Active Site Modulation in Aurivillius Oxides for Efficient Solar to Fuel Production Amr Sabbah[1], Nguyen Quoc Thang[2], Kuei-Hsien Chen[2] and Li-Chyong Chen[1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

The photoreduction of CO_2 into chemical fuels is a promising solution for addressing greenhouse gas emissions and energy shortages. The primary aim of photocatalysis research is to develop efficient and selective photocatalysts. Achieving better catalytic efficiency and controlled selective production can be facilitated by a deeper understanding of chemical pathways, reaction mechanisms, and active site nature. Metal oxide-based catalysts are particularly promising due to their valuable insights into reaction mechanisms and catalytic improvements. This presentation focuses on the modulation of active sites within metal oxides, especially n-type Aurivillius oxides, to enhance CO_2 reduction. By systematically manipulating oxygen vacancies and dopants, we tailor the catalytic properties of metal oxides to improve performance in CO_2 reduction. Our integrated approach employs in-situ DRIFTS and in-situ XAS supported by theoretical calculations to uncover reaction intermediates, and the role of specific sites in CO_2 reduction and H_2O oxidation. This work elucidates the fundamental aspects of photocatalytic CO_2 reduction, paving the way for the development of efficient metal oxide photocatalysts for sustainable energy production.

Structural, Optical and Chemical Surface Properties of Copper Oxide Thin Films Eleicer Ching-Prado[1], George Pitti[1], Amanda Watson[1], Elida I. de Obaldia[1], Carlos Samudio[2] and Joao Krause[3]; [1]Universidad Tecnológica de Panamá, Panama; [2]ICE-UPF, Brazil; [3]DCET-URI, Brazil

Thin films of copper oxide were prepared on glass substrates at 200 and 300°C calcination temperatures, respectively. For this, copper acetate monohydrate was used as a precursor and glucose monohydrate as a reducing agent. The deposition technique was spin-coating, and the samples were structural, chemical, and optically characterized. Thus, X-ray Diffraction (XRD) measurements indicate the formation of CuO, while X-ray Emitted Photoelectron Spectroscopy (XPS) shows that the CuO phase is on the surface of the material, and the bulk is composed of Cu_2O for the sample annealed at 300°C. While the sample annealed at 200°C, the bulk shows the formation of Cu_2O structure coexisting with CuO phase. Furthermore, transmittance (T) spectra in the UV-visible region, from 190 to 1100 nm, were collected and fitted using the classical Lorentz scattering model of the complex dielectric function to obtain additional optical properties, such as the refraction index, and the extinction coefficient. In addition, first-principles calculations were performed using the Electronic Density Functional Theory (DFT) of Cu_2O and CuO systems to obtain the electronic band structure, density of state, and optical properties. These theoretical results were compared with those obtained experimentally and are discussed.

EN01.11.27

Z-Scheme g-C_3N_4/TiO_2/CdS Heterostructures for Photocatalytic Hydrogen Production Ihsan Emre Yigiter[1], Cagla Unal[1] and Fatih Piskin[1,2]; [1]Mugla Sitki Kocman University, Turkey; [2]HyEn Materials Technologies Research Development and Consultancy Inc., Turkey

Carbon nitrides can exist in several allotropes that have been identified with various properties. Among them, graphite-like carbon nitride (g-C_3N_4), a metal-free semiconductor, has attracted immense attention due to its potential applications in solar energy conversion/storage, photocatalyst, electrocatalyst, and sensing. g-C_3N_4 is a promising semiconductor that may exhibit superior photocatalytic performance since it has an appropriate band gap energy (2.7 eV). In this context, its use as a photocatalyst in water splitting to produce hydrogen comes to the forefront. However, the photocatalytic performance of bulk g-C_3N_4 is limited by the rapid recombination of electron-hole pairs and low effective surface area. To overcome these limitations, numerous researchers have addressed investigating more active sites of g-C_3N_4 by exfoliating the bulk material into 2D g-C_3N_4 nanosheets with single-layer or few-layer structures. This approach may reduce the migration distance for charge carriers, leading to enhanced transport of charge carriers from the internal layers to the surface layers. Nevertheless, 2D g-C_3N_4 nanosheets suffer from low efficiency, photo corrosion, and slow charge carrier kinetics in water splitting. To tackle these challenges, various strategies can be employed such as metal deposition, non-metal doping, and direct-Z Scheme heterojunction. Among them, the direct-Z Scheme heterojunction approach may be an effective way in supporting the separation of photogenerated carriers and reducing the recombination rate.

In the current work, we investigated the synthesis, characterization, and photocatalytic hydrogen production capacities of a ternary direct-Z Scheme heterostructure, which is composed of 2D g-C_3N_4 nanosheets, TiO_2 and CdS. We performed a sequential synthesis in which TiO_2 and CdS were co-deposited onto 2D g-C_3N_4 nanosheets successfully synthesized by polycondensation of urea at 550 °C for 2 hours. The crystal structure of g-C_3N_4/TiO_2/CdS synthesized was identified by the Rietveld refinement of the XRD patterns collected. BET analyses were performed to measure the surface area of the heterostructures, and UV-VIS analyses were performed to calculate their band gaps. Photocatalytic hydrogen production tests were carried out in a quartz top-irradiation reactor under UV and visible light for 1 hour. 100 mg of as-synthesized heterostructure was added into a 100 mL aqueous solution of 0.5 M Na_2S/Na_2SO_3 without using any noble metal. Photocatalytic water splitting results depicted that the hydrogen production capacity of the ternary heterostructure exceeds 500 μmol/g under UV light in an hour.

Development of g-C_3N_4/α-Fe_2O_3/α-MnO_2 Ternary Heterostructure for Hydrogen Production by Photocatalytic Water Splitting

Mehmet Poyraz[1] and Fatih Piskin[1,2]; [1]Mugla Sitki Kocman University, Turkey; [2]HyEn Materials Technologies Research Development and Consultancy Inc., Turkey

Graphitic carbon nitride (g-C_3N_4), a metal-free semiconductor, has attracted immense attention due to its relatively narrow band gap (~2.7 eV) that is suitable for photocatalytic activity under visible light. g-C_3N_4 with its appropriate band gap has the potential to exhibit superior photocatalytic performance under visible light for hydrogen production via water splitting. However, its photocatalytic activity is restricted by the rapid recombination of electron-hole pairs and its limited effective surface area. To overcome these limitations, the efforts concentrate on investigating more active sites of g-C_3N_4 by exfoliating the bulk material into 2D g-C_3N_4 nanosheets having single- or few-layer. This approach may reduce the migration distance for charge carriers, leading to enhanced transport of charge carriers from the internal layers to the surface layers. However, g-C_3N_4 nanosheets may still suffer from low efficiency, photo corrosion, and slow charge carrier kinetics in water splitting. To tackle these challenges, various strategies can be employed such as doping, surface decoration, and formation of heterojunctions (Type-I, Type-II, Type-III, or Z-scheme). Among them, the Z-Scheme heterojunction approach might be an effective way to promote the separation of photogenerated carriers and reduce the recombination rate.

In the current work, dual Z-Scheme heterojunctions composed of g-C_3N_4, α-Fe_2O_3, and α-MnO_2 were systematically investigated to reveal their photocatalytic activity for hydrogen production. We performed a sequential synthesis in which α-Fe_2O_3 and α-MnO_2 were co-deposited onto g-C_3N_4 nanosheets. Structural, chemical, optical, and morphological investigations were carried out to identify the ternary catalyst system. Following the material characterizations, 100 mg of as synthesized heterostructure was added into a 100 mL aqueous solution of 0.5 M Na_2S/Na_2SO_3 without the use of any noble metal. Photocatalytic water splitting tests were performed under UV (250-385 nm) and visible lights (385-740 nm) created by Asahi Spectra MAX-350 300W Xenon light source equipped with a mirror system to isolate the desired range of wavelengths. The products of water splitting reaction were monitored by an online gas analyzer (Hiden Analytical QGA) connected to the reactor outlet. Photocatalytic water splitting results depicted that the hydrogen production of the ternary heterostructure exceeds 570 μmol/g under UV light in an hour.

Acknowledgments: The authors gratefully acknowledge the financial support of this research from Izmir Natural Gas Distribution Inc. and the Republic of Turkiye Energy Market Regulatory Authority.

Electrostatic Dust Removal Using Transparent Conductive Nano-Textured Surfaces for Efficient Light Harvesting

Fabian J. Dickhardt, Sreedath Panat and Kripa K. Varanasi; Massachusetts Institute of Technology, United States

Dust accumulation is a major operational challenge faced in light harvesting, such as the photovoltaics industry. Removing dust using water-based cleaning is expensive and unsustainable. Dust repulsion via charge induction is one of the most promising ways to clean solar panels and recover power output without consuming a single drop of water. However, it is still challenging to remove particles smaller than 10μm, which comprise a significant fraction of dust, because the Van der Waals force of adhesion dominates electrostatic force of repulsion. Here we propose nano-textured, transparent, electrically conductive glass surfaces to significantly enhance electrostatic dust removal for particles smaller than 10μm. We performed AFM pull-off force experiments and demonstrate that nano-textured surfaces reduce the force of adhesion and that the reduced adhesion results in significantly better electrostatic dust removal compared to plain or micro-textured surfaces. We fabricate transparent, electrically conductive, nano-textured glass that can be retrofit on light harvesting devices using copper nano-mask based scalable nano-fabrication technique and show that we can recover 90% of lost power output for particles smaller than 10μm.

EN01.11.30

Light-Harvesting Semiconductor Metasurfaces for the Enhancement of Photocatalytic Activity

Anton Kyrylenko[1,2], Yamuna Paudel[1,2] and Matthew Y. Sfeir[1,2]; [1]CUNY Advanced Science Research Center, United States; [2]CUNY Graduate Center, United States

Utilization of the enormous and constant amount of available solar energy as a clean alternative to fossil fuels is a task of utmost importance. However, a fundamental challenge in the field of heterogeneous photocatalysis is the design and optimization of visible and NIR absorbing semiconductors to maximize the light harvesting efficiency. We posit that a key limitation at longer optical wavelengths results from a mismatch of the characteristic length scales for charge transport, as determined by the depletion width, and absorption. To address this issue, we present a general framework for tailoring light absorption in nanopatterned arrays of conventional semiconductors. This approach maximizes the generation of carriers in the depletion region and overcomes limitations imposed by relatively poor material quality and weak absorption by nanoscale materials in the visible and NIR spectral region. Key to our design is the optimization of magnetic dipolar Mie resonances with near-unity absorption that preferentially generate charge carriers near the liquid-solid interface, enabling short transport distances and high conversion efficiencies. We demonstrate this approach using moderately doped (~ 10^{18} cm^{-3}) Gallium Arsenide (GaAs) thin films that are patterned to create plasmonic/dielectric hybrid metasurface of 2-D periodically surfaces of nanostructured resonators. These nanostructures are resonant scatterers that enhance absorption to near unity through a broad, geometrically determined Mie resonance that exploits the interference of the 1st (magnetic dipole (MD) and 2nd electric dipole (ED) resonance modes as well as confines the electromagnetic field within the nanostructures. This allows for a simultaneous suppression of almost all reflectance and transmittance and enhancement of the electron-hole generation rate near the liquid-solid interface of each nanostructure. We will discuss the modeling and simulation of the metasurface, the fabrication process for nanostructures of ~200 nm height, and the analysis of the resonant mode on the incident photo-to-current efficiency in a photoelectrochemical cell. Our optical measurements on the GaAs metasurface showed a strong absorption resonance near ~ 700 nm, which is inferred through the optical reflectivity being below 10 %. The incident photon-to-current conversion is 22x higher in fabricated GaAs metasurfaces for resonant excitation as compared to flat film of GaAs, which is strong evidence that these metasurfaces exhibit a strong electric field enhancement profile and maximize the charge carrier generation near the solid-liquid interface. Furthermore, we extend this approach to thin films of amorphous silicon (a-Si) to produce metasurfaces with strong absorption resonance at ~600 nm. These structures facilitate the carrier generation on non-epitaxial heterostructures and the use of high-sensitivity ultrafast spectroscopy methods. Transient optical measurements are used to understand the effect of the Mie resonance on charge carrier generation and collection.

