuki Sashida2, Kenichi Yoshida2, Ichiro Yamada2, Yoshio Mita1 and Shin’ichi Warisawa1; 1The University of Tokyo, Japan; 2Shindengen Electric Manufacturing Co., Ltd., Japan

Tin dioxide (SnO2) enables us to detect various low concentration gases for the application of environment monitoring and healthcare. Therefore, a great number of research and development has been carried out. However, relationships between surface responsivity and the other properties such as device structure and fine structure have not been completely clarified. We conducted basic researches on surface responsivity in order to understand SnO2 thin film more deeply, as well as in order to achieve the higher sensitivity. In this study, SnO2 thin film-based gas sensing devices were fabricated on SiO2/Si substrate. Length and width of SnO2 film for gas sensing were 500 μm and 100 μm, respectively. Pt catalyst was placed on SnO2 film to enhance the gas sensitivity. It was confirmed by Raman spectroscopy that the structure of the sputtered thin film was SnO2 although it contained SnO and SnO2-δ slightly. As a basic property, sensitivities for acetone gas (concentration: approx. 200 ppm - 800 ppm) and ethanol gas (concentration: approx. 10 ppm - 40 ppm) were increased with a decrease in thickness of SnO2 film. Thickness of SnO2 thin film on device were 120 nm, 200 nm and 340 nm. This indicates that the proportion occupied by the
gas sensitive region increases with decrease of thickness. Then, we carried out researches on the gas sensitive region. Considering the mechanism of gas sensing, the presence or absence of oxygen in an atmosphere around the device is important to discuss the gas response on the surface. Therefore, the relationships between the electrical property, thickness, operating temperature and atmosphere were evaluated systematically using the device with thickness of 100 nm and 700 nm under the atmosphere of pure air and N2. As a distinctive result, we found that the both devices had almost the same resistance under the N2 atmosphere, even though the thickness was different. Resistance at the operating temperature of 300 deg. C was approximately 40 kΩ. It seems that this was caused by the removal of the influence of oxygen that SnO2 surface was responding to. This is an interesting property for elucidating the depth of the sensitive region because it may imply that the sensitive region can be made to appear under N2 atmosphere. There is also a possibility that surface fine structure is different from the inner structure and this difference may be a key for the higher sensitivity. Although the fine structure and surface condition need to be clarified, fabrication of the higher sensitive devices can be expected if the sensitive region can be structured effectively. The relationships between surface responsivity, material fine structure, and device structure will be reported in detail.

2:45 PM EN16.02.05
Chemical Sensing with Amorphous Oxide Quantum Materials Yifei Sun and Shriram Ramanathan; Purdue University, United States

Chemical sensing is an active area of research with wide implications in environmental monitoring including air quality in urban areas, inside air-conditioned buildings, near natural gas pipelines and confined underground areas. Advancing the limits of detection as well as designing new mechanisms for sensor response to external stimuli is therefore of interest. In this presentation, we will report on a class of rare-earth nickelate systems as gas sensors, with specific results on hydrogen and ozone monitoring. Typical oxide semiconductor sensors such as In2O3 operate based on surface or near-surface redox processes that change their electrical resistance depending on the nature of chemical species encountered. In quantum materials such as nickelates, one can exploit instead strong electron correlations from electrode-mediated electron transfer from the chemical gas to induce change in electrical resistance or optical transmittance. The change in resistance is non-linear with electron filling due to Coulomb repulsion within the oxide lattice opening the possibility for trace gas detection. We will compare and contrast single crystal perovskite nickelates such as NdNiO3 films grown on LaAlO3 substrate versus their amorphous counterparts (deposited at room temperature on glass and polymers) with respect to both dynamics of resistance modification under dilute hydrogen or ozone exposure and the self-limited sensor response. Our initial results show > 800% change in electrical resistance in the amorphous mixed Ni oxides to hydrogen in forming gas near room temperature, while the crystalline counterparts show few orders of magnitude change in conductivity. Both materials show reversible modulation of resistance once the sensor is exposed to air and can be cycled multiple times. Finally, we will contrast the nickelates with better-studied wide gap oxide semiconductor sensors to discuss future materials challenges in this field.

3:30 PM EN16.02.06
Fabrication of Pt/WO3-Coated Polydimethylsiloxane Membrane for Transparent/Flexible Hydrogen Gas Monitoring Ryo Ishihara1,2, Yuki Yamaguchi1, Kanta Tanabe1, Yoshihiro Makino1 and Keishi Nishio1; 1Tokyo University of Science, Japan; 2Juntendo University, Japan

Hydrogen gas has attracted significant attention as a promising next-generation clean energy source[1]. For sustainable hydrogen energy generation systems, safe, repeatable, and cost-effective hydrogen gas-leakage monitoring is urgently needed. In this study, transparent and flexible hydrogen gas sensor membranes that satisfy the above requirements were prepared utilizing two techniques; ultraviolet light-induced graft polymerization (UV grafting) of hydroxyethyl acrylamide (HEAAm) and platinum-catalyst-loaded tungsten trioxide (Pt/WO3) deposition using a novel sol-gel method.

Pt/WO3 thin film coated materials render promising hydrogen gas sensing[2]. Pt/WO3 particles show clear colorimetric changes from yellow to blue in response to hydrogen gas without the need for heating[3]. This color change is reversible and repeatable, enabling the detection of colorless hydrogen gas with the naked eye. In addition,
due to the complex shape of pipes and joints for hydrogen gas transportation, flexible and easy-to-attach sensors are desirable. The general coating methods of Pt/WO₃ thin film on substrates require heat treatments above 350°C for WO₃ crystallization on the solid substrates; however, such heat treatments prevent soft organic materials from being used as substrates. Still, the use of soft organic materials is preferable owing to their superior flexibility, cost effectiveness, and lightweight.

To achieve Pt/WO₃ thin film coating on soft organic materials, a novel Pt/WO₃-thin film coating protocol was developed. The present protocol using only a sol–gel method involves acid and mild heat treatments; thus, soft organic materials with acid- and mild heat-resistant-hydrophilic surfaces can be employed as substrates. In this process, the acid acts as the catalyst to enhance the sol–gel reaction. Polydimethylsiloxane (PDMS) membranes were used as the substrate for Pt/WO₃-thin film coating, because PDMS exhibits high gas permeability, high optical transparency, and cost effective in addition to the typical properties of soft organic materials. These properties are ideal for hydrogen gas-leakage monitoring. However, because the surface of bare PDMS is hydrophobic, the sol–gel method could not be applied directly. Thus, to obtain an acid- and mild heat-resistant hydrophilic surface, UV grafting of HEAAm was performed. We selected UV grafting and HEAAm because, unlike other modification techniques the technique can easily provide stable hydrophilic surfaces.

The UV light irradiation time, the reaction temperature, and monomer concentration for UV grafting of HEAAm were optimized. Stability of the obtained hydrophilic surface was confirmed by water contact angle. The presence of a Pt/WO₃ film on the HEAAm-modified PDMS surface was confirmed by X-ray diffraction analysis. The stability of the prepared WO₃ H₂O structure was demonstrated because the membrane retained 80% color response even after the heat treatment at 250°C for 30 min. The thickness of the thin film was ca. 100 nm, as determined from the cross-sectional scanning electron microscopy image. The fabricated Pt/WO₃ thin film-coated PDMS membranes were transparent, flexible, easy-to-attach and exhibited a clear and selective colorimetric change soon after exposure to 1.0 vol% hydrogen gas, which is below the concentration range for the rapid combustion of hydrogen-containing air (4–75 vol%). The membrane color returned to transparent immediately after switching back to air flow. The prepared Pt/WO₃-thin film-coated PDMS membrane is likely to play an important role in the future hydrogen economy.

This work was partly supported by JSPS KAKENHI Grant Number 16K12901 and 18K18404. We would like to thank Profs. Akihiko Kikuchi and Kenjiro Fujimoto for their help.

3:45 PM EN16.02.07
BTEX Gas Sensor Based on Hematite Nanocrystals—Preparation and Characterization Luis F. da Silva¹, Tomas Fiorido², Sandrine Bernardini², Ariadne C. Catto¹, João V. de Palm¹, Waldir Avansi¹, Khalifa Aguir² and Marc Bendahan²; ¹Universidade Federal de São Carlos, Brazil; ²Université Aix-Marseille, France

The development in industrial and agricultural activities, mainly in emerging economies, has resulted in an increase of toxic gases dumped into the atmosphere, such as CO, NOₓ, NH₃, O₃, and VOC’s (volatile organic compounds). Among the VOC’s, BTEX (benzene, toluene, ethylbenzene, xylene) is the most harmful gas; being used as organic solvents in the production of paints, dyes, etc. It becomes prejudicial to human health may cause some sickness, such as respiratory irritative symptoms, headaches, rashes, and fatigue. Gas sensors based on metal semiconducting oxides (MOX) have drawn the attention due to their potential for detection of various gases. Among the MOX, hematite (α-Fe₂O₃) has been investigated as resistive gas sensors, mainly, for detection of acetone, and ethanol. Based on these motivations, we present herein an investigation on the gas-sensing properties of α-Fe₂O₃ nanocrystals towards BTEX gas. The nanocrystals were synthesized by the hydrolysis of iron (II) chloride and then crystallized via hydrothermal treatment. The structural, surface and morphological properties were characterized by X-ray diffraction (XRD), X-ray absorption near-edge structure and, X-ray photoelectron spectroscopies, and high-resolution transmission electron (HR-TEM) analyses. The XRD and Fe K-edge XANES measurements indicated that pristine hematite phase was obtained, where iron ions are in octahedral coordination. In addition, XPS spectroscopy indicated the presence of Fe³⁺ ions on the sample surface. HR-TEM analyses showed that hematite crystals exhibit a rhombus-like shape with an average size of approximately 80 nm. Gas-sensing measurements
revealed that α-Fe₂O₃ nanocrystals are sensitive towards lower BTEX levels, i.e., from 3 till 400 ppb (parts-per-billion) when kept at 280°C. Additionally, the experiments showed that hematite nanocrystals presented total reversibility, good repeatability and stability, and high selectivity (towards ethanol and acetone). These findings demonstrate the potential of hematite nanocrystals as sensing material to manufacture BTEX gas sensor devices for practical applications.

4:00 PM EN16.02.08
Influence of the O₂/Ar Flow Ratio on the Gas Sensing Properties of Reactive Sputtered ZnO Thin Films
Adrian Camacho-Berrios¹, Zulmari Silva-Pedraza² and Wilfredo Otaño-Rivera²; ¹Univ of Puerto Rico-Rio Pedras, United States; ²University of Puerto Rico-Cayey, United States

Metal oxides such as zinc oxide (ZnO) are potential candidates for gas sensors for environmental monitoring. Oxygen-deficient ZnO, in particular, has attracted much attention due to the possibility to adapt their electrical response to sensing oxidative and reducing gases. The introduction of oxygen vacancies (V₀) modifies the surface by creating active sites where the molecular or atomic gas can interact with environmental gases of concern. They can be used to modify the band structure changing the electrical properties of ZnO. In the preparation of oxygen-deficient ZnO nanomaterials, it is essential to understand how the growth parameters promote the formation of V₀. Thus, this work focuses on studying the influence of plasma processing parameters on the formation of V₀ and testing oxygen-deficient ZnO thin films as gas sensors for environmental monitoring. The thin films were deposited on interdigitated transducers at room temperature by reactive magnetron sputtering at different O₂/Ar flow ratios. The influence of the flow ratio on the composition and sensing response of the thin films was examined by X-ray Photoelectron Spectroscopy and by measuring the change in electrical current in argon and hydrogen atmosphere. The results show that films prepared at low percent of oxygen in the sputtering gas exhibit the best response, at working temperatures of 200 °C and 1 % of hydrogen in Ar, with an increase in electrical current from 0.17 μA to 48.3 μA. The results will be discussed in terms of the oxygen partial pressure key role in the formation of oxygen vacancies during plasma deposition, which in turn produce excellent sensing responses.

4:15 PM EN16.02.09
Mesoporous Silica Metal Oxide Nanocomposites—An Extremely Sensitive RH Sensor
Ekta Poonia¹, Jasbir Sangwan² and Krishan Kumar¹; ¹Deenbandhu Chhotu Ram University of Science and Technology, Murthal, Haryana, India; ²Tau Devi Lal Govt. Girls College Murthal Sonipat Haryana, India

Scientific investigation for the development of extremely sensitive nanohybrid sensors and precise detection of internal climatic conditions has always remained a challenging task. It deals with template synthesis of 3D-cubic mesoporous silica with in-situ loading of metal oxides to obtain a nanocomposite material with huge number of surface active sites. The humidity sensing behavior of synthesized nanostructures divulge the high sensitivity, fast response/recovery (4.5/3.3s), negligible hysteresis and high stability to relative humidity (%RH) in the 11–98%RH range. The structural insights have been reported by analyzing the results obtained for HRTEM, FESEM, LAXRD, HAXRD, BET and FTIR absorption analysis. X-ray diffraction confirmed 3D-cubic structure of silica with Iad symmetry and existence of anatase metal oxide species and a decrease in surface area on loading of metal oxide nanoparticles is exposed via BET surface area analyzer. The present work highlights an efficient scheme in designing of high performance %RH sensors and suggested their promising applicability in futuristic humidity/gas sensing applications.

4:30 PM EN16.02.10
1D Anodic TiO₂ Nanotube Layers with Secondary Materials for Gas Sensing
Siow Woon Ng¹, Jan Prasek¹,¹, Raul Zazpe²,¹, Jan Príkryl², Hanna Sopha²,¹, Jaromír Hubalek¹,¹ and Jan M. Macák¹,²; ¹Brno University of Technology, Czechia; ²University of Pardubice, Czechia

Gas sensors are extensively used in various fields, such as medical, automotive, automation, agriculture, biogas, and mining industries for safety and environmental monitoring. This includes also the detection of toxic compounds to prevent hazardous emission and explosion along with an air quality monitoring. The increasing development of various technologies and processes signify the increase of monitoring demands for the human’s health impact.[¹,²]

1D nanostructured sensing materials have shown potential in the miniaturization of the physical size of a sensor. The high surface-to-volume ratios provide large absorption sites, fast diffusion of gas molecules. In addition, the 1D
Self-organized anodic TiO$_2$ nanotube layers have garnered considerable scientific and technological attention over the past 15 years, particularly for photo-catalysis, solar cells, hydrogen generation and biomedical uses.$^5$ The synthesis of 1D TiO$_2$ nanotube structure is carried out by conventional electrochemical anodization of a Ti sheet. This technique has matured into a well-controlled synthesis process with the flexibility to tailor the tube dimensions such as diameter and layer thickness.$^6$ On the other hand, Atomic Layer Deposition (ALD) enables a conformal and homogeneous deposition of a thin layer of various chemical compositions, with precise control of the coating thickness, according to the deposition cycles. Therefore, very thin films matching the thickness of the Debye length of a material can be deposited by ALD. The Debye length on the scale of nanometers is the key factor of the sensitivity of a semiconductor gas sensor.$^7$ The ALD was shown to conformally coat the high-aspect-ratio TiO$_2$ nanotube layers with ultrathin coatings of secondary materials$^8$ such as Al$_2$O$_3$,$^9,10$ ZnO$^{11}$ and TiO$_2$.$^{12,13}$

This presentation will focus on the coating of the nanotube layers by various secondary materials using ALD. Experimental details and some very recent sensing results based on ZnO$^{14}$ and SnO$_2$ modified TiO$_2$ nanotubes will be presented and discussed.

Reference
Using the regime of constant voltage homogeneous alloys (Fe-Ni, Fe-Co and Fe-Ni) were obtained. Pulse deposition was used for synthesis of heterogeneous layered NWs (Ni/Cu and Co/Cu) using “one-bath” technique. “Double-bath” method was used for synthesis of another layered NWs- Fe/Ni and Fe/Co. Specific features of galvanic process for processes mentioned above were investigated. Topography and crystal structure were estimated by SEM, TEM and X-ray methods. Magnetic properties were also investigated by magnetometry and MFM methods. For ALLOY NWs it was found: non-linear dependence of grooving process on time, dependence of NWs composition on deposition voltage. It was also found that ratio of elements (Fe to Co or Fe to Ni) was changed along the wires length. Effect of anomalous co-deposition of Fe was detected- it was much higher for FeNi alloys (than for FeCo NWs). The difference of NWs elemental composition from the same in electrolyte also was higher for FeNi NWs.

For LAYERED NWs deposition parameters (voltages in pulse-regime for deposition in “single-bath” regime) were determined. Element mapping (in TEM experiments) determined the concentration of elements: for example, in Ni/Cu NWs there were layers of pure Cu and Ni-based alloy (83%Ni and 17%Cu). Using of the “constant time” leads to formation of layers with variable length (due to the diffusion limitations for ions in the narrow pores). In order to obtain the NWs with regular layer length the regime of “constant charge” should be used. TEM with diffraction analysis demonstrated the polycrystalline structure of NWs. Symmetry of Ni (Fm3m), Cu (Fm3m) and oxides (Cu2O and CuO) were determined. It was shown that decrease of time of each pulse effectively leads to decreasing of layer length down to 20 nm. For shorter time the mixed structure or the “stick-shell” structures could be obtained.

Magnetic properties data for both types of NWs are given and discussed. The effect of application of external magnetic field on grooving process (acceleration of electrodeposition) and obtained NWs (texture, formation of cavities) also presented.

It is expected that layered NWs could be used as effective gas sensors.

EN16.03.02
Facilitated Gold Standard Microbiological Safety Assessment Supported by Paper Device Rapidly Profiling Bacterial Enzymatic Phenotypes Hyeok Jung Kim1, Chanho Kwon2, Hyeon Ah Lee1 and Hyeran Noh1, 1Seoul National University of Science and Technology, Korea (the Republic of); 2Research Institute, Biomax Co., Ltd., Korea (the Republic of)

Cultural methods based on bacterial growth rates have played a key role in all spheres related to biosafety—including food industry and medical areas—as long regarded as the ‘gold standard’. Despite profitable advantages such as low cost, manifestations of biochemical traits in a specimen, and less susceptibility to food matrix effects, still are limitations associated with the requirements of facilities and expertise workforces, and specific laborious procedures such as plating and colony counting. Paper substrates have been remarked as a platform material with high efficacy, an array of applications and other beneficial features like non-powered fluid delivery, facile sensor fabrication, and biocompatibility when used as a sensing platform. Under the supportive conditions with these traits, numerous applications have been released into the microbiological field with majorly incorporating with biosensing molecules such as antibody and aptamer. Chromogenic agar substrates have been recently involved in paper-based microbiological assessments; the paper-based diagnostics with this detecting motif compensates the drawbacks of the conventional gold standard microbiological assessment, as it diminishes time spends, the number of steps and total cost for analysis.

Herewith, we present a device aiding a rapid report of specific enzymatic phenotypes in microbiological analytes. The device was devised with stratifying paper layers that each contains chemical reagents for cell lysis, oxidation, and coloration. Optimal colors charging each detection zone on the array were respectively determined with either single uses of chromogenic substrates or blended mixtures for a selective coloration. Time length for an enzymatic assay and an enrichment step were optimized for shorted total analysis bringing about enhanced its feasibility. Provided respected sensitivities of each assay, specimens at low bacterial concentrations below 10 cfu/mL were readily sensed expending time around four hours. The robust sensing capability, when situated with food matrices, was validated by real-food spiking tests. Sophisticated sensor designs and analysis of RGB channel pattern enabled an evolution toward to a multiplex reporting for predominant hazardous pathogens in a simultaneous manner.
The multiplex biosafety assessment was miniaturized based on visually reporting respective enzymatic phenotypes of bacterial analytes. Its potentials in practical uses are appreciated when considering the high applicability to the current standardized methodology for water- and foodborne pathogen testing. Furthermore, the diagnostic device can benefit particularly in dealing with an outbreak setting by the outstanding features, low-cost, ready-to-use, and feasible traits, to name but a few.

**Preparation of Nanostructures and Their Application as UV-Light Assisted Gas Sensors**

Ariadne C. Catto¹, Luís F. da Silva¹, Sandrine Bernardini², Khalifa Aguir² and Waldir Avansi¹; ¹Universidade Federal de São Carlos, Brazil; ²Aix Marseille Univ, Université de Toulon, CNRS, IM2NP, France

The investigation of metal oxide semiconductors (MOX) is a fundamental point in the area of physics, chemistry, and material science, in particular nanostructured compounds. Despite the potential application of MOX, the electronic effect adverse during the charge separation process reduces the efficiency of the isolate semiconductors. Thus, great efforts have been made to further improve the MOX properties, for example, the coupling of junctions between semiconductors has been a promising option to hinder the charge recombination and thus enhancing their performance. In this way, heterostructures such as NiO/ZnO, Co₃O₄/ZnO, ZnO/CuO and ZnO/SnO₂ obtained by different methodologies, have exhibited potential properties to be applied as sensing layer. The photoactivation process has been an efficient way for the operation of sensors devices at room temperature. Based on these motivations, we present herein an investigation on the UV-assisted gas-sensing properties of the ZnO, Fe₂O₃, and SnO₂ as well as their respective heterostructures applied as ozone and nitrogen dioxide sensors operating at room temperature. The samples were prepared via microwave-assisted method. The structural, surface, and morphological properties were characterized by X-ray diffraction (XRD), X-ray absorption near-edge structure and, X-ray photoelectron spectroscopies, and high-resolution transmission electron (HR-TEM) analyses. The XRD patterns indicated the presence of ZnO, α-Fe₂O₃ and SnO₂ crystalline phases, without the evidence of solid solution formation. HR-TEM analysis reinforced the incorporation of α-Fe₂O₃ and SnO₂ nanostructure onto ZnO nanorods. The gas sensing properties were investigated for several concentrations of ozone (O₃), carbon monoxide (CO), and nitrogen dioxide (NO₂) gases. The experiments showed that nanocomposites presented total reversibility, good repeatability and selectivity toward oxidant gases. Furthermore, we also observed an enhancement of the gas-sensing properties of the heterostructures when they were kept under UV-illumination, suggesting a reduction in the charge carriers recombination. These findings demonstrate the potential of as sensing material to manufacture gas sensor devices operating at room temperature.

**Geometric Structure Modification in Nanoweb Impacting Liquid Resistance/Repellency**

Jihye Lim¹,², JR Kim² and Juhea Kim²; ¹Delaware State University, United States; ²Korea Institute of Industrial Technology, Korea (the Republic of)

A liquid resistant/repellent surface is beneficial to improving human health and safety when people are exposed to harsh or harmful environment. The surface can protect people from a direct contact with toxic liquids or enhance the hydrophobic filters’ functionality, purifying air or water. The lotus leaf in nature repels water and is characterized by superhydrophobic and self-cleaning effects. And, the features are attributed to its hierarchical structure and wax coating on the surface. Particularly, roughness on the lotus leaf’s surface contributes to creating the liquid-vapor interface, reducing the liquid contact area to a solid surface, and this plays an important role in maximizing the liquid resistance/repellency. The surface roughness is varied in size and geometric structure and those affect its performance.

In this study, creating nano-scale roughness is considered in nanoweb by incorporating nano particles into an electrospinning process. To identify the most efficient geometric structure, a geometric model is developed by extending the Cassie-Baxter model and the newly developed model is justified through evaluating liquid resistance/repellency in nanoweb with nano-scale roughness. It is expected that the works including modeling, modifying and evaluating the nano-scale surface will contribute to developing a liquid resistant/repellent material, highly performing for sensing and controlling fine/ultrafine particle (PM 2.5) pollutants, which can cause lungs and heart diseases and threaten human life.

**EN16.03.05**
Fabrication of Nanofiber Air Filter with Self-Cleaning through Superhydrophobic Bead Coating

Hyonguk Kim1, Seong Kyung Hong2, Chan Park1, Cheol Jeong Park1, Byeongjun Lee1, Jungmin Kim1, Yeon-Do Jeong1, Geunbae Lim2 and Seong Jin Cho1; 1Chungnam National University, Korea (the Republic of); 2Pohang University of Science and Technology, Korea (the Republic of)

Recently, in air quality management has gained great attraction as PM2.5 has been shown to have a close association to causing health problems123. The Global Burden of Disease Study reported that exposure to outdoor PM2.5 was responsible for around 3.2 million premature deaths in 2010 worldwide4. Such outdoor air pollution can enter the indoor environment through ventilation and infiltration processes.

Various nanofiber filters have been developed for the removal of PM2.55,6,7. These filters exhibit high fine dust removal efficiency and relatively low air resistance. However, these filters have a problem in that their filtration performance degrades in long-term operation. To grant the previous fine dust filters with recyclability, self-cleaning effect via superhydrophobic surface can be considered, though few studies have been conducted on the application of superhydrophobicity to air filters.

In this study, polyacrylonitrile (PAN) nanofibrous membrane was fabricated on aluminum mesh and Polydimethylsiloxane/Polyvinylidene fluoride (PDMS/PVDF) microbeads were coated to make a superhydrophobic air filter. The filter exhibited high PM2.5 removal efficiency and superhydrophobicity. The filter was washed with water after a long-term filtering operation as the running water removed fine dust on the filter. The filter with the contaminants removed was tested and it was confirmed that PM2.5 removal performance was restored.

Mechanical Cleaning for Barristor-Based Gas Sensor to Achieve Sensitivity of 10^4 % for 1 ppm of NO2

Do-Hyun Park1, Young Jin Cho1, Jun-Ho Lee1, In-Chul Choi1, Stephen Hodge2 and Hyun-Jong Chung1; 1Konkuk University, Korea (the Republic of); 2University of Cambridge, United Kingdom

Impurities of graphene during fabrication process increase doping level and decrease electron mobility. To fabricate gas sensor with high sensitivity, cleaning process is essential. In this poster, we present a mechanical cleaning for barristor-based gas sensors with high quality graphene. We adopted mechanical cleaning method based on contact mode of atomic force microscopy (AFM) to remove residues. During the cleaning processes, 2D/G intensity ratio by Raman spectroscopy increased and Dirac voltage of graphene decreased. Finally, the sensibility was improved significantly.

Also, we demonstrated a barristor-based gas sensor. Barristor junctions, graphene and tungsten disulfide (WS2) junctions, were cleaned using contact-mode AFM. Then the cleaned sensor exhibits sensitivity of 10^4 % at 1 ppm of nitrogen dioxide (NO2). The sensitivity could be projected to sub ppb concentration of NO2.
We studied a facile and practical 1D PC for real-time monitoring humidity sensor with remarkable color change, sensitivity and reversibility. High refractive index polymer and four different quaternization degree of low refractive index polymers were synthesized. Multilayers polymeric 1D photonic crystal(PC) films were fabricated by alternating low/high refractive index polymer by a simple spin-coating. 1D films were prepared 5 films of similar thickness and four samples of varying thickness, and the color change and photonic stop band are observed relative humidity from 10% to 90%. Depending on the degree of quaternization of the low refractive polymer, the color change and response time which are sensitive to the relative humidity are changed. A film having a relatively low hydrophilicity can be applied as an anti-counterfeiting film, and a film having a high hydrophilicity and remarkable sensitivity, rapid response time, various color change can be applied as a humidity sensor.