EN01.11.31

Phase Stabilization of the Metastable Piezoelectric Phase of Barium Nickelate for Oxygen Evolution

Ian C. Graham and Lauren M. Garten; Georgia Institute of Technology, United States

Oxygen evolution reaction (OER) is the rate limiting step limiting the efficient production of fuel from water.[1,2] The potential generated in a piezoelectric material under stress has long been proposed as a route to increase OER catalytic activity, potentially decreasing the required overpotential. A lack of suitable materials has slowed progress in piezocatalysis due to surface instability. Barium nickelate ($BaNiO_3$) is an ideal piezocatalytic candidate because it has been shown to have an order of magnitude higher OER activity than the current benchmark rare earth catalyst iridium oxide (IrO_2).[1] However, the ground state $P6_3/mmc$ phase of $BaNiO_3$ is centrosymmetric which cannot be piezoelectric, but the piezoelectric $P6_3mc$ phase of $BaNiO_3$ is predicted to be close in energy to the ground state and thus likely accessible.[3]

In this work, we describe the stabilization of the metastable piezoelectric $P6_3mc$ phase of $BaNiO_3$. Barium nickelate powders were synthesized via an adapted sol-gel solution processing method described by Lee et al.[1] The sol-gel solution pH and calcination temperature were varied to reduce secondary phase formation. A calcination atmosphere of flowing ultra-high purity oxygen was used to control the final oxidation state of the product. The addition of barium carbonate ($BaCO_3$) during the calcination process was found to influence the phase formation pathway leading to the $P6_3mc$ phase of $BaNiO_3$. In-situ x-ray diffraction (XRD) and x-ray photoelectron spectroscopy (XPS) were used to elucidate the differences in the phase formation pathways of the $P6_3/mmc$ and the $P6_3mc$ phases. Both in-situ XRD and XPS suggest that the addition of $BaCO_3$ preferentially forms the $BaNi_{0.83}O_{2.5}$ $R32$ phase which is more structurally equivalent to the $P6_3mc$ phase of $BaNiO_3$. XPS and energy-dispersive x-ray spectroscopy (EDS) were used to determine the final oxidation states after calcination. XRD, Rietveld refinements, Raman spectroscopy, and transition electron microscopy (TEM) were used to verify the phase of the resulting powders after calcination. These results provide insights into new pathways for the stabilization of metastable materials via targeting polymorphs that are structurally similar to the desired metastable phase. Furthermore, these results allow for the future development of piezoelectric catalysts for OER, potentially enabling the production of fuel from water.

Mn2V2O7 Nanocrystals—Investigation of Photocatalytic Efficiency Icamira C. Nogueira[1], Nulliany Cristina S. da Silva[1], Sérgio Manuel A. Portilho[1] and Edson R. Leite[2]; [1]Universidade Federal do Amazonas, Brazil; [2]Universidade Federal de São Carlos, Brazil

Purifying wastewater to eliminate harmful organic molecules has been a major focus of both industrial and academic research. Many solutions have been suggested, and one promising approach is to use catalyst materials to break down organic pollutants while they are still in water. This method is cost-effective, environmentally friendly, and efficient at removing contaminants from wastewater. Among catalysts, photocatalysts are particularly interesting because external radiation, such as sunlight, can help the organic compounds degradation.
To assess the photocatalytic potential of β-phase manganese pyrovanadate ($Mn_2V_2O_7$), we successfully synthesized $Mn_2V_2O_7$ particles using urea as the precipitating agent in a homogeneous solution. We obtained single-phase β-$Mn_2V_2O_7$ crystals after heat treatment at 410 °C. A phase transition to α-$Mn_2V_2O_7$ was observed at 560°C. Morphological analysis revealed that the β-$Mn_2V_2O_7$ particles have a plate shape formed by smaller crystallites, suggesting a growth mechanism known as "oriented attachment." The band gap energy of β-$Mn_2V_2O_7$ measured by UV-vis spectroscopy was 4.1 eV. We evaluated the photocatalytic efficiency by studying the degradation of Rhodamine B and Methylene Blue dyes in an aqueous solution under UV radiation. The β-$Mn_2V_2O_7$ crystals showed low photocatalytic activity, with no degradation observed for the Rhodamine B dye and a 47% degradation of the Methylene Blue dye. The energy used (UV) for activation in the photocatalytic process is close to the band gap energy of the semiconductor, which may make it challenging to generate the electron/hole pair. Additionally, the low photocatalytic efficiency may be due to recombination of the electron/hole pair in the semiconductor/solution interface, preventing the formation of oxidative radicals responsible for photodegradation.

EN01.11.33

Thickness Dependence of the Physical Properties of Mn and Cu Co-Doped $BiFeO_3$ Hector S. Miranda, Elida I. de Obaldia and Eleicer Ching-Prado; Universidad Tecnológica de Panamá, Panama

Thin films of $BiFeO_3$ (BFO) co-doped with manganese (Mn) and copper (Cu) were deposited on FTO/glass substrates using the spin-coating technique. The stoichiometry used was $BiFe_{0.94}Mn_{0.04}Cu_{0.02}O_3$, ensuring an appropriate proportion of elements to study the effects of co-doping on the physicochemical properties of the films. The films were fabricated with different thicknesses, varying the number of layers from 1, 3, 5, 10, and 15. Additionally, a pure BFO sample with 15 layers was fabricated to quantify the effects of co-doping on the material. X-ray diffraction (XRD) analyses revealed that co-doping and increased thickness significantly improved crystallinity, showing a transition from a mixed R3c-P1 structure in the thinner films to a predominantly R3c structure in the thicker ones. Scanning Electron Microscopy (SEM) images showed an increase in grain size and better adhesion with an increased number of layers, suggesting improved nucleation and growth of the grains. Raman spectra indicated a reduction in structural defects and the appearance of a Jahn-Teller band in the co-doped samples, suggesting additional distortions in the FeO_6 structure due to co-doping. XPS analyses confirmed stable oxidation states for Bi, Fe, Mn, and Cu in the co-doped films, with a significant reduction in oxygen defects. Hysteresis (P-E) measurements showed an improvement in remnant polarization (Pr), reaching 1.1208 μC/cm^2 for BFMCO$_{15}$ films compared to 0.0215 μC/cm^2 in for BFO$_{15}$, and an increase in coercive field (Ec) from 75.73 kV/cm in BFO$_{15}$ to 508.32 kV/cm in BFMCO$_{15}$, indicating better alignment of ferroelectric domains and greater structural stability. Regarding optical properties, the co-doped films showed slightly lower transmittance in the visible range, attributed to increased light absorption due to the introduction of dopants. The band gap energy decreased with the increase in the number of layers and co-doping, from 2.34 eV in BFO$_{15}$ to 2.32 eV in BFMCO$_{15}$, suggesting greater interaction between the dopants and the BFO matrix. Additionally, the absorption coefficient and refractive index varied significantly in the range of 200 to 800 nm. The results demonstrate that both Mn and Cu co-doping, as well as thickness control, are effective strategies for improving the properties of BFO films for various technological applications.

EN01.11.34

First-Principles Phase Diagram and Electronic Structure Properties of Potassium-Based Copper Poly-Chalcogenide Alloys for Photoelectrodes

Arini Kar, Balasubramaniam Kavaipatti and Dayadeep S. Monder; Indian Institute of Technology Bombay, India

A recent high-throughput study of copper-based semiconductors has identified potassium-based copper chalcogenides as optimal light absorbers in PV/PEC devices. In this work, we investigate the applicability of materials in the homologous series $KCu_3Se_{2(1-x)}S_{2x}$ ($0 \leq x \leq 1$) as proton reduction photocathodes. We first calculate the temperature-composition phase diagram of $KCu_3Se_{2(1-x)}S_{2x}$ through solid solution models and Monte Carlo simulations based on cluster expansion. Our calculations predict that the alloy forms a solid solution in the monoclinic structure over the entire composition range although ordered ground states at x = 0.125 and 0.5 are present at low temperatures. On the bases of the stable structure of the alloys, we calculate the electronic structure properties via DFT. Unlike the bandgap bowing typical of highly mismatched alloys, predicted by band-anticrossing (BAC) model the electronic band gap of potassium-based copper poly-chalcogenide alloys obey the simple rule of mixtures. The optical absorption coefficient, mobility, and band alignment of the alloy with water redox potentials suggest its effectiveness as a photocathode.

EN01.11.35

Designing High-Efficiency Photocatalysts—Insights from a Photo-Assisted Kelvin Probe Force Microscopy Study

Ming-Chung Wu, Ting-Han Lin, Jia-Mao Chang, Yin-Hsuan Chang and Ying-Han Liao; Chang Gung University, Taiwan

Introducing dopants and constructing heterostructures are viable strategies for separating electron-hole pairs by creating energy barriers, such as the Schottky barrier or built-in potential, at the interfaces between two photocatalysts. In the case of a heterostructure photocatalyst, the surface potential difference between the parent material and the co-catalyst plays a decisive role in determining the photocatalyst's photoreduction or photooxidation abilities. Consequently, understanding and manipulating this surface potential difference is instrumental in designing the nanostructure of photocatalysts.

Kelvin Probe Force Microscopy (KPFM) is a direct and straightforward technique for measuring the surface potential of a material. By utilizing KPFM with various light sources ranging from UV to red light, the surface potential of materials can be characterized either under light illumination or in the absence of light. The surface potential, referred to as the contact potential difference (CPD) of a material, can be quantified using **Equation (1)**.

$CPD=(\Phi_{tip}-\Phi_{sample})/e$ **Equation (1)**

$\Delta CPD=CPD_{\text{under light illumination}}-CPD_{\text{under dark condition}}$ **Equation (2)**

Here, Indicates the material’s potential difference under light illumination and dark conditions. Therefore, can be obtained from the **Equation 2**. The increased for a material after light illumination indicates a high electron density present at the material's surface. The is closely linked to the light response and electron generation in the material. Therefore, a larger indicates a higher activity of photocatalysts because it leads to the excitation of more charges.
Observing the surface potential evolution of different materials allows for a rational prediction of how to pattern a material that can achieve the highest photocatalytic activity. This technique provides a promising path for designing novel materials. In this work, I will detail our research group's strategic approach to enhancing photocatalytic activities for different applications: (1) photoreduction, (2) photocatalytic hydrogen production, (3) plastic photoreforming, and (4) CO_2 reduction. Our findings offer a deeper understanding of carrier transport routes in heterostructures and provide valuable insights for designing future photocatalytic materials.

EN01.11.36

Size-Controlled and Localised Nanoparticles on Photoactive Covalent Organic Frameworks for Artificial Photosynthesis

Kathryn McCarthy, Roberto Gonzalez Gomez and Pau Farras; University of Galway, Ireland

Concerning levels of CO_2 in the atmosphere have urged researchers to develop technologies that can not only reduce its atmospheric concentration, but also use CO_2 as a feedstock for producing carbon-based fuels and value-added chemicals. Solar irradiation, a renewable and abundant source of energy, can be used to drive these chemical transformations in a process known as artificial photosynthesis[1]. Recently, porous materials, such as covalent organic frameworks (COFs), have been explored as photo-responsive supports for catalysts due to their remarkable physical and chemical stability, structural diversity and large surface areas[2]. Furthermore, through careful selection of building blocks, a wider photo-absorption window can be targeted, while also tuning the bandgap to extend the lifetime of electron-hole pair separation, thus establishing a thermodynamically favourable process[3].

The incorporation of metal catalysts, such as metal nanoparticles (MNPs), into these types of organic, photo-active supports creates a hybrid material which can facilitate redox reactions via an electron “donor-acceptor” type mechanism, i.e., electrons excited within the framework can be accepted by the MNP and subsequently used to carry out CO_2 reduction[3]. Furthermore the use of another MNP co-catalyst allows for effective separation of charges within the framework, retaining the photogenerated holes and facilitating the oxidation of a sacrificial agent, such as water in this case[4]. MNPs are widely used for catalysis due to their high surface energy and quantum size effects; in particular, gold nanoparticles (Au NPs) are highly selective towards CO_2 reduction to CO[5]. However, their aggregation can result in gradual loss of catalytic activity, therefore uniformly immobilising them on light-harvesting, porous supports is effective in extending their photocatalytic performance[6]. In addition, RuO_2 nanoparticles, which are widely used in oxidation reactions, possess excellent affinity toward O_2 gas with a favourable O_2 binding energy, low overpotential, and high OER activity[7].

In this work, a photo-absorbing porphyrin-perylene COF has been decorated with Au NP and RuO_2 NPs, thus creating a novel, robust material for the purpose of artificial photosynthesis. The COF was functionalised with thiol groups to assist in localisation and stabilisation of the Au NPs, resulting in the formation of well-distributed and locally separated NPs anchored into the COF network. The size of the Au NPs has been modulated by adjusting the concentration of gold salt precursor vs. the number of thiol ligands. Previously synthesised RuO_2 nanoparticles were incorporated into the COF unoccupied pores to produce the final MNP-COF hybrid material. NPs size effect and metal loading concentration have been evaluated to enhance the material performance. Results of their photocatalytic efficiency for the simultaneous photocatalytic CO_2 reduction and water oxidation under visible light irradiation will be presented.

Finding new solar absorbers for photovoltaic (PV) or photoelectrochemical cells (PEC) is a cumbersome process involving complex synthesis and characterization. Materials are often selected serendipitously or by structural analogies (e.g., CIGS and CZTS). In this talk, we will present how high-throughput computational screening can be used to select materials of interest with adequate band gap, transport but also most importantly low bulk carrier recombination. By including defects within the high-throughput process, we have been capable to focus our search on materials with few defect recombination centers. Our screening on tens of thousands of materials identified a few new candidates including a new ternary phosphide $BaCd_2P_2$ (BCP) which was experimentally synthesized and characterized.[1] Very long carrier lifetime for an unoptimized material were measure up to 30 ns. Importantly, BCP is stable in air and water. Next to BCP, we will show that ternary Zintl phosphide of formula AM_2P_2 offer an attractive chemical space for new materials including candidates for tandem and PEC applications. Finally, we will highlight the challenges and opportunities in bringing theoretical screening to work hand-in-hand with experiments in a team-based approach.

Band Gap Narrowing by Tailored Lone-Pair Orbital Interactions in Bi^{3+} Materials Kanta Ogawa[1] and Aron Walsh[2]; [1]Tokyo Institute of Technology, Japan; [2]Imperial College London, United Kingdom

Post-transition metal cations such as Sn, Sb, Pb, and Bi are important components for solar-to-energy conversion systems including photovoltaics and photocatalysis.[1] Their unique structural and electronic features are derived from the lone pair (ns^2np^0) configuration. Often, the stereochemical activity of the lone pair results in a distorted local atomic environment of these cations in crystals.

Our question is “what happens if the cationic lone pair is confined to an un-distorted site in a crystal”. Based on the underlying orbital interactions, we predict that such a confined lone pair significantly narrows the band gap and enhances visible light absorption. Validation is performed for Bi^{3+} using a cation substitution approach. To realize a high-symmetry Bi^{3+} site, we focus on isovalent substitutions with Y^{3+} because of its similar ionic radius and absence of a lone pair. Through the survey of the coordination environments, Bi_2YO_4X with un-distorted Y^{3+} is singled out as a candidate for Bi substitution.

DFT calculation supported that introducing Bi^{3+} to the Y^{3+} in Bi_2YO_4X results in a redshift in the band gap. The key component is the anti-bonding Bi 6s – O 2p combination and Bi 6p. The Bi 6s and – O 2p interactions create filled bonding and antibonding combination, the latter contributing to the upper valence band. When Bi is at an asymmetric environment, the anti-bonding combination can interact with Bi 6p, accompanied by the stabilization of its energy. On the other hand, when Bi is on Y site, the anti-bonding combination is not stabilized by Bi 6p because of the non-net orbital interaction owing to the symmetry difference. This results in the negative shift of the upper valence band and the narrowed band gap. The band gap narrowing was also demonstrated experimentally through the Bi^{3+} doping to Y^{3+} by using solid-state reaction synthesis. The present lone pair engineering offers a strategy for controlling the optoelectronic structure of the post-transition metal compounds for the intended application beyond the limits of known materials.[2]

Orthorhombic Structures as High-Throughput Models for Inorganic Halide Perovskites Suxuen Yew, Ryan Morelock and Charles B. Musgrave; University of Colorado Boulder, United States

Inorganic halide Perovskite’s (HP) low-cost solution processing, defect tolerance, long carrier lifetimes, and band gap tunability via compositional engineering have propelled interest in their use as light absorbers in photovoltaic (PV) devices. The perovskite PV literature is primarily populated by lead (Pb) containing perovskites with compositions such as $CsPbI_3$ having taken the PV community by storm due to their exceptional PV performance. However, recently there has been a push towards discovering new HP compositions that may offer superior performance while moving away from the health and safety concerns commonly associated with Pb.

Engineering new HP compositions by substituting different elements for Cs on the A site, Pb on the B site, and up to 4 halides on the X site yields approximately 10^4 theoretical ternary (ABX3) compositions. Moreover, the HP materials space explodes to upwards of 10^8 possible compositions when considering double and alloyed perovskite compositions. These spaces are too large to characterize with experimental methods alone, motivating the use of density functional theory (DFT) and machine learning (ML) for materials screening.

The field has used different crystal structures, such as the primitive cubic structure and polymorphous networks (PN), to compute perovskite properties using DFT. The former is a 5-atom unit cell that is computationally inexpensive to calculate but often severely underestimates experimental band gaps; conversely PNs use large unit cells (160 atoms) that yield good band gap agreement with experiment but are computationally expensive to calculate. This makes neither model suitable for HT screening. Hence, we propose the orthorhombic perovskite structure as a surrogate model that strikes a balance between accuracy and cost. The surrogate model is a medium sized cell of 20 atoms that we initialized with stabilizing orthorhombic octahedral tilting, rescaled the lattice, and displaced the atomic sites to help maintain a realistic representation of the perovskite structure prior to DFT optimization. Our surrogate model provides a ~40x speed up in calculations compared to PNs, whilst being able to replicate PN band gaps with a MAD of only 0.09 eV. The orthorhombic surrogate model is useful for constructing large datasets of theoretical perovskite properties to enable HT perovskite materials screening and provide large sets of high quality DFT data for data mining and machine learning applications.

Phase Transitions and Overdamped Dynamics in Halide Perovskites Erik Fransson[1], Petter Rosander[1], Fredrik Eriksson[1], Terumasa Tadano[2] and Paul Erhart[1]; [1]Chalmers University of Technology, Sweden; [2]National Institute for Materials Science, Japan

Halide perovskites have emerged as one of the most interesting materials for photovoltaic and optoelectronic applications due to their favorable properties, often attributed to their dynamic softness. The soft nature of these materials arises mainly from a few specific phonon modes that drive the material to undergo several phase transitions. These soft modes are associated with strong anharmonicity, leading to overdamped phonons near the phase transitions.

Here, we present a study on phase transition and phonon dynamics in halide perovskites using molecular dynamics simulations (MD) with machine-learned potentials (MLP). The simulations capture the correct phase transition from the orthorhombic phase to the tetragonal phase and from the tetragonal to the cubic phase for the prototypical CsPbBr3 halide perovskite. These phase transitions are driven by the condensation of the in-phase and out-of-phase tilt modes of the PbX6 octahedra. The transition temperatures obtained are slightly underestimated compared to experimental studies but are in good qualitative agreement, indicating that the simulations capture the dynamics of these modes well.
The dynamics of these modes are studied with phonon mode projections, and we find that they have a strongly anharmonic and overdamped character. We demonstrate this behavior and show that the overdamped region extends almost 200 K above the cubic to tetragonal phase transition temperature. Lastly, we simulate the quasi-elastic neutron scattering (QENS) spectra and obtain excellent agreement with experimental results. We show that these overdamped modes give rise to large intensities at low frequencies (0-2 meV), explaining why the spectra of the perovskite phases differ in this frequency range compared to the non-perovskite phases.

Photo & Electro Catalysis for Sutainable Fuel Production Jingshan Luo; Nankai University, China

The massive combustion and utilization of fossil fuels has caused environmental pollution and global warming. In order to achieve the goal of carbon neutrality, we need to increase the development and utilization of clean and renewable energy. Using solar energy or renewable electricity to convert small molecules such as water and carbon dioxide into green fuels and chemicals through photo/electrocatalysis can replace fossil fuels and reduce carbon dioxide emissions. At the same time, solar energy and renewable electric energy can be stored to solve their intermittency and regional issues, which has important scientific research value and application prospects. In this talk, I will briefly introduce the background and significance of photo/electrocatalytic synthesis of fuels and chemicals, and report some research progress we have made in the past few years in water splitting and CO_2 reduction for sustainable fuel production.

10:45 AM EN01.13.02

Operando Ambient-Pressure X-Ray Photoelectron Spectroscopy of Adsorbate-Induced Band Bending and Photocatalytic Intermediates in CO_2 Reduction Reaction Chih-Yang Huang[1,2,3], Yi-Fan Huang[4], Po-Tuan Chen[5], Kuei-Hsien Chen[2] and Li-Chyong Chen[3,1,6]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan; [3]Center for Condensed Matter Sciences, Taiwan; [4]National Chin-Yi University of Technology, Taiwan; [5]National Taipei University of Technology, Taiwan; [6]Center of Atomic Initiative for New Materials, Taiwan

Photocatalytic CO_2 reduction reaction (PC-CO_2RR) has attracted significant attention in the renewable energy field due to the urgent need to address climate change. However, the current efficiency of PC-CO_2RR is limited by its low conversion rates. To overcome this bottleneck, it is crucial to gain a deeper understanding of the material variations and charge transfer processes that occur during the photocatalytic reaction. Ambient pressure X-ray photoelectron spectroscopy (APXPS) is a powerful surface-sensitive technique for measuring the electronic and chemical properties of catalysts and detecting adsorbents during chemical reaction. In this work, MoS_2 was selected as the model catalyst due to its simple surface and unified crystal orientation, which helps minimize complicating effects during the catalytic reaction. The APXPS results revealed that adsorbed H_2O molecules lead to downward band bending, facilitating the transfer of photo-generated electrons. Conversely, adsorbed CO_2 molecules caused dissipation of surface electrons, resulting in upward band bending. Density Functional Theory (DFT) calculations further corroborate these findings, indicating shifts in the band structure upon introducing CO_2 or H_2O into the model. Furthermore, the APXPS results also revealed that the sequence of introducing CO_2 and H_2O can alter the formation of bent $CO_2^{\delta-}$, which is regarded as the key intermediate in determining the conversion efficiency. Experimental results also showed that the production of CO was enhanced when pre-adsorption of H_2O was applied, proving that H2O can the promote PC-CO_2RR. These findings provide new insights into designing more efficient PC-CO_2RR systems.

$BaCd_2P_2$—A Defect Resistant "GaAs" Gideon Kassa[1], Zhenkun Yuan[1], Guillermo Esparza[2], Muhammad R. Hasan[3], Kirill Kovnir[3], David P. Fenning[2], Geoffroy Hautier[1] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]University of California, San Diego, United States; [3]Iowa State University of Science and Technology, United States

Zintl phosphide $BaCd_2P_2$ (BCP) has recently received attention as a promising solar cell absorber. In this work, we present a comparative study of the optical properties of BCP and GaAs, providing a theoretical explanation for the excellent photovoltaic performance of BCP. Despite having much lower purity, BCP exhibits similar photoluminescence (PL) response, open circuit voltage, and radiative emission efficiency as high-purity GaAs. Further, by combining PL with first-principles defect calculations using Density Functional Theory, we identified the impact of prominent point defects in the two materials. BCP contains a lower density of its dominant deep nonradiative recombination center, P_{Cd}, compared to GaAs, whose dominant trap is As_{Ga}. Moreover, both BCP and GaAs show PL emissions from radiative point defects. The radiative defect emission in BCP likely involves V_{Ba} and is less detrimental than the radiative defect in GaAs, which we identified as B_{As}. Further, we characterize the mechanisms behind the optical transitions in the PL of BCP and GaAs; this revealed that V_{Ba} is likely part of a donor-acceptor pair. Our results suggest a high degree of impurity and defect tolerance in BCP compared to GaAs, making it an easily synthesizable, efficient solar absorber.

11:15 AM EN01.13.04

Mesoporous $CuFe_2O_4$ Photoanodes for Solar Water Splitting Oxidation—Impact of Surface Morphology on the Photoelectrochemical Properties Marcus Einert; Technische Universität Darmstadt, Germany

Metal oxide-based photoelectrodes for solar water splitting often utilize nanostructures to increase the solid-liquid interface area. This reduces charge transport distances and increases the photocurrent for materials with short minority charge carrier diffusion lengths. While nanostructuring is well established, the effect of surface order on the photocurrent and carrier recombination has not yet received much attention in the literature. To evaluate the impact of pore ordering on the photoelectrochemical properties, mesoporous $CuFe_2O_4$ (CFO) thin film photoanodes were prepared by dip-coating and soft-templating.
Here, the pore order and geometry can be controlled by addition of copolymer surfactants poly(ethylene oxide)-block-poly(propylene oxide)-block-poly(ethylene oxide) (Pluronic F-127), polyisobutylene-block-poly(ethyleneoxide) (PIB-PEO) and poly(ethylene-co-butylene)-block-poly(ethylene oxide) (Kraton liquidTM-PEO, KLE). The non-ordered CFO showed the highest photocurrent density of 0.2 mA/cm^2 at 1.3 V vs. RHE for sulfite oxidation, but the least photocurrent density for water oxidation. Conversely, the ordered CFO present the best photoelectrochemical water oxidation performance. These differences can be understood on the basis of the high surface area which promotes hole transfer to sulfite (a fast hole acceptor), but retards oxidation of water (a slow hole acceptor) due to electron-hole recombination at the defective surface. This interpretation is confirmed by intensity-modulated photocurrent (IMPS) and vibrating Kelvin probe surface photovoltage spectroscopy (VKP-SPS). The lowest surface recombination rate is observed for the ordered KLE-based mesoporous CFO, which retain spherical pore shapes at the surface resulting in fewer surface defects.
Overall, this work shows that the photoelectrochemical energy conversion efficiency of copper ferrite thin films is not just controlled by the surface area, but also by surface order. These findings will be of importance for the fabrication of improved metal oxide photoelectrodes and address the issue that nanostructuring of photoanodes with low minority charge carrier diffusion lengths are not generally beneficial for solar water oxidation. [1]

Emerging Oxide-Based Light Harvesters for Bias-Free Water and CO_2 Splitting Robert Hoye; University of Oxford, United Kingdom

Oxides have long been investigated for solar water splitting, but generally have wide bandgaps beyond the visible wavelength range. As such, there have been efforts to tune the species at the cation and anion sites to lower the bandgap. This presentation will explore two nontoxic bismuth-based compounds part of the wider oxide-based family: bismuth oxyiodide (BiOI) and bismuth vanadate ($BiVO_4$). Whilst $BiVO_4$ is a well-established visible light absorber for photoanodes, BiOI has only had a handful of investigations as photocathodes, partly because of its degradation when used in semiconductor-electrolyte junctions. In this work, we develop inorganic charge transport layers sandwiching the BiOI light absorber, and combine with conducting encapsulants to improve the stability of BiOI photocathodes from minutes to months. By working in tandem with $BiVO_4$ photoanodes, we achieve photoelectrochemical tandems capable of bias-free syngas (CO + H_2) and H_2/O_2 production, which we show to be stable for hundreds of hours. Furthermore, we demonstrate that fabricating large-area devices from a combination of pre-selected pixels leads to improved performance over the use of a single large-area pixel, and is a promising route to scaling up these photoelectrochemical tandems. This talk finishes with a discussion of the potential of materials from the wider family of perovskite-inspired materials as the light harvesters for solar water splitting.