**EN16.03.08**

**Polyacetylene-Like Modified Graphene Oxide Aerogel and Its Enhanced Electrical Properties for Electro-Catalytic Devices**

Enrico Greco, Jing Shang, Jiali Zhu and Tong Zhu; Peking University, China

A graphene-based or carbon-based aerogel is a three-dimensional (3D) solid material in which the carbon atoms are arranged in a sheet-like nanostructure. In this study, we report the synthesis of low-density polymer-modified aerogel monoliths by 3D macro-assemblies of graphene oxide sheets that exhibit significant internal surface areas (982 m²/g) and high electrical conductivity (~0.1 to 1 × 10² S/cm). Different types of materials were prepared to obtain a single monolithic solid starting from a suspension of single-layer graphene oxide (GO) sheets, and a polymer, made from the precursors 4-carboxybenzaldehyde and polyvinyl alcohol. These materials were used to cross-link the individual sheets by covalent bonds with polyacetylene (resulting from the transformation of polyvinyl alcohol). The obtained wet-gels were supercritically dried and then, in some cases, thermally reduced to yield graphene aerogel composites. The average densities were approaching 15-20 mg/cm³. This approach allowed for the modulation of the distance between the sheets, pore dimension, surface area, and related properties. This specific GO/Polymer ratio has suitable malleability making it a viable candidate for use in conductivity 3D printing; it also has other properties suitable for energy storage, catalysis, sensing and biosensing applications, bioelectronics, and superconductors. An electro-catalytic prototype device for environmental monitoring and remediation is under development for the municipality of Beijing in China.

**EN16.03.09**

**Ultrasensitive and Highly Stable Humidity Sensor Using Cesium Lead Halide Perovskite/Ceramic Nanocomposite Films by Aerosol Deposition Method**

Sunghoon Kim¹², Sang-Wook Kim¹ and Jong-Min Oh³;

¹Ajou University, Korea (the Republic of); ²LG Innotek, Korea (the Republic of); ³Kwangwoon University, Korea (the Republic of)

Humidity sensing devices have attracted significant attention for their numerous potential applications, such as structural health monitoring, precise control for living systems, hospital apparatus, and agricultural fields, etc. Recently, various transduction mechanisms and sensing materials for a humidity sensor have been widely studied to provide high sensitivity, fast response/recovery time, excellent linearity, and low hysteresis by reading out electrical or optical signals (e.g., capacitance, resistance, photoluminescence, and gate effect in semiconductor devices). Recently, metal halide perovskites (MHP) have received great attention in optoelectronic application fields including solar cells, down-converting materials, light-emitting diodes, and photodetectors, due to their superior optical properties. Particularly, CH₃NH₃PbI₃₋ₓClₓ and CH₃NH₃PbBr₃ have been shown by converting the moisture exposure with increasing relative humidity using photoluminescence intensity or resistance, resulting in an ultrasensitive performance. Nevertheless, major problems of halide perovskites were shown up by the dissolution or chemical reaction with water molecules in humid environments. It is inevitably weaker in their reproducibility and stability as a long-term humidity sensor. For overcoming stability and response/recovery issues by water-MHP reaction, the latest research suggested Cs₂BiAgBr₆ with outstanding stability in the ambient environment. From this research, an excellent stability below 70 RH% and superfast response/recovery time (1.78 sec/0.45 sec) was obtained, whereas the sensing performance still exhibited high attenuation above 80 RH%. Therefore, the sole use of
the MHP is recognized as a disposable sensor and is not preferable in a humidity sensing material. In order to prevail all previous shortcomings, our pilot study demonstrated a novel capacitive-type humidity sensor combining aerosol deposition (AD) process and MHP-based ceramic composite materials employed on fully room-temperature to achieve high sensing performance as well as good stability.

Herein, by keeping the room temperature during the process, we fabricated the composite films with CsPb2Br5 nanocrystals embedded in ceramic matrices for novel sensing characteristics with ultra-sensitivity, fast response/recovery time, and long-term stability. The humidity sensor exhibited the high sensitivity of 17773.5 pF/RH%, linearity of 0.9954, and hysteresis of 2.98%.

**EN16.03.10**

**Influence of Boron Contamination in Mg$_2$Si Substrate on the Device Performance of Mg$_2$Si SWIR Sensor**

Yuutarou Fuse, Ryouhei Masubuchi, Fumiya Takahashi and Haruhiko Udono; Ibaraki University, Japan

The detectors in the short wavelength infrared (SWIR: 1 - 2.5 um) light are applied to imaging and sensing such as astronomical observation, remote detection of minerals and chemical process monitoring [1]. Commercially available SWIR light detectors are used toxic substances as their constituent elements like mercury-cadmium telluride-MCT and indium-gallium-arsenide (InGaAs). The Mg$_2$Si is inexpensive and nontoxic semiconducting material consisting of abundant elements. The Mg$_2$Si has attracting attentions as a novel, mass-consumable SWIR photodetector with low environmental impact and low cost because its band gap of about 0.6 eV at room temperature corresponds to the cut-off wavelength at 2.1 um[2-4]. However, Mg$_2$Si substrates has not been sufficiently advanced and is not commercially available, so far. One of the significant problems to overcome the developing of high quality Mg$_2$Si substrate is a sticking of Mg$_2$Si crystal to common crucibles used in melt growth. The high purity Mg$_2$Si single crystals which were grown in the PG-coated graphite crucible by the vertical Bridgman (VB) method contained the small angle tilted grains [3] due to the sticking of the crystal to the crucible. In this report, we grew the Mg$_2$Si crystals in a pBN or BN crucibles and investigate the influence of contaminated boron on the device performance of Mg2Si pn-junction photodiode. The crystals grown in the pBN crucible was unstuck to the crucible and had a nearly convex crystal tail. The contamination of B was found to be about 30 ppm in the grown crystals by the GDMS analysis. In addition, increase of electron concentration was also found in the crystals grown using pBN. The value of (6.8-7.0) 10$^{16}$ [cm$^{-3}$] in the pBN-crystal is more than one order of magnitude than that of PG-crystals (3×10$^{15}$ [cm$^{-3}$]). We also investigated the I-V characteristics and photosensitivity of the Mg2Si pn-junction photodiodes. Those results will be discussed in the presentation.

**EN16.03.11**

**Effect of Band Alignment on the Photosensitivity of Mg$_2$Si-SWIR Detector**

Daisuke Niioka$^1$, Fumiya Takahashi$^1$, Misa Yoshida$^2$, Daiju Tsuya$^2$ and Haruhiko Udono$^1$; $^1$Ibaraki University, Japan; $^2$NIMS, Japan

A high sensitive and high responsive short wave infrared detector (SWIR-detector) is expected to be use in a variety of industrial and scientific applications such as environmental monitoring, remote sensing of resource, growing observation in agriculture and night vision systems in social safety. We have been developing the Mg$_2$Si photodiode (PD) [1-4] as an alternative low-cost SWIR-photodetector suited for mass-consumption compared with the commercially available MCT and InGaAs photodetectors in the SWIR region. In this paper, we investigated the spectral photosensitivity of ring-electrode type Mg$_2$Si pn-junction PDs of which the band alignment between the p-Mg$_2$Si and metal ohmic contact was varied using Au/Ti or Au/Ni electrode. The spectral photosensitivity of the PDs was measured using a conventional lock-in technique with a monochromatic incident light which passed through a 10 cm- monochromator from a silicon carbide light source. The temperature of the PDs was varied between 77K and 300K in the cryostat (Oxford, Optistat DN2). The photosensitivity of the PD with the Au/Ti/p-Mg$_2$Si electrode was increased approximately 400 % compared with that of the PD with the Au/Ti/p-Mg$_2$Si electrode due to the favorable band alignment of Au/Ni/p-Mg$_2$Si electrode, where the band off-set could not form between the p-Mg$_2$Si and Ni. The photosensitivity was raised below about 2.1 um in both Au/Ni and Au/Ti electrode type Mg$_2$Si PDs and increased with decreasing the wavelength. The maximum photosensitivity under zero bias condition in the Au/Ni electrode type PD was about 0.17 A/W at about 1.42 um. The maximum photosensitivity was increased with decreasing the temperature and reached to 0.67 A/W at 1.3 um at 100K. Decrease of cut-off wavelength due to the
band gap widening was also observed with decreasing the measurement temperature. The value of cut-off wavelength was about 1.85 um at 100K.

EN16.03.12
Fabrication of Thermoelectric Based Hydrogen Sensor Using Tellurium Nanowire with Graphene Supported Pt Catalysts for H₂ Sensing Gwang-Myeong Go, Yoseb Song, Han Kim, Hong-Baek Cho and Yong-Ho Cho; Hanyang University, Korea (the Republic of)

For decades, hydrogen has been considered the most renewable and sustainable energy source which can be alternative of fossil fuel, owing to its environmentally friendly and perfect combustion without carbon included emissions.[1, 2] Despite these advantages, it is required to ensure safety regarding the use of hydrogen gas due to its colorless, odorless properties and especially its explosive behavior in wide range of concentration (from 4% to 75%) in ambient air.[3] Therefore, most of research efforts have been focused on the development of hydrogen gas sensor with high sensitivity and fast response time to prevent unexpected risks.

Among various hydrogen gas sensor devices, thermoelectric based hydrogen sensors, which are composed of a thermoelectric layer that generates voltage due to temperature difference from exothermic reaction of hydrogen oxidation by catalyst layer, have shown a great potential as a next generation of hydrogen gas sensor, owing to low power consumption, fast response time and room temperature operability.[4, 5]

In this research, we have developed an ultra-fast thermoelectric hydrogen gas sensor composed of tellurium nanowires-based thermoelectric layer and graphene-supported Pt catalysts layer. The tellurium nanowires which is a p-type semiconductor were synthesized by solvothermal method without any additives. The thermoelectric layer was fabricated by tape casting method using tellurium nanowire paste and exhibited excellent Seebeck coefficient of 428 µV/K. Graphene supported Pt catalysts were synthesized by anchoring effect and confirmed the impact of the amount of Pt precursor. The device showed great sensing performance due to the high Seebeck coefficient of tellurium at room temperature and excellent exothermic performance of graphene-supported Pt catalysts. The device can detect with a wide range from 50 ppm to 3% of H₂ concentrations and which showed relatively fast response and recovery time at room temperature. In addition, interference of relative humidity was greatly minimized by using the graphene-supported Pt catalysts.

WS2: Synthesized on Porous SiO₂ Nanorods Template for Highly Sensitive NO: Sensor at Room Temperature Jun Min Suh, Ki Chang Kwon, Tae Hyung Lee, Kootak Hong, Seokhoon Choi and Ho Won Jang; Seoul National University, Korea (the Republic of)

There have been increasing demands on high-performance sensors with the development of technologies in data acquisition and processing. Especially, those for gas detection can give various helpful information about human health and life. For example, exhaled breath of human has many biomarkers for potential diseases, and indoor air monitoring can alert any harmful gaseous species before exposure to human. In order to collect gaseous information from various sources in real-time, the gas sensors should be small-sized for portability and exhibit low power consumption to be embedded on mobile devices. To date, various types of gas sensors have been developed.
including electrochemical sensors, optical sensors, mass-sensitive sensors, or chemoresistive sensors. Among them, chemoresistive gas sensors are the most suitable candidates for future commercialization into mobile devices due to their simple structure and relatively cheap fabrication processes. Previously reported chemoresistive gas sensors have widely adopted metal oxide semiconductors (MOS) like SnO₂ or WO₃, and they are actually commercialized. However, MOS gas sensors need a relatively high operating temperature over 300°C for reliable operation and this leads to inevitable high power consumption. Although some manufacturers have been optimizing off-state current and on-state current for reduced power consumption, still lower power consumption is desired for mobile application. Therefore, two-dimensional (2D) materials have been proposed as an alternative to MOS for their high surface-to-volume ratio beneficial for operation at room temperature. Among various 2D materials, transition metal dichalcogenides (TMDs) have attracted a great amount of attention due to superior mechanical properties and remarkable electronic properties. Herein, we synthesized tungsten disulfide (WS₂) on a porous SiO₂ nanorods template for highly sensitive NO₂ sensors operating at room temperature. The SiO₂ nanorods with 500 nm thickness were prepared by the glancing angle deposition method using an e-beam evaporator. The precursor solution for WS₂ was spin-coated on SiO₂ nanorods and sulfurization was conducted using a chemical vapor deposition system. Uniformly coated WS₂ on SiO₂ nanorods exhibited the gas response of 152% to 5 ppm NO₂ at room temperature with a theoretical detection limit of 13.7 ppb. This promising gas sensing properties with excellent recovery at room temperature can offer a new perspective towards the real application of TMDs-based gas sensors.

**EN16.03.14**  
**Synthesis of Bismuth Nanoflowers and Their Application for Electrochemical Sensing of Heavy Metal Ions**  
Edward Fratto, Mary Joens, Jirui Wang and Zhiyong Gu; University of Massachusetts Lowell, United States

Heavy metal ion contamination is a significant, invisible threat to public health largely presupposed as eliminated by governmental supervision. Government agencies actively survey and maintain established regulatory limits on heavy metal contamination, but only prioritized to localized hotspots in high-risk communities. The characterization techniques of heavy metal ions are typically expensive and time consuming, requiring specialized training and extended sample shipping times, with a purview restricted to public infrastructure. As residential plumbing systems corrode and contaminants leach into private water systems, independent means of oversight are becoming increasingly vital in effectively identifying and mitigating toxic exposure. In this work, a bismuth nanoflower structure has been developed as a potential nontoxic sensor material for detection of heavy metal ions. The high surface area nanostructure was synthesized via aqueous chemical reduction of bismuth chloride salt in a micellar environment of sodium dodecyl sulfate, designed for high sensitivity by consideration of the crystallization mechanism in optimization of associated parameters. The nanoflower structure was deposited onto a glassy carbon electrode and coated with a protective Nafton layer, prior to cyclic voltammetry analysis of analyte ion reactivity, achieving a lower detection limit for lead and zinc, respectively. These results indicate the viability of bismuth-based nanoflower structures for portable, accessible detection of heavy metal ions, with enhanced sensitivity.

**EN16.03.15**  
**Structural and Property Modification of Wide-Bandgap β-Ga₂O₃ and ZnO Thin Films via Laser-Assisted Room-Temperature Epitaxy for Gas Sensor Applications**  
Hiroyuki Morita¹, Tomoaki Oga¹, Takumi Matsushima¹, Nobuo Tsuchimine², Satoru Kaneko³, Akifumi Matsuda⁴ and Mamoru Yoshimoto⁴; ¹Tokyo Institute of Technology, Japan; ²TOSHIMA Manufacturing, Japan; ³Kanagawa Institute of Industrial Science and Technology, Japan

Thin-film gas sensors utilizing oxide and nitride semiconductors have attracted interests according to the materials high thermal and chemical stability as well as to their sensitivity improved by nanostructures and surface effects. Gallium oxide (Ga₂O₃) and zinc oxide (ZnO) are anticipated wide-bandgap semiconductors for gas sensing applications, which have been researched detection of reactive gases (e.g. H₂, O₂, CO, CH₄) utilizing the oxides with their conductivity modified by doping technique [1–3]. On the other hand, epitaxial thin films with high crystal orientation would contribute to gas sensing characteristics in β-Ga₂O₃ and ZnO by modifying surface chemistry and carrier mobility of crystal materials to obtain sufficient on/off ratio in the devices. The β-Ga₂O₃ and ZnO epitaxial thin films generally have been grown at high-temperature above 400°C, though reduction of epitaxy temperature advances development of refined devices according to improved surface flatness, interfacial sharpness, and compositional reproducibility [4]. The increased specific surface due to nanoparticulation would also enhance the gas detection properties. In this study, room-temperature syntheses of heteroepitaxial β-Ga₂O₃ and ZnO thin films using excimer laser processing, and the effect of structural and morphological modification of the films on physical
properties were investigated. The ZnO and precursor amorphous Ga2O3 thin films were prepared by pulsed laser deposition technique equipped with a KrF excimer laser (λ=248 nm, d=20 ns, and E~1.5 J/cm²). The films were deposited on atomically stepped α-Al2O3 (0001) substrates with NiO (111) buffer layers at room-temperature. The obtained amorphous Ga2O3 thin film were subsequently solid-phase crystallized by atmospheric excimer laser annealing (ELA) process, in which KrF excimer laser beam (not focused, E~250 mJ/cm²) was irradiated on the film at room-temperature circumstances. As a result, room-temperature formation of both β-Ga2O3 (-201) / NiO (111) / α-Al2O3 (0001) and ZnO (0001) / NiO (111) / α-Al2O3 (0001) heteroepitaxial thin films was obtained. The β-Ga2O3 (-201) and ZnO (0001) films revealed ultra-flat surface well reflecting morphology of the substrates. The gas sensing properties of the heteroepitaxial ZnO thin films were evaluated with pure H2 gas at room-temperature, in which the result revealed fast response that sheet resistivity was reduced by 30% from ~1×10⁻³ to ~7×10⁻⁴ Ωcm. In addition, the optical bandgap of the obtained β-Ga2O3 (-201) film was 4.9 eV comparable to high-temperature grown films. Structural analyses of β-Ga2O3 crystallization process by ELA, and conduction property modification of both materials would also be presented.

EN16.03.16
The Sensing of Oxygen Partial Pressure in Air Based on ZnO Nanoparticles Xin Chang and Daping Chu;
Centre for Photonic Devices and Sensors, University of Cambridge, United Kingdom

Oxygen-related defects are dominant to the properties of Zinc Oxide nanoparticles (NPs) and thus making ZnO NPs a potential candidate for oxygen sensing applications. A solution-processed and highly sensitive oxygen partial pressure sensor based on ZnO NPs thin film was fabricated and characterized. The sensor was capable of measuring the oxygen partial pressure in air from 10⁻⁵ mBar to 10³ mBar and it also featured a heat-erasing capability. In the meanwhile, it was observed that the annealing temperature has a notable effect on sensor sensitivity and the highest sensitivity was realized at 600°C. In order to explain the annealing effect and understand the fundamental physics behind it, ZnO NPs were investigated on their trap states and dielectric properties. In the end, mould-guided drying technique was introduced to pattern ZnO NPs into lines in micrometer and even nanometer scale directly from its dispersion, and an oxygen partial pressure sensor was fabricated based on the patterned ZnO NPs lines, which makes it extremely promising in miniaturized and integrated sensing applications.

EN16.03.17
Gas Sensing by Nanostructured Tin Dioxide Films Decorated with Polyoxometalates Martin Vrnata¹, Jan Vlcek¹,², Masooma Ibrahim¹, Jaroslav Otta¹,², Martin Hruska¹ and Premysl Fitl¹,²; ¹University of Chemistry and Technology, Prague, Czechia; ²Institute of Physics, Czech Academy of Sciences, Czechia; ³Karlsruhe Institute of Technology - Institute of Nanotechnology, Germany

This contribution brings connection of two impressive kinds of oxide semiconducting materials for using as enhanced sensitive material for chemical gas sensing. The first kind of material is nanostructured tin dioxide (SnO₂) in form of thin film consisting of nanowires and nanoporous structures. SnO₂ and its nanostructures are well known for years as an effective material for chemiresistive gas sensor for detection of gases with redox features (H₂, hydrocarbons, vapor of alcohols etc.). The second kind of material is transition metal oxide single molecule nanocrystal (polyoxometalate) with catalytic features. Polyoxometalates consist of large number of Mo, W, V, Ta, Nb, P. As atoms with oxygen and form lacunary (vacant) molecules with features of high chemical stability and catalytic activity. They can accommodate/incorporate transition metal ions or transition metal clusters at specific sites of the rigid structure, leading to interesting molecules with specific topologies and highly symmetric environments.

In this work we present sensor structure consists of nanostructured SnO₂ decorated with polyoxometalates. As sensor substrates we use alumina plates with interdigitating platinum electrodes (50 microns between electrodes) and platinum heater element. SnO₂ thin films are prepared by thermal CVD from tin monoxide and tin acetylacetonate source material. Different polyoxometalates are subsequently applied by using wet-techniques from water solution onto the SnO₂ nanostructures. Morphology studies are performed by electron microscopy (SEM) and chemical composition analysis is done by EDX and XPS. Sensor behavior of such structures was tested as responses
to basic analytes (H₂, alkanes, alcohols and aldehydes) in concentration of up to 100 ppm in synthetic air. Sensor results from polyoxometalates decorated sensors are compared to bare SnO₂ sensors. We demonstrate that polyoxometalates significantly improve sensitivity of presented sensor structures as well as they decrease the detection limit to ppb concentrations region.

EN16.03.18
Hydrothermally and Anodized Titanium Dioxide Nanotubes Powder (TNTP) as an Antibacterial Agent under Light and Dark Conditions for Water Microbial Purification Walaa Abbas, Mohamed Ramadan, Amged Ouf and Nageh K. Allam; The American University in Cairo, Egypt

The use of titanium dioxide nanotubes in the powder form (TNTP) has been a hot topic for the past decades in many applications. The high quality of the fabricated TNTP by various synthesis routes may meet the required threshold of performance in a plethora of fields such as drug delivery, sensors, supercapacitors, and photocatalytic applications. In this research work, the TNTP were used as an antibacterial agent for water microbial purification with different synthesis techniques of the powder form as hydrothermal and rapid breakdown anodization methods. The TNTP were characterized by SEM, X-Ray Diffraction (XRD), Raman, FTIR, and UV-Visible Spectroscopy to study the effect of the structure, surface morphology, chemical composition, crystallinity and the optical properties of them. The antibacterial activity test was carried out using a viable count method against Escherichia. coli as a model of gram-negative bacteria in the presence and absence of solar radiation. Upon UV irradiation, hydrothermally synthesized-TNTP showed higher efficiency in deactivating E. coli (~96.7%) than the anodized TNTP. Several factors play a significant role in determining the antibacterial activity of TNTP. These factors including the crystalline phase, surface hydroxyls, physicochemical properties of TiO₂ as well as the experimental conditions.

EN16.03.19
Effect of Channel Morphology and Gating Medium on Tio2 Ion-Gated Transistors Arunprabaharan Subramanian, Ben George, Irina Valitova, Sanyasi Rao Bobbara, Clara Santato, Fabio Cicoira and Jo’Elen R. Hagler; Polytechnique Montréal, Canada

Nowadays transistors are used for the production of lightweight, transparent, flexible, portable and biocompatible electronics for a variety of applications, such as flexible displays, chemical or biological sensors, wearable and textile integrated systems, medical implants and artificial skins. Metal oxide ion-gated transistors (IGTs) are attractive for chemo- and bio-sensing platforms as they operate at a low voltage (e.g. below 1 V). Metal oxides are of interest as transistor channel materials in IGTs due to chemical stability and ease of processability in the air at a lower temperature. These include oxides of tin, indium, zinc, tungsten, titanium, and iron. Indium oxide-based channel material shows superior transistor performance, but the availability of indium is limited in the earth crust, so there is a necessity to explore alternative materials. Titanium dioxide is an abundant material, whose conductivity can be strongly modulated by ion-gating and is useful as an n-type semiconducting channel material for IGTs. IGTs use ionic liquids, polymer electrolytes or aqueous saline solutions as gating media to modulate the charge carrier density in the transistor channel. In this work, we investigate the role of TiO₂ film morphology (porous versus dense films) and cation size in the gating medium ([EMIM]⁺ versus Li⁺) on the electrical characteristics of IGTs. The solution processed film yields a porous structure with a mixture of anatase and rutile phases, whereas e-beam evaporated TiO₂ yields a dense and smooth film with mostly anatase phase. Electrical characteristics of dense-film IGTs gated by large-size cation gating media are relatively unaffected by scan rates in current-voltage measurements, as the ions cannot permeate the films. However, in these same films, small-size cations can permeate the films such that reducing the scan rate increases drain current and ON/OFF ratio.

Detection of Volatile Organic Compounds by Freestanding Aligned Ag/QR/PMMA Texture Chi-Hung Lin¹, Ming-Chung Wu¹, Tz-Feng Lin², Shun-Hsiang Chan¹, Ting-Han Lin¹, Kai Wang¹ and Chao-Sung Lai¹; ¹Chang
Gung University, Taiwan; 2Feng Chia University, Taiwan; 3Southern University of Science and Technology, China

Volatile organic compounds (VOCs) are organic chemicals having a high vapor pressure at ordinary room temperature, and they are potentially dangerous to human health once chronically breath in. Daily exposure to VOCs has serious harmful effects including a wide range of sensory irritation and chronic diseases (e.g., nervous system impairment, asthma, or potential to cancer). On the other hand, severe injury and lethal death could occur in the gas explosion and consequent fire since the VOCs concentration gets above the lowest explosion limit in air. Monitoring of VOCs and delivering of the alarm message in the very early stage therefore becomes important for modern society, especially in chemical factory management. In order to guard our homeland and eliminate accidental factors, a gas sensor is urgent to be developed as a precaution tool. High-performance VOCs sensor should be a device with real-time detection, high sensitivity, and high reproducibility. In this study, we build a high-performance freestanding aligned Ag/CdSe-Cds/poly(methyl methacrylate) (PMMA) texture to detect VOCs. The insight of this new VOCs sensing materials is based on electrospinning techniques, ultraviolet (UV)/ozone treatments, and nano-optics. The incorporation of CdSe-Cds core-shell quantum rods (QRs) and silver nanocrystals in the PMMA nanofibers amplifies the polarization response of long rods from VOCs detection so as to increase the sensitivity of VOCs sensing materials. Further, the uniaxial aligned Ag/QR/PMMA was treated by UV-ozone etching to a certain increment of surface absorption. Metal frame substrate is employed for 15 min UV-ozone etching on double-side. The higher specific surface area was successfully made on the freestanding Ag/QR/PMMA sensing materials enabling advanced VOCs sensing efficient. The advanced UV-ozone etching on the double-side of uniaxial aligned Ag/QR/PMMA efficiently enhances the extinction changes of VOCs. The freestanding Ag/QR/PMMA sensing materials has characteristics of polarization at 90° and 270°. It amplifies extinction changes in light to a significant level for the VOCs sensitivity judgment. Moreover, when the freestanding Ag/QR/PMMA sensing materials was exposed in high concentrations (10,000 ppm) of volatile organic gases, the alcohols, esters, and the aromatic can be detected instantly. The results showed that even under a low concentration (100 ppm) n-butanol atmosphere can still be detected within one minute. The freestanding aligned Ag/QR/PMMA texture is a newly designed nanocomposite device for environmental risk monitoring. It could be accepted by the market compared to the other commercial highly sensitive VOCs sensing materials.