Photoelectrocatalysis of $CaCd_2P_2$—A Case Study in Novel Ternary Zintl Phosphides for Solar Fuel Production Guillermo Esparza[1], Zhenkun Yuan[2], Muhammad R. Hasan[3], Gideon Kassa[2], Yagmur Coban[2], Andrew Pike[2], Jifeng Liu[2], Kirill Kovnir[3], Geoffroy Hautier[2] and David P. Fenning[1]; [1]University of California, San Diego, United States; [2]Dartmouth College, United States; [3]Iowa State University of Science and Technology, United States

No known solar fuel photo(electro)catalyst displays the intersection of high-performance, stability, strong absorption, and Earth abundance necessary for deployment at scale. These ongoing challenges present an urgent need for discovery of new material candidates. Ternary Zintl phosphides, with an AM_2P_2 composition, have recently been identified in computational discovery efforts for solar energy conversion applications.[1] Continued computational screening has identified many AM_2P_2 family members as having promising optoelectronic properties with stabilities suitable for synthesis and solar energy conversion. Here, we introduce the synthesis and photoelectrochemical characterization of the first material of photocatalytic interest originating from these efforts, $CaCd_2P_2$ (CCP). CCP exhibits intense optical absorption and a predicted direct bandgap of 1.62eV, corroborated by strong band-to-band photoluminescent emission at ~1.6eV. In water splitting measurements under simulated 1-sun illumination, as-synthesized CCP powder demonstrates photoelectrochemical activity for both hydrogen and oxygen evolution, as well as robust stability in alkaline conditions. Its photocatalytic potential, stability, and semiconducting properties will be discussed, as well as opportunities for further discovery and solar fuels development in this new Zintl phosphide family of materials.

Functional Coatings for III-V Semiconductor Photo(electro-)catalysts Haoqing Su, Devan Solanki and Shu Hu; Yale University, United States

Over the past decade, protective coatings have been essential for light-harvesting semiconductors. It provides multiple functionalities including anti-reflection, catalysis, and photo-corrosion protection. We report advances in coating discovery and interfacial tunability for photoelectrocatalysts and photocatalysts. First, we show that precise microstructural control, in the length scale across angstroms to micrometers, is vital for device performance.[1] The challenge remains for all practical semiconductor photoabsorbers of 0.7-2.3 eV bandgaps, that leaky TiO2 protective coating cannot achieve the theoretical efficiency limit for any III-V semiconductors, e.g., Gallium Phosphide. We will discuss the rationale of discovering manganese-alloyed titanium oxides and achieving a 1 V photovoltage and 100 hour stability from GaP/(Ti,Mn)Ox/iridium-cocatalyst photoelectrocatalysts [2] by tuning microstructures using thermal processing.[3] Another challenge is the lack of stable coatings for fuel-forming photocatalysts that drive reductive reactions: TiO2 is not stable under reductive potentials, because Ti^{4+} ions in the coating can be easily reduced to Ti^{3+} and dissolved under cathodic conditions. We further developed a novel gallium nitride (GaN_x) coating to stabilize and passivate III-V semiconductors using atomically abrupt interfaces. During photo-electrocatalytic H2 evolution, the GaNx/p-InP photocathode exhibits a photocurrent density of 34 mA/cm2 under 1 sun illumination, and stability of at least 150 hours in pH 0 acid. Beyond efficiency and stability, we can tune the effective band edge positions of semiconductor photocatalysts via unique electronic structures and charge density. [4] We discuss the principle of using microstructures, oxidation states, and point defects as tuning knobs.

2:30 PM EN01.14.04

Light-Harvesting Metal-Covalent Organic Frameworks—Atomic-Scale Characterisation for the Design of Photoactive Noble-Metal-Free Materials Roberto Gonzalez Gomez[1], Seán Hennessey[1], Aibhe Boran[1], Nicolás Arisnabarreta[2], Max García Melchor[3], Pau Farras[1] and Kathryn McCarthy[1]; [1]University of Galway, Ireland; [2]KU Leuven, Belgium; [3]Trinity College Dublin, The University of Dublin, Ireland

Renewable and sustainable energy sources are becoming essential in addressing the growing problem of global warming. In order to decrease the use of non-renewable energy sources, solar technologies to drive chemical reactions represent a significant milestone for the scientific community.[1] The development of new multifunctional materials that respond to the stimulus of visible light is an ever-growing area of materials chemistry. Recently, photoactive coordination complexes covalently anchored into materials have proven to be a good strategy to improve the molecules' photostability required to efficiently drive photochemical reactions.[2] Furthermore, researchers have incorporated Co, Ru and Re-based molecules into covalently linked interpenetrated networks, namely metal-covalent organic frameworks (MCOFs), showing excellent performance for both visible-light-driven hydrogen evolution and photoreduction of CO_2, highlighting the potential of these materials for photocatalysis.[3] Besides, due to their high molecular tunability, supramolecular functionality and excellent structural definition, MCOFs arise as promising materials for enhancing solar-driven reactions.[4]

Despite a few examples in the literature, the structure control and development of MCOFs are still in an early stage. Due to their complexity and presence of dynamic covalent bonds lead to the formation of nano- and submicron-sized crystals, which are often unsuitable for diffraction, making their atomic-scale characterisation a bottleneck for designing more efficient materials. Moreover, further research is required to explore the use of non-expensive, earth-abundant-based MCOFs.

In this work, a nanoscale characterization of a photoactive Ru-based MCOF designed to reduce CO_2 efficiently under visible light is presented. A combination of experimental and computational techniques will be shown to support without uncertainty the MCOF structure at a nanoscopic level.[5] The atomic mapping obtained from the Ru-based MOCF provided crucial insight for the design and development of a novel earth-abundant Fe-based MCOF analogue. Their characterisation and light-harvesting properties will be also presented.

10% Efficient Solar-to-Hydrogen Generation Via Organic Semiconductor with Ni-Heazlewoodite Electrocatalysts

Jaemin Park and Wooseok Yang; Sungkyunkwan University, Korea (the Republic of)

A 10% efficient and cost-effective solar-to-hydrogen conversion device was developed through the integration of low-cost Ni Heazlewoodite-based catalysts for the hydrogen evolution reaction (HER) and ternary bulk heterojunction organic semiconductor (OS)-based light absorbers. Se-incorporated Ni_3S_2 was synthesized by a one-step hydrothermal method, which demonstrated a low over potential and Tafel slope, indicative of its superior HER activity. The theoretical calculation results validate the enhanced HER performance of the Se-Ni_3S_2 catalyst in alkaline electrolytes. The ternary phase organic light absorber is designed to generate tailored photovoltage and maximized photocurrent, allowing a photocurrent density of 8.24 mA cm^{-2} under unbiased conditions. Low temperature photoluminescence spectroscopy results revealed that the enhanced photocurrent density originates from a reduction in both phonon- and vibration-induced inter- and intramolecular non-radiative decay.

EN01.15 .02

Enhancing Photocatalytic Performance of $KNbO_3$ Through Ba and Sc Co-Doping— A Comprehensive Experimental and Theoretical Investigation of Electronic and Optical Properties

Devender Takhar[1], Ram Krishna Ghosh[2] and Balaji Birajdar[1]; [1]Jawaharlal Nehru University, India; [2]Indraprastha Institute of Information Technology Delhi, India

Ferroelectric materials have recently emerged as prominent candidates in photocatalysis, offering significant advantages due to their superior electron-hole separation and catalytic efficiency. This enhancement is driven by their non-centrosymmetric structure and internal spontaneous polarization. [1,2] Photocatalysis, as an eco-friendly technology, addresses energy crises and environmental challenges by enabling the degradation of environmental pollutants and by facilitating the splitting of water (H_2O) into hydrogen (H_2) and (O_2) as well as carbon dioxide (CO_2) reduction through redox reactions. Among these processes, water splitting stands out for its potential to produce clean H_2, highlighting the transformative impact of advanced photocatalytic materials [3,4]. This study presents a combined experimental and computational investigation of potassium niobate ($KNbO_3$) doped 5% with barium (Ba) at the potassium (K) site and scandium (Sc) at the niobium (Nb) site (5KBSNO), aimed at tailoring its electronic and optical properties for enhanced photocatalytic performance. The XRD and Raman spectroscopy study revealed the orthorhombic structure of the perovskite samples. SEM and HRTEM studies were also performed to see the variation in grain size, morphology, and structural information. The elemental composition analysis was tested using EDS. UV-visible spectroscopy revealed that doping $KNbO_3$ with 5% Ba and Sc reduced the bandgap of 5KBSNO to 2.44 eV, compared to 3.21 eV for the undoped $KNbO_3$. This reduction was further corroborated by density functional theory (DFT) calculations using the generalized gradient approximation with Hubbard U correction (GGA+U). The photocatalytic performance of 5KBSNO was assessed through dye degradation and photoelectrochemical (PEC) water-splitting tests. The results indicated that the 5KBSNO sample achieved around 50% degradation of rhodamine B dye under light exposure, in contrast to 30% degradation observed for the undoped $KNbO_3$. Additionally, PEC measurements demonstrated increased photocurrent for 5KBSNO under visible light, relative to $KNbO_3$, for water splitting. These findings open an avenue to effectively tune the electronic and optical properties of $KNbO_3$ via Ba and Sc co-doping, making it a promising ferroelectric candidate for photocatalytic applications in environmental and energy-related fields.

Indoor Photovoltaic Energy Harvesting Based on Organic Materials Toward Future IoT Applications Sadok B. Dkhil; Dracula Technologies, France

The need of scalable fabrication of high-efficiency organic photovoltaic cells and modules has gradually emerged. In particular, indoor organic photovoltaics (IOPV) constitutes an attractive energy harvesting solution to power IoT devices, given its deployability, reliability, and power density. A substantial portion of the billions of new IoT devices that will be installed in the coming years are expected to be located inside buildings. Such devices like environmental sensors, can have several shapes and sizes, hence the need to develop custom-made conformable photovoltaic devices to facilitate their integration into the final product. In this context, inkjet printing has become a very attracted printing technology for large-scale printed flexible cells and modules with freedom of shapes and designs.

Herein we demonstrate the challenge to go from lab-scale to industrial scale to achieve highly efficient fully inkjet printed IOPV cells and module. To prove the great advantage of inkjet printing as a digital technology allowing freedom of forms and designs, particular OPV modules with different shapes are demonstrated and integrated into different IoT devices to operate autonomously without using batteries or connections to the grid to ensure sufficient flexibility in their placement.

EN01.15 .04

Microstructured-Black Photoanodes with Spatially Decoupled Light Absorption and Catalysis for Unassisted Solar Urea Oxidation Fei Xiang, Ning Li, Arturo Burguete-Lopez, Zhao He, Maxim Elizarov and Andrea Fratalocchi; King Abdullah University of Science and Technology, Saudi Arabia

Photoelectrochemical (PEC) urea oxidation reaction (UOR) is a promising alternative anode reaction to the conventional oxygen evolution reaction (OER), which takes more than 90% energy input in PEC water splitting with oxygen byproducts lacking commercial value, enabling simultaneous energy-saving solar hydrogen production and urea-rich wastewater treatment. Current state-of-the-art photoanodes for PEC-UOR focus on large-bandgap semiconductors, including TiO_2, Fe_2O_3, and $BiVO_4$, reporting a highest saturated current density of 5.4 mA cm^{-2}. Further research efforts are highly desirable to enhance the current density value to above 10 mA cm^{-2} for large-scale implementations of PEC-UOR. Recent research efforts start to explore Si and report a saturated current density of 39.5 mA cm^{-2} with the monofacial architecture on Si photoanodes. However, the stability limits to less than 1 hour due to the compromise between catalytic activity and stability on the co-catalyst thickness in the traditional monofacial architecture with light absorption and reactive interface on the same side. In this work, we present microstructured-black Si photoanodes with spatially decoupled light harvesting and catalytic reaction sides for PEC-UOR. By employing ultrathin nickel-iron (Ni-Fe) alloy nanofilm that self-reconfigures the Ni-Fe (oxy)hydroxides-alloy structure as an efficient co-catalyst layer, the engineered bifacial microstructured-black Si photoanode shows a low onset potential of 0.807 V vs. RHE, a high saturated current density of 40.7 mA cm^{-2}, and long-term stability over 20 hours with 82% initial current retention. These performances represent the lowest onset potential among the reported Si-based photoanodes and an enhancement of 33% in stability compared to the most stable competitor. Moreover, the photoanodes show 94 mV lower onset potential in PEC UOR than OER, reducing around 10.8% energy input in urea-assisted solar hydrogen production. We employ aberration-corrected scanning transmission electron microscopy (STEM) to visualize the atomic-level structural evolution of the Ni-Fe alloy nanofilm during the PEC-UOR process and apply high-resolution X-ray photoelectron spectroscopy (HR-XPS) to analyze the corresponding chemical species changes. The tandem device with three microstructured-black Si connected in series reports a current density above 10 mA cm^{-2} under unbiased status for stable running over 5 hours, validating the implementation of unassisted solar hydrogen production with urea-rich wastewater purification directly powered by sunlight. The engineered bifacial microstructured-black Si photoanodes with ultra-thin Ni-Fe alloy co-catalyst opens the pathway to the large-scale applications of simultaneous urea-rich wastewater treatment and solar fuels production beyond hydrogen, including CO_2-to-carbon fuels production and ammonia synthesis.