EN16.03.21
Highly Selective and Sensitive Ammoina Gas Sensors Using Naphthalene Diimide(NDI)-Based N-Type Organic Field-Effect Transistors Byeong M. Oh, Seung Cheol Lee, Su-Kyo Jung, Gyeong G. Jeon, Sung-Ha Park, Jong H. Kim and O-Pil Kwon; Ajou University, Korea (the Republic of)

In this presentation, we report highly selective and sensitive ammonia gas sensors using highly electron deficient naphthalene diimide (NDI)-based organic field-effect transistors (OFETs). In order to control π-electron deficiency of NDI core, we designed the NDI derivatives by introducing various electron withdrawing groups (EWGs). In contrast to conventional FET gas sensors that operate through resistive mechanism, NDI-based OFETs exhibited high responsivity by showing high current increase when exposed to NH3 gas with excellent selectivity. From the optical and electrical characterizations, we revealed that the origin of high selectivity and sensitivity were the efficient radical formation between the NDI derivative and gas molecules, and degree of radical formation, respectively. Through the morphology optimization with device engineering, we achieved outstanding responsivity up to 250% current increase and sensitivity down to sub-ppm gas concentration. We suggest that employing different types of EWGs on organic n-type semiconductors can be a potential design strategy for developing highly selective and sensitive gas sensors.

EN16.03.22
Microscale Phthalocyanine Gas Sensors Prepared by Laser-Induced Forward Transfer Jaroslav Otta1,2, Joris More-Chevalier2, Premysl Fitl1,2, Martin Vrana1 and Jan Vlcek1,2; 1University of Chemistry and Technology Prague, Czechia; 2Institute of Physics of the Czech Academy of Sciences, Czechia

The miniaturization of sensors plays a significant role in the development of wireless and complex detection systems. We suggest continuous-wave laser-induced forward transfer (CW-LIFT) combined with photolithography as a suitable manufacturing process for the creation of micro-chemiresistors. The laser deposition system consisted of a CW laser with a 405 nm operating wavelength, 50 mW power source and 4x microscope objective. A donor substrate was composed of borosilicate glass, a thin layer of sputtered gold and a layer of zinc phthalocyanine. The interface of the glass substrate and sacrificial gold layer absorbed the laser energy resulting in a local thermal
transfer of the zinc phthalocyanine from the donor substrate to a receiving substrate with golden electrodes. The absorbed laser energy was controlled by altering a laser scan speed in a range of 0.1 to 5 mm/s. At the speed that produced the best results, the transferred phthalocyanine had a spatial resolution of less than 5 µm and a very high surface-to-volume. SEM scans showed the transferred zinc phthalocyanine structure with confirmation by FTIR. The response of microchemiresistors was tested on a wide variety of gasses with the highest response above 200 to 10 ppm of nitrogen dioxide. Our results showed CW-LIFT as a suitable high-resolution deposition technique for creation of micro-chemiresistors.

EN16.03.23
High-Resolution Deposition of Phthalocyanine-Fullerene Heterojunctions by Laser-Induced Forward Transfer
Jaroslav Otta1,2, Joris More-Chevalier3, Ladislav Fekete1, Premysl Fitl1,3, Martin Vrnata1 and Jan Vlcek1,2;
1University of Chemistry and Technology Prague, Czechia; 2Institute of Physics of the Czech Academy of Sciences, Czechia; 3Institute of Physics of the Czech Academy of Sciences, Czechia
Phthalocyanine-fullerene thin films, a promising material for solar cell technology and chemical sensing, are typically formed by evaporation and PLD. However, such deposition techniques require vacuum systems and do not offer high-resolution. Here, we investigate the use of continuous wave laser-induced forward transfer (CW-LIFT) as a suitable deposition technique for the formation of zinc phthalocyanine-fullerene nanocomposites. In particular, we seek to determine the laser energy range at which nanocomposites are formed with suitable morphology and composition. The laser deposition system consisted of a CW laser with a 405 nm operating wavelength, 50 mW power source and 4x microscope objective. The laser energy was controlled by altering the laser scan speed in the range of 0.05 – 5 mm/s. A donor glass substrate/sputtered gold layer interface was used to absorb the laser energy for the local thermal transfer of thin phthalocyanine and/or fullerene films to a receiver substrate. SEM scans showed that microcrystals were formed in a wide laser scan speed range. At the speed that produced the best results, the transferred nanocomposite had a spatial resolution of less than 5 µm and a very high surface-to-volume ratio. In addition, AFM showed that the surface roughness of the donor layers was homogeneous. Collectively, our results suggest that CW-LIFT is a suitable deposition technique when operated with the appropriate laser scan speed.

EN16.03.24
Nanopatterned Structures of Molecularly Imprinted Polymer Films for the Selective Detection of Endocrine Disrupting Chemicals
Jihye Lee, Sangheon Jeon, Seon Yeong Chae and Suck Won Hong; Pusan National University, Korea (the Republic of)
Molecularly imprinted polymers (MIPs) are an intriguing class of synthetic materials capable of selectively recognizing both biological and chemical molecules for a variety of high-value applications in chemical sensors, catalysis, drug delivery, antibodies, and receptors. The concept of molecular imprinting is widely known to perform a tailored recognition process by the selective adsorption of the certain molecules often observed in natural biological systems such as enzyme catalysis or antigen-antibody interactions. In principle, the MIP technique involves the imprinting process of specific molecules in a polymer matrix by chemical synthetic approaches, which provide stable cavity configurations after the simple removal of the template molecules. Here, we report a simple one-step technique to craft a set of highly ordered MIP structures in micro- and nanoscale generated from the drying-mediated self-organization in a confined geometry where the polymer solution containing molecular templates is trapped by capillary force. MIP solutions containing a crosslinking agent, photoinitiator, and molecular templates (e.g., 2,4-D) was constrained within a roll-to-flat geometry, and the capillary held solution readily induced repetitive stick-slip motions of the contact line as the roll was slowly moved over the flat substrate. As a result, we observed highly organized MIP nanopatterns with unprecedented regularity over large areas. This self-organization of MIPs by the controlled roll-print process under UV exposure can be fully utilized to produce layered architectures with the enhanced surface area. The gravimetric quartz crystal microbalance was used to evaluate the relative selectivity of the resultant MIP sensors towards 2,4-D against 2-chloro-4-ethylamino-6-isopropylamino-1,3,5-triazine, 4-N-ethyl-6-methylsulfanyl-2-N-propan-2-yl-1,3,5-triazine-2,4-diamine, and benzoic acid. Our self-organization technique is simple and cost-effective, offering a promising route to organize molecularly imprinted polymeric materials into nanoscopic sensing devices for the selective detections of endocrine disrupting chemicals.

EN16.03.25
Steam-Aided Chemical Vapor Deposition of Metal–Organic Frameworks for Chemiresistive Sensing
Jing-Kai
Huang, Lance Li and Sean Li; University of New South Wales, Australia

Suitable on-surface film deposition methods are prerequisite to incorporating metal-organic frameworks (MOFs) into functional platforms and microdevices. Heretofore, the development mostly relies on the solvent-based procedures, typically altered from powder synthesis routes, which are obstacles to the nanofabrication process. Besides, although few vapor-phase growth approaches were presented, the proposed procedures are devious and involved with a relative high-end instrument, atomic layer deposition (ALD). Here, we report a steam-aided chemical vapor deposition (CVD) approach for directly producing ZIF-67 and associated zeolitic imidazolate frameworks (ZIFs). The introduction of solvent steam, as a mediator, thoroughly prompts ZIF crystal ripening. The introduction of solvent steam, as a mediator, thoroughly prompts ZIF crystal ripening. Also, the straightforward depositing method enables the growth of highly oriented ZIF thin films by properly adjusting the growing window. With the technique, we seek to prove that the steam-assisted CVD is a microelectronics-compatible MOF thin film synthesis route by demonstrating miniature ZIF-67 chemiresistors based on a conventional microfabricating process. The ZIF-67 chemiresistors exhibit certain response to the molecules which are equipped with the ability to form hydrogen bond and penetrate into the cages of ZIF-67. The proposed steam-assisted CVD approach not only opens new avenues to explore various MOFs preparing ways but also expedite the integration of MOF materials in microelectronics and related applications.

EN16.03.26
Optical Spectroscopy and Electrical Characterization of PEI/PAA LbL Films with Embedded Ag Nanoparticles  
Rafael C. Ferreira¹, Maria H. Gonçalves¹, Matthias Hillenkamp², Osvaldo Oliveira Jr.³, Antonio Riul¹ and Varlei Rodrigues³; ¹University of Campinas, Brazil; ²Institut Lumière Matière, France; ³University of São Paulo, Brazil

The Layer-by-Layer (LbL) technique is a versatile method to modify surfaces by spontaneous adsorption of charged molecules. This technique allows assembling highly ordered nanostructured films with specific tunable properties, which makes them suitable for various applications, including catalysis, optics, biomedicine and sensors. It has been demonstrated that both sensitivity and selectivity of sensors based on polyelectrolyte LbL films can be significantly enhanced by doping them with metal nanoparticles (NPs).¹,² The underlying mechanisms for this enhancement are, however, unclear today, notably because important parameters such as nanoparticle concentration are difficult to control in wet-chemical assembly. We propose here a different approach to sample fabrication, based on the implementation of surfactant-free silver nanoparticles in prefabricated LbL films, giving us full and independent control over all sample parameters. We can then study the influence of individual parameters like NP size, composition and concentration on optical and electric properties of the nanostructured films before implementing them in sensor prototypes. LbL films composed of polyethylenimine (PEI) and poly(acrylic acid) (PAA) in (PEI/PAA)n architecture, were grown on quartz substrates and interdigitated gold electrodes. Bare Ag NPs around 3 nm diameter, fabricated in the gas phase in a magnetron cluster source are then implanted at controlled deposition energy. The first prerequisite is to verify the correct spatial dispersion of the NPs in the polymer. This is achieved by optical spectroscopy of the localized surface plasmon resonance of Ag NPs, which allows distinguishing between isolated and coupled NPs, up to the formation of (discontinuous) metallic films. Further experiments comprise in situ impedance measurements, which were performed using an impedance meter developed in our research group. The impedance measurements allow keeping track of the hybrid material ’s electrical properties during NP deposition. Thus, we observe that Ag NP deposition causes a competition between capacitive and resistive behavior. Following the electrical ac response during continuous accumulation of metal NPs within the polymer matrix gives us crucial information, not only about the NP dispersion but also on how the electrical properties of the nanostructured film can be tuned for future implementation in electrochemical sensors.

Fast-Response Humidity Sensor Based on Transition Metal Dichalcogenide Nanosheets and Metal Ion
Humidity sensors have been studied for decades. Most sensing elements are either ceramic or polymeric and the sensing platform is either capacitive or resistive. Recently 2D material, in particular MoS₂, based capacitive relative humidity sensors have shown much higher sensitivity than existing relative humidity (RH) sensors based on ceramics. The other major performance characteristics of RH sensors is the range that should ideally cover the entire range of non-condensing humidity percentage and the response time. Typical range for modern sensors is now 10 – 97% and response time is larger than 1 second (typically 10s).

In order to integrate the sensors in real-life applications, such as health monitoring system, the sensing needs to exhibit sub-second response time to obtain real-time information and be able to measure an extended range of humidity with high resolution in order to detect when humidity surpasses normal operating levels but also sense human presence in proximity with the system.

In this work we have studied the application of 2D materials such as MoS₂ or WS₂ for humidity sensing. For this purpose, we have developed the sensing platform based on TMDCs/metal nanoparticles composite sensing element. Both MoS₂ and WS₂ have been identified as promising candidates for sensing application and nanoparticles of metals such as Ag, Au and Cu were added to improve the sensitivity and stability of the sensor.

Solution-exfoliated MoS₂ and WS₂ nanosheets were obtained using a probe sonicator system and nanosheets with different sizes were extracted by a vacuum filter system. Humidity sensors with different nanosheet sizes were assembled and tested against the commercial humidity sensor. The devices showed good response to RH in the range of 5 - 75% and response time below 1 s. Moreover, they show excellent stability in time.

MoS₂ nanosheets with smaller size show better humidity sensing behavior than the original MoS₂ nanosheets without filtering and centrifugation, mainly due to their higher surface-to-volume ratio. We have also observed different resistance response to humidity between the MoS₂ and WS₂. Finally, the influence of metal nanoparticles on the sensing capabilities was studied.

EN16.03.28

Transparency-Based Visual Sensor for Easy-to-Use Detection of Organic Liquids Kyeong Min Song and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

With growing demand for fast and accessible testing device for health and environment monitoring, easy-to-use visual sensors has been gaining wide attention. Especially, visual based detection system for organic liquids has been gaining interest due to increase in awareness of the negative effects of the organic liquids to the health and the environment, and is increasing in demand because use in a wide variety of applications from food inspection and fuel quality control to synthesis monitoring. Currently, the most conventional visual sensors are based on colorimetric system, which produces its signal based on color change to external stimuli. However, several challenges are present for colorimetric sensors to detect liquid-phase chemicals, and needs to meet strict requirements for the sensing medium to perform liquid sensing capabilities. Therefore, development of a new visual sensing platform for detecting target liquids is highly desired.

In order for effective detection of organic liquid based on visual sensing, we took a different approach and used transparency as the visual que for the organic liquid sensing platform. The idea is to use a light scattering polymer medium that changes its transparency in response to the presence of the organic liquid. The sensing medium was designed to produce three transparency state: transparent, semi-transparent, and opaque, according to the interaction between the organic liquid and the sensing medium. The sensing medium was fabricated by engineering the shrinkage stress relaxation between the polymer matrix and the embedded particle, which produces a porous structure with micro-sized voids embedded in hollow particles. This porous structure is essential for producing the three transparency state, which is crucial for effective differentiation of various organic liquids. The advantage of the fabricated porous sensing medium is that the structure is produced by controlling polymer dynamics rather than polymer assembly, allowing use of a wide selection of polymer and control of the thickness. An array of the transparency-switching scattering medium using different polymers is able to differentiate a wide variety of organic liquids, and even liquids with similar structures and chemical properties. Furthermore, by varying the thickness of the responsive medium, the transparency-based sensing medium is able to identify the liquid composition in ternary mixture. This work shows the effectiveness of a newly designed sensing material using transparency as a visual que for organic liquid sensing.

EN16.03.30
Optical Nano-Antennas for Short Wave Infrared Sensing of Water Vapour and Aerosols in the Atmosphere
Kritika Bhattacharya, Akshita Mishra, Priya Vinayak and Madhusudan Singh; Indian Institute of Technology Delhi, India

Earth's atmosphere is a complex and dynamic system that directly impacts, and is impacted by human activity. Levels of water vapour in air and their spatial distribution determine major weather events such as the Indian monsoon. Human activity generated aerosols (especially PM2.5) have lasting impacts on human health, and their presence is in turn affected by relative humidity through the hygroscopic growth factor. Space-based sensors such as MODIS (specifically bands 20 - 22), and VIIRS (specifically I4 and M12 bands) regularly image the Earth's atmosphere in an interesting short wave infrared range (2.5-4 μm) that contains fundamental band for water (~ 2800 nm) and absorption bands for several other atmospheric gases/pollutants - O₃ (low absorption), N₂O (significant absorption), O₂ (low absorption), CO₂ and CH₄ (significant absorption for both these greenhouse gases), CO (low absorption), etc. In this work, we have designed and fabricated a bowtie nanoantenna (400 nm arm length, apex angle = 60°, thickness = 80 nm) reflectance-based sensor exhibiting a strong response in the wavelength range 2.55-2.85 μm. An array of these nanoantennas (apex to apex gap = 100 nm) was designed using finite difference time-domain (FDTD) simulations (Lumerical, using polarized light parallel to antenna axis). A hundred fold electric field enhancement in the gap, tuned to match this wavelength range (averaged efficiency ~60%, predicted using HFSS, with a 1 kΩ source impedance), resulting in maximal absorption was predicted. To fabricate the antennas, a positive photoresist (A4 (450K)) was deposited on a cleaned (RCA) silicon substrate (University Wafers). A pre-bake step was carried out at 180°C for 20 minutes. The photoresist was patterned using electron-beam lithography (eLine Plus, Raith) with a dose of 120μC/cm² to write a layout of the antenna array (Cadence Virtuoso). A post-bake step (110°C, 30 minutes) was employed before pattern development in a methyl isobutyl ketone (MIBK): isopropanol (IPA)=1:1 developer for 60 seconds. Gold (Sigma-Aldrich, 4N pure) was then deposited on the substrate through thermal evaporation (Advanced Process Technologies) at a base pressure of 4x10⁻⁶ Torr, followed by lift-off (acetone). Scanning electron microscopy (SEM) scans of the bowtie array were found to agree with the designed periodicity of 1000 nm. Fourier Transform Infrared spectroscopy (Thermo Electron Scie) measurements in the range 2.55 μm to 2.85 μm revealed a broad minimum in reflectance at ~2.75 μm, in reasonable agreement with the simulation results, which are being refined to achieve a better match with the measurements. This nanoantenna array can be tuned to a different band by changing the geometry of the antenna, and thus provides significant flexibility when compared to narrow band detectors based on InSb and HgCdTe. Space-based light-weight sensors based on these nanoantenna arrays can potentially be used for addressing several bands of interest in short wave infrared for mapping water vapour and derived aerosol content in the air column beneath a satellite in conjunction with sensors working in visible and near infrared regimes.

SESSION EN16.04: Carbon Nanotubes, Graphene and Other Carbon-Based Materials for Gas Sensors

Countering Variability of Carbon Nanotubes in Printed Gas Sensor Jin-Woo Han, Dong-Il Moon and Meyya Meyyappan; NASA Ames Research Center, United States

Despite the early promise of high sensitivity and detection limit of carbon nanotube-based gas sensors, the practical implementation has been delayed. The primary reason is the imperfection of commercially available carbon nanotube material and the variabilities involved in the sensor fabrication procedure. A key longstanding issue has been the production of tightly controlled nanotube properties such as chirality, length and diameter. In addition, placing the nanotube in a controlled volume and orientation is another challenge. As a result, the device responses often vary from device to device and batch to batch. Therefore, a successful transition of the promise of nanotechnology into practical implementation depends on how to design a device that is tolerant to inherent material and process variations and other imperfections. Herein, we present a variation-tolerant sensor design where the sensor response is defined by a statistical value of sub-sensors array in contrast to a traditional deterministic value of a single sensor. Thanks to recent development in microfabrication or inkjet printing technology, one can easily
fabricate a few hundreds of sensors in a stamp size chip. With the printed sensor chip containing multiple sub-sensor array, the sensor response can be obtained by stochastic decision, i.e. single input and multiple output (SIMO). In this work, we present the inkjet printed SIMO gas sensor. The data processing method to remove outlier data point from signal distribution is explained and the origin of outliers is investigated. The repeatability and reproducibility of SIMO sensor is demonstrated. An analytical model to support the hypothesis is addressed.

9:00 AM EN16.04.02
Carbon Black Templated Gold Nanoparticles for Detection of a Broad Spectrum of Environmental Analytes by Surface Enhanced Raman Spectroscopy Akram Abbasi, Geoffrey D. Bothun and Arijit Bose; University of Rhode Island, United States

Surface Enhanced Raman Scattering (SERS) is a powerful tool for detection of analytes at low concentrations. To enhance the Raman signal, the analyte must be in close proximity to the substrate. This often requires customization of substrate, making it useful for the detection of only a specific subset of molecules. We have produced hybrid carbon-gold nanoparticles for the detection of a broad spectrum of molecules using Surface Enhanced Raman Scattering (SERS). Carboxyl-terminated carbon black (CB) nanoparticles were coated with the cationic polyelectrolyte poly-L-lysine (PLL), and exposed to a tetrachloroauric acid solution. Gold-carbon black (Au-PLLCB) particles were formed by the reduction of gold chloride ions that concentrate on the surfaces of the PLL-coated CB templates. The Au-PLLCB particles produced strong SERS signals for 4-nitrobenzene thiol (4-NBT) in ethanol, and for Congo red, crystal violet, and nitrate ions in water. The fractal morphology of the carbon black template and the presence of PLL promote the formation of sharp gold spikes on the surface, yielding hot spots for Raman enhancement. The underlying carbon acts as an absorbent for organic molecules, allowing analytes with poor affinity for the gold surface to concentrate in regions close enough to the particle surfaces to enable detection by SERS. The morphology and chemical nature of the underlying template make the Au-PLLCB a broadly applicable type of particle for detecting of a wide range of analytes in solution.

A Practical Hydrogenated Graphene Gas Sensor for CO₂ & CO Monitoring Samuel Escobar, Solimar Collazo, Alexis Lavin, Leandro Paulino, Ernesto Espada, Brad Weiner and Gerardo Morell; University of Puerto Rico at Río Piedras, United States

The development of a practical gas sensor is of great interest for the monitoring of toxic and non-toxic gases that might endanger our safety and wellbeing in different settings. Hereby we present a practical gas sensor based on hydrogenated graphene for CO₂ & CO monitoring. Hydrogenated graphene was synthesized by “non-conventional” method, directly, onto an Au-pattern insulating substrate. Hydrogenated graphene was then characterized using RAMAN spectroscopy, X-ray photoelectron spectroscopy (XPS) and X-ray Diffraction (XRD). Then, the interaction of the materials with CO₂ & CO was systematically study at different PPM to determine our sensor’s detection limits. Some preliminary research reveals that the hydrogenated graphene-based sensor is capable of sensing CO₂ at the mid ppm level, while the detection limit for CO could be as low as low-ppb.

9:30 AM EN16.04.04
Graphene-Based Environmental Sensors Sensitized by Laser-Deposited Receptor Layers Raivo Jaaniso, Artjom Berholts, Tauno Kahro, Margus Kodu, Dmitri Lanevski, Indrek Renge and Pavel Rubin; University of Tartu, Estonia

As an atomically thin electric conductor, graphene is an ideal transducer of electrical signals from a molecular receptor. Concerning small gas molecules, graphene itself is a poor receptor, supporting only physical, non-specific adsorption. Monolayer graphene functionalized with nano-layers or –clusters of metal oxides (MOX) or noble metals using pulsed laser deposition (PLD) produces a sensitive chemiresistive sensor for air pollutants. The deposition of even a sub-nanometer amount on the CVD-grown graphene increases the gas sensitivity up to 2 orders of magnitude due to the formation of effective adsorption centers. Also, the selectivity can be introduced by the selection of the deposited material. For example, a layer of ZrO₂ or similar oxide lead to high selectivity towards NO₂ or O₃ with low (<10%) cross-sensitivity to other tested gases (CO, SO₂, NH₃, H₂S), whereas V₂O₅ layer leads to a similar result for NH₃ gas. Further improvement of sensitivity and recovery rate occurs when the sensor material is exposed to UV light (< 0.2 mW/mm², 365 nm). The sensitivity level of 1%/ppb was achieved. The increase of signal amplitudes in the UV
light, compared to the conductivity change in the dark state, indicates that the adsorption is photo-chemically promoted. Potential light absorbers – graphene itself, MOX, adsorbed gas molecule – were considered to establish the most plausible photochemical mechanisms. In a different approach, CVD monolayer graphene was successfully transferred to and functionalized by PLD on microheater platforms. It will be demonstrated how the pulsed or modulated heating allows achieving further gas selectivity or significantly reduced response times. The proposed sensor materials have additional merits, such as insensitivity to air humidity and long-term (> 3 years) stability in ambient air. First principle calculations of hybrid nanomaterials consisting of single-layer graphene with MOX clusters on top of it are performed for clarifying the origin of the adsorption sites.

Enabling In Situ Electrochemical Sensing in Water Treatment Using Electrically Conductive Water Filtration Membranes Bezawit Getachew, David S. Bergsman and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Population growth and urbanization has increased the vulnerability of urban water systems. To maintain the quality of water supplied in the face of increased pollution, there is a need for a more proactive monitoring of contaminants within water distribution systems. Incorporating sensing capabilities into technologies that are already part of the water treatment process, such as water filtration membranes, can help meet this need. The use of water filtration membranes as simultaneous sensors also benefits from the high surface area that is inherent in membranes and reduction in mass transfer limitations that restrict the effectiveness of traditional submerged sensors. While traditional polymeric membranes cannot be exploited for sensing, recent advances in the fabrication of electrically conductive membranes present an unexplored opportunity to incorporate in situ electrochemical sensing into membrane filtration. This study discusses the design of conductive membranes for in situ electrochemical sensing using laser induced graphitization (LIG), a facile and scalable method to form porous graphitic surface on a wide range of substrates under ambient conditions. LIG is used to fabricate conductive membranes directly from polyethersulfone (PES) and graphene oxide (GO) membranes. The conductive membrane is then used for the detection of heavy metals using anodic stripping voltammetry. The membrane acts as the working electrode in a three-electrode system while filtering water spiked with Pb²⁺ standard solution. The performance of two types of conductive membranes, namely, PES and GO derived conducive membranes, is evaluated. The effect of solution conductivity, deposition time, as well as filtration rate on the detection limit are investigated. The results of this study will introduce novel sensing architectures for monitoring contaminants within water treatment systems.

Suspended Carbon Nanotube FETs for NO₂ Sensing—Signal Readout and Noise Christofer Hierold¹, Peter F. Satterthwaite², Sebastian Eberle¹ and Cosmin Roman¹; ¹ETH Zurich, Switzerland; ²Stanford University, United States

We report on recent investigations of signal readout concepts and advantageous biasing conditions for suspended single walled carbon nanotube field effect transistors (SWNT FETs) as functional building blocks in ultra-low power NO₂ sensors for environmental applications [1]. Advances in fabrication processes as well as better understanding of the signal characteristics of SWNT FETs has enabled the vision of using individual tube devices directly for NO₂ gas sensors. Suspended devices, which have the potential for upscaling in an industrial process flow, and the optimization of device contact architecture by selective Pt ALD help maintaining the cleanliness of the carbon nanotubes for low hysteresis, low contact resistance and improvement of the noise performance [2],[3], as well as improvement in the cross-sensitivity to humidity. Suspended devices are also attractive for self-heated, low-power architectures [4]. We will discuss signal readout options for ultra-low power sensing with carbon nanotubes. The comparison of transient (e.g. signal rise or change) and steady-state (i.e. working point related) parameters in the presence of 1/f noise allow the conclusions that due to the Langmuir binding behavior of NO₂ on carbon nanotubes, sensing using the considered transient parameters decreases response time relative to steady-state sensing. However, noise analysis further shows that with current devices, transient sensing has a lower SNR relative to steady-state sensing [5]. With improving control over fabrication processes gas sensor functional devices operating at extremely low power can be envisioned.