First Evidence of Aliovalent Fluorine Doping in Barium Stannate—Combined Experimental and Theoretical Analysis

Sushobhita Chawla[1], Arini Kar[1], Dayadeep S. Monder[1], Patrick M. Woodward[2] and Balasubramaniam Kavaipatti[1]; [1]Indian Institute of Technology Bombay, India; [2]The Ohio State University, United States

Fluorine-doped barium stannate nanoparticles ($BaSnO_3$:F) are synthesized using a previously established solution combustion method.[1] The incorporation of fluorine into the lattice depends on how the fluorine source is introduced during synthesis. A synthesis protocol is developed wherein the addition of the fluorine source to peroxo precipitates, followed by annealing in a reducing environment, yields not only phase-pure $BaSnO_3$ but also an optical response characteristic of Drude behavior in aliovalently doped $BaSnO_3$. X-ray photoelectron spectroscopy (XPS) and STEM-EDS confirm the presence of fluorine in both synthesized nanoparticles and pressed pellets. Analysis of fluorine binding energy and shifts in cation binding energy due to fluorine incorporation elucidates bonding and defects within the system, revealing that fluorine binds to metal cations in the bulk with no indications of interstitial or surface fluorine defects. Hall measurements on the pellets indicate n-type conductivity with mobility around $\sim 10^1$ cm^2 V^{-1} s^{-1}, albeit with significantly fewer carriers than anticipated from complete fluorine ionization. Fluorine substitution at oxygen sites may be counterbalanced by electron localization and, consequently, reduced Sn valence, while fluorine occupying oxygen vacancies complicates electron concentration dynamics. DFT calculations of fluorine-doped $BaSnO_3$, both with and without oxygen vacancies clarify the atomic orbital contributions to the electronic states in the conduction band, corroborating the XPS findings.

2D Zinc Sulfoselenides as Photocatalysts for Enhanced Hydrogen Peroxide Production with DFT Analysis

Akshay Tikoo[1], Shelaka Gupta[1] and Praveen Meduri[2]; [1]Indian Institute of Technology Hyderabad, India; [2]Advanced Energy Materials LLC, United States

Hydrogen peroxide (H_2O_2) is a crucial chemical in various industries due to its strong oxidizing capabilities, high energy density, and clean decomposition into oxygen and water[1]. However, the conventional anthraquinone process for producing H_2O_2 is energy-intensive and results in toxic by-products, spurring the search for more sustainable alternatives[2]. Among these, photocatalysis has gained attention as an eco-friendly method, leveraging sunlight and water to produce H_2O_2 without generating harmful by-products or requiring significant energy input[3]. Two-dimensional (2D) layered transition metal chalcogenide (TMC) photocatalysts are promising candidates for such applications due to their excellent light-harvesting abilities, large surface area, and favorable optoelectronic properties[4]. In particular, transition metal sulfoselenides (MS_xSe_{1-x}) are emerging as novel materials due to their tunable properties and low charge transfer resistance, making them highly efficient for photocatalytic processes[5]. In this study, we developed and tuned zinc sulfoselenides (ZnS_xSe_{1-x}) via a facile hydrothermal process, demonstrating superior H_2O_2 production compared to pure ZnS and ZnSe. Specifically, $ZnS_{0.5}Se_{0.5}$ achieved the highest H_2O_2 production rate of 415 μM h^{-1}, outperforming ZnS (166 μM h^{-1}) and ZnSe (262 μM h^{-1}). The synthesized catalysts were characterized using X-ray diffraction (XRD), Raman spectroscopy, UV-vis spectroscopy, and transmission electron microscopy (TEM). These zinc sulfoselenides exhibited a homogenous morphology, enhanced charge transport, and a higher number of active sites, contributing to their improved photocatalytic performance. To further explore the reaction mechanism, radical scavenger studies were conducted alongside Mott-Schottky analysis and density functional theory (DFT) simulations. DFT calculations revealed favorable energetics for oxygen reduction to H_2O_2 on the distorted $ZnS_{0.5}Se_{0.5}$ (110) surface, which showed strong interactions with O_2 (Eb = -170 kJ/mol) and hydrogen atoms (Eb = -56 kJ/mol). These results highlight the importance of material modification in optimizing photocatalytic performance. By combining experimental results with theoretical insights, this research advances our understanding of the mechanisms behind H_2O_2 production on zinc sulfoselenides and paves the way for the development of more sustainable photocatalytic technologies for industrial applications.

Hydrophilic Carbon Dots for Enhanced Wettability and Hydrogen Evolution Rate in Polymeric Nanoparticle Photocatalysts Mohamed H. Elsayed[1,2]; [1]King Fahd University of Petroleum and Minerals, Saudi Arabia; [2]Academia Sinica, Taiwan

Organic semiconducting polymers have demonstrated significant potential as photocatalysts for hydrogen (H2) evolution, particularly when synthesized in the form of polymer dots (Pdots). Traditionally, these Pdot structures are fabricated using non-conjugated amphiphilic polymers, which adversely impact charge transfer between photocatalysts and reactants, while also being inactive in the photocatalytic process. In this study, we propose a novel approach to constructing Pdot photocatalysts by replacing the non-conjugated amphiphilic polymer with hydrophilic carbon quantum dots (Hy-CDs). The resulting Hy-CDs/hydrophobic Pdots composite enhances electron transfer between the platinum (Pt) cocatalyst and the polymer photocatalyst, exhibiting superior water dispersibility. Furthermore, unlike their non-conjugated counterparts, transient absorption (TA) spectroscopy reveals that Hy-CDs function as efficient electron mediators, facilitating enhanced electron transfer between the polymer photocatalyst, Pt cocatalyst, and water molecules. Consequently, the engineered Pdot photocatalysts achieve a remarkable hydrogen evolution rate (HER) of 68,400 μmol/g/h under visible light irradiation.

Bandgap Engineered Non-Metal Doped C_3N_4 for Efficient Photoelectrochemical Hydrogen Production

Maryum Ali and Muhammad Nawaz Tahir; King Fahd University of Petroleum and Minerals, Saudi Arabia

The ever-increasing population, depleting fossil fuel reserves, and continuously evolving industrialization is causing serious environmental pollution and energy shortage concerns. For a sustainable future, issues associated with clean energy and environmental remediation need to be addressed and solved. This can be done by mitigating these crises by shifting towards renewable energy sources and through the development of sustainable techniques.

Solar energy is a safe, abundant, green, and effecient renewable resource. However, a major challenge is to discovering how to effectively harvest solar energy into usable forms. Solar energy conversion applications like photocatalysis and photovoltaics have been extensively reaserched. However, the materials employed in these technologies have scarce reserves, limited efficiency, and high costs which limits their use on an industrial scale. Innovations in material science and engineering result in creation of new materials that offer better performance, sustainability, and affordability.

Graphitic carbon nitride (g-C_3N_4) is considered a promising metal-free solar energy conversion catalyst owing to its chemical stability, abundance availaiblity, non-toxicity and environment friendly nature. g-C_3N_4 however offers low photocatalytic activity in its pristine form due to its stacked bulk structure. The structure leads to reduced specific surface area and accelerated photocharge recombination of limiting its photocatalytic performance. g-C_3N_4 also has relatively wide bandgap (~2.7 eV) which limits its ability in utilizing visible light. In this study, we focus on bandgap engineering of g-C_3N_4 through non-metal doping to enhance its solar energy conversion efficiency. By introducing non-metal dopants such as S, F, N we successfully narrowed the bandgap, improving visible light absorption and boosting photocatalytic activity.

Our findings confirm that non-metal doping effectively modulates the electronic structure of g-C_3N_4, resulting in enhanced solar-driven processes, particularly in photocatalysis and hydrogen generation. The improved performance highlights the potential of bandgap-engineered, non-metal doped g-C_3N_4 for sustainable energy conversion applications. This research contributes to the advancement of green chemistry by developing efficient photocatalysts for renewable energy technologies.

A Pathway to 7.5% Efficient Sb_2S_3 Thin Film Solar Cells by Ultrasonic Spray Pyrolysis—Challenges and Prospects Towards Further Developments *Ilona Oja Acik; Tallinn University of Technology, Estonia*

Photovoltaic (PV) solar energy conversion is one of the leading technologies to meet present days' energy demand and it is a green process, which is an important step towards pollution-free energy production. Sb-chalcogenide (Sb_2S_3, Sb_2Se_3, $Sb_2(S,Se)_3$) absorbers have prospect for booming development in the near future due to their binary composition, suitable bandgap (1.1-1.7 eV), high absorption coefficient (10_5 cm$_{-1}$ at 450 nm), earth-abundant and non-toxic constituents. The solar cells with $Sb_2(S,Se)_3$ as a absorber layer have reached power conversion efficiency above 10% whereas the ones with Sb_2S_3 have attained around 8%. Most of the high efficiency Sb_2S_3 devices (7-8 %) utilize an absorber thickness of at least 200 nm, are fabricated by either spin coating, chemical bath deposition (CBD) or vacuum deposition techniques.
This talk will discuss the recent results on Sb_2S_3 thin film solar cells development, show the pathway towards achieving a 7.5% efficient Sb_2S_3 solar cell device, utilizing an absorber layer thickness of approximately 100 nm and average visible transmittance of around 30%, and give insights into their future applications. Additionally, we'll explore cost-effective wet-chemical ultrasonic spray pyrolysis method offering unique resource saving and rapid approach to fabricate thin films and solar cells on large substrate areas.

11:00 AM *EN02.01.02
Solar Hydrogen Production with Antimony Selenide Thin Film Photoelectrodes *David Tilley; Universität Zürich, Switzerland*

Antimony selenide (Sb_2Se_3) is a highly promising material for practical large-scale water splitting due to its low cost, appropriate bandgap (~1 eV), excellent charge transport properties, ease of synthesis, and resistance to photocorrosion in strongly acidic environments. In this presentation, I will explore several methods for fabricating antimony selenide thin film photocathodes and various treatments to enhance their performance. One method involves the selenization of electrodeposited antimony metal films, resulting in thin films with a favorable orientation for charge transport to the semiconductor/electrolyte interface. To address the main challenge of improving photovoltage, post-synthesis etching and doping treatments are employed. Another method involves a hydrothermal synthesis process, with strategies for doping the material during synthesis, which significantly enhances performance. I will conclude with a perspective on photoelectrochemical (PEC) research in the context of large-scale water electrolysis.

11:30 AM EN02.01.03
Variation in Parameters of Graded Bandgap Antimony Sulfide Selenide Solar Cells *Fabiola De Bray Sanchez, M.T. Santhamma Nair, P.Karunakaran Nair, Priyanka Bamola and Yareli Colin; Universidad Nacional Autónoma de México, Mexico*

Antimony sulfide selenide solar cells of 6 – 7.5% in conversion efficiency (η) with open circuit voltage (V_{oc}) 0.4 – 0.55 V and short circuit current density (J_{sc}) 20 – 35 mA cm^{-2}, are obtained for $Sb_2S_xSe_{3-x}$ thin film absorbers. A higher band gap (E_g, 1.6 eV, $x_1 = 2$) $Sb_2S_xSe_{3-x}$ thin film is deposited on a CdS window and a lower E_g (1.3 eV, x = 0.5) thin film is subsequently added to form CdS/$Sb_2S_{x1}Se_{3-x1}$/$Sb_2S_{x2}Se_{3-x2}$/graphite-Ag solar cells. These cells are prepared on commercial SnO_2:F (FTO, TEC 7) in lots of four substrates of 2.5 cm x 7.5 cm in area with a chemically deposited CdS thin film, 80 – 100 nm in thickness. Sequential chemical deposition of $Sb_2S_xSe_{3-x}$ in 80 mL baths at 80 °C during 180 min (total) with increased selenide source in the second bath, or of sequential thermal evaporation from crucible with increasing content of antimony selenide powder in the Sb_2S_3-Sb_2Se_3 in the evaporation source-mix on to FTO at 425 °C placed 40 cm above the source are used to prepare the absorber film stack. External quantum efficiency measurements on the cells show systematic increase in its value above 0.9 and hence of J_{sc} toward 25 – 35 mA cm^2 with an increase in the Se-content in the rear absorber. The J-V characteristics show increase in V_{oc} with an increase in the S-content in the entrance absorber. Six series connected solar cells of nearly 6 cm in active cell area produce functional prototype modules with V_{oc} of 3 V operating at a maximum power 25 – 30 mW and η, 4.8 – 6%. Three to four series connected modules operate at 100 mW power with excellent operational stability prompting further work.