Acknowledgments:
Conjugated polymers have been widely investigated in thin film devices because of their low cost, flexibility, and room-temperature operation. Recently, a variety of solution-processed polymer materials have been explored for sensing toxic gases such as nitrogen dioxide based on thin-film transistors and it is particularly relevant for health and safety in work and ambient environments when NO2 concentrations reach the 1−10 ppm range. Recent efforts have been directed towards increasing sensitivities by adjusting film thickness, tailoring device structures and judicious tailoring of conjugated polymer backbones and sensing functional groups. Nevertheless, the role of molecular designs the mechanistic principles behind the interactions between the polymers backbones and the gases is less understood. In this work, ammonia and nitrogen-dioxide responsive polymer-based organic field-effect transistors (OFETs) are fabricated from diketopyrrolopyrrole (DPP)-fluorene (F) based polymers and room-temperature detection with high sensitivity and minimal current drifts entirely from the semiconductor was achieved. Six polymers (PF1-PF6) were employed as active layers to detect NO2 gas of concentrations 0.5-30 ppm. The polymer backbones were designed by coupling DPP to fluorene containing the linear n-octyl side-chains, spiro-fluorene, thiophene and N-methyl-N-phenylnaphthalen-1-amine bridges. The proportional on-current change of OFETs using these polymers reached over 200% for the DPP-fluorene polymer with thiophene-bridges over a concentration spanning 0.5-30 ppm of nitrogen-dioxide. From cyclic voltammetry studies, we found that the introduction of thiophene into the backbone raises the highest occupied molecular orbital (HOMO) levels. This work demonstrates the capability of increasing balancing current drifts with good sensitivity by modulating redox and aggregation properties of polymer semiconductors.

Peptide based molecules have shown to interact with charged molecules, like DNA and various polar molecules. However, charge transfer through peptide thin films is not favourable. As a result, fabrication of OFET using peptide molecules are not explored. We have attempted to fabricated peptide based organic field-effect transistors combining Pentacene molecules as one of the semiconductor channel materials. In this work, we fabricated \(^{\text{A}}\text{TAA-Py-Py Pentapeptide}\) - pentacene based bilayer organic thin film transistor for volatile organic compound (VOC) vapours sensor with selectivity and enhanced sensitivity. Ultra-thin \(^{\text{A}}\text{TAA-Py-Py Pentapeptide}\) molecules of different thickness were grown using spin coating on pentacene semiconducting films. The device designs are
optimized to enhance the detection performance. We have studied the morphology of the films using atomic force microscopy (AFM) and also optical properties of the films were studied using UV-Vis spectroscopy. The gas sensing performances of different thickness devices were tested for different volatile organic compound (VOC) vapours relevant to environmental monitoring, such as, ethanol, 2 propanol and acetone at room temperature (RT). It was observed that sensitivity of OFET increased when reduced the thickness of peptide film. From literature we have seen that these VOCs are generally detected at higher temperature but it is indeed interesting to emphasize that we could able to sense those gases efficiently at RT. Additionally, the OFET based devices exhibit higher selectivity, enhanced sensitivity with comparably fast response time (~ 3sec) and recovery time (~4sec). Gas sensing results confirmed that \[^{AcTAA}_{Py-Py}\] Pentapeptide based OFETs show excellent response towards ethanol gas at room temperature.

Development of Chemical Sensors Using Polymer Composite Materials for Monitoring Oil Spillage Perpetual E. Idehen: The University of Manchester, United Kingdom

Detection and control of petroleum contaminants resulting from oil spillage pollution activities to the environment remain a major challenge to both developed and developing countries. Generally, the crude oil spill discharge to the environment is regulated and one of the key parameters used for compliance monitoring is the measure of oil concentration. Environmental laws require oil companies to keep oil spill total hydrocarbons concentration at 50 mg/kg soil (50 ppm). Mostly, soil analyses for oil spills use the standard gas chromatographic methods, but these methods are expensive, require high expertise and not suitable for in-situ analysis. This study was conducted to evaluate the possibility of developing low power and inexpensive chemiresistive material based sensors for in-situ detection of hydrocarbons in soils. Contaminated soils obtained at different depths from different oil spillage sites were extracted using Soxhlet technique and analysed by gas chromatography-flame ionization detector to determine types of hydrocarbons and their concentrations, as they are required to be detected by chemiresistors. The results recorded carbon numbers ranging from C\(_8\) – C\(_{36}\) with varying concentrations up to 20125 mg/kg at different sampling sites. Composites of non-conducting polymers (Poly(methyl methacrylate) (PMMA) and Polyvinyl chloride (PVC)) and conductive filler (carbon black) were prepared to make chemiresistors. The films were dried to evaporate the solvent and the morphology of the films was characterised using scanning electron microscopy (SEM). The impact of carbon concentration and geometry on the measured resistance of the polymer composite to hydrocarbons was determined. The optimum response was found to be with 10% w/w carbon black (CB) with 90% w/w polymer. Three sets of chemiresistors CB-PMMA, CB-PVC and CB-PMMA+PVA were constructed by depositing thin films of a carbon black/polymer onto interdigitated electrodes and investigated. The CB-PMMA sensors showed much higher responses when exposed to a range of hydrocarbons with varying sensitivities compared to the other two, however, the three sensors detected diesel range hydrocarbon concentrations up to Eicosane (C\(_{20}\)) more than the existing devices [3]. The sensors responses to the EPA maximum concentration (50mg/kg soil) limits are large (resistance changes), fast (90% in less than 1s), reversible and selective, hence validating high adaptability of this method. The underlying mechanism of this high sensitivity of sensors might be due to the strength of the hydrophobic interactions between the polymer and the hydrocarbons. The findings reported here expand the potential applications for inexpensive composite thin-film chemiresistor for oil spillage monitoring.

Engineered Bacteria for Electrochemical Pollutant Detection in Water Ariel L. Furst: Massachusetts Institute of Technology, United States

Endocrine disruptors, pollutants that interfere with the normal function of hormones in the body, are found nearly
everywhere. These compounds are components of plastics, medications, and pesticides, and many have been found in high concentrations in water sources. Endocrine disruptors have been implicated in health problems, ranging from cancer to diabetes. However, due to the chemical dissimilarity of compounds that interact with a single hormone receptor, detecting endocrine disruptors in complex solutions has remained a challenge. We have developed a novel detection strategy for estrogenic compounds that is both rapid and portable. Our platform is based on *E. coli* engineered to surface express a native estrogen receptor construct. These *E. coli* enable the detection of many dissimilar compounds with inherent signal amplification from impedance measurements due to their binding to a modified electrode. We have detected sub-ppb levels of the native hormone estradiol and ppm levels of the endocrine disruptor bisphenol A (BPA) in complex solutions. As our system reports the total estrogenic activity of a sample rather than the concentration of specific components, we can measure the activity of unknown compounds, including chemicals released from a BPA-free plastic baby bottle following microwave heating. Importantly, this approach is broadly applicable to the detection of chemically diverse compounds that bind to a single receptor.

SEASON EN16.05: Advanced Architectures for Improved Gas Sensing

Sheraton, 3rd Floor, Berkeley AB

1:30 PM *EN16.05.01
**Scalable Miniaturized Low Power Gas Sensors** Olga Casals, Cristian Fabrega and J. Daniel Prades; University of Barcelona, Spain

Our research of the last 10 years has been focused on the implementation of new approaches to improve power consumption. In this presentation we will review our main contributions in the context of the state-of-the-art.

First, we will show how power consumption in semiconductor devices can be lowered to just a few microwatts by means of the self-heating effect occurring in nanomaterials [1]. Only a decade ago, this principle was proved with fully hand-made devices [2]. Today, it is possible to achieve comparable efficiencies with devices produced in mass scale, using widely spread micro and nanofabrication techniques.

Second, we will move to light activated chemical sensors [3], where dramatic power savings can be achieved by combining the power efficiency of light emitting diodes (LED) with aggressive miniaturization efforts. Using industry standard technologies, it is possible to offer sub-milliwatt power demands in monolithic integrated microLED devices that can be produced in large amounts. We will also show how optical activation opens the door to complementary operation approaches, based on light energy harvesting that can enable virtually zero-power devices in the near future [4].

**Material-Based Gas Sensors Research at GE—New Design Rules, Performance Capabilities and Applications** Radislav A. Potyrailo; GE Research, United States
Modern gas-monitoring requirements for numerous demanding applications push the limits of existing detection concepts to the point where we may reach their fundamental performance limits. Thus, without violating the laws of physics, chemistry, and electronics and without crossing the border into the 21st century science fantasy, we need to develop new analytical concepts and instruments. This talk will stimulate your scientific and engineering senses by (1) posing several fundamental and practical questions on principles of gas sensing and (2) by demonstrating on how modern multidisciplinary research addresses these questions in the developments of sensors with previously unthinkable capabilities. We will discuss new sensor-design criteria that allow multi-gas detection with individual sensors and the key roles of advanced sensing materials, transducers, and data analytics to achieve desired sensor performance. These developed multi-gas sensors are attractive when selectivity advantages of classic analytical instruments are cancelled by requirements for no consumables, low power, low cost, and unobtrusive form factors. We will conclude with a perspective for future needs in fundamental and applied aspects of gas sensing and with the 2030 roadmap for ubiquitous gas monitoring.

2:30 PM EN16.05.03
Eco-Friendly Transfer Printing of Electronic Devices in Nature with Adhesive Nanostructure for Sustainable Environmental Monitoring System Seonggwang Yoo, Youngkyu Hwang and Heungcho Ko; Gwangju Institute of Science and Technology, Korea (the Republic of)

The capability of monitoring, collecting, transferring, analyzing various environmental information in nature enables hyper-connected society around the rural and urban area. Among the related device fabrication technologies, the development of membrane-type electronic devices and transfer printing onto desired surfaces is very important to provide electronic functions to the desired surfaces, which is so-called ‘Stick-&-Play’ system. The transfer printing naturally confronts the controversial issues between sufficient interfacial adhesion and environmental friendliness. For example, the use of too much glue to accommodate the surface mismatch enhances the adhesion but tends to lose the latter whereas simple laminating of a planar substrate with no chemical suffers from easy delamination. In this study, we introduce a nanotubular cilia structure underneath the substrate to allow conformal wrapping on complex surfaces. After transfer printing on the polymer substrate, the nanotubular structures undergo omnidirectional conformal wrapping by flattening motion to have a large contact area and thereby enhance the interfacial adhesion of the polymer substrate. The mechanical experiments with simulations confirm that the polymer substrate with highly deformable nanotubular structure strongly adheres to the target surfaces under harsh conditions which may occur in nature, such as wind and rain. Finally, we demonstrate successful transfer printing with a temperature sensor and thin film transistors on various surfaces including an eggshell, textile, and a stone.

2:45 PM EN16.05.04
Nanowire-Based Electronic Nose for Gas Classification Albert Romano-Rodriguez1,2, Guillem Domenech-Gil1,2, Lukas Hrachowina3, Antonio Pardo1, Michael Seifner1, Isabel Gràcia4, Carles Cané4 and Sven Barth3; 1Universitat de Barcelona, Spain; 2In2UB, Spain; 3Physikalisches Institut, Goethe University, Germany; 4Institut de Microelectrònica de Barcelona-Centre Nacional de Microelectrònica, CSIC, Spain

The current concern about toxic and harmful gases is substantiate in a great number of related health problems and in the unceasing global warming. Gas sensors systems are used to survey these gas species, avoiding dangerous situations and controlling the emitting sources. A low-cost choice that offers high sensitivity performances towards several types of gases of interest are the solid-state gas sensors, including devices based in metal oxide semiconducting nanowires, presenting remarkable performance in terms of sensitivity and response time, but lacking in selectivity. To compensate the lack of selectivity of this type of sensors to discriminate between various dangerous gases, the electronic nose configuration is used and, in this work, the use of site-selective growth and in-situ integration nanowires of different materials, is proposed. Tin oxide, tungsten oxide and germanium nanowires are grown on different membranes of a single chip surface using a chemical vapor deposition method modification to characterize them later towards carbon monoxide, nitrogen dioxide and water vapor diluted in dry synthetic air. To study the sensing behavior of the sensor arrays, with various sensing patterns arising from the differences between materials, the sensors are exposed to mixtures of the mentioned gases, mimicking real ambient scenarios. Each of the studied nanowires are sensitive to all the exposed gases, compromising the ability of the fabricated sensing systems to distinguish the composition of gas mixtures. However, the measured set of responses from the different materials was studied using the well-known principal component analysis representation that allows to
distinguish between all three studied analytes by pattern recognition. Moreover, the system is able to work under high relative humidity concentration (70 %), still maintaining the sensitivity towards nitrogen dioxide, proving the potentiality of the here-proposed approach.

Self-Powered Sensing Based on Triboelectric Nanogenerator and Impedance Matching Effect  
Xuhui Sun; Soochow University, China

Triboelectric nanogenerators (TENGs) based on the coupling effect of triboelectrication and electrostatic induction have been developed to be a promising strategy to harvest mechanical energy and convert them to electricity. Traditional TENG-based self-powered sensing systems have been demonstrated by measuring the triboelectric effect of the sensing materials altered by the external stimulus. However, the limitations of triboelectric sensing materials and instable outputs caused by ambient environment significantly restrict their practical applications. In this talk, I will illustrate the impedance matching effect based self-powered sensing process which can avoid the external impacts. Since a TENG is intrinsically a capacitor, while connecting with an external load, the output current from the TENG will decrease with the increment of the load resistance. By using a traditional sensor as the external load of TENGs, a self-powered sensing system can be achieved through monitoring the variation in the current or voltage signals. Several powered systems will be introduced in this talk, such as real-time ultraviolet photodetector, vehicle emission testing system, self-powered weighing/pressure system, on-line ion concentration monitor, etc. This novel self-powered sensing system is not affected by working frequency and requires no external power supply, which is favorable to improve the stability and reliability for practical application.

4:00 PM EN16.05.06
Compact, Versatile and Cost-Effective Colorimetric Gas Sensors  
J. Daniel Prades, Christian Driau, Olga Casals, Ismael Benito and Cristian Fabrega; Univ of Barcelona, Spain

We report on an inexpensive and very selective gas sensor implemented by simply combining colorimetric indicators cast on top of Scotch tape, with a commercial microchip adapted here to measure optical reflectance. This sensor can be easily reproduced (leading to quantitatively consistent results), refreshed and reconfigured to sense different target gases (CO₂, NH₃) just replacing the colorimetric tape. Colorimetric methods provide many compounds and reaction mechanisms to detect a wide variety of gaseous molecules. These techniques offer unprecedented levels of selectivity and specificity towards the target species. Regarding their readout, spectrophotometers have been traditionally the technique to measure the light absorption spectra of these indicators, but they are costly and bulky. To achieve a continuous readout and compact form factors, development focused on miniaturized systems that measure color changes at specific spectral ranges. Many different configurations have been proposed so far, but most are based on confronting a narrow-spectrum light source with a photodetector. To maximize their sensitivity, enlarging the optical path from the emitter to the detector through the indicator medium is the preferred option. Therefore, the integration of the different components is challenging. Furthermore, the efforts in miniaturization complicate refreshing the indicator substances, which are prone to degradation over time. In summary, the continuous readout of colorimetric indicators still raises a set of inconveniences.

Here, we propose an approach to colorimetric detection of gases with the following advantages: it is based on easily accessible, off-the-shelf commercial components; it is compatible with a wide range of colorimetric indicators, operating at different wavelengths; it is easily resettable/refreshable with good stability in a time frame of weeks, and offers an excellent repeatability among devices. Our gas sensor is based on the MAX30105 component. This integrated microsystem encloses a set of 3 internal LEDs (red, green and infrared), a broadband photodiode, and the corresponding control, driving, acquisition and communication modules. We use this device to excite and monitor the indicator in a reflection configuration. The sensor has a cost of less than 4$ and can be easily replicated, with excellent reproducibility. The device operates at different wavelengths and with moderate power requirements (starting from a few mW). The approach has also the advantage of being easily resettable/refreshable, as the gas sensitive color indicator layer can be easily removed and replaced by a new one. This also allows for addressing other target gases, as simple as just replacing the indicator, and reusing the readout chip. Therefore, the proposed principle offers a good trade-off between cost, simplicity, convenience, and good gas sensing performance; circumventing some of the limitations of colorimetric
Earthquakes are lethal natural disasters frequently burying people alive under collapsed buildings. Tracking entrapped humans from their unique volatile chemical signature with hand-held devices would accelerate urban search and rescue (USaR) efforts. Here, a compact and orthogonal sensor array has been designed to detect the breath- and skin-emitted metabolic tracers acetone, ammonia, isoprene, CO₂ and RH, all together serving as sign of life. It consists of three nanostructured metal-oxide sensors (Si-doped WO₃, Si-doped MoO₃ and Ti-doped ZnO), each specifically tailored at the nanoscale for highly sensitive and selective tracer detection along with commercial CO₂ and humidity sensors. When tested on humans enclosed in plethysmography chambers to simulate entrapment, this sensor array rapidly detects tracers of human presence with low parts-per-billion (ppb) level accuracy and precision, unprecedented by portable detectors but required for USaR. These results were validated by bench-top selective reagent ionization time-of-flight mass spectrometry (SRI-TOF-MS). As a result, an inexpensive nanostructured sensor array is presented that can be integrated readily into hand-held or even drone-carried detectors for first responders to rapidly screen affected terrain.

Photo-Physics of FRET and PET for Highly Sensitive Detection of Nitro-Compounds Vishal Kumar and Soumitra Satapathi; Indian Institute of Technology Roorkee, India

Förster Resonance Energy Transfer (FRET) is a powerful technique used to probe close-range molecular interactions. Physically, the FRET phenomenon manifests as a dipole-dipole interaction between closely juxtaposed fluorescent molecules (10–100 Å). For instance, after photoexcitation, a fluorophore may de-excite through direct emission with a bathochromic spectral shift. However, in the presence of a nearby acceptor, the donor non-radiatively transfers energy to the acceptor molecule, resulting in quenched donor fluorescence. With the advent of genetically encoded fluorescent molecules, this method has found widespread biological applications as a spectroscopic atomic-scale ruler, biochemical reaction kinetics and chemical sensor. [1] Our effort is to employ this FRET technique to make a prototype device for highly sensitive detection of environmental pollutants. Among the most common environmental pollutants, nitroaromatic compounds (NACs) are of particular interest because of their durability and toxicity. That’s why, sensitive and selective detection of small amounts of nitroaromatic explosives, in particular, TNP, DNT and TNT has been a key challenge due to the increasing threat of explosive-based terrorism and the need of environmental monitoring of drinking and wastewater. In addition, the excessive utilization of TNP in several other areas such as burn ointment, pesticides, glass and the leather industry resulted in environmental accumulation and is eventually contaminating the soil and aquatic systems. To date, A great number of elegant methods, including fluorimetry, gas chromatography, mass, ion-mobility and Raman spectrometry have been successfully applied for explosive detection. Among these efforts, fluorescence-quenching methods based on the mechanism of FRET show good assembly flexibility, high selectivity and sensitivity. [2] Here, we report a FRET-based sensor system for the highly selective detection of NACs, such as TNP, DNT and TNT. The sensor system is composed of a copolymer Poly[(N,N-dimethylacrylamide)-co-(Boc-Trp-EMA)] (RP) bearing tryptophan derivative in the side chain as donor and dansyl tagged copolymer P(MMA-co-Dansyl-Ala-HEMA) (DCP) as an acceptor. Initially, the inherent fluorescence of RP copolymer is quenched by non-radiative energy transfer to DCP which only happens once the two molecules are within Förster critical distance (R₀). The excellent spectral overlap (I₀= 6.08×10¹⁴ nm²M⁻¹cm⁻¹) between donors’ (RP) emission profile and acceptors’ (DCP)
absorption profile makes them an exciting and efficient FRET pair i.e. further confirmed by the high rate of energy transfer from RP to DCP i.e. 0.87 ns⁻¹ and lifetime measurement by time correlated single photon counting (TCSPC) to validate the 64% FRET efficiency. This FRET pair exhibited a specific fluorescence response to NACs such as DNT, TNT and TNP with 5.4, 2.3 and 0.4 μM LODs, respectively. The detection of NACs occurs with high sensitivity by photoluminescence quenching of FRET signal induced by photo-induced electron transfer (PET) from electron-rich FRET pair to electron-deficient NAC molecules. The estimated stern-volmer constant \( (K_{SV}) \) values for DNT, TNT and TNP are \( 6.9 \times 10^3 \), \( 7.0 \times 10^3 \) and \( 1.6 \times 10^4 \) M⁻¹, respectively. The mechanistic details of molecular interactions are established by time-resolved fluorescence, steady state fluorescence and absorption spectroscopy confirmed that the sensing process is of mixed type, i.e. both dynamic and static quenching as the lifetime of FRET system (0.73 ns) is reduced to 0.55, 0.57 and 0.61 ns DNT, TNT and TNP, respectively.

In summary, the simplicity and sensitivity of this novel FRET sensor open up the possibility of designing an optical sensor of various NACs in one single platform for designing a multimodal sensor for environmental monitoring and future field-based study.

Reference
energy transduction is still being understood, the technological potential can be truly realized if multiple interactions can be detected simultaneously. This talk will focus on both the scientific understanding as well as the technological progress in the development of micro/nanostructures for physical, chemical and biological sensing. Recent results for achieving high selectivity in chemical and biological detection using multi-physics approach will be presented.

Humidity Sensing Behavior of Microporous Titanosilicate and Vanadosilicate Thin Films Ramona Davoudnezhad, Duygu Kuzyaka, Ibrahim Çam and Burcu Akata; Middle East Technical University, Turkey

The growing demand for environmental control for a variety of chemical molecules has led to considerable interest in the research devoted to the development of new materials for sensor devices. Since humidity is a very common component in our environment, measurements and/or control of humidity are important not only for human comfort but also for a broad spectrum of industries and technologies. The constructive design of a good humidity sensor is a rather complicated topic, because high performance humidity sensors claim many requirements, including linear response, high sensitivity, fast response time, chemical and physical stability, wide operating humidity range and low cost.

Zeolites and zeo-type materials are known for their well-defined porous structure, moisture holding capacity and ionic conduction properties. Therefore, a study is done to investigate humidity sensing properties of microporous titanosilicate and vanadosilicate thin films. Two different zeo-type materials with different type of quantum wires in their structures (i.e.,–Ti-O-Ti-O-Ti- and –V-O-V-O-V- in the structures of ETS-10 and AM-6, respectively) were produced and the humidity sensors by using these types of films were fabricated for the first time. Developed humidity sensors are examined by impedance spectroscopy method. By this means, conductive properties of the films dependent on the relative humidity will be revealed. The results showed that stable, sensitive, and cheap resistive type humidity sensors that operate in a wide range of relative humidity can be designed by using titanosilicate ETS-10 and Vanadosilicate AM-6 films.

Acknowledgment: This study is supported by Scientific and Technological Research Council of Turkey (TUBITAK), with the project number 118M631.

9:15 AM EN16.06.04
Highly Sensitive Chemical Sensors Based on InAs Nanowires David Lynall1,2, Selvakumar V. Nair2, Igor Savelyev2, Marina Blumin2, Shiliang Wang3, Zhiming Wang1 and Harry Ruda2,2,1; 1University of Electronic Science and Technology of China, China; 2University of Toronto, Canada; 3Defence Research and Development Canada, Canada

Semiconductor nanowires have received much recent attention in the fields of chemical sensing and catalysis due to their high aspect ratio. The confinement of charge carriers to one dimension is ideal for environmental charge-based detection since no classical conducting paths exist where local perturbations at the surface are not felt by the electron gas, provided the nanowire diameter is similar to or less than the electronic screening length. Such a system is realized in InAs nanowires where the high electron mobility, low effective mass, and dielectric confinement of the electron gas leads to weakened screening and high charge sensitivity [1]. Indeed, InAs nanowires have demonstrated extraordinarily high charge sensitivity at room temperature [2], and thus present an excellent material system in which to probe and study the behaviour of molecules at their surfaces. In low-dimensional systems such as InAs nanowires, surface states play a dominant role in dictating transport properties. InAs nanowires have been shown to contain high densities (~ $10^{13}$ cm$^{-2}$) of slow surface traps originating from the native surface oxide [3]. These dynamic surface state capture and emission processes exhibit time constants on the order of seconds to several hours and dictate the time-dependent conductivity of the material in response to external stimuli [4]. Dynamic capture and emission from surface states is thus the primary mechanism determining the transport and chemical sensing behaviour.

So far, nanowire-based environmental gas sensors have relied on slow, activated processes restricting their applicability to high temperatures and macroscopic adsorbate coverages (> 1 ppm). Here, we demonstrate the ppb-level detection capabilities of InAs nanowire-based chemical sensors towards volatile organic compounds (VOCs) at room temperature. The sensors are based on globally back-gated field-effect transistors with channels consisting of parallel arrays of thousands of MBE-grown InAs nanowires transferred by a mechanical contact printing method [5]. We present a model for non-equilibrium carrier dynamics based on thermally activated capture and emission from
surface states to provide insight into the chemical sensing behaviour observed in our devices and discuss factors that can be used to tune the sensitivity and dynamic range.

Wide-Bandgap Perovskite Indoor Photovoltaic Cells for Self-Powered Sensors Ian Mathews¹, Sai Nithin Reddy Kantareddy¹, Shijing Sun¹, Mariya Layurova¹, Janak Thapa¹, Juan Pablo Correa Baena², Rahul Bhattacharyya¹, Tonio Buonassisi¹, Sanjay Sarma¹ and Ian Marius Peters¹; ¹Massachusetts Institute of Technology, United States; ²Georgia Institute of Technology, United States

Owing to their high efficiency, bandgap tunability, and potential to be fabricated at low-cost on many different substrate types, perovskite photovoltaic cells present an exciting opportunity as power sources in many autonomous systems. In this work, we evaluate their suitability as power sources for wireless sensors located in buildings and harvesting only ambient light. Wide-bandgap 1.63 and 1.84 eV perovskite photovoltaic cells are fabricated for indoor-light harvesting with measured efficiencies of 21% and 18.5%, respectively, under low-intensity compact fluorescent lighting. We increase the Br content in our (Rb0.01Cs0.05)(MAxFA1-x)0.94Pb(BrxI1-x)3 composition to produce an 1.84 eV cell, that achieves a high open-circuit voltage of 0.95 V cell under a light intensity as low as 0.16 mW/cm². To demonstrate the application of these cells as power sources for Internet of Things (IoT) nodes, three perovskite photovoltaic cells are connected in series to create a module that produces 14.5 mW output power under 0.16 mW/cm² of compact fluorescent illumination, with an efficiency of 13.2%. We create a self-powered sensor, by using this indoor IoT power module as an external power source for a semi-passive RFID temperature sensor. The combination of perovskite indoor photovoltaic modules and backscatter radio-frequency sensors is further discussed as a route to ubiquitous sensing in buildings, given the potential of all components to be manufactured in an integrated manner on plastics.

9:45 AM EN16.06.06
Ultrasonically-Exfoliated Layer-Controlled Black Phosphorus Nanosheets as High-Performance Humidity Sensors Ying-Hao Pai, Hung-Chieh Lin and Chun-Hua Chen; Department of Materials Science and Engineering, National Chiao Tung University, Taiwan

Atomically thin black phosphorus (BP), a new family member of the two-dimensional (2D) material, has attracted considerable attention in these years due to its exceptional electrical, mechanical, and surface properties offering great potential in a variety of applications. However, synthesis, dimensional control, particularly the thickness, and even the preservation of BP remain the challenges since BP is extremely sensitive to humidity, which would lead to severe structural damage. In this work, extremely-high-energy ultrasonic exfoliation was performed not only for effectively fabricating dimension-controlled BP nanosheets (~1 nm to 250 nm and ~8 nm to 10 μm in thickness and width, respectively) but for substantially reducing the risk of overexposure to harmful organic solvents. The well-clarified BP nanosheets were then made into single-nanosheet and nanoassembled chemical sensors for evaluating their performance and stability in detecting humidity.

10:00 AM BREAK
Zinc-Adeninate Metal-Organic Framework—A Versatile Photoluminescent Sensor for Rare Earth Elements in Aqueous Systems Scott E. Crawford1, Xing Yee Gan1, Peter C.K. Lemaire1, Jill Millstone1, John P. Baltrus2 and Paul R. Ohodnicki2,3; 1University of Pittsburgh, United States; 2National Energy Technology Laboratory, United States; 3Carnegie Mellon University, United States

Rare earth elements (REEs) are critically important to numerous advanced materials, including electronics, magnets, catalysts, phosphors, and others, leading to their use in applications including catalytic converters, permanent magnet based motors, turbines, rechargeable batteries, petroleum refinement, and lighting displays, among others. The attainment of a stable supply of REEs is also a vital goal of national security policies due to their use in advanced technologies, including defense systems. Yet factors including monopolistic conditions, expensive separation of co-mined REE ores, and environmental concerns as a result of REE extraction have hindered the attainment of this goal. Consequently, significant effort has been devoted to increased REE domestic production, including the extraction of REEs from coal, coal combustion byproducts, and their associated waste streams such as acid mine drainage. Analytical techniques for rapid quantification of REE content in aqueous phases can facilitate REE recovery through rapid identification of high-value waste streams. Here, the metal-organic framework BioMOF-100 is used as a fluorescent-based sensitizer for emissive REE ion detection in water, providing rapid (<10 minute) analysis times and sensitive detection (part-per-billion detection limits) for terbium, dysprosium, samarium, europium, ytterbium, and neodymium, even in the presence of acids or secondary metals in aqueous conditions or following REE extraction into organic solvents. Taken together, the BioMOF-100 system is a promising step towards the rapid, sensitive detection of valuable REEs in real-world waste streams.

A Portable, Single-Use, Paper-Based Microbial Fuel Cell Sensor for Rapid, On-Site, Water Quality Monitoring Jonghyun Cho and Seokheun Choi; State University of New York at Binghamton, United States

Water quality monitoring is essential for providing clean and safe drinking water to the public as well as for ecological safety. Recent advances in miniaturization and microbial fuel cells (MFCs) have shown great promise for the monitoring of toxic compounds in water. In this work, we demonstrate a novel paper-based, single-use, MFC-based biosensor for rapid detection of formaldehyde in water. The MFC-based biosensor was created by combining two layers of paper for a low-cost, disposable, and simple structure. *Shewanella oneidensis* MR-1 was pre-inoculated in the anodes and was left to be air-dried at room temperature for bacterial accumulation and for long-term storage and portability. When a drop of water sample (100mL) with formaldehyde was introduced to this MFC biosensor, rapid and sensitive voltage responses were obtained over a concentration range of 0.001% to 0.02%. To compensate for any external factors and variations among different devices, the inhibition ratio of each device before and after drying were obtained and compared. The inhibition ratio increased proportionally with the formaldehyde concentration giving R² of 0.908.

Due to the recent advances in rapid urbanization, industrialization, and excessive farming, providing access to clean water has become one of the greatest challenges in the coming decades for both developing and developed countries. To maintain safe water quality, there is an urgent need for a rapid and portable sensor for on-site and real-time measurements of toxic components in water. Conventional techniques for water monitoring allow for accurate and sensitive detection of various chemicals, but they are time-consuming, costly, and require a wide range of external equipment which may not be easily portable. Recently, MFCs have shown great potential as generic biosensors for water quality monitoring. MFCs utilize microorganisms to breakdown organic substrates to produce electrical energy. When these microorganisms are exposed to toxic components, their metabolic activities can be inhibited, thus decreasing their electron transfer reactions. Therefore, the changes in the output voltage or current of an MFC can be used to qualitatively or quantitatively measure toxic components in water. The paper-based MFCs proposed here have several advantages over the traditional MFCs in that they are cost-effective, flexible, biodegradable, and easily portable. They do not require any other external equipment, such as external pumps, which make these paper-based MFCs a truly stand-alone and self-sustainable device. Additionally, pre-inoculated and air-dried bacteria on the paper anode allow for long-term storage and on-site measurements. The dried bacteria can easily resume their biological activities by rehydrating them with a drop of water sample to be tested.

Formaldehyde was chosen as a model toxin because it has distinct biological toxicity and stability with other chemicals in media. The EPA has set the threshold limit for formaldehyde to be 10 ppm (equal to 0.001% v/v). As
such, the proposed MFC-based biosensor would be suitable for the monitoring of formaldehyde in water. The MFC-based biosensor was made by combining two layers of paper: one layer for the anode and the other layer for cathode and proton exchange membrane (PEM). The PEM and the boundaries of the anode and cathode were defined by printing wax onto the papers. The functional and hydrophilic areas of anode and cathode were made conductive by injecting poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS). Furthermore, the cathode was treated with Ag₂O to act as a solid electron acceptor.

11:00 AM EN16.07.03
Organic Molecule Based Chemiresistive Sensor for the Detection of Hexavalent Chromium Shweta Shekar and Praveen C. Ramamurthy; Indian Institute of Science, India

The extensive use of chromium in steel manufacturing, leather tanning, metal finishing, electroplating, and alloy manufacturing has made the element commercially important. The biologically stable and environmentally non-toxic trivalent chromium is considered to be an essential nutrient in humans as it regulates the effect of insulin in lipid and carbohydrate metabolism. The other kinetically stable form of chromium, Cr(VI) is recognized as a toxic substance. However, its thermodynamic instability results in spontaneous reduction in presence of reducing agents to the ultimate trivalent chromium ion.

In the recent years, several electroactive materials have been employed to probe Cr(VI) ion. 4-dimethylaminoazobenzene, 1-(2-(1H-imidazole-1-yl)-1-(4-methoxyphenyl)ethylidene)-2-phenyl hydrazine, 2-acetylpyridine, p-(4-Acetanilidazo)calix[4]arene, glyoxal bis(2-hydroxyanil), Aurin TCA, tributyl phosphate are some of them. Poly-L-histidine has been successfully used to detect Cr(III) and Cr(VI) by electrochemical methods. Despite the presence of the above molecular designs, the quest for an efficient, portable and miniature sensing device remains unaccomplished.

The present work reports the synthesis of a guanidine based small organic molecule which has exhibited potential to detect hexavalent chromium from contaminated water samples. The chemiresistor fabricated herein has shown selectivity towards chromium over other interfering anions such as carbonate, sulfate, phosphate, fluoride and chloride. The biguanide molecule also reveals fluorescence quenching in the presence of hexavalent chromium. The bio-mimicking nature of the organic molecule presented herein is manifested by the nature of complexation of hexavalent chromium to the guanidine derivative. The thermodynamically stable chromium-histidine complex in mammalian cell shows the use of hydroxyl and amine groups acting as active sites to co-ordinate to the chromium ion. The guanidine derivative being a small molecule requires the use of conductive fillers such as multi-walled carbon nanotubes (MWCNTs) to be used as an electroactive sensing material in the chemiresistor fabricated in this work. The chemiresistor evaluation shows repeatability, reproducibility, sensitivity, selectivity and a lower limit of detection of 1 ppm.

Methodologies for the Clean-up of Workplace Spills Containing Engineered Nanomaterials Viridiana L. Perez, Irene Andreu, Tony Ngo, Cameron Hodgins, Matthew Bilton, Kelly Cadieux, Michael T. Paul, Tania Hidalgo Castillo, Clifton Bright Davies and Byron D. Gates; Simon Fraser University, Canada

Nanomaterials occur as a result of natural events such as forest fires, ocean spray, volcanic activity, and dust storms. Engineered nanomaterials were created to exploit their enhanced properties. They have found a myriad of applications as components of electronic devices, sensors, commodity chemicals, therapeutics and even food packaging. Their increased use on consumer products has raised health and safety concerns. However, studies on the short and long term of nanomaterials toxicity are limited due to the large variety of nanomaterials prepared and commercialized. Furthermore, their physicochemical properties have shown to largely influence their interactions with living organisms, their toxicity, accumulation and elimination pathways. The large variety of existent nanomaterials turns the investigation of their specific adverse health effects into an insurmountable task. Thus, unintentional exposure to nanomaterials is a concern for workers involved in the manufacturing and handling of nanomaterials.

The development of methodologies to protect workers health is now a necessity. Our work has focused on the development of analytical methodologies to assess the presence of engineered nanomaterials on workplace surfaces. Methodologies for detection using X-ray fluorescence spectroscopy and inductively coupled plasma mass spectrometry were used to detect traces of nanomaterials on laboratory countertops. The results of our research are intended to inform and enable scientist to continue innovating in the field of nanomaterials in a safe manner. We have shown that protecting workers from unintentional exposure can be achieved by adopting simple modifications.
Aerosols consist of two systems, solid and particles which are suspended in gas. These days, there are many harmful aerosols, which badly affect to human health such as yellow dust, air pollution, bioaerosol like a fungus, even fine particle which can deposit human’s lung. These aerosol particles have a many toxic factors which can affect to the health of humans, animal even plants. Especially, in urban areas, many pollution factors that from automobile and buildings are exist almost everywhere. Because of this, monitoring and analysis of these harmful aerosols are very important for human health in urban areas. In order to measure and monitored these aerosols, we were researching about aerosol sampling technology and analysis using by simulation. There are many aerosol sampling methods such as particle measurement using optical principle which is using optical aerodynamic to measure the relaxation time, also, scattering size of particle about light sources and measurement of scattering and absorption. In this study, Autodesk Inventor and FLUENT 16.1 will use for the design of the new aerosol sampler. The basic design of designing an aerosol sampling device is cyclone sampler which generates a cyclone inside the tube. The basic theory of this aerosol sampling device is Stokes number and Reynolds number. Using these theories, we can derive an equation which is can get a proper size of the aerosol sampling device. Also, we will use a FLUENT 16.1 program for numerical analysis and simulation for designing an aerosol sampling device as a proper size. In the experiment, we can measure the particle use a Raman spectroscopy, Ion trap mass spectroscopy, Induced Fluorescence. In this study, we will collect aerosols on the outside using by existing aerosol sampling device before the development of aerosol monitoring device, and we are planning to use an aerosol sampling device for aerosol collection, which is such as ELPI (Electrode Low Pressure Impactor), CPC (Condensation Particle Counter) and SMPS (Scanning Mobility Particle Sizer). These aerosol sampling devices are not only collecting various aerosol, but also, can evaluate a collected aerosol in real time. Therefore, we expect to collect various aerosol samples in outside conditions like an environmental condition. After this process, we expect we can get an aerosol number concentration, aerosol particle size, aerosol flow rate and so on that can use for evaluating which aerosol suspended in the environmental air. Also, it can classify sampled aerosol which aerosol is more harmful, and more badly affects to human health. Furthermore, it can not only classify sampled aerosol, but also can conjecture which aerosol is coming from which factor such as automobile or building and so on. In our plan, we expect can show the sampled aerosol in outside condition and results of classified various sampled aerosols. Through these experiments we can show various results of aerosol sampling and monitoring data on the environmental condition. In addition, according these results we will development of aerosol monitoring systems for monitoring air quality of urban areas.
The tutorial will provide an introduction to the challenges faced by nuclear materials, whether they be within or outside the core. It will discuss the materials choices that have been made historically, the impacts they endure during operation, and how these impacts have themselves impacted material design. It will cover topics such as radiation damage, property changes during operation and future materials options.

1:30 PM
**Material Choices within the Reactor Core, Radiation Damage and Its Impacts** Karl Whittle; University of Liverpool

This will cover the historical reasoning behind the choices, the changes induced by radiation damage, and how they impact the operational usage.

2:15 PM
**Characterization and Visualization of Materials from Within the Core** Karl Whittle; University of Liverpool

This will look at how nuclear materials can be characterized, what can be determined, and what the new techniques are capable of.

3:00 PM BREAK

3:30 PM
**Historical Fuel Development, Performance, and Selection** Maria Okuniewski; Purdue University

In core challenges and interdependencies associated with fuel performance.

4:15 PM
**New Materials and Their Potential for New Technologies** Karl Whittle; University of Liverpool

Taking on board the first hour, linking it with new manufacturing methods and discussing future reactor technologies and their requirements.

**SYMPOSIUM EN17**

Structure–Property Processing Performance Relationships in Materials for Nuclear Technologies

**Fission Products in Thoria** Robin W. Grimes¹, Navaratnarajah Kunganathan¹, Partha S. Ghosh² and Ashok K. Arya²; ¹Imperial College London, United Kingdom; ²Bhabha Atomic Research Centre, India

While fuels based on thoria have been considered as alternatives for urania for decades, there is considerably less data concerning the accommodation of fission products at the atomic scale. Here atomic scale computer simulation based on density functional theory is used to predict the energies and accommodation sites for a range of fission products and He in stoichiometric ThO₂ and hypo-stoichiometric ThO₂ₓ.

Nine sites were considered including point defects and vacancy clusters with multiple species. Neutral and all possible defect charge states up to full formal charge were investigated. For Xe and Kr, in ThO₂ₓ, the most favourable solution equilibrium site is a neutral tri-vacancy while in ThO₂ it is the di-vacancy. The most favourable solution site for I and Br is the single positively charged oxygen vacancy in ThO₂ₓ while in ThO₂, I demonstrates the same solubility in all clusters. Rb, Cs, Sr, Ba, Y and Zr are accommodated at the thorium vacancy but the charge state of the vacancy is important. Finally for He, a relationship is generated that describes the incorporation energy of the xᵗʰ He atom, Eₓ (n, m), into a cluster consisting of n thorium vacancies and m oxygen vacancies.

**Radiation Effects in ThO₂** Tiankai Yao¹, Vinay S. Chauhan², Maniesha Kaur Salaken Singh³, Zilong Hua¹, Marat Khafizov², Anter El-Azab³, Matthew Mann⁴, Thierry Wiss⁵, Jian Gan¹, David Hurley¹ and Lingfeng He¹; ¹Idaho National Laboratory, United States; ²The Ohio State University, United States; ³Purdue University, United States; ⁴Air Force Research Laboratory, United States; ⁵European Commission Joint Research Centre, Germany

Oxide nuclear fuels have been widely used in light water reactors. The thermal conductivity of nuclear fuels is closely related to energy conversion efficiency as well as reactor safety margins. Understanding the mechanisms that cause the degradation of thermal conductivity in a high radiation environment is important for the design and development of new high-burnup fuels. For oxide nuclear fuels, phonon scattering by point defects, extended defects such as dislocation loops and bubbles, and grain boundaries plays a significant role in limiting the thermal transport properties. ThO₂ is an actinide-bearing material that does not contain 5f electrons and will serve as a baseline that enables the investigation of phonon transport mechanisms in defective fuel without the effects of 5f electron. In this work, defect evolution in both single crystal and polycrystalline ThO₂ has been studied by a combination of in situ ion irradiation and modeling. In addition, the effects of point defects and extended defects on the phonon transport in ThO₂ have performed on ion irradiated samples. The microstructure of pristine and ion irradiated ThO₂ has been characterized by using electron backscatter diffraction (EBSD), scanning transmission electron microscope (S/TEM), and time-domain Brillouin scattering (TDBS) techniques. The thermal conductivity before and after irradiation has been determined using laser-based modulated thermoreflectance (MTR) technique.

9:30 AM EN17.01.03
**Atypical Melting Behaviour of (Th,U)O₂, (Th,Pu)O₂ and (Pu,U)O₂ Mixed Oxides** Conor O. Galvin¹, Patrick A. Burr¹, Michael W. Cooper³, Paul Fossati⁴ and Robin W. Grimes²; ¹University of New South Wales, Australia; ²Imperial College London, United Kingdom; ³Los Alamos National Laboratory, United States; ⁴CEA, France

Numerous experimental studies have investigated the melting point of mixed oxides in the ternary UO₂–ThO₂–PuO₂ system, with significant discrepancies. In particular, a few studies have reported anomalous reduction in the melting point of mixed oxide, below that of the end members, which have variously been attributed to uncontrolled deviations of stoichiometry and limitations in the experimental setup. Here we provide a mechanistic understanding of the peculiar melting behaviour using molecular dynamics simulations, which are inherently free of the above limitations, combined with a robust pair-potential and a novel technique for calculating solidus and liquidus lines. We show that a dip in melting temperatures is indeed observed in the solidus and liquidus of the mixed oxides (Th,U)O₂, (Th,Pu)O₂ and (Pu,U)O₂ and that this is an inherent property of the solid solutions. This dip is found at
~5% additions of the oxide with higher melting point, in agreement with experimental observations. We propose that the root cause for this reduction in melting point is the formation of low-energy Frenkel pairs in the vicinity of small amounts of dissimilar cations of larger ionic radius: the random (and therefore locally heterogeneous) distribution of cations leads to a spread of Frenkel pair formation energies, depending on the local environment around the vacancy and interstitial. Overall this results in an increase in the average Frenkel pair formation energy, but a small portion of Frenkel configurations exhibit a significantly lower formation energy, which may act nucleation sites for early-onset melting.

9:45 AM EN17.01.04
Equilibrium and Irradiation-Induced Point-Defect Disorder in ThO₂ and U-Doped ThO₂—Modeling and Ion Irradiation Experiments Maniesha Kaur Salaken Singh¹, Tiankai Yao², Lingfeng He², Anter El-Azab¹ and Sanjoy Kumar Mazumder¹; ¹Purdue University, United States; ²Idaho National Laboratory, United States

As a part of EFRC Project titled ‘TETI: Thermal Energy Transport under Irradiation,’ the impact of irradiation induced defects in ThO₂ and U-doped ThO₂ is investigated. Prior to irradiation, the defect content of this material is tied to off-stoichiometry and hence it is dependent upon the U doping level and the temperature and external oxygen pressure or chemical potential. Under irradiation, non-equilibrium defects are produced by energetic particle bombardment, leading to the formation of nanoscale and sub-nanoscale defect clusters that influence thermal transport in ways that are not fully understood to the community. In this presentation we discuss our modeling results for the equilibrium and non-equilibrium defects in ThO₂ and U-doped ThO₂. A thermodynamic defect disorder model was used to investigate the off-stoichiometry behavior in ThO₂ and U-doped ThO₂ in an oxygen partial pressure and temperature environment. The model shows that while ThO₂ remains mostly hypo stoichiometric at relevant thermodynamic conditions, U doping expands the thermodynamics window over which ThO₂ becomes hyper-stoichiometric, thus illustrating the impact of 5f electrons introduced by the U doping on defect disorder. For example, U₀.₅₂Th₀.₄₈O₂₊ₓ can sustain disorder up to an oxygen off-stoichiometry content of x = 0.4 at high temperatures, up to 2000 K, and high oxygen pressures, up to 0.316 atm, whereas U₀.₂Th₀.₈O₂₊ₓ can only exist up to an oxygen off-stoichiometry content of x = 0.05. The extent of hyper-stoichiometry in the oxide reduces with increasing temperature and decreasing oxygen partial pressure values. We will also present the results of a recent cluster dynamics model of vacancy and interstitial cluster formation in ThO₂ under irradiation in conjunction with microstructure and chemical analysis of pure and ion-irradiated ThO₂ at different temperatures by EELS imaging technique in TEM. The impact of cluster composition on matrix composition is illustrated both computationally and experimentally, showing that irradiation provides a further mechanism of altering the stoichiometry of the matrix by forming clusters not commiserating with the chemical formula of the crystal.

10:30 AM EN17.02.01
Atomistic Level Study of Oxidation of Ce₆Si₂ as an Accident Tolerant Nuclear Fuel Surrogate Robert W. Harrison, Robert Worth, James Buckley and Tim Abram; University of Manchester, United Kingdom

Since the Fukushima accident in 2011 there has been a large international effort in the development of accident tolerant fuel and cladding materials for water cooled reactors [1]. Uranium silicide intermetallics are being considered as accident tolerant fuels (ATF) to replace UO₂ currently used in light water reactors (LWRs) [2]. Primarily U₃Si₂ is being examined due to its good thermal conductivity (~15 W/m/K at 500°C) [3], higher U metal density, (giving economic advantages by requiring lower ²³⁵U enrichments) and reduced radiation swelling compared to the higher U containing silicides such as U₃Si [4,5]. However, little is known on the oxidation behaviour of U₃Si₂ under high temperature air and steam environments which could be experienced under a loss of coolant accident (LOCA) scenario with water and/or air ingress into the fuel pin.
The oxidation process of Ce₃Si₂ (as a surrogate for U₃Si₂) has been studied to develop an oxidation mechanism. Samples were oxidised under flowing air to 750°C finding discrepancies between the terminal and theoretical mass gains for complete oxidation similar to previous works on the U₃Si₂ system. As oxidised materials were studied using scanning transmission electron microscopy (S/TEM) with energy dispersive x-ray (EDS) and energy filtered (EF)TEM mapping to elucidate the reaction products and develop a mechanism. The fate of the Ce and Si in the system will be presented and mechanistically discussed and discrepancy in the differences in mass gains revealed. The resulting composition and structure of the as-oxidised materials will also be presented, discussing potential consequences on mechanical stability of the fuel material under a LOCA scenario. The oxidation mechanism, comparison with the U-Si system and consequence of the resulting material structure on fuel performance under a LOCA will also be discussed.

10:45 AM EN17.02.02
Specific Heat Measurements on USi from 2.4 K to 398 K Jason Baker, Joshua White, Aiping Chen, Robert Roback and Hongwu Xu; Los Alamos National Laboratory, United States

The use of uranium-silicide compounds as potential nuclear reactor fuels requires knowledge of thermophysical properties as a function of temperature. At elevated temperatures, a great deal of research has been performed to understand the thermodynamic properties of U-Si compounds; however, in the low-temperature regime, only limited data are available [1-4]. Operating temperatures of nuclear reactors are high, yet important thermodynamic quantities such as Debye temperature and standard entropy (S°) can be derived from low-temperature measurements. S° is an imperative quantity in determination of the Gibbs free energy which depends on $S^\circ$ and enthalpy. Among the U-Si compounds, stoichiometric USi has typically received significantly less attention in the literature with regards to characterization; however, uranium-silicide phases used as nuclear fuels may include appreciable fractions of USi either introduced through fuel synthesis or fabrication. The potential of USi both as a nuclear fuel itself and as a fraction of other U-Si samples, implies a need to further the thermophysical understanding of this material.

Here we present investigations of the low-temperature thermal properties of USi by measuring its specific heat capacities from 2.4 to 398 K using a Quantum Design Physical Properties Measurement System (QD-PPMS). A smooth curve is observed over the entire temperature range measured, and the specific heat capacity at the maximum temperature tested (398 K) was determined to be 67.2 J mol⁻¹ K⁻¹. Additionally, the Debye temperature has been determined from fitting the low-temperature (below 30 K) specific heat capacity data as 252.3 K. Furthermore, by performing integration of the specific heat capacity over the temperature range, the standard entropy at room temperature has been determined as 88.5 J mol⁻¹ K⁻¹.

11:00 AM EN17.02.03
Fission Gas and Creep Behaviour in U₃Si₂ from DFT Calculations and Atomistic Simulations David Andersson¹, Michael W. Cooper¹, Xiang-Yang Liu¹, Benjamin Beeler², Kyle Gamble² and Giovanni Pastore²; ¹Los Alamos National Laboratory, United States; ²Idaho National Laboratory, United States

The U₃Si₂ compound has a high uranium density and thermal conductivity compared to standard UO₂ fuel and, for these reasons, it is being considered as a possible replacement fuel in the current fleet of light water nuclear reactors. It could bring significant performance and economic benefits, while the exothermic reaction with the coolant upon cladding breach is a known drawback that needs to be addressed. Material properties such as the diffusion rate of fission gas atoms and point defects must be determined in order to model the in-reactor behaviour of U₃Si₂. Here we
use density functional theory (DFT) calculations and empirical potential simulations to study diffusion of Xe and point defects in bulk U$_3$Si$_2$ as well as at grain boundaries. The DFT calculations apply the GGA+U methodology to calculate defect energies, entropies and migration barriers of point defects as well as of Xe atoms interacting with point defects. Xe and point defect diffusion rates are predicted from a point defect model parameterized by results from DFT calculations. The diffusion rate under irradiation due to ballistic damage is derived from molecular dynamics simulations based on a MEAM potential for the U-Si-Xe interactions. Molecular dynamics simulations are also used for investigating grain boundary diffusion and segregation of point defects and Xe atoms. We find that Xe diffusion in U$_3$Si$_2$ is faster than in conventional UO$_2$ nuclear fuel in the intrinsic regime, but lower in the regime where transport is dominated by ballistic mixing. The latter observation is a consequence of the high thermal conductivity of U$_3$Si$_2$ preventing high-temperature thermal spikes, which leads to transport by ballistic mechanisms being dominant. The impact of the diffusion properties on fission gas release and swelling in U$_3$Si$_2$ is investigated by parametrizing a fuel performance model in the Bison code with results from the atomic scale simulations. The results are compared to recent irradiation experiments available in the literature. Finally, we discuss the importance of bulk and grain boundary diffusion on creep rates in U$_3$Si$_2$.

11:15 AM EN17.02.04
Ceramic Oxide Coatings for Accident Tolerant Fuel Concept in Light Water Reactors Mattia Cabrioli$^{1,2}$, Matteo Vanazzi$^1$, Erkka Frankberg$^1$, Koba Van Loo$^3$, Jozef Vleugels$^3$, Konstantina Lambrinou$^4$ and Fabio Di Fonzo$^1$; $^1$Istituto Italiano di Tecnologia, Italy; $^2$Politecnico di Milano, Italy; $^3$KU Leuven, Belgium; $^4$SCK-CEN, Belgium

Accident Tolerant Fuel (ATF) concepts aim at providing radical performance and safety improvements for the Light Water Reactors (LWR) at economically attractive conditions. Coatings as near-term evolutionary option take advantage of the reliability of traditional Zirconium-based cladding materials for structural purposes, while conferring engineering of the surface properties. In particular, they are expected to reduce corrosion rates, retain structural integrity and adhesion, minimize hydrogen uptake by the cladding matrix and improve high temperature oxidation resistance.