11:45 AM EN02.01.04

ZnSe/ITO and ZnSe/SnO_2 Thin Films as Window Layer for Sb_2Se_3 Heterojunction Solar Cells by CSS Method

Tamara Potlog[1], Ivan Gadiac[1], Dumitru Untila[1], Ion Lungu[1] and Nicolae Spalatu[2]; [1]Moldova State University, Moldova (the Republic of); [2]Tallinn University of Technology, Estonia

ZnSe, an A_2B_6 semiconductor compound with a wide band-gap (about 2.7 eV) and cubic zinc blend structure, it seems to be very promising window for Sb_2Se_3 heterojunction solar cells. In this paper, we study the effect of substrate temperature on the physical properties of ZnSe films deposited on SnO_2/glass and ITO/glass substrates by the closed-space sublimation method (CSS).Thin films were characterized using SEM, energy dispersive analysis (EDX), X-ray diffractogram (XRD), and UV–Vis spectra. The XRD studies of ZnSe thin films deposited on both, SnO_2/glass and ITO/glass substrates, show that the structure is zincblende, with preferred orientation along the (111) plane and nanograins sizes depend on the substrate temperature. Also, the lattice parameters showed a dependence on the substrate temperature, for example, with increasing substrate temperature from 500 K to 600 K, the lattice parameter of ZnSe/SnO_2/glass changed from 5.6707 Å to 5.6571 Å, respectively. SEM images in both cases, indicate uniform deposition without pin holes and EDS patterns confirm the deposition of the as-grown Zn-deficient thin films. The average transmittance in the domain from 600 nm to 1200 nm of the spectra was ranged between 85% and 90% for all studied samples. The measured reflectance spectra have been transformed in the absorption spectra, and by applying the Kubelka−Munk function, the values of the band-gap width were estimated. These values slightly change but are in good agreement with those reported for bulk ZnSe samples. The properties of as-deposited ZnSe thin film on different nature substrates were tailored by chemical activation and thermal annealing. The effects of chemical activation and thermal annealing in different atmosphere, on the structural, optical and electrical properties of the films will also be discussed in this paper.

***Facile Reconstruction of Extended Defects in Antimony Selenide Demonstrated by First-Principles Calculations and Electron Microscopy** Keith McKenna; University of York, United Kingdom*

Antimony selenide (Sb_2Se_3) and sulfoselenides have rapidly emerged as promising materials for application as solar absorbers in thin film photovoltaic and photoelectrochemical cells with device efficiencies now in excess of 10% [1-3]. These materials exhibit a highly anisotropic crystal structure (consisting of $(Sb_4Se_6)_n$ ribbons oriented along the [001] direction) with weaker bonding between ribbons [4]. In polycrystalline films most extended defects (such as grain boundaries and surfaces) are observed to cut across these $(Sb_4Se_6)_n$ ribbons and as a result break bonds. The conventional picture that emerges from studies of many other compound semiconductors is that dangling bonds introduced at such extended defects give rise to deep gap states that contribute to non-radiative recombination, reducing material performance relative to single crystals [5].

By employing density functional theory (DFT) calculations to model the structure and properties of a wide range of extended defects our previous work predicted that (in the absence of point defects) surfaces and grain boundaries in Sb_2Se_3 and Sb_2S_3 are unusually free of deep gap states associated with dangling bonds [6,7]. The reason is that extended defects undergo a facile reconstruction where undercoordinated atoms reconfigure to restore their coordination and eliminate associated defect states within the band gap (an effect we termed 'self-healing'). While the absence of deep gap states is consistent with recent experimental results obtained by deep level transient spectroscopy [8] and Kelvin probe force microscopy [9], directly probing the atomic structure and electronic properties of extended defects remains challenging.

Associated with the reconstruction of extended defects DFT calculations predict significant long-range strain fields. In fact, the relative softness of these materials, with significant space between ribbons, likely facilitates the significant atomic rearrangements needed to eliminate dangling bonds at extended defects. This prediction is one that is more amenable to experimental investigation. In a recent study we have mapped the strain field within $(Sb_4Se_6)_n$ ribbons terminating at using scanning transmission electron microscopy [10]. Strains of up to ~4% extending approximately 2 nm into the grain interior are observed for a (041) grain boundary with results in good agreement with the DFT predictions. This provides further evidence to support our prediction that there are significant atomic reconstructions that take place at extended defects that bestow Sb_2Se_3 and related materials with a high level of grain-boundary-defect tolerance.

***Investigating the Rare Earth Dichalcogenides as Functional P-Type Semiconductors** Christopher Savory; University of Birmingham, United Kingdom*

The rare earth polychalcogenides $LnCh_{2-x}$ (Ln = La-Lu, Ch = S, Se, Te) are a family of compounds that have been investigated for their structural and magnetic tunability: occupying variants of the ZrSSi Zintl-like motif, but with wide variability depending on which chalcogenide, and the proportion of chalcogenide vacancies. The fully stoichiometric, non-magnetic members of the family (Ln = La, Lu; x=0) are semiconductors due to a Peierls distortion within the 'Ch^-' layer: of these, $LaSe_2$ has seen recent investigation as a promising p-type transport thin-film material with intrinsic carrier concentrations beyond 10^{19} cm^{-3},[1] although with limited exploration for the microscopic origin of its favourable electronic behaviour.

In this study, we thoroughly examine the $LnCh_2$ family (Ln= La, Lu; Ch = S, Se) using a combination of hybrid Density Functional Theory and GW calculations to investigate their electronic and optical properties. Initially, we demonstrate that despite suitable fundamental band gaps, these systems will be poor photovoltaic absorbers due to forbidden optical transitions, however, we also establish the key role of Se-Se dimerization in the structure of $LaSe_2$ in engineering valence band dispersion and low hole effective masses.[2] We then compare $LaSe_2$ to the lutetium and sulfide analogues in the family using calculations of individual scattering mechanisms within the recently-developed AMSET code to establish the trends and limits in carrier mobilities, and to establish the potential of these compounds as hole conductor layers in functional devices with careful growth control.[3] Finally, we calculate their thermal transport properties, with comparison between the hiphive and ALAMODE packages,[4, 5] to also assess the suitability of $LaSe_2$ and the other compounds in the family as low-temperature p-type thermoelectrics.

Intrinsic and Extrinsic Point Defect Chemistry of Selenium *Seán R. Kavanagh[1], Rasmus Nielsen[2], Alp E. Samli[3], Aron Walsh[4] and David O. Scanlon[5]; [1]Harvard University, United States; [2]Surfcat, Denmark; [3]University College London, United Kingdom; [4]Imperial College London, United Kingdom; [5]University of Birmingham, United Kingdom*

Selenium was the first material used in a photovoltaic (PV) solar cell and has recently experienced a renaissance in research interest as a candidate solar absorber, due to several desirable properties (suitable band gap, earth abundance, low-temperature processing), its potential implementation in silicon tandem cells and 'simple' elemental chemistry.[1,2] While cell efficiencies have improved significantly since its initial application in 1883,[3] t-Se still lags behind leading PV technologies primarily due to a low open-circuit voltage relative to the band gap. The atomistic origins of this voltage deficit and fundamental limitations of t-Se-based solar cells remain unclear, however, with controversy regarding both the doping concentrations of as-grown selenium films and calculated defect levels muddying our understanding of defect activity in this material.

In this work, we investigate the intrinsic and extrinsic defect chemistry of t-Se using both theoretical and *experimental approaches. We find a strong ability for the helical selenium chains to reconstruct and valence alternate in order to compensate charged defects, yielding amphoteric behaviour for most low-energy extrinsic species. We demonstrate that intrinsic point defects are not the cause of apparent high hole concentrations in as-grown samples, but could be active for non-radiative electron-hole recombination.*

Intermediate-Band Solar Cells—From Atoms to Devices Through Computational Materials Design *Matteo Cagnoni; Politecnico di Torino, Italy*

Intermediate band (IB) solar cells (SC) have been proposed to outperform commercial devices based on the Shockley-Queisser (SQ) model. By introducing "intermediate" energy levels between the valence (VB) and conduction (CB) band of the photo converting material, the trade-off between photo-generated current and voltage is improved, while preserving the same simple device architecture. This is due to the activation of the sequential absorption of two sub-gap photons, and the collection of the corresponding photo-generated charge carriers. The theoretical power conversion efficiency limit thus increases from ~30% to ~45%.
Despite their enormous potential, IBSCs have failed to outperform SQSCs thus far, because of the lack of materials with optimal properties. In fact, IB photo-converters are typically realized as highly mismatched alloys (HMA), or III-V semiconductors "doped" with quantum dots. In addition to complex manufacturing, the disorder-/defect- based nature of these solutions degrades charge transport properties to such an extent that true IBSC operation is hindered.
To overcome this problem, though facing a very tough materials design challenge, one could envision the realization of materials naturally born with an intermediate band, that is, having the IB electronic structure in their intrinsic state.
In this talk, I will present the research activities carried out in this direction, with focus on the highly tunable and industrially appealing class of chalcogenides. In particular, I will discuss:
1) material property requirements and approaches to quantify the quality of a material for IBSC operation;
2) screening of large material property databases and infererence of correlations between atomic structure and relevant optoelectronic properties;
3) identification of promising IB chalcogenides by combining the gained chemical intuition with crystal structure prediction methods and semi-empirical band structure models;
4) characterization of these promising materials by state-of-the-art DFT and many-body-perturbation-theory methods, and their optimization through tight-binding approaches;
5) some basic solar cell design incorporating these optimized IB materials, to exceed the SQ limit.
The work has been carried out as part of the project PhANTOM, funded by the Italian Ministry of University and Research (MUR) through the National Recovery and Resilience Plan (PNRR) with the call Young Researchers – Seal of Excellence (CUP number: E13C22002920006).

2:45 PM EN02.02.05

Strong Electron-Phonon Coupling and Bipolarons in Sb_2S_3 *Yun Liu[1], Julia Wiktor[2] and Bartomeu Monserrat[3]; [1]Institute of High Performance Computing, Singapore; [2]Chalmers University of Technology, Sweden; [3]University of Cambridge, United Kingdom*

Sb_2S_3 is an Earth-abundant and non-toxic material that is under investigation for solar energy conversion applications. However, it still suffers from poor power conversion efficiency and a large open circuit voltage loss that have usually been attributed to point or interfacial defects. More recently, there has been some discussion in the literature about the role of carrier trapping in the optical properties of Sb_2S_3, with some reporting self-trapped exciton as the microscopic origin for the performance loss, while others have found no evidence of carrier trapping with only large polarons existing in Sb_2S_3. By using first-principles methods, we demonstrate that Sb_2S_3 exhibits strong electron-phonon coupling, a prerequisite for carrier self-trapping in semiconductors, which results in a large renormalization of 200 meV of the absorption edge for the temperature range of 10 K to 300 K. When two electrons or holes are added to the system, corresponding to a carrier density of 1.6×10^{20} cm^{-3}, we find wavefunction localization consistent with the presence of bipolarons accompanying a significant lattice distortion with the formation of Sb and S dimers. The formation energies of the electron and hole bipolarons are -330 meV and -280 meV per carrier, respectively.
Our results reconcile some of the controversy in the literature regarding carrier trapping in Sb_2S_3 , and demonstrate the existence of large electron-phonon coupling and carrier self-trapping that might place a fundamental limit on the open circuit voltage and consequently the maximum efficiency of the photovoltaic cells[1].

***Emerging Customized Kesterite Technologies for Next Generation PV Integration** Alejandro Perez-Rodriguez[1,2]; [1]Fundació Institut de Recerca en Energia de Catalunya, Spain; [2]Universitat de Barcelona, Spain*

BIPV and PIPV are identified as key enabling technologies to make “near Zero Energy Buildings” and “net Zero Energy Districts” more realistic, through the integration of a new generation of photovoltaic modules capable of entirely replacing architectural/mobility/urban-furniture passive elements. This promising scenario of mass realization of BIPV and PIPV solutions can only be achieved by developing cost-efficient and sustainable thin film technologies with unbeatable aesthetic functionalities, including mechanical flexibility and optical tuneability.