In this work, the process of selection, design, production and testing of ceramic oxides as protective coatings for LWR fuel cladding is presented. It is worth mentioning that all these activities have been performed in the framework of the European project IL TROVATORE. In the first stage, candidate materials are selected by matching neutronic requirements and chemical stability in pressurized-water environment. This phase is followed by the production of ceramic oxides, in the form of sintered pellets or as thin films by the Pulsed Laser Deposition (PLD) technique. Specimens are then exposed to Pressurized Water Reactor (PWR) environment. Specifically, compatibility tests are performed in pure water at 360°C and saturation pressure, in order to simulate the PWR core during normal operating conditions. Mass changes are monitored during the exposure, then correlated to modifications on the surface and in the structure of the tested samples. The specific dissolution and oxidation processes related to the measured mass changes are also investigated. This initial phase allows us to simultaneously evaluate the behaviour of candidate materials as bulk oxides and coatings, hence confirming the feasibility of PLD as a viable technique to produce high-performance ceramic films, with strong adhesion and interfacial bonding. Eventually the screening phase leads us to the selection of best candidate oxide to uptake an additional phase of optimization of the coating fabrication process.

The selected material is grown on relevant substrates such as Zirconium-based alloys and AISI 316L via an optimized PLD process. The exposure of the new coated specimens to the simulated PWR ambient is performed, up to 30 days in saturated pure water at 360°C. The analysis of the mass change confirms that the coatings act efficiently as barriers against oxidation by reducing significantly the oxidation of the metal alloy. In addition, structural integrity and good adhesion to the substrates are confirmed by spectroscopic characterization and electron microscopy.

Furthermore, the improvement of tolerance against severe accidents is considered with respect to the specific case of Loss Of Coolant Accident (LOCA). Preliminary tests at high temperature (up to 1000°C) and in a controlled atmosphere are conducted in order to evaluate the performance of the selected ceramic material during accidental transients. The coatings show structural integrity and good adhesion, suggesting the high capability of protecting the underlying alloy and their potential for a relevant delay of uncontrolled oxidation of the claddings during accidental transients. On the other hand, the importance of correct alignment of the thermal expansion coefficients between coating and substrates becomes evident at higher temperatures (≥1200°C).

In conclusion, the overall results collected show that PLD ceramic coatings are capable of sustaining both normal and off-normal reactor conditions and consequently constitute a promising option for coated-cladding ATF.
concepts.

**DFT+U Point Defect Calculations of Uranium Mononitride Ground State and Metastable States**

Bryant B. Jerome and Dilpuneet S. Aidhy; University of Wyoming, United States

Uranium mononitride (UN) is a proposed nuclear fuel for upcoming generation IV nuclear reactors, due to its higher thermal conductivity, greater melting point, and higher concentration of fissile material compared to conventional oxide fuels. DFT+U is used to capture the anti-ferromagnetic ground state of UN. However, the +U correction leads to the possibility of convergence to metastable states, thereby disrupting the correct predictions of electronic-level properties, particularly point-defect energies. In this work, we provide a comprehensive analysis of ground and metastable states and the resulting defect properties using three methods, namely occupation matrix control (OMC), quasi-annealing (QA), and U-ramping. We preform each of these calculations using both the Dudarev and Liechtenstein rotationally-invariant forms of DFT+U. We find that QA and OMC reproduce the ground state, whereas U-ramping converges to metastable states as previously observed. All three methods predict the nitrogen interstitial to be the most favorable defect, whereas the uranium interstitial is the least favorable defect among the vacancies and interstitials of both elements. For example, the calculated formation energies of defects calculated using the QA method across the Dudarev form are 1.76 eV and 9.38 eV for the U vacancy and interstitial, respectively, and for the N vacancy and interstitial are 3.86 eV and 0.94 eV, respectively. The migration barriers for both the U and N vacancies are similar, i.e., ~3 eV. Finally, our results show there are significant deviations in defect formation energies among various metastable states.

**11:45 AM EN17.02.06**

**Multifunctional Nano-Ceramic Coatings—The Enabling Technology for Next Generation Nuclear Reactors (Including Fusion)**

Matteo Vanazzi, Mattia Cabrioli, Boris Paladino, Daniele Iadicicco, Erkka Frankberg and Fabio Di Fonzo; Istituto Italiano di Tecnologia, Italy

Next generation nuclear systems are meant to outperform current ones, by providing disruptive solutions in terms of non-proliferation, fuel cycle efficiency, radioactive waste management, safety and economics. However, the real occurrence of this scenario is directly linked to the availability of suitable materials for the more demanding conditions of these advanced plant concept, in terms of higher burnup and operating temperature, intense radiation fields, liquid metal or molten salt corrosion and tritium permeation. Interposing an engineered surface layer between qualified structural materials and the reactor environment makes this scenario reachable in the short term. In the last years our group developed multifunctional nanoceramic coatings by Pulsed Laser Deposition and Atomic Layer Deposition for Accident Tolerant Fuel for Light Water Reactors and as a solution to high-temperature Heavy Liquid Metal (HLM) corrosion in Generation-IV (GIV) and fusion systems. Accident Tolerant Fuel (ATF) concepts are developed by depositing on ZIRLO® and Zircaloy-4 suitable nanoceramic coatings, which are found to minimize hydrogen uptake and to improve high temperature oxidation resistance. On the other hand, in respect to GIV and fusion systems, Al₂O₃ and Y₂O₃ on AISI316, 1515-Ti and EUROFER-97, has been tested as anti-corrosion, radiation-resistant tritium permeation, insulating barriers. In particular, the compatibility in Pb and Pb-Li has been proven up to 10,000 hours. The tritium permeation reduction of these films is in the order of 10⁴-10⁵, well above the design requirements. Furthermore, Al₂O₃ coatings have been tested under heavy ions irradiation, at damage levels relevant for fission and fusion applications. The ceramic film under irradiation preserves its integrity and mechanical behaviour, evolving structurally from an amorphous to a crystalline state. To conclude, engineered coatings deposited by PLD/ALD techniques represent promising candidates to face the major issues related to future nuclear technologies and allow the design of innovative and economically attractive power plants.
Microstructure-Based Model of Gas Bubble Swelling in Polycrystalline UMo Fuels by Integrating Cluster Dynamics and Phase-Field Approaches

Shenyang Hu1, Benjamin Beeler2 and Douglas Burkes1; 1Pacific Northwest National Laboratory, United States; 2Idaho National Laboratory, United States

Experiments show that recrystallization dramatically speeds up the gas bubble swelling kinetics in UMo nuclear fuels. This implies that gas bubbles inside the recrystallization zone, which has hundred nano-meter sized grains in diameter, grow much faster than those inside coarse grains. However, the mechanism of fast gas bubble growth is not well understood. In this work, a gas bubble evolution model integrating cluster dynamics and phase field models is developed to study the effect of vacancy and interstitial clustering on gas bubble evolution and volumetric swelling kinetics in the recrystallization zone. Cluster dynamics is used to describe the evolution of interstitial loops, vacancy clusters, and dislocation density. The phase field model is used to describe the gas bubble nucleation and growth. With this integrated model, the effect of defect generation rate, defect clustering rate, defect sink strength, and interstitial emission rate from interfaces on gas bubble evolution were systematically simulated. The comparison of gas bubble size, density and volumetric swelling from simulations and experimental data demonstrate that the nucleation and growth of interstitial loops in recrystallization zone is one of key mechanisms behind the fast swelling kinetics.

2:00 PM EN17.03.02
Modeling Irradiation Induced Grain Refinement Utilizing Cahn’s Time Cone Method

Alejandro L. Figueroa1, Joshua Pribe1, Walter J. Williams1,2, Rayaprolu Goutham Sreekar Annadanam1, Edwin Garcia1 and Maria Okuniewski1; 1Purdue University, United States; 2Idaho National Laboratory, United States

Irradiation induced grain refinement is a high burnup phenomenon associated with the fuel’s response to high strain fields created through in reactor irradiation. The increase in grain boundary area from the refinement increases the nucleation rate of fission gas bubbles which leads to a sharp increase in the swelling rate of the fuel. Understanding this phenomenon will allow for more accurate fuel life predictions and can lead to more efficient fuel design. The fission process creates multi-dimensional defects, including fission products, which strain the lattice. The defects produced by this process propagate through material creating both pinning points for dislocations and grain-boundaries, as well causing dislocation propagation by acting both as a source and a climb mechanism. This increases the internal energy of the material, which provides a driving force for recrystallization. Current models of this phenomenon approach the behavior sequentially; addressing grain nucleation first, then growth of the nuclei. This approach is useful but does not fully capture the temporal inhomogeneity of the system. By utilizing Cahn’s time cone method and adapting it to a temporally inhomogeneous reactor environment the nucleation and growth of the irradiation induced grain refinement can be modeled concurrently and can provide an analytical solution to the phenomenon. To address the temporal inhomogeneity of the system, strain which affects both the nucleation and growth was defined as a function of fission density. The mobility of the system was also adapted for irradiation enhanced diffusion. Heterogenous nucleation was used as the dominant nucleation mechanism. Utilizing this technique to model irradiation induced grain refinement showed comparable results to experimental observations demonstrating that the adapted Cahn time cone method can effectively model the phenomenon, while addressing both nucleation and growth simultaneously.

2:15 PM EN17.03.03
The Effects of Fabrication Parameters on the Microstructure of Monolithic U-Mo Nuclear Fuels

Jan-Fong Jue, Dennis Keiser, Adam Robinson, Brandon Miller, Jian Gan and Glenn Moore; Idaho National Laboratory, United States

Monolithic U-Mo fuels have been down-selected for the conversion of several US high performance research and test reactors. In order to qualify this new fuel type, more than a hundred fuel plates have been fabricated and irradiated to date in the Advanced Test Reactor at Idaho National Laboratory. The size of fuel plates fabricated for these irradiation campaigns varies from 4 inches (mini-plates) to more than 40 inches (full-size plates) in length. The fabrication parameters used in fabricating mini-plates and full-size plates are very different, thus resulting in different as-fabricated microstructures. The microstructure of as-fabricated and irradiated mini-plates and full-size plates will be presented. The impact of the fabrication parameters on the microstructure and irradiation performance will be discussed.
Density Functional Theory Study of Uranium-Based Compounds

Edmanuel Torres, Thaneshwor Kaloni and Jeremy Pencer; Canadian Nuclear Laboratories, Canada

The accurate description of the electronic and thermal properties of uranium-based compounds is fundamental in the development of novel nuclear fuels. Density functional theory calculations (DFT), within the plane wave pseudopotential approach using Quantum ESPRESSO (QE), has been applied to the study of uranium-based compounds. The lack of widely accessible pseudopotentials to perform DFT studies of uranium compounds significantly limits the capability of innovation in nuclear materials. As such, we have developed a set of projector augmented-wave (PAW) pseudopotentials for uranium, oxygen, nitrogen, and carbon atoms. The pseudopotentials were optimized to be used with a low kinetic energy cutoff of 37 Ry, which is considerably lower in comparison to PAW pseudopotentials available for QE. The set of pseudopotentials is then used to perform DFT calculations of uranium-based compounds, such as uranium metal, uranium oxides (UO$_2$, UO$_3$, and U$_3$O$_8$), uranium mononitride, and uranium monocarbide. Systems with strong electron correlations were described using Hubbard corrected DFT+U calculations. As such, monitoring the occupation matrix for 5f electrons of the uranium atoms was required to avoid metastable state solutions, and therefore to obtain reasonable ground properties. The reported results are shown to be accurate in comparison to reported theoretical and experimental results. This new set of PAW pseudopotentials are thus suitable for use in modelling a variety of uranium compounds, but also have the advantage of enhanced computational efficiency, due to the reduced kinetic energy cutoff.

Defect Clustering in Irradiated Alpha Uranium—Cluster Dynamics Modeling and Ion Irradiation Experiments

Fabia Farlin Athena$^1$, Tiankai Yao$^2$, Lingfeng He$^3$, Anter El-Azab$^1$ and Sanjoy Kumar Mazumder$^1$; $^1$Purdue University, United States; $^2$Idaho National Laboratory, United States

There is limited information in the literature about defect clustering in irradiated alpha uranium in spite of the fact that defect clustering is responsible for irradiation growth of that material. The limited available data shows that two types of dislocation loops form in alpha uranium on the (010) and (100) planes, with Burgers vectors of $\sqrt{a^2+b^2} <110>/2$ and $a [100]$ respectively, under neutron irradiation. Under He ion irradiation, however, small cavities, which are assumed to be He bubbles were observed. We present a cluster dynamics model for loop formation in alpha uranium. The defect clusters considered at prismatic loops of interstitial type, those on (010) planes, and vacancy type, those on (100) planes. The dynamics model parameters were partly taken from open literature and partly fixed by molecular dynamics simulations. Cluster dynamics simulations were carried out and at different temperatures and dose rates, and the comparison with the existing neutron irradiation data for the loop size distribution and average loop size and density shows that the model is able to make reasonable predictions. We also present the results of proton irradiation of alpha uranium, where the proton beam was used to produce a microstructure dominated by dislocation loops. The formation and evolution of dislocation loops were studied by TEM technique, which provided further data for validation of the cluster dynamics model.

SESSION EN17.04: Oxide Nuclear Fuels
Session Chairs: Lingfeng He and Simon Middleburgh
Monday Afternoon, December 2, 2019
Sheraton, 3rd Floor, Hampton

Structural and Microstructural Features Observed in (Ln,U)O$_{2-x}$ Systems

Gianguido Baldinozzi$^1$, Bernardo Herrero-Bocco$^{1,2}$, Fabienne Audubert$^2$, Lionel Desgranges$^2$, Luis Casillas$^1$, Maulik K. Patel$^3$, Haixuan Xu$^2$ and Kurt Sickafus$^3$; $^1$University of Paris Saclay, France; $^2$CEA, France; $^3$Linköping University, Sweden; $^4$University of Liverpool, United Kingdom; $^5$The University of Tennessee, Knoxville, United States

The majority of periodic table elements are created within the conventional uranium dioxide fuel matrix during its
time in pile. These elements are accommodated in quite different ways within the nuclear ceramic. Ba, Zr, Y and the lanthanide atoms are typically substituted within the uranium dioxide matrix. At high burnup, the number of phases that form and the differences between them can result in the development of highly complex structures and microstructures. Similar effects might be encountered in manufactured advanced actinide fuels for the transmutation of minor actinides or in fuels containing significant amounts of burnable poisons (typically Gd). Those systems constitute then a large class of compounds, generally with fluorite or fluorite-derived structures, exhibiting high radiation tolerance, possibly related to their peculiar ability to accommodate a variety of defects and to exist as nonstoichiometric compounds within a large homogeneity range. Nevertheless, a variety of behaviours and different phases is observed after quenching or annealing in several of the pseudo-binary systems of type (Ln,U)O$_2$$_x$, suggesting that the thermal history of those systems is of paramount importance. Some of these systems, like (U,Ce)O$_2$$_x$ are particularly complex, display an intriguing structural variety, and therefore present a fundamental interest. In this talk we would try to address some of those interesting structural features induced by aliovalent substitutions in UO$_2$.

4:00 PM EN17.04.02
Modeling Fission Gas Behavior in Doped UO$_2$ Michael W. Cooper$^1$, Topher Matthews$^4$, Kyle Gamble$^2$, Giovanni Pastore$^2$, Chris Stanek$^1$ and David Andersson$^1$; $^1$Los Alamos National Laboratory, United States; $^2$INL, United States

Advanced fuels are being considered for deployment in light water reactors (LWRs). Advanced fuels are designed to improve performance and fuel economics during normal operation and/or safety margins during accidents. For example, additives such as Cr$_2$O$_3$ can be used during fuel fabrication to modify the UO$_2$ microstructure. Specifically, the resultant enhanced grain size is considered to benefit pellet-clad interactions by modifying the mechanical properties of the fuel and by increasing fission gas retention, which reduces the plenum pressure. The effect of increased grain size on fission gas release can be readily captured within physics-based fission gas models, such as that implemented in the BISON fuel performance code. However, the dopant could modify the defect chemistry of UO$_2$ during reactor operation, thus altering the fission gas diffusivity and potentially undermining the enhanced fission gas retention obtain through enlarged grains. Fission gas diffusivity exhibits three diffusion regimes for reactor conditions: high T intrinsic diffusion, intermediate T irradiation enhanced diffusion, and low T athermal diffusion. In this work, we present a cluster dynamics model developed and validated for the description of irradiation enhanced diffusion in undoped UO$_2$. Large defect clusters play a crucial role in the reproduction of irradiation enhanced diffusion. For doped UO$_2$, it is assumed that the oxygen potential is controlled by the preferential reduction of Cr$_2$O$_3$ to Cr (over UO$_2$$_x$ reduction to stoichiometric UO$_2$). The resultant doped UO$_2$ Xe diffusivity is enhanced with respect to undoped UO$_2$. The enhancement in Xe diffusivity relative to undoped UO$_2$ has been implemented in BISON. The predicted fission gas release from BISON has been compared to Halden experiments.

4:15 PM EN17.04.03
Prediction of the Shape, Size and Pressure of Intragranular Fission Product Bubbles in Spent Nuclear Fuel Michael J. Rushton$^1$, Conor O. Galvin$^{1,2}$, Michael W. Cooper$^4$, Patrick Burr$^2$, Simon C. Middleburgh$^1$, William E. Lee$^{1,3}$ and Robin W. Grimes$^3$; $^1$Bangor University, United Kingdom; $^2$University of New South Wales, Australia; $^3$Imperial College London, United Kingdom; $^4$Los Alamos National Laboratory, United States

During its life in a reactor fission products build up in nuclear fuel. Some of these such as Xe, Kr and He form bubbles in the fuel. Whilst in a reactor, these have a detrimental effect on fuel performance as fission product bubbles may lead to swelling and a degradation of mechanical properties, and when released from the fuel, where the gas degrades the thermal conductance of the fuel-clad gap and leads to an increase in fuel temperature and cladding pressure. Understanding the size, shape and pressure of bubbles also allows the fission product inventory of nuclear fuel to be gauged. This information is important in developing improved fuel performance codes, pushing fuel to higher burn-up and has relevance to back-end processes such as reprocessing and ultimate disposal of spent fuel.

In this work, molecular dynamics simulations have been used to study fission product bubbles in UO$_2$. The results of this work will show the behaviour of small fission product bubbles in the range of diameters below <100nm. In particular bubble morphology is considered with both spherical and faceted Wulff shapes being compared. The effect of bubble internal pressure on morphology and its dependence on bubble size will be presented. The
simulation results will be described in terms of the bubble size and pressure distribution expected in spent fuel.

4:30 PM EN17.04.04
Effect of High Burnup Structure on Fuel Rod Performance with Burnup Extension  Jianguo Yu and Hongbin Zhang; Idaho National Laboratory, United States

The formation of high burnup structure (HBS) or rim structure is possibly the most significant restructuring processes at the rim of pellets in-pile with burnup extension in LWR and the effect of HBS on fuel thermo-physical or mechanical properties is a key requirement to ensure the successful implementation of extended burnup. There is independently experimental evidence to support that HBS concomitantly affects thermal and mechanical properties of fuel. But it is still not well understood how such HBS affects fuel thermo-physical or mechanical properties. In this work, we present results how HBS impacts the fission gas behavior of fuel rod under normal operating conditions. The fuel performance code FRAPCON-4.0 was used to simulate fission gas related properties, such as plenum pressure, fission gas release, and gap conductance. The effect of HBS under different boundary conditions, i.e. power history profiles, will also be discussed.

4:45 PM EN17.04.05
Fracture Behavior of Pure UO₂ Using Small-Scale Mechanical Testing  Brent Heuser and Shen J. Dillon; University of Illinois at Urbana Champaign, United States

Fracture of UO₂ affects fission gas release in fuels. Predicting, understanding, and controlling within UO₂ fuel pellets is of considerable practical interest. An ongoing fundamental challenge is understanding the constituent contributions form grain boundaries and the bulk to the fracture response of the polycrystal. In this work, micro-scale mechanical testing has been used to induce single grain transgranular fracture and bicrystal intergranular fracture in samples isolated from polycrystalline UO₂. The results are discussed in the context of bulk UO₂ fracture and similar measurements performed on other oxides.
annealing temperature after irradiation. The results will be discussed in regard of the role of impurities on the microstructure evolution in the first stages of irradiation in tokamak and of the impact on the swelling of the material.

Void Evolution in Tungsten and Tungsten-5wt.% Tantalum under In Situ Proton Irradiation Iuliia Ipatova1, Simon C. Middleburgh1, Robert W. Harrison2, Michael Rushton1, Enrique Jimanez-Melero2 and Stephen Donnelly3; 1Bangor University, United Kingdom; 2University of Manchester, United Kingdom; 3University of Huddersfield, United Kingdom

Void evolution during in-situ irradiation in polycrystalline W and W-5wt.%Ta material has been examined at 800 and 1000°C, via TEM. No dislocation loop formation was observed prior to void nucleation. The irradiated W microstructure was characterised by the presence of a population of voids, randomly distributed in the region. The number density of the voids reduces when the irradiation temperature is raised. In contrast, the excess of free vacancies in the W-5wt.%Ta material irradiated at 800°C only leads to the formation of visible voids after post-irradiation annealing of the sample at 1000°C. Solute Ta atoms also cause a significant decrease in the number density of voids when comparing the microstructure of both materials irradiated at 1000°C, and a gradual progression towards saturation at 0.2 dpa. Moreover, for the first time, we have detected a progressive transition from a spherical to a faceted shape in a number of voids present in both materials at damage levels 0.3 dpa.

9:00 AM EN17.05.03
High Irradiation Resistance of Nanocrystalline W-Based High Entropy Alloy Enrique Martinez1, Osman El Atwani1, Nan Li1, Meimei Li2, Arun Devaraj3, Kevin Baldwin1, Matthew Schneider1, Damian Sobieraj4, Jan Wrobel4, Duc Nguyen-Manh2 and Stuart Maloy1; 1Los Alamos National Laboratory, United States; 2Argonne National Laboratory, United States; 3Pacific Northwest National Laboratory, United States; 4Warsaw University of Technology, Poland; 5Culham Center for Fusion Energy, United Kingdom

A novel W-based refractory high entropy alloy with outstanding radiation resistance has been developed. The alloy was grown as thin films showing a bimodal grain size distribution in the nanocrystalline and ultrafine regimes and a unique 4 nm lamella-like structure revealed by atom probe tomography (APT). Transmission electron microscopy (TEM) and X-ray diffraction show an underlying body-centered cubic crystalline structure with certain black spots appearing after thermal annealing at elevated temperatures. Thorough analysis based on TEM and APT correlated the black spots with second phase particles rich in Cr and V. After both in situ and ex situ irradiation, these precipitates evolve to quasi-spherical particles with no sign of irradiation-created dislocation loops even after 8 dpa at either room temperature or 1073 K. Furthermore, nanomechanical testing shows a large hardness of 14 GPa in the as-deposited samples, with a slight increase after thermal annealing and almost negligible irradiation hardening. Theoretical modeling based on ab initio methodologies combined with Monte Carlo techniques predicts the formation of Cr and V rich second phase particles and points at equal mobilities of point defects as the origin of the exceptional radiation tolerance. The fact that these alloys are suitable for bulk production coupled with the exceptional radiation and mechanical properties makes them ideal structural materials for applications requiring extreme conditions.

9:15 AM EN17.05.04
Modified Deformation Behavior of Ion-Implanted Tungsten Felix Hofmann, Suchandrima Das, Hongbing Yu and Edmund Tarleton; University of Oxford, United Kingdom

Tungsten is the main candidate material for plasma-facingarmor components in future fusion reactors. During operation bombardment with high-energy fusion neutrons will create collision cascades that leave behind lattice-
Helium, injected from the plasma and produced by transmutation, strongly binds to these defects, and modifies their behavior and retention. We investigate the impact of helium-implantation-induced and self-ion-implantation-induced damage on the deformation behavior of tungsten, comparing spherical nano-indenters in unimplanted, helium-implanted and self-ion-implanted tungsten crystals of 001-orientation. Ion-implantation increases hardness and causes large pile-ups that increase with increasing implantation dose. Lattice rotations and indentation-induced residual strains beneath indents, probed using 3D-resolved synchrotron X-ray micro-diffraction, are smaller in the ion-implanted material, suggesting a more confined plastic zone. The increase in pile-up points to a reduction in strain hardening capacity or even a strain softening. Based on these results, as well as TEM observations of defects beneath indents, we hypothesize that while dislocation motion is initially obstructed by implantation-induced defects, the strength of these obstacles is reduced by the passage of dislocations. A 3D crystal plasticity finite element (CPFE) model founded on this hypothesis, with only three fitting parameters, reproduces these effects and is directly compared to the experiments. We also explore the orientation dependence of the indentation-response by considering grains with <001>, <110> and <111> out-of-plane orientations. Indents in unimplanted tungsten show little orientation dependence. In the helium-ion-implanted material, <110> and <111>-oriented grains show a much lower pile-up and hardness than <001>-oriented grains. The CPFE formulation, with all parameters unchanged except the crystal orientation, captures these orientation-dependent changes. The results suggest an orientation-independent mechanism governing the interaction of implantation-induced defects with glide dislocations, with differences in pile-up morphology arising just due to the relative orientations of the crystal slip systems, sample surface and spherical indenter tip.

9:30 AM EN17.05.05
Microstructural Features and Hydrogen Isotope Diffusion and Retention in Ion Irradiated Lithium Aluminate
Weilin Jiang and David J. Senor; Pacific Northwest National Lab, United States

As a tritium (T) production material, ⁶Li enriched tetragonal lithium aluminate (γ-LiAlO₂) has been used in support of the Tritium Sustainment Program. It also has been investigated as a candidate blanket material for fusion reactor designs. When γ-LiAlO₂ is irradiated with thermal neutrons, 2.75 MeV T and 2.05 MeV He particles from reaction ⁶Li (n, He) T will emit. These energetic particles collide with the lattice atoms and initiate damage cascades, generating point defects in the crystalline structure. The accumulation and interaction of point defects and gas species lead to the formation of extended defects and bubbles. In addition, radiolysis due to electronic energy deposition causes the material to decompose. The modified microstructure will affect T diffusion in the irradiated material.

In order to gain a physical insight into the defect production and gas species diffusion processes, ion irradiation experiments have been designed and performed in reactor-relevant conditions. Both protium and deuterium (D) have been used as surrogates for T in this study. Sequential irradiation with 90 keV He⁺ and 80 keV H₂⁺ ions as well as 120 keV He⁺ and 80 keV D₂⁺ ions with an equal ion fluence was performed over temperatures from 188 to 773 K. The ion energies were so chosen that the H or D profile peak was located at the He⁺ damage peak. The ion fluence ranged from 2×10¹⁶ to 4×10¹⁷ He⁺+H⁺ (or He⁺+D⁺)/cm². Isochronal and isothermal annealing experiments were followed up to 873 K and 60 min, respectively. The irradiated samples were characterized using a number of spectroscopy and microscopy techniques, including RBS/C, ToF-SIMS, STEM, STEM-EDS, STEM-EELS, HIM, Nano-SIMS and APT.