In this work, the main results achieved in the Custom-Art (www.custom-art-h2020.eu) European project will be reviewed. The project has involved an intense activity on the development of advanced BIPV and PIPV modules based on earth abundant kesterite materials which are at the forefront of emerging inorganic thin film technologies. By combining advanced strategies for materials properties management with customized modules design in a circular economy approach, two types of products have been developed including flexible PV modules on polymer and steel-based substrates with different device architectures corresponding to monograin (MGL) and thin film microcrystalline solar cells. This has involved a relevant activity in the development and optimization of highly innovative cost-efficient processes for the improvement of device efficiency, stability and scalability.

Main results achieved in the project have included the include the optimization of the processes for highly efficient kesterite solar cells, with the demonstration at cell level of a record device efficiency of 12.06% (active area) of MGL Cu_2ZnSnS_4 solar cells that has been achieved with the modification of the absorber/buffer interface by using two-step heterojunction formation process. For the thin film microcrystalline solar cell configurations, new solution based processes have been developed leading to a record 14.1% $Cu_2ZnSn(S,Se)_4$ device efficiency (active area, w/o antireflective coatings). These are based on the implementation of innovative Li and Ag co-doping processes allowing for materials and device optimization. Solution and PVD highly resilient process strategies have also been demonstrated leading to device efficiencies > 11%, and a strong effort has been devoted to the up-scaling of the processes up to 10x10 cm^2, achieving very good uniformity results that allow the transfer of these processes for the development of medium size customized modules with targeted efficiencies > 10%. Transferability of the processes to flexible substrates has also been demonstrated, with efficiency results similar to those achieved on glass substrates, demonstrating monolithically interconnected flexible modules with relative efficiency loss ≤ 20% versus cell efficiency. This has allowed the design and implementation of medium size customized modules integrating novel flexible cost efficient integrating novel flexible cost efficient encapsulants based on the implementation of organic multinanolayer stacks and compatible with efficient recycling processes. Application of these processes for the development of customized modules integrated in different kinds of advanced BIPV and PIPV product demonstrators will be reviewed, and results on the assessment of the device demonstrators at real world operative conditions will be presented.

The Pathway to >15% Efficiency Emerging Kesterite Solar Cells *Qingbo Meng; Chinese Academy of Sciences, China*

The ongoing exploration of diversified compound photovoltaic materials is creating more opportunities for the efficient, low-cost, and environmentally-friendly utilization of solar energy. The emerging multinary chalcogenide, $Cu_2ZnSn(S, Se)_4$ (CZTSSe), is therefore being developed as a promising candidate to promote the large-scale and low-cost application of thin-film photovoltaics, by taking advantage of its high element abundance, nontoxicity, excellent material stability, and outstanding industrial compatibility. CZTSSe solar cell has experienced a rapid development in the first decade after it was developed. However, this cell has encountered a bottleneck in efficiency in the past ten years and still has a long way to go to be comparable to the commercialized counterparts, such as CIGS and CdTe.

To find a way to overcome this impasse, scientists in this field have paid numerous efforts. From our side, we have conducted systematical investigations into the charge dynamics in CZTSSe solar cells and found that the charge loss in this device mainly lies in the bulk nonradiative recombination arising from the deep electronic defects and microstructural distortions.[1] This finding has guided us to introduce a series of regulations on metal-molecular coordination in environment-friendly aqueous solution system, film growth mode, and crystal growth kinetics of CZTSSe to improve the film microstructure and phase evolutions.[2-5] Especially, we have explored three routes to control the reaction kinetics of the CZTSSe selenization.[4-6] In route 1, we introduced high environment pressure in the selenization chamber, which could delay the Se volatilization and dilute the Se vapor on the surface region of the precursor film. This would subsequently decrease the reaction activity between the Se and the metal elements in the film and thus could suppress the rapid formation of binary or ternary secondary phases. In route 2, we developed a dual-zone selenization strategy and introduced a solid-liquid/solid-vapor synergistic selenization approach. We firstly pre-deposited liquid Se onto the surface of the precursor film. The liquid Se could provide very high Se concentration to drive the direct and fast formation of the Kesterite phase. In route 3, we developed a multinary alloying strategy to regulate the stability of intermediate phases to facilitate the phase evolution and cation exchange process. These efforts finally helped us to realized efficiencies of >15% in Kesterite solar cells. Overall, this efficiency breakthrough brings new opportunities for the development of emerging inorganic thin-film *solar cell systems, with CZTSSe as a representative.*

Exploring the Potential of ZnMgO Thin Films as a Sustainable Alternative to CdS Buffer Layer in CZTSSe Solar Cells *Prabeesh Punathil, Giray Kartopu, Pietro Maiello, Vincent Barrioz, Neil S. Beattie and Guillaume Zoppi; Northumbria University, United Kingdom*

Recently, Copper Zinc Tin Sulfide Selenide [$Cu_2ZnSn(S,Se)_4$ or CZTSSe] absorbers based solar cells have exhibited efficiencies exceeding 14%, ending a period of stagnation lasting over a decade. Although a notable V_{oc} deficit still exists, it is possible to enhance the overall efficiency by optimizing the optical properties of the CZTSSe device. This study aims to investigate the potential of $Zn_{1-x}Mg_xO$ (ZMO) as a buffer layer material for CZTSSe solar cells, with the goal of replacing the toxic CdS buffer layer. The use of ZMO buffer layers offers advantages such as band alignment, high electron mobility, good transparency, and chemical stability. ZMO thin films were deposited using magnetron co-sputtering with different Mg/(Mg+Zn) ratios. The sputtering conditions and film properties were optimized and analyzed. CZTSSe solar cells were fabricated using the ZMO buffer layer and their performance was also evaluated. The ZMO thin films exhibited a tunable bandgap ranging from 3.21 eV to 4.88 eV, depending on the Mg/(Mg+Zn) ratio. The grain size of the films increased with increasing Mg ratio and then decreased at higher Mg concentrations. The highest power conversion efficiency (PCE) of 3.3% with V_{oc}= 343 mV, J_{sc}=27.3 mA/cm^2 and FF=35.5 % was achieved with a ZMO buffer layer composition of $Zn_{0.84}Mg_{0.16}O$ having a bandgap of 3.76 eV. This performance compared favorably with that of reference cells utilizing the CdS buffer. This study demonstrates the potential of ZMO as a substitute for the toxic CdS buffer layer in CZTSSe solar cells. The findings contribute to the development of more environmentally friendly and efficient thin-film solar cell technologies.

4:45 PM EN02.03.04

Impact of Diverse ETLs on the Efficiency of Tunable Band Gap Kesterite Based-Solar Cells *Yudania S. Gonzalez[1], Yuancai Gong[2,3], Alex Jimenez Arguijo[2,3], Lorenzo Calvo Barrio[4], Edgardo Saucedo[2,3] and Alejandro Perez-Rodriguez[1,4]; [1]Fundacio Institut Recerca Energia Catalunya, Spain; [2]Escola d'Enginyeria de Barcelona Est, Spain; [3]Universitat Politècnica de Catalunya, Spain; [4]Universitat de Barcelona, Spain*

Open circuit voltages deficit (Voc,def) in kesterite solar cells remains the primary limitation to achieving performance parity with CIGS technology. One key strategy to address this issue is the optimization of the Kesterite/ETL interface. However, CdS remains the primary ETL material in second-generation solar cell technology, including kesterite. It has been proven that interface recombination at Kesterite/CdS interface is a significant limitation for performance enhancement. Therefore, integrating an effective Electron Transport Layer (ETL) is crucial for improving the performance of these technologies. A cadmium-free ETL is important not only for performance improvement but also for health and environmental reasons, enhancing market acceptance, promoting recycling, and stimulating innovation in the photovoltaic industry. However, significant progress is necessary to achieve higher efficiencies in kesterite devices with alternative ETLs.
In this study we report the effectiveness of CdS as reference ETL layer and explore cadmium-free ETL alternatives.

Thin-film In_2S_3, ZnS, ZnOS, and ZnSnO are promising ETL candidates due to their wider bandgap and good lattice match with kesterite absorbers. Several deposition methods for these ETL films have been explored, including Chemical Bath Deposition (CBD), Successive Ionic Layer Adsorption and Reaction (SILAR), and Atomic Layer Deposition (ALD). ALD is recognized for its precise and reproducible thin film deposition. The SILAR, employing a similar chemical principle, enables the formation of semiconductor films by immersing a substrate repeatedly in separated precursor solutions of cations and anions, achieving deposition at the nanometer scale. These methods offer potential to create optimal heterojunctions in solar cells using kesterite as the light-absorbing material. This study explores three growth techniques and emphasizes the utilization of environmentally safer and more abundant materials.
For ALD and SILAR, different growth parameters such as precursor concentration, process temperature, time and number of cycles were studied to assess their influence on device performance. Characterization techniques like XRD, XPS, GDOES, XRF, and SEM were employed to analyze the thin film properties. The study focuses on the fabrication of CZTSSe-based solar cells in a substrate configuration, demonstrating the significant impact of ETL selection on the electrical performance. Currently, efficiencies higher than 8% have been achieved using a ZnSnO-ALD ETL nanolayer, and a relevant improvement in device efficiency is observed in relation to the reference CdS ETL one, likely related to its higher band gap and better band alignment with the kesterite aborbers. These results underscore the promising potential of alternative ETL materials to CdS, particularly in addressing environmental and health concerns associated with cadmium usage.

SESSION EN02.04: Solar Fuels

Molecular-Ink Based Solution Processing for Ultrahigh Light Absorption Coefficient AgBiS2 and Chalcogenide Perovskite BaZrS3 Wooseok Yang; Sungkyunkwan University, Korea (the Republic of)

Solution processing to fabricate metal chalcogenide thin films has gained considerable interest because of its low cost and scalability. Among the various types of solution processing, homogeneous molecular ink-based processes can lead to high-quality metal chalcogenide thin films, a prerequisite for high-efficiency solar energy conversion devices. In this talk, our group's recent works on molecular-ink derived AgBiS2 and BaZrS3 light absorbers will be presented.
AgBiS2 is an attractive light absorber owing to its high light absorption coefficient over 10^5 cm-1. An intriguing feature of this material is the change in the light absorption coefficient depending on the transition of cation order to disorder. We developed a strategy for controlling the cation disorder in AgBiS2 thin films, by carefully controlling the coordination chemistry in the Ag and Bi containing molecular inks.
BaZrS3, which has the perovskite crystal structure, is an emerging light absorber that has attractive properties. However, the required temperature (~1000 oC) for the preparation of BaZrS3 is a major bottleneck for BaZrS3 to be applied to solar energy conversion devices. A novel molecular-ink based method for preparing BaZrS3 with a moderate temperature will be presented in this talk.

9:00 AM *EN02.04.02
Advancing Kesterite-Based Photocathodes for Water Splitting and Beyond Shujie Zhou[1], Rose Amal[1], Cui Ying

Toe[2] and Xiaojing Hao[1]; [1]University of New South Wales, Australia; [2]The University of Newcastle, Australia

Converting the solar energy to storable and transportable chemicals via photoelectrochemical (PEC) reactions offers unique advantages of overcoming the intermittence features of solar irradiation. Kesterites have long been ideal candidates standing as cost-efficient, environmental-friendly, and efficient semiconductor photoelectrode materials for PEC solar fuel production. With significant progress made in hydrogen production, there is increasing attention paid to extending the applications in CO_2 reduction, ammonia synthesis, etc. However, when designing efficient kesterite based photoelectrodes (i.e. Cu_2ZnSnS_4 (CZTS)) for water splitting and beyond, it is crucial to make comprehensive consideration on both photoelectrode activity and reaction selectivity.

Our works elaborate the strategies on rationally design the kesterite based photoelectrodes by both optimising photoactivity in terms of photogenerated charge migration and regulating the surface catalytic sites. Specifically, it demonstrates the successful application of CZTS photocathode in CO_2 reduction with enhanced photoactivity by post heat treatment and controllable selectivity towards CO and alcohols by surface S vacancy regulation. In addition, it also extends the application of CZTS photocathode into NOx reduction to ammonia by rationally incorporating a TiOx cocatalyst with optimal surface oxygen vacancy. Powered by the CZTS based solar cells, standalone solar to ammonia synthesis was achieved with Co-TiOx/Ag/TiOx/CdS/CZTS photocathode, leading to nearly 100% of ammonia faradaic efficiency. More recently, by replacing the toxic CdS buffer layer with the environmental-friendly and cost-effective ZnSnO buffer layer, a competitive half-cell solar to hydrogen conversion efficiency of more than 5.2 % has been achieved.

These findings have brought important insights into rationally designing kesterite based photoelectrodes for advancing their PEC applications to achieve both enhanced activity and target product selectivity.

9:30 AM EN02.04.03

The Electronic and Transport Properties of Sr2Sb2O2Q3 (Q=S,Se) for Photocatalytic Water Splitting *George E. Smith, Alexander Squires and David O. Scanlon; University of Birmingham, United Kingdom*

Hydrogen is a green fuel source, as no carbon emissions are produced upon combustion or conversion within a fuel cell. However, the most common source of hydrogen is from steam-reforming of hydrocarbons, which is not a zero-carbon method. The photocatalytic splitting of water is a heavily researched green alternative for the generation of hydrogen. A successful material for photocatalytic water splitting requires an appropriate band gap to absorb in the visible light region, and the correct alignment of the valence band maximum (VBM) and conduction band minimum (CBM) with the redox potential of water[1].