This presentation will report our main results from ion irradiation studies of monocrystalline γ-LiAlO₂ and polycrystalline pellets. Major conclusions from these studies include the following. Saturation stages of lattice disorder are found in γ-LiAlO₂ irradiated at 573 K. Complete amorphization with gas bubble formation starts from the surface. Cubic LiAl5O₈ precipitates surrounded by cavities form in the damage peak region. Li out-diffusion and vacuum evaporation from the sample surface occur during ion irradiation at elevated temperatures. STEM-EELS provides evidence for preferred pathways of Li diffusion along the grain boundaries. In situ HIM shows volume swelling, He bubble formation in grains and He release via grain boundaries. In situ TEM reveals a rapid formation of cavities due to radiolysis in γ-LiAlO₂ under low-energy electron irradiation. The thermal annealing data suggest that the D diffusion coefficients in the irradiated material have a value on the order of 2×10⁻¹⁰ cm²/s at 773 K. There is an exponential decay behavior of D release at room temperature from γ-LiAlO₂ pellets irradiated at 188 K; at the low temperature, D atoms appear to be immobilized in the irradiated structure. The data from this study also show significant H and D diffusion and release from γ-LiAlO₂ during irradiation at 573 K; D retention increases with increasing D⁺⁺ ion fluence and tends to saturate at 4×10¹⁷ He⁺+D⁺/cm².

9:45 AM EN17.05.06
Defects, Stoichiometry and Transport Processes in Be12X Intermetallics Robin W. Grimes1, Matthew Jackson2, Patrick A. Burr3 and Simon C. Middleburgh4; 1Imperial College London, United Kingdom; 2University College London, United Kingdom; 3University of New South Wales, Australia; 4Bangor University, United Kingdom

Be12X (X = Ti, V, Mo and W) intermetallics are a promising family of materials for the first wall and neutron multiplying applications in future nuclear fusion reactors. Due to the difficulties of working with Be they are often poorly characterized. Thus, the crystallography, elastic properties, atomic transport processes, thermodynamical stability and deviation from stoichiometry have been investigated using computer simulation based on density functional theory.

Surprisingly there has been considerable controversy regarding the structure of TiBe12, which is variously reported as hexagonal and tetragonal. Lattice dynamics simulations show the I4/mmm tetragonal phase to be more stable over all temperatures. The formation enthalpies of intrinsic point defects and the elastic constants of all the Be12X intermetallics are then predicted. Defect concentrations were shown to be dominated by antisite disorder and Be vacancies, suggesting these materials can accommodate excess X much more easily than excess Be. In Be12Ti it was found that titanium defects have much higher hopping energy than beryllium across the majority of migration pathways studied. Both beryllium vacancy and interstitial diffusion is weakly anisotropic, however, migration of beryllium divacancies is isotropic with energy equal to that of the isolated vacancy.

10:30 AM *EN17.06.01
Influence of Irradiation Conditions on Precipitation Behavior in Fe-Cr and Ni Alloys Li-Jen Yu1, Elaina Reese1, Takuya Yamamoto2, G. Robert Odette2, Julie D. Tucker3, M. Grace Burke4 and Emmanuelle A. Marquis1; 1University of Michigan, United States; 2University of California, Santa Barbara, United States; 3Oregon State University, United States; 4University of Manchester, United Kingdom

The use of heavy ions, protons, or electrons to understand the effect of irradiation on microstructures and therefore materials properties presents many experimental benefits over the use neutrons. However, extrapolating the laboratory observations to behaviors found under neutron irradiation in reactor conditions is not a straightforward process. In particular, dose rates that are orders of magnitude apart and can play a significant role on the development of microstructures, through mechanisms that include higher point defect production and cascade mixing effects. Here, we will discuss the behaviors under ion, proton, and neutron irradiation of alloys that would normally phase decompose under thermal conditions. Specifically, using atom probe tomography to characterize microstructures at high spatial and chemical resolution, the evolution of microstructures in model ferritic Fe-Cr alloys and austenitic Ni alloys was quantified as a function of dose and dose rates. In Fe-Cr alloys, precipitation of the α’ phase is expected under long thermal annealing times. In the selected commercial Ni alloys (625, 625 Plus, and 690), the γ” phase, an ordered Pt2Mo-type phase, and in some cases the γ’ phase are expected to precipitate. Under irradiation conditions, both alloy systems exhibit different precipitation regimes that are dependent on dose rate. Generally, accelerated precipitation by radiation-enhanced diffusion is observed at lower dose rates, establishment of a steady state regime occurs at intermediate dose rates, and precipitation is entirely suppressed at higher dose rate.

11:00 AM EN17.06.02
In Situ Micromechanical Testing of Unirradiated and Ion Irradiated Reactor Pressure Vessel Steels Claudia Gaparrini1, Alan Xu2, Tao Wei2, Ken Short2, Joel Davis2, Tim Palmer2, Dhruti Bhattacharyya2, Nick Riddle2, Lyndon Edwards2 and Mark R. Wenman1; 1Imperial College London, United Kingdom; 2Australian Nuclear Science and Technology Organisation, Australia; 3Rolls-Royce, United Kingdom
Recently there has been a considerable need to extend the lifetime of the world’s pressurised water reactor (PWR) fleet from 40 to 60 or possibly 80 years. The continued safe operation of these reactors is intrinsically linked to the structural integrity of the steel used for the reactor pressure vessel (RPV). Matrix damage and solute clustering induced by neutron irradiation are considered one of the main causes of embrittlement of RPV steel. Intensive research has been ongoing to investigate embrittlement mechanisms of the low alloy ferritic RPV steel, however, testing neutron irradiated materials can take a long time and is very costly. The recent development of micro mechanical testing allows researchers to evaluate mechanical properties of ion irradiated materials which aim to simulate the damaging effects observed on neutron irradiated materials.

This work presents in situ micro tensile testing of a novel manufactured RPV steel: hot isostatic pressed (HIP) SA508 grade 3 steel. Micro tensile specimens with dimensions of $5 \times 5 \times 15 \mu m$ were manufactured using a gallium focused ion beam (FIB) and tensile testing was performed under displacement control at a rate of 20 nm/s in situ in a scanning electron microscope (SEM). Tests were performed under the same conditions on unirradiated and ion irradiated specimens which were irradiated by He$^{2+}$ ions at 5 MeV at room temperature to the damage of 0.6 dpa using a 2 MV tandem accelerator with energy degrader at ANSTO. The mechanical properties (in terms of ultimate tensile stress and 0.2% proof stress) of the unirradiated micromechanical tests agreed well with data obtained via conventional mechanical testing. The effects of ion irradiation on the mechanical properties of this RPV steel were measured as an increase of ultimate tensile stress and yield strength via micro tensile testing. The hardening of the irradiated specimens was also measured using nanoindentation performed on the top sample surface. The hardening mechanism can be correlated to the implantation induced features observed on the ion irradiated material that were resolved using a transmission electron microscope. Fine bubbles/voids with an average diameter of $1.2 \pm 0.5 \text{ nm}$ were observed.

11:15 AM EN17.06.03
Energetic Drive for Ni, Mn and Si Clustering at Dislocation Loops in $bcc$ Iron

Thomas Whiting, Daniel J. King and Mark R. Wenman; Imperial College London, United Kingdom

There are currently concerns that clusters of Cu, Mn, Ni and Si could limit the operational lifetime of reactor pressure vessels (RPVs) through reductions in fracture toughness, unaccounted for in regulatory models. As there is much debate over the origin of these clusters and whether they are radiation-enhanced or radiation-induced and whether they can be classified as discrete phases, there is an ongoing global research effort to investigate their mechanism of formation.

Using density functional theory (DFT) simulations, we have conducted investigations into the effect of strained environments on the binding energies of solutes, solute pairs, vacancy-solute pairs and dumbbells in bcc Fe to better understand the conditions that favour nucleation and growth of solute clusters as it is expected that these are dependent on both strain fields and the local chemical environment. Atom probe tomography studies have found that clusters are frequently associated with dislocation loops and grain boundaries, suggesting that these could act as nucleation sites for solute clustering. As modelling large dislocation loop sizes is computationally expensive using DFT, we have used interatomic potentials for Fe to model both small (19 atom) and large (65 atom) $<111>$ dislocation loops to identify the range of strain on the lattice. We have then used these results to parameterize DFT simulations by modelling defects in strained lattices that are typical of these loops.

Our findings show that: (1) vacancies will be dragged to these locations as vacancy formation energies are reduced by more than 1 eV when subject to large volumetric strains, (2) solutes will be dragged due to the strong solute-vacancy binding energy for Ni, Mn, Si in both first and second nearest neighbour positions, (3) solutes remain bound to vacancies even in significantly strained environments, and (4) magnetic effects are important to model the energetics of systems, particularly for complex environments such as those including self-interstitial atoms.

Measuring Microstructure Changes in Ion-Irradiated 316LN Stainless Steel

I-Hsuan Lo¹, Philip D. Edmondson² and Karl R. Whittle¹; ¹University of Liverpool, United Kingdom; ²Oak Ridge National Laboratory, United States

UK’s nonprescriptive regulatory system has incentivised the nuclear industry to invest in the research and development of reliable structural integrity codes since 1970’s. To support the UK structural integrity services, the
UK project on the ‘Multi-scAle INTegrity assessment for Advanced high-temperature Nuclear system (MAINTAiN)’ offers the ability to further strengthen UK’s position in structural integrity through developing a novel computer model-based assessment code. The aim is to develop the knowledge that is necessary to reliably assess the integrity of critical nuclear components that operate in extremes of high-temperature, high mechanical stress, and irradiation. To this end, a predictive three-dimensional multi-scale creep deformation model, informed by the materials' microstructure, will be established. The MAINTAiN project will provide the scientific foundation for the next generation of high temperature structural integrity assessments.

The University of Liverpool has carried out a part of irradiation damage on the dislocation creep behaviour of three materials that are of interest for the next generation of nuclear power plants: Stainless Steel Type 316LN, ODS Steel, and FeCrAl alloys.

The presentation will illustrate the details of the MAINTAiN and the latest results on the irradiation test of 316LN stainless steel. The irradiation damage was induced by self-ion implantation using the Dalton Cumbrian Facility (DCF). In order to investigate changes, this works has included high resolution transmission electron imaging and spectroscopic analysis of damage in order to investigate the changes in irradiation.

11:45 AM EN17.06.05
Irradiation Assisted Stress Corrosion Cracking in 508-304 Weldment in BWR/NWC Simulated Environment
Brent Heuser and Zhen Li; University of Illinois at Urbana Champaign, United States

Reactor pressure vessel steel SA508 (a low-alloying steel) and 304 (Fe-Cr-Ni austenitic stainless steel) are widely employed in both PWRs and BWRs. Weldments typically have high residual stress and composition gradients within the fusion zone (FZ) and heat affected zone (HAZ) that lead to greater stress corrosion cracking (SCC) susceptibility. Irradiation assisted SCC can be controlled by factors including water chemistry, localized deformation, tensile stress, radiation induced segregation and radiation damage. In particular, the redistribution of Cr, the element responsible for oxidation/corrosion resistance via chromia formation, can sensitize these alloys to SCC phenomenon. These materials can be preferentially attacked at active paths, such as GBs in the FZ and HAZ, when exposed to chemically reactive environment and to radiation.

Slow strain rate tests (SSRT) with strain rate up to $10^{-9}/s$ were applied on proton irradiated EPRI SA508-309 weldment in an autoclave system with simulated the BWR/NWC environment (10.2 Mpa, 288 °C and 2000 ppb oxygen) in order to investigate the radiation assisted SCC. The effect of radiation to induce segregation in the FZ and HAZ of SA508-309 weldment is of typical interest. In addition, SSRTs were employed on as-received SA508-309 weldment to separate the effect of irradiation from environment factors such as LWR water chemistry and applied tensile load. Moreover, SSRTs were conducted on as-received weldment at room temperature and atmosphere pressure. The yield strength and ultimate tensile strength of as-received and proton irradiated SA508-304 weldment under NWC environment is 25% lower compared to that under room temperature and atmosphere pressure. The redistribution of elements such as Cr in the grain boundary of as-received and irradiated weldment is investigated with STEM-EDS. The initiation of cracking was studied by SEM and TEM in the as-received and irradiated weldment. This talk will focus on identification of the primary factors of SCC in Fe-based weldments.

1:30 PM EN17.07.01
Studying Corrosion in Materials for Nuclear Applications Using Synchrotron-Based X-Ray Methods
Simerjeet Gill; Brookhaven National Laboratory, United States

Development of next generation materials for nuclear energy structural applications requires understanding structural changes and failure mechanisms under extreme environments. Reactions at interfaces under corrosive environments play a crucial role in material failures in current and advanced reactors.

Our research focuses on utilizing synchrotron characterization techniques such as spectroscopy, multi-modal
imaging and diffraction for characterizing material interfaces and their properties when subjected to extreme environments of high temperature and radiation fluxes present in nuclear reactors. Synchrotron based characterization studies performed for structural materials and molten salt systems, elucidating corrosion at interfaces will be presented.

X-ray absorption spectroscopy has been utilized to investigate local coordination environment, bonding dynamics and electronic properties of metal species, and their changes at elevated temperatures in molten salt systems. Using a custom-designed in situ cell, we used Ni and Co dopants in single component ZnCl₂ and ZnCl₂-KCl eutectic and studied their properties using Ni, Co and Zn K-edge spectra. The local structural changes and speciation of metallic species in molten salt systems will be discussed.

3D multi-modal imaging techniques will be discussed to provide quantitative characterization of Cr segregation at grain boundary inside the sensitized steel sample using X-ray Fluorescence. Tomographic image reconstruction of stainless steel deteriorated by IG corrosion is combined with 3D imaging of phase contrast using Differential Phase Contrast imaging. This combined structural and chemical analysis of the Cr segregation at grain boundaries allows us to understand IG corrosion in sensitized stainless steel at nanoscale.

To track degradation of materials in real time, we built and commissioned an in situ sample environment for studying interfaces under high-temperature and pressure conditions using x-ray diffraction to investigate corrosion mechanisms in cladding materials. Capabilities of the in situ sample environment will be discussed.

2:00 PM EN17.07.02
First Principles Investigation of Cr Segregation Behaviors in Ni-Cr Alloy in Molten Salt Systems Jacob Startt¹, Stephen S. Raiman² and Chaitanya Deo¹; ¹Georgia Institute of Technology, United States; ²Oak Ridge National Laboratory, United States

The development of new structural materials that can withstand the degradative and corrosive environments exhibited by molten salt systems currently stands among the most important remaining scientific targets that must be reached before viable molten salt systems can be realized at an industrial scale. In corrosion focused studies, the prevailing trend observed in the most commonly investigated alloys (such as Hastelloy N or 316 stainless steel) is the depletion and dissolution of Cr atoms near the alloy surface and along grain boundaries. The atomic level mechanisms and forces that drive the migration of Cr and its eventual removal from the surface are not well understood, and due to the harsh environments intrinsic to molten salt systems experimental efforts may struggle to observe these fundamental processes. Carefully devised computational modelling offers another avenue to study the nature of these interactions and may even help to suggest potential mechanisms and to narrow the field of possible reaction pathways for future experimental studies to investigate.

In this study, the segregation behavior of Cr near an (100) fcc Ni surface is investigated with first-principles density functional theory (DFT), first for a clean surface and then for surfaces with various salt species adsorbed above the segregating Cr atom. Surface segregation energies describe the energetics associated with the location of a solute atom near a surface (i.e. the relative energy of an atom when its located in the bulk versus in a specific surface layer).

Calculations show that under a clean surface (i.e. no adsorbed salt atoms) it is energetically favorable for the Cr atom to inhabit the 3rd or 2nd surface layer, but largely unfavorable for it to sit in the topmost 1st layer. When a Cl adatom is placed above the Cr atom, the segregation energy for the top-most layer decreases, suggesting Cl surface adsorption lowers the barrier for Cr to move to the top layer. When F or O are adsorbed to the surface, the segregation energy not only decreases but becomes significantly negative, suggesting that Cr segregation to the top layer not only becomes more favorable with these species on the surface but also actually preferred relative to a remaining in a bulk position. Further investigation into the effects of H-Cl, H-F, and H-O will also help to understand the role of H and H₂O salt impurities in the corrosion process. The additional presence of an H atom may also allow the highly electronegative surface adsorbates to increase their local electron occupation level, which would more closely resemble the charged ionic nature exhibited by the salt in a molten state. This talk will report new insights into material-salt interfaces through atomistic modeling.

Corrosion Mechanism of Molten Salts on Haynes 230 Alloy Studied Using In Situ Neutron Reflectometry
Joohyun Seo, Mathieu Doucet, Gabriel M. Veith, Sheng Dai and James F. Browning; Oak Ridge National Laboratory, United States

Molten salt eutectics are used as heat transfer fluid in concentration solar power systems. One of the technological challenges with such systems is the control of corrosion of the materials used for transport of the molten salts. For this reason, understanding how the interface between salts and alloys change as a function of temperature is important. In this study, we focused on the interfacial structure at the interface of KCl-MgCl$_2$ molten salt eutectic and Haynes 230 alloy using neutron reflectometry. This binary molten salt eutectic was deposited on Haynes 230 alloy to characterize the multilayer as a function of temperature. Our measurements were carried out in situ under ultra-high vacuum conditions. First, a thin film of a single Haynes 230 alloy layer was studied to characterize the alloy as a function of temperature before exposing it to molten salts. The structure of the Haynes 230 alloy film was measured between room temperature to 451 °C. Subsequent measurements were made with a thin film of salt sandwiched between two layers of Haynes 230 alloy at temperatures below the salt’s melting point with sample temperatures ranging from ambient to 383 °C. In both cases, a change in the Haynes 230 alloy structure is observed at around 160 °C. We will describe the environment chambers used for these measurements as well as our results of the behavior of the interfacial structure in these thin film systems.

2:30 PM EN17.07.04
Tritium Mobility and Local Chemistry in Fluoride Molten Salts Stephen Lam, Ronald Ballinger, Ju Li and Charles Forsberg; Massachusetts Institute of Technology, United States

Molten fluorides have been proposed for use as coolant in various advanced nuclear concepts including molten-salt reactors (MSRs), fluoride high temperature salt-cooled reactors (FHRs) and fusion devices. In these systems, significant quantities of tritium will be produced which must be captured and controlled to prevent a radioactive release. In order to efficiently remove tritium from the system, the transport and chemical properties must be well characterized and understood. Yet, difficulty in the handling of fluoride salts and tritium has resulted in relatively few experiments being conducted and large discrepancies across different studies. In this work, the transport and local chemistry of different tritium species (tritium fluoride and diatomic tritium) has been studied in the prototypical fluoride salts FLiBe (66.6-33.3 mol% LiF-BeF$_2$) and FLiNaK (46.5-11.5-42 mol% LiF-NaF-KF) using ab-initio molecular dynamics (AIMD). The methods were validated using experimentally well-characterized fluorides. Salts examined in this study include binary fluorides LiF, NaF, and NaF, and ternary fluorides LiF-BeF$_2$ and LiF-KF at various compositions. Radial distribution functions and coordination numbers from neutron diffraction, and diffusivities and activation energies from nuclear-magnetic resonance are accurately reproduced. Chemical species and structures were found by using graph-theoretic representations of the system at each time step and removing noise with probabilistic filtering methods. Over the temperature range from 873 to 1373K, the T$_2$ and TF diffusivities in FLiBe were found to be $D[\text{m}^2/\text{s}]=4.14E^{-7}\exp(-33.0[\text{kJ/mol}]/RT)$ and $D[\text{m}^2/\text{s}]=1.724E^{-7}\exp(-32.0[\text{kJ/mol}]/RT)$ respectively. At the same temperatures in FLiNaK, T$_2$ and TF diffusivities were $D[\text{m}^2/\text{s}]=1.38E^{-6}\exp(-39.0[\text{kJ/mol}]/RT)$ and $D[\text{m}^2/\text{s}]=4.94E^{-7}\exp(-41.0[\text{kJ/mol}]/RT)$ respectively. In both systems, TF exhibited 3-4 times lower diffusivity than the reduced form of tritium T$_2$. In both cases, decrease in diffusivity due to loss in mobility is attributed to TF reactivity and complexation in the salt. In FLiBe, TF was found to be bound to various BeF$_2$ molecules, while in FLiNaK, TF$_2$ complex was formed. In contrast T$_2$ molecules in both simulations were found to be stable in pure salt with limited chemical interaction in the solvent. The tritium diffusivities fall within range of experimental values and discrepancies between different experimental studies in literature were attributed to a combination of the following factors: differences in measured species (TF and T$_2$), presence of impurities (corrosion products, moisture) and differences in isotopes used (H, D, T). Large differences in tritium transport will have significant impact on assessing tritium control strategies, which typically rely on mass transport (adsorbents, permeation windows) and chemical condition (redox controls). This study provides a deeper understanding of chemical interactions and accurate chemical-transport data that can be used to predict macroscopic behavior and design engineering and control systems.

High Temperature Cell for In Situ Reflectometry of Molten Salts Mathieu Doucet, James F. Browning, Joohyun Seo and Gabriel M. Veith; Oak Ridge National Laboratory, United States

Next generation concentrated solar power systems and molten salts reactors have created new interest in molten salt
chemistry. The corrosion processes of the alloy used to contain the molten salts as a function of temperature remains to be fully understood. In particular, we are interested in the corrosion of Haynes 230 (approximately Ni>57 Cr22 W14) in contact with a KCl/MgCl₂ eutectic mixture for application in solar power systems. Our team has focused on studying this corrosion process in situ using neutron reflectometry. We will present the design of the high temperature cell that will enable us to perform those in situ measurements from room temperature to 850 C.

Free-Energy Functional of the Zirconium-Hydride System from First Principle Calculations Michele Fullarton¹, Simon R. Phillpot¹, Yongfeng Zhang² and Larry K. Aagesen²; ¹University of Florida, United States; ²Idaho National Laboratory, United States

Zirconium based alloys for nuclear fuel cladding are known to precipitate hydride phases during operation. These precipitates can cause several issues including embrittlement leading to cracking and failure of the cladding. In order to predict the materials properties of the cladding the hydride phases must be accurately simulated. In this work the thermodynamic stability of phases in the zirconium-hydride system was evaluated using first principles-based methods. Cluster expansion techniques were employed to assess the stability of each phase over a range of concentrations at zero temperature. Phonon contributions for each ground state were calculated and combined with results of finite-temperature Monte Carlo simulations to create Gibbs free energies of the phases as a function of temperature and concentration. From these results a new phase diagram was generated, which will clarify discrepancies between different experimental phase diagrams. Moreover, the free energy functionals of all relevant phases were parameterized, allowing for more accuracy calculating microstructure and materials properties of cladding, for instance, in phase field simulations with INL’s MARMOT code.

3:45 PM EN17.08.03
Oxygen Stoichiometry Deviation in Amorphous ZrO₂ and Yttria-Stabilized Zirconia Simon C. Middleburgh¹, Michael Rushton¹, Iuliia Ipatova¹, Lee Evitts¹ and William E. Lee¹,²; ¹Bangor University, United Kingdom; ²Imperial College London, United Kingdom

Amorphous zirconia (a-ZrO₂) has been modelled using a combination of reverse Monte-Carlo, molecular dynamics and density functional theory together. This combination has enabled the complex chemistry of the amorphous system to be efficiently investigated. Interestingly, the a-ZrO₂ system was observed to accommodate excess oxygen readily through the formation of neutral peroxide (O₂²⁻) defects – a result that has implications not only in the a-ZrO₂ system, but also in other systems employing network formers, intermediates and modifiers. Similar conclusions are made for the yttria-stabilized zirconia system and has been corroborated with Raman spectroscopy data. These results have potential implications for materials behaviour in reactor systems: notably a mechanism for oxygen to be accommodated and transported through thin, amorphous zirconia films such as those expected at highly damaged grain boundaries - providing a mechanism for zirconium cladding corrosion.

4:00 PM EN17.08.04
Deformation and fracture of Zirconium Hydrides During Plastic Straining of Zr-4 Luca Reali, Said El Chamaa, Daniel S Balint, Mark R. Wenman and Adrian P. Sutton; Imperial College London, United Kingdom

Crack initiation in zirconium alloys is an important issue affecting the safety of nuclear reactors. Zirconium hydrides that precipitate in service are potential crack nucleation sites. In this work, the deformation and cracking of zirconium hydrides was studied during the deformation at room temperature of Zircaloy-4 samples up to fracture. Two hydrogen concentrations of 100 and 200 ppm were considered.
Hydrides precipitate both inside and at the boundary of the grains. It is expected that thicker hydrides and hydrides at the grain boundary are more prone to fracture. The main objective of this study was to better understand which of the two is the most important factor, and to identify at which point in the deformation of the alloy the first hydrides break. Micro voids thus nucleated may coalesce and be an important factor in understanding the fracture of these alloys. Scanning microscopy (SEM) images of a number of hydrides, both intergranular and intragranular, were taken at discrete increments of deformation, and the fraction of those that show evidence of fracture was estimated.

The results show that intergranular hydrides possess a lower deformability, which can be rationalised by analysing the conditions for slip transmission into and out of the hydride.

4:15 PM EN17.08.05
Hydrogen Pickup and Oxidation Kinetics of Zirconium Alloy—Dopant Effects from the Chemo-Mechanical Perspective Jing Yang, Mostafa Youssef and Bilge Yildiz; Massachusetts Institute of Technology, United States

Effect of alloying elements on zirconium alloy degradation properties has been widely studied because of its application in nuclear water reactors. It is observed in experiments that alloying element in zirconium alloy could result in different morphology of the passive film as well as different oxide film growth kinetics. The goal of this work is to study oxygen diffusion and hydrogen pickup processes in the ZrO2 passive film system under the effect of alloying elements, with varying temperature and chemical environment. In particular, we focus on the chemo-mechanical effect of Fe, Cr, Sn and Nb dopants in ZrO2 that exist in the oxide matrix as point defects from first-principles calculations. We show that the change in defect chemistry imposed by doping is strongly correlated with the valence states of the dopants. Fe and Cr, which are dominantly in +3 valence states, tend to decrease the concentration of oxygen interstitials and increase the concentration of hydrogen interstitials in ZrO2, thus suppressing oxide growth while increasing hydrogen pickup. Nb, on the other hand, is dominantly +5 and has the opposite effect. Changes in defect chemistry are accompanied by change in phase stability. We have discovered that Fe and Cr can strongly stabilize tetragonal-phase ZrO2 while Nb has a strong destabilizing effect. This effect provides insight for the different oxide film morphology of zirconium alloys with varying alloying element.

4:30 PM EN17.08.06
Influence of Boron Isotope Ratio on the Thermal Conductivity of Uranium Diboride (UB2) and Zirconium Diboride (ZrB2) Lee Evitts1, Simon C. Middleburgh1, Erofili Kardoulaki2, Michael Rushton1, Iuliia Ipatova1 and William E. Lee1,3; 1Bangor University, United Kingdom; 2Los Alamos National Laboratory, United States; 3Imperial College London, United Kingdom

Uranium diboride is being considered as an advanced fuel, while zirconium diboride remains a leading candidate for use as a burnable absorber, often coated on uranium dioxide fuel pellets. To ensure safe and efficient operation models need to be developed to enable the material to be modelled within a fuel performance code. Thermal properties of these materials are therefore investigated using density functional theory methods. It was found that the boron isotope ratio significantly varied the thermal conductivity for both materials. When compared to experimental data, the thermal conductivity for ZrB2 is well predicted, however, a significant discrepancy is observed for UB2. Potential reasons for the discrepancy, including the Hubbard factor and phonon relaxation times, are explored and discussed.
Radiation technology is widely used medical radiation therapy, radiation dosimeter, food preservation and other industrial applications. These include scientific research such as high energy physics, radiochemistry, change of material properties and so on. Radiation detection is one of important research area to safely use ionizing radiation. Several devices are investigated for radiation detection such as Silicon diode, metal-oxide semiconductor field effect transistors, thermo-luminescent dosimeters, optically stimulated luminescence dosimeters. These devices use semiconducting properties of organic and inorganic materials with electrical or optical connection for readout. In this study, we synthesized organic conjugated molecule for application to detection of gamma-ray without any readout devices. This molecule is consisted of two main parts. One is low-band gap conjugated core part, which is dithiophene moiety, for wide absorption in visible range. And the other is dicyanomethylene parts which are possible to induce band-gap change of dithiophene core part by gamma-ray. After irradiation gamma-ray with 1 Gy on film of the molecule, dark blue color is changed to yellow color due to change of band-gap from 1.74 eV to 2.16 eV. We investigate optical and electrical properties of the molecule by gamma-ray and we also discuss detail mechanism of color change and effect on the molecule by gamma-ray.

EN17.09.04
Anode Material Development for Scale-Up Oxide Reducer in Pyroprocessing Sung-Wook Kim, Min Ku Jeon, Sang-Kwon Lee and Eun-Young Choi; Korea Atomic Energy Research Institute, Korea (the Republic of)

Pyroprocessing has been investigated as an option to recycle and to manage spent nuclear fuels (SNFs) from pressurized water reactors. The oxide SNFs needs to be transformed to metallic states for electrochemical recovery of transuranic elements. In this respect, oxide reduction (OR) technique has been developed for the metal conversion. LiCl molten salt-based electrochemical reaction is the common OR technique. Conventional OR process is designed based on Li₂O recycle reaction. Li₂O is electrolyzed to form Li metal at cathode and O₂ gas at anode (2Li₂O → 4Li + O₂(g)). The Li metal subsequently reduces the oxide SNFs (e.g., UO₂ + 4Li → U + 2Li₂O) to release new Li₂O. Hence, Li₂O concentration in the LiCl salt is expected to be constant during the OR operation. Pt has been widely used as the O₂-evolving anode material because of its superior mechanical and chemical stabilities in the high-temperature oxidation environment.

Scale-up is an important issue on feasibility examination of pyroprocessing. The Pt anode, however, is not preferred in the large-scale system because it is gradually damaged upon the operation resulting in high processing cost. The Pt anode is known to have three anodic reactions depending on anode potential: Li₂PtO₃ formation (2Li⁺ + Pt + 3O²⁻ → Li₂PtO₃ + 4e⁻ at low potential), O₂ evolution (2O²⁻ → O₂(g) + 4e⁻ at medium potential), and anodic dissolution (Pt = Pt²⁺ + 2e⁻ at high potential). Only the O₂ evolution is required and thus the operation voltage of the Pt anode system should be carefully controlled (normally, ~3 V). Nevertheless, it was revealed that the side reactions cannot be avoided to induce the Pt anode deterioration, even in small-scale experiments (~15 g-UO₂). This would be due to non-uniform potential distribution across the Pt anode (by iR drop and other reasons) and local inhomogeneity of the Li₂O concentration in the salt. This should become more severe with the scale-up and it is considered that the precise control of the reaction pathway of the Pt anode would be very difficult in the large-scale equipment.

KAERI (Korea Atomic Energy Research Institute) has examined several materials to replace the Pt anode. One approach is to develop the O₂-evolving anode with better electrochemical stabilities using conductive ceramics and other noble metals. C anode was also suggested. The C anode system operates at high voltage range (>4 V) compared to the Pt anode system to decompose the LiCl salt to generate Cl₂ gas (2Cl⁻ → Cl₂(g) + 2e⁻) at the C anode. The advantages of the C anode are non-concern on the anodic reaction control and high operation current. In this presentation, the recent studies on the anode material development done at KAERI will be introduced.

EN17.09.05
Interaction Behavior between U-Zr Alloy Containing Lanthanides and Reusable Crucible Materials Seoungwoo Kuk, KyungChai Jeong, SeokJin Oh, KiHwan Kim and Jeong-Yong Park; KAERI, Korea (the Republic of)

A U-10 wt.% Zr alloy containing lanthanide elements (Nd, Ce, Pr, La) was introduced as a surrogate for transuranium alloys in metallic nuclear fuel. U-Zr alloys containing the lanthanide elements interact significantly with graphite crucibles. Conventional coating material, Y₂O₃ reduced the interaction, but partially interacted and detached from crucible after casting due to the difference in the thermal expansion coefficients of the crucible and the coating layer. The crucible was contaminated and could not thereafter be reused. Thus, it was considered a form of radioactive waste. Moreover, interacted materials could not be removed from the casting part and amounts of the
reaction reduced casting yields. Materials such as LaYO₃, SiC, TiC, and TiN along with density-improved Y₂O₃ were considered as candidates for use in the creation of a reusable crucible, which could be used to improve casting yields and to reduce radioactive wastes. The interactive behaviors of the candidate materials were considered by means of a sessile drop test. The annealing temperature was set to 1,450 °C for investigating interactions of the casting method. Microstructures of the candidate materials were observed using a scanning electron microscope (SEM), and their elemental distributions were characterized using energy-dispersive X-ray spectroscopy (EDS). Phase formations of the candidate materials were identified using an X-ray diffractometer (XRD). The material interaction was reduced by the enhanced Y₂O₃ coating and LaYO₃. A shortlist of candidate materials for use in the creation of a reusable crucible was drawn up based on the results of this research.

EN17.09.06
Reaction Characterization between Graphite Crucible and U-Zr Melt Seong-Jun Ha¹,², Jeong-Yong Park², Seoungwoo Kuk³, KyungChai Jeong², Sang Gyu Park², Young-Mo Ko³, Yoon-Myeng Woo³ and Young-Kook Lee¹; ¹Yonsei University, Korea (the Republic of); ²Korea Atomic Energy Research Institute, Korea (the Republic of)

U-Zr metallic fuels have been developed as a nuclear fuel for Sodium-cooled fast reactor because metallic fuels are related to excellent reactor safety and fuel cycle economy. In the fabrication process of U-Zr metallic fuels, the graphite crucible is commonly used for melting and casting and yttrium oxide is coated on the inner surface of the graphite crucible to prevent the reaction with melted U-Zr alloy. It is crucial to prevent the reaction between the melt and crucible for controlling the loss in the fabrication. In this study, we investigated the reactivity between uranium, zirconium and graphite crucible. The graphite crucible was used to clarify how the graphite react with melt uranium and zirconium. U-10wt.%Zr alloy was melted using injection casting apparatus which is an induction furnace. Raw materials consisting of zirconium sponge and uranium metal were charged in the graphite crucible in the order named. The materials were superheated at 1,600°C for alloying and it was cooled in the furnace after alloying. Microstructures in the surface region of the melt-residue of U-Zr alloy were characterized using Scanning electron microscopy (SEM) equipped with Energy dispersive X-ray spectroscopy (EDS). Although the graphite crucible was used for melting uranium and zirconium, the U-10wt.%Zr melt residue was fabricated without alloying between uranium and the graphite crucible. The melt residue was easily separated from the graphite crucible. However, the reaction layer was formed on the surface of U-10wt.%Zr melt residue. The reaction layer mostly consisted of carbon and zirconium. The thickness of reaction layer was about 5 μm at side region and 10 μm at bottom region. The bottom region had the thickest reaction layer among whole surface because first of all, zirconium was reacted with graphite crucible at the bottom region when the charged raw materials were heated. The thickness of the reaction layer was assumed as the depth penetrated into the U-Zr matrix from the graphite crucible depending on the volume of the zirconium, melting temperature and time. The surface of melt residue was investigated using X-ray diffractometer (XRD). As a result of XRD analysis, ZrC and U₃O₇ were detected on the reaction region. It is likely that C was contaminated from graphite crucible. The quantitative chemical composition of graphite crucible was investigated using Inductively coupled plasma-atomic emission spectroscopy (ICP-AES). As a result of ICP-AES analysis, uranium and zirconium were contaminated at contact region. On average, uranium and zirconium contents of graphite crucible were 281 and 31 ppm but it was a considerable difference according to the position. In this study, U-10wt.%Zr alloy was fabricated in the optimizing manufacturing process to examine the reactivity between uranium, zirconium and graphite crucible. The reaction layer consisted of zirconium and carbon is formed on the whole surface of the melt residue because zirconium is commonly reacted with carbon at the contact region with graphite crucible. The graphite crucible is also contaminated with uranium and zirconium when melting.

EN17.09.07
Combined Ab Initio and Empirical Model for Irradiated Metal Alloys with Focus on Uranium Alloy Fuel Thermal Conductivity Shuxiang Zhou¹,², Ryan Jacobs¹ and Dane Morgan¹; ¹University of Wisconsin-Madison, United States; ²Idaho National Laboratory, United States

High-quality thermal conductivity data is critical to the rational design of materials for applications ranging from thermoelectrics to nuclear reactors. However, such data is experimentally and computationally challenging to obtain due to any or all of cost, technical hurdles, and time requirements. The thermal conductivity of these materials can be further influenced by their working conditions, e.g. irradiation, due to the microstructure changes. Therefore, practical models and quantitative understanding of the thermal conductivity, including changes due to microstructure, is essential to support the development of new materials. In this work, we developed a computational model of thermal conductivity of irradiated metal alloys based on
density functional theory (DFT) calculations, semi-classical scattering theory, and experimental data. This approach has been applied to model the electrical and thermal conductivity of alpha uranium previously, and can be extended to model the conductivities of U-alloys like U-Zr and U-Mo. The present model incorporated the contributions of point defects (vacancies and transmutation products), grain boundaries, and noble gas bubbles (inter- and intra-granular) resulting from irradiation. The effects of point defects and grain boundaries are modeled by both DFT calculations and semi-classical scattering theory, and the effect of noble gas bubbles are modeled using empirical models. The utility of our model is demonstrated on U-Mo alloys, which are promising nuclear fuel materials for use in next generation nuclear reactors, and displays semi-quantitative agreement with experimental data with a root-mean-square error of about 0.8 W/m-K (~7% error versus experiment) over the typical operating temperature and burn-up range for U-Mo alloys. This work provides insight into the semi-quantitative relationships of the thermal conductivity changes resulting from the different irradiation-induced changes in atomic structure and microstructure over a wide range of temperatures, and shows that scattering of electrons from point defects produce the majority of the reduction of the thermal conductivity of U-Mo alloys under irradiation. As an example, at 50% U235 burn-up, the thermal conductivity decreases about 20% due to the effect of point defects, while grain boundary and gas bubble formation contribute only about another 10% decrease. Furthermore, our model can be straightforwardly applied to different irradiation conditions or microstructures by changing the values of a few corresponding parameters.

The present model both serves as a powerful tool for quantitative semi-empirical modeling of thermal conductivity in irradiated metals, and for materials design insight for the control of thermal conductivity in metal alloys in applications experiencing irradiation, such as the further development of advanced metallic U-alloy nuclear fuels.

EN17.09.08
Effects of Initial Microstructure on the Hot Extrusion Properties of Annular Fuel after Extrusion Sang Gyu Park, Seoungwoo Kuk and Jeong-Yong Park; KAERI, Korea (the Republic of)

The innovative fuel development is the development of the advanced sodium-cooled fast reactor metallic fuel concepts. The fabrication experiment seeks to investigate advanced fuel designs with the following features: decreased fuel smeared density, venting of the fission gas to the sodium coolant, reduce the FCCI (Fuel Cladding Chemical Interaction), and an advanced fabrication method that includes consideration of annular fuel and extrusion method. The one of most attractive advantage of extrusion method is save the process waste by omitting the sodium process. From the previous study, annular fuel shows the possibility of the reduction of swelling effect and then prevention of the FCMI (Fuel Cladding Mechanical Interaction). However, the fabrication technology of the annular fuel has not been developed yet. Hence, KAERI is developing the extrusion type metal fuel manufacturing technology as a part of the development of the original technology for the production of innovative metal fuel. In this study, the prototype of annular fuel has been fabricated by using Cu billet. The design of billet and annular fuel has been determined, and then and design and material for the mold has been determined by using Deform 3D program. After the mold fabrication, the prototype annular fuel has been fabricated and its texture were examined by us EBSD (Electron Back Scatter Diffraction). There are two types of billets were used for the extrusion in this study; one is drawn billet which has very fine grains(<less than 100um), and the other is casted billet that has very coarse grains (<500um). When we compared the grain size after extrusion, the microstructure of the drawn billet showed a grain size of at most 100um or more, which is relatively coarser than that of the extruded annular fuel. Therefore, it is considered that the non-anisotropic crystal tendency analyzed after extrusion production is attributed to the fact that the crystal grains used in the processing billet are already small in size. On the other hand, the texture of annular fuel from the casted billet shows very coarse and anisotropic tendency after extrusion. Therefore, the control of initial texture of billet seems the main factor for the annular fuel microstructure. The fabrication methods for the billet microstructure control will be discussed.

EN17.09.10
Determination of Dose Effects on Defect Accumulation under Irradiation in Nanoporous Gold and Niobium via Atomistic Simulations Daniel E. Vizoso1,2, Chaitanya Deo1 and Remi Dingreville2; 1Georgia Institute of Technology, United States; 2Sandia National Laboratories, United States

This study explores the radiation resistance of metallic nanofoams and nanowires via atomistic simulations. Nanostructured metals present a high density of interfaces and surfaces as sinks for radiation produced point defects and thus may offer a means to developing radiation tolerant materials. Current work in the modeling of radiation
damage in nanofoams and nanowires typically considers defect accumulation due to a small number of primary knock on atoms. For this work, dose effects have been investigated by varying the number and energies of primary knock on atoms, including the consideration of damage accumulation due to damage events with a spectrum of energies. The study investigates the impact of structural properties such as ligament length and diameter on defect accumulation mechanisms and defect properties, such as formation and binding energies as well as the relationship between energies of the primary knock on atoms and changes in mechanical properties. This analysis is performed in two different nanoporous material systems: gold and niobium. The radiation response of nanoporous gold has been studied both experimentally and computationally, although previous computational works have been limited in the doses considered. Nanoporous niobium is a material system that has been previously synthesized but not had its radiation response characterized either computationally or experimentally. The comparison of the radiation responses of nanoporous gold with that of nanoporous niobium also allows for an investigation into the differences in behavior between bcc and fcc nanoporous media. Results suggest that the presence of interfaces and surfaces in nanofoams affects the formation and migration of defect clusters leading to a more radiation resistant metallic structure.

EN17.09.11
Reusable Multifunctional 3D Graphene Electrode for Highly Efficient In Situ Extraction of Uranium from Mining and Contaminated Solution
Ahmed Elwakeil, Chao Wang and Ju Li; Massachusetts Institute of Technology, United States

The potential strategic application of uranium in nuclear power industry, as well as the environmental and human health problems caused by uranium, promotes the development of reliable methods for in situ extraction of U (VI) from different solutions. Herein, a unique multifunctional three dimensional electrodes have been fabricated by simple hydrothermal method and used as outstanding electrosorbent for uranium extraction from different aqueous solution. The electrochemical sorption method solves the conventional drawbacks of other methods by using fixed potential to guide the movement of uranium ions in the solution and increase the collision rate onto the electrode surface, resulting in faster kinetics and higher adsorption capacity, easier scaling up, and high selectivity due to specific grafted functional groups. The fabricated electrode was characterized by RAMAN, FTIR, XRD, STEM, EDS, XPS before and after uranium loading. The adsorption capacity for U(VI) ions with our multifunctional 3D electrode is estimated to be 4800 mg/g at pH 5.2 without reaching saturation exhibiting the highest reported sorption capacity compared with other electrochemical methods. The fabricated electrode can be efficiently regenerated and recycled for at least 7 times in uranium solution with concentration 40th times higher than initial concentration without any observable change in efficiency. This work represents the first application of multifunctional 3D electrode for uranium extraction from mining solution and contaminated ground water.

EN17.09.13
Glass Degradation and pH Changes in Narrow Openings of Cracks
Rama Krishna Chinnam1,2 and William E. Lee2,3; 1University of Limerick, Ireland; 2Imperial College London, United Kingdom; 3Bangor University, United Kingdom

In an earlier degradation study on partially immersed international simple glass (ISG), it was found that water near the surface of the ISG or localised variation in pH resulted in discrepancy of glass dissolution and variation in precipitates size on the glass surface. Another finding in the study was the formation of pits on the glass surface under the gel layer [1].

In continuation to the above study, new experiments were designed to understand and measure the pH changes in the localised regions of the glass. For this purpose
1. A study was performed to understand the influence of confined narrow opening on the glass degradation. This experiment helps to understand the environment between gel layer and glass, and to simulate the degradation conditions inside a glass crack.
2. A study was performed to understand the change in pH of the water inside a glass crack with access to fresh water and glass cracks without access to fresh water.
In 1st study, two ISG slides were stacked, an excessive gel layer was found at the outer rim of the interface and the gel layer was found absent at the centre of the interface with a clear boundary between the two regions. This effect was studied under the electron microscope and the TOF-SIMS to confirm the chemical composition difference between the two regions. Thus indicating that degradation in narrow openings of glass is quite different.

In 2nd study, water inside cracks with access to fresh water was found to exhibit pH 10 and pH 8. Water in the cracks with no access to fresh water was found to exhibit pH 11, pH 12 and pH 13. The change in the pH of water in cracks is related to the depth of the crack and position in the water. Thus confirming that cracks exhibit different pH conditions than surrounding water, fresh water availability and their position within water.

EN17.09.14
Investigations in the UB2-UO2 Advanced Fuel System Fabio Martini¹, Iuliia Ipatova¹, Lee Evitts¹, William E. Lee¹, Michael J. Rushton¹, Antoine Claisse² and Simon C. Middleburgh¹; ¹Bangor University, United Kingdom; ²Westinghouse Electric Sweden AB, Sweden

Uranium borides are attractive candidates for advanced nuclear fuels. In particular, uranium diboride-based fuels are expected to outperform – in terms of thermal conductivity and spatial uranium density – their currently-used counterparts based on uranium dioxide. Nevertheless, uranium diboride is expected to be less tolerant than uranium dioxide upon accidental contact with water and other oxidizers at high temperatures. The dispersion of uranium diboride in a uranium dioxide matrix is seen as a possible solution that combines the advantages of both compounds, affording a composite material that has a greater thermal conductivity and spatial uranium density than pure uranium dioxide while maintaining its resistance to oxidation.

The interface chemistry of UO2-UB2 systems has been investigated via temperature dependent atomic scale simulations.

EN17.09.15
Multifunctional Nanoceramic Barrier for DEMO Breeding Blanket Concepts Boris Paladino¹,², Daniele Iadicicco¹, Matteo Vanazzi¹,², Patricia Munoz¹, Teresa Hernandez¹, Serena Bassini¹, Marco Utili¹ and Fabio Di Fonzo¹; ¹Istituto Italiano di Tecnologia, Italy; ²Politecnico di Milano, Italy; ³CIEMAT, Spain; ⁴ENEA, Italy

The realization of the breeding blanket system represents one of the crucial points in the design of future generation fusion reactors. At the time being, issues related to materials compatibility persist. According to the most relevant design, fusion reactors will take the Tritium-Deuterium fusion as the reference reaction for power generation. Thus, the availability of Tritium to fuel the reactor core assumes relevant importance. The breeding process represents one of the main focus points of technological R&D activities and the inhibition of Tritium permeation is mandatory to achieve Tritium balance in the reactor chain: once Tritium is produced, an adequate permeation barrier is required to confine it. At the moment, two are the eligible breeding materials under investigation: a flowing Pb-16Li eutectic alloy and a pebble bed composed by sintered Lithium ceramics and Beryllium. It was demonstrated that both these two materials lead to severe corrosive attack of the steel constituting the breeding blanket modules (RAFM steel), hence threatening the mechanical integrity of the whole structure. It is thus clear that materials are proving to be one of the major bottlenecks for this technology. In order to undertake these issues, we report on multifunctional nanoceramic oxide coatings grown by Pulsed Laser Deposition (PLD) technique. Oxides were chosen because of their chemical inertia and thermodynamic stability. Among these, Aluminium Oxide and Yttrium Oxide were identified as promising candidates. Deposited films appear dense, compact and well adherent on the steel substrates, showing optimal metal-like mechanical properties combined with high hardness. Morphological and crystalline features were evaluated in the case of as-deposited and annealed samples. A deep characterization was performed by Scanning Electron Microscopy (SEM), Energy Dispersive X-ray (EDX), Fourier Transform Infrared spectroscopy (FTIR) and X-ray Diffraction (XRD). Also, coatings of these materials have been tested as Tritium permeation barriers with Hydrogen at different temperatures (from 350°C to 650°C). They showed a permeation reduction factor (PRF) up to 10⁵ at 650°C. These results have been confirmed also in the case of Deuterium permeation, both under 1.8 MeV electron irradiation and for samples that were previously irradiated with ions. In addition, to evaluate the chemical compatibility of the films with the selected breeding materials, samples have been exposed to corrosion tests (both Pb-16Li and Lithium ceramic pebbles) up to 10000 hours. No corrosive attacks on the steel substrate were detected. Finally, Atomic Layer Deposition technique has been studied and recently employed as a
complementary deposition technique to the PLD. The deposition process is still at its early stages of development, but preliminary results show that the coatings thus produced are dense, compact and defect-free. A deeper characterization of these coatings will follow. To conclude, in a DEMO-oriented perspective, oxide coatings present interesting properties as multifunctional protective barriers, proving to be one of the few possible solutions for the material-related issues of all the breeding blanket concepts currently considered.

**Experimental and Computational Study of Lattice Anharmonicity Effects in Oxide Nuclear Fuels** Zilong Hua¹, Amey Khanolkar¹, Marat Khafigov², Yuzhou Wang³, Chris Marianetti³, Lyuwen Fu¹ and David Hurley⁴; ¹Idaho National Laboratory, United States; ²The Ohio State University, United States; ³Columbia University, United States

Thermal transport in nuclear fuels under irradiation is directly linked to reactor efficiency and safety. An insight into the fundamental thermal transport properties of 5f-electron materials under extreme irradiation environments is central to the development of advanced nuclear fuels. Investigating the effects of lattice anharmonicity can provide a deeper understanding of the thermal properties such as thermal conductivity, heat capacity and thermal expansion, and be used to accurately model thermal transport. Here, we present the latest study on lattice anharmonicity effects in advanced oxide fuels. Time-domain Brillouin Scattering (TDBS) has been used to generate and detect lattice vibrations associated with the propagation of quasi-longitudinal and quasi-shear elastic phonon modes along the (311), (111), and (100) directions in single crystal thorium oxide (ThO₂). Measurements of the temperature-dependent change in phonon velocities have been performed at various temperatures ranging from 77 up to 350 K to experimentally obtain the Gruneisen parameter. The value is then compared with those obtained from first-principles computation using density functional theory (DFT), and more related simulation and experimental work (i.e., Boltzmann Transport Equation (BTE) modeling, inelastic neutron and x-ray scattering measurements, and the characterization of thermal conductivity, heat capacity, and thermal expansion) are underway. This study is supported by Thermal Energy Transport under Irradiation (TETI), a recently awarded Energy Frontier Research Center. The mission of the center is to provide foundational work to understand the role of 5f electrons on phonon and electron structure of related materials and how irradiation defects influence electron and phonon transport and corresponding thermal conduction.

**Combined Molecular Dynamics and Sol-Gel Synthesis to Investigate the Properties of the Pellet-Clad Bonding Layer** Dillon Frost¹,², Jessica Carolan-Veliscek², Conor O. Galvin¹, Edward Obbard¹, Michael W. Cooper³ and Patrick A. Burr¹; ¹UNSW, Australia; ²Australian Nuclear Science and Technology Organisation, Australia; ³Los Alamos National Laboratory, United States

The typical burnup of currently operating nuclear reactors is around 47 GWd/MTU, which coincides with the onset of permanent bonding between UO₂ fuels and zirconium alloy claddings in water cooled reactors. The bonding between pellet and cladding occurs as a result of the oxidation of Zr-alloy cladding and subsequent bonding with the UO₂ forming a solid solution of (U,Zr)O₂. The impact of this pellet-clad bonded layer increases with increasing burnup. In order to extract more energy from nuclear fuels and increase time between refuelling, operators are increasing burnups beyond 50 GWd/MTU. This research looks at the impact of urania-zirconia mixed oxides [(UₓZr₁₋ₓ)O₂] on nuclear fuels at high burnups.

The following thermophysical properties of (UₓZr₁₋ₓ)O₂ were investigated as a function of composition and temperature: lattice parameter, thermal expansion, heat capacity and thermal conductivity. A combination of molecular dynamics and experimental methods were used to provide a means of prediction and validation. Mixtures of (UₓZr₁₋ₓ)O₂, where x = 0.25, 0.50, 0.75 and 0.9, were produced using sol-gel synthesis to enhance the mixing of cations and achieve a homogeneous solid solution. The results indicate that by increasing the concentration of Zr in (UZr)O₂ mixtures the thermal conductivity is degraded slightly at room temperature, becoming negligible at temperatures at and above reactor operating temperatures. However, the formation of t-ZrO₂ on the inner surface of the cladding at moderate burnups (20 – 30 GWd/t) is a barrier to thermal transfer being that the thermal conductivity of t-ZrO₂ is 50% lower than that of UO₂. Additionally, the lower temperature access to superionic transitions due to oxygen disorder could provide some benefit under accident conditions due to the significant increase in heat capacity around 1500-2000 K. This research shows that the impact of (U, Zr)O₂ at high burnups is positive in that it does not affect the thermal conductivity of UO₂ significantly and, due to the permanent bonding of clad and fuel, could enhance thermal throughput given the thermal conductivity of the bonded layer is an order of magnitude