Recently, $Sr_2Sb_2O_2S_3$ and $Sr_2Sb_2O_2Se_3$ were highlighted as promising candidates for photocatalytic water splitting[2]. They were reported to possess bandgaps of 2.44 eV and 1.72 eV for $Sr_2Sb_2O_2S_3$ and $Sr_2Sb_2O_2Se_3$, respectively – well within the ideal region for photocatalytic materials[1,2]. In addition to this, UV-vis measurements indicate promising photocatalytic efficiency for both materials. In this presentation, we have conducted a comprehensive computational analysis of the electronic properties of both materials through density functional theory (DFT) and the Vienna ab initio simulation package (VASP), utilising the hybrid functional HSE06. Analysis includes the electronic structure and band alignment for both structures. Additionally, the electronic transport properties have been investigated using the first principles package, AMSET, to elucidate carrier properties for the material and better characterise the material. The phonon band structure and optical properties of the materials have also been analysed using DFT. We demonstrate that these materials possess ideal direct band gaps and disperse band edges for a high mobility photocatalyst.

Enhancing the Photocurrent Density and Stability in CZTSSe Photocathode for PEC System Through Defect Control Inside Grain Boundary of Active Layer *Suyoung Jang, Gaikwad M. Anandrao and Jin Hyeok Kim; Chonnam National University, Korea (the Republic of)*

$Cu_2ZnSn(S,Se)_4$(CZTSSe) has been shown to overcome CIGS disadvantage as a favorable material applied to thin film solar cells and photocathodes because of its eco-friendly, earth-abundant, and high absorption. However, the device performance like the power conversion efficiency and solar to hydrogen was still low, therefore further study is essential to decrease the resistance and control defects in the active layer. CZTSSe was known to be very difficult to control its phase and had many defects such as voids, vacancies, and mismatch band energy levels. In this work, we have synthesized the CZTSSe thin films by doping the Cd atom using the CBD method to control defects inside its grain boundary which caused recombination. When a proper Cd amount is doped, the deep level and shallow defects in grain interior and boundary are reduced, significantly preventing recombination. As a result, the Cd-doped CZTSSe thin film solar cells demonstrated the highest average current density and performance of ~9.26% and ~34.76 mA/cm^2, respectively. Furthermore, the Cd-doped CZTSSe photocathode had a promising photocurrent density of ~19.05 mA/cm^2 in neutral electrolyte. Therefore, affected by the Cd doping, the CZTSSe photodevices showed remarkable performance among photocathodes synthesized using a DC-sputtering system.

10:30 AM *EN02.05.01

Chalcogenide Perovskite Thin Films for Photovoltaics *Rafael Jaramillo; Massachusetts Institute of Technology, United States*

Chalcogenide perovskites have much to recommend them for photovoltaics (PV). They absorb light strongly, with direct band gap tunable (at least) over the range 1.4 – 1.9 eV. They have limited polymorphism and are stable in air, water, and at high temperature. They are made of Earth-abundant, and (mostly) non-toxic elements, and have isotropic properties. However, there are substantial challenges facing the development of chalcogenide perovskite PV. Synthesis requires aggressive conditions - oxygen-free sulfurization or selenization at high temperature – that severely constrain thin-film growth. The few published reports of transport properties describe n-type material with high electron concentration, undesirable for thin-film PV. Photoluminescence (PL) has been reported, but the quantum yield is often low, and sample-to-sample variability is high. The defects that limit performance are not yet understood, and even less is known about interface and heterojunction design. Clearly, it will be a long road to chalcogenide perovskite PV technology.

I will motivate why, despite these challenges, research on chalcogenide perovskites for PV is worthwhile and exciting. I will then describe our own efforts, which center on the processing and properties of thin films. We have achieved a number of synthesis milestones, including growing thin films of $BaZrS_3$ and $BaZr(S,Se)_3$ alloys with *tunable band gap, in epitaxial and polycrystalline forms. Selenium alloying can produce films with band gap suitable for single- and dual-junction PV, but the vast majority of synthesis procedures reported to-date focus on pure sulfides. I will discuss our finding of rapid alloying by post-growth selenization of sulfide thin films. This recalls the sulfurization-after-selenization process in CIGS manufacturing, and may make alloy studies more widely accessible. I will also present findings on how variations in cation composition affect crystallization kinetics. These results bolster evidence for* BaS_3*-liquid-assisted crystal growth, and may be useful for lowering the temperature of thin film synthesis.*

I will then discuss our ongoing studies of photoluminescence (PL) and electronic transport. We have previously reported long excited-state PL lifetimes for $BaZrS_3$ *and* $Ba_3Zr_2S_7$*, and others have reported band-edge PL even from powder samples. However, PL emission is highly variable, sample-to-sample, and many samples have no measurable band-edge emission. To understand this variability, we carry out a quantitative comparison of temperature-dependent PL of* $BaZrS_3$ *and a prototypical halide perovskite,* $CsPbBr_3$*. The halide has PL yield between 100 and 10,000 times larger than the chalcogenide. By comparing the vibrational properties of the chalcogenide and the halide, we suggest why defect-assisted recombination may be faster in the chalcogenide. On the other hand, the variability between chalcogenide samples suggests a substantial upside, if the recombination-active defect(s) can be identified and diminished. Our temperature-dependent Hall transport studies find that mobility at room temperature is limited by electron-phonon scattering, even in highly-doped samples; this may be related to our previous finding that chalcogenide perovskites have exceptional dielectric polarizability. At cryogenic temperature, the role of ionized defect scattering varies sample-to-sample. All films are n-type as grown, but with tremendous variability in electron concentration. Studies of post-growth annealing support the hypothesis that the predominant intrinsic shallow donors are sulfur vacancies; we use this understanding to vary electron concentration by over a million-fold.*

I will end by highlighting exciting next-steps including alternative methods of thin film deposition to make thicker films at lower temperature, studies of device semi-fabricates including detailed investigation of Mo/$BaZrS_3$ *interfaces, and controlling carrier concentration and type through aliovalent doping.*

11:00 AM EN02.05.02

Assessing Carrier Mobility, Dopability and Defect Tolerance in the Chalcogenide Perovskite $BaZrS_3$ *Zhenkun Yuan[1], Diana Dahliah[2,3], Romain Claes[2], Andrew Pike[1], David P. Fenning[4], Gian-Marco Rignanese[2] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]Université Catholique de Louvain, Belgium; [3]An-Najah National University, Palestine, State of; [4]University of California, San Diego, United States*

The chalcogenide perovskite $BaZrS_3$ *has attracted much attention as a promising solar absorber for thin-film photovoltaics. In this talk, we present our first-principles results on carrier transport and defect properties in this material. We find that* $BaZrS_3$ *has a phonon-limited electron mobility of 37* cm^2/Vs *comparable to that in halide perovskites but lower hole mobility of 11* cm^2/Vs*. The defect calculations, based on advanced hybrid density functional theory, indicate that* $BaZrS_3$ *is intrinsically n-type due to shallow sulfur vacancies, but that strong compensation by sulfur vacancies will prevent attempts to make it p-type. We also establish that* $BaZrS_3$ *is a defect-tolerant absorber with few low-formation-energy, deep intrinsic defects. Among the deep defects, sulfur interstitials are the strongest nonradiative recombination centers which in sulfur-rich conditions would limit the carrier lifetime to 10 ns. Our work highlights the material's intrinsic limitations in carrier mobility and suggests suppressing the formation of sulfur interstitials to reach long carrier lifetime.*

11:15 AM EN02.05.03

Measuring and Controlling the Electronic Transport Properties of $BaZrS_3$ ***Chalcogenide Perovskite Thin Films***

Jack Van Sambeek, Jessica Dong, Ida Sadeghi and Rafael Jaramillo; Massachusetts Institute of Technology, United States

Chalcogenide perovskites are an emerging class of semiconductor materials that are of interest for optoelectronic applications, and especially for photovoltaics (PV). Within this broader class of materials, $BaZrS_3$ (BZS) is the most widely-studied to date, showing several promising properties for PV application. BZS consists of Earth-abundant elements with minimal toxicity, it is stable in ambient conditions, in water, and up to at least 500 C in air. It has strong optical absorption and has a suitable bandgap (1.8 – 1.9 eV) for tandem PV applications. In recent work, we showed that the bandgap can be tuned over the range 1.4 – 1.9 eV by chalcogen alloying, while remaining entirely within the perovskite phase [1, 2]. However, understanding of the electronic properties of chalcogenide perovskites – and the factors that may limit performance of future devices – remains elusive. Little has been reported on defect characterization, carrier mobility, mobility-limiting mechanisms, or dopability.

In this work, we report electronic transport measurements and trends for epitaxial and polycrystalline BZS thin-films grown by physical vapor deposition. Hall effect measurements show n-type behavior as-grown, with carrier concentration and mobility correlated to synthesis parameters and structural properties measured by x-ray diffraction (XRD). Temperature-dependent Hall measurements show that mobility is primarily limited by phonon scattering at room temperature, with a transition to impurity-scattering at cryogenic temperatures. The carrier concentration can be tuned by post-growth annealing, nearly to intrinsic levels, and our results support the hypothesis that sulfur vacancies are the predominant shallow donors. As time allows, we will also present work exploring the doping limits, explored via n- and p-type ion implantation. Insights from this work will support future efforts towards PV device design, fabrication, and optimization.

A Processing Route to Chalcogenide Perovskites Alloys with Tunable Band Gap via Anion Exchange

Kevin Ye, Ida Sadeghi, Michael Xu, Jack Van Sambeek, Tao Cai, Jessica Dong, Rishabh Kothari, James M. LeBeau and Rafael Jaramillo; Massachusetts Institute of Technology, United States

Chalcogenides perovskites are of growing interest for photovoltaics (PV), for reasons including their chemical stability, Earth-abundant elements, and tunable direct band gap [1,2]. Unlike their halide cousins, chalcogenide perovskites are challenging to make, requiring high temperature and aggressive sulfurizing environments. This challenge is being met by a growing number of researchers; in recent years there have appeared reports of synthesis of powders, crystals, nanocrystals, and thin films, and strategies to lower the synthesis temperature. Almost without exception, these reports focus on the most widely-studied compound, $BaZrS_3$. $BaZrS_3$ is highly stable in the perovskite phase, but its direct band gap of 1.9 eV limits its usefulness for single- or dual-junction PV. Last year, we demonstrated that the band gap of $BaZr(S,Se)_3$ alloys can be tuned over the range of 1.4 – 1.9 eV, entirely within the perovskite phase [3]. This synthesis included co-delivery of sulfur and selenium during epitaxial thin film growth, which is an uncommon set of capabilities.

Here we demonstrate an alternative and more-accessible route to making $BaZr(S,Se)_3$ alloys with tunable band gap: selenization-after-sulfurization [4]. We first grow $BaZrS_3$ thin films, and then convert to $BaZr(S,Se)_3$ alloys by selenium exposure. At sufficiently high temperature, the process of sulfur-selenium anion exchange proceeds rapidly, without disrupting the phase or even the crystal microstructure of the as-growth film. The alloy films resulting from this process have lower defect concentration than the alloys made by direct growth (using co-

delivery of sulfur and selenium), and superior electronic transport properties, measured by photoconductive response. The selenization-after-sulfurization process can be carried out immediately after film growth (without breaking vacuum), or after an intervening air exposure. The thin, self-limiting native oxide that forms on $BaZrS_3$ after air exposure does not impede the subsequent selenization process. We also find that the perovskite structure is stable in high-selenium-content thin films with and without epitaxy. For instance, we demonstrate that a textured, polycrystalline $BaZrS_3$ thin film grown on a 2" sapphire wafer can be completely converted to an $BaZr(S,Se)_3$ alloy with band gap of 1.5 eV. These samples have excellent uniformity and no apparent change to the film morphology, microstructure, or crystal structure, besides an increase in unit cell size to accommodate the larger selenium atoms.

The selenization-after-sulfurization process is similar to processing steps developed and established at industrial scales for CIGS manufacturing. It may enable other researchers, having developed innovative ways to synthesis $BaZrS_3$, to expand their work into alloys with tunable band gap, and move the field closer to relevance for single- and dual-junction PV.

SESSION EN02.06: CdTe
Session Chairs: Jon Major and Feng Yan
Tuesday Afternoon, December 3, 2024
Hynes, Level 1, Room 107

1:30 PM *EN02.06.01
Recent Advances of CdTe Photovoltaics *Gang Xiong; First Solar, United States*

In recent years, CdTe solar cell research has transitioned to p-type doing using group-V elements such as As or P. Compared to traditional Cu-doping, group-V doping can result in two orders of magnitude higher carrier concentrations, implying an open-circuit voltage gain of more than 100 mV. In addition, the long-term degradation rate, and temperature coefficient of CdTe solar cells are further reduced, suggesting higher energy yield at the same name plate efficiency/wattage.

In 2023, efficiency measured at standard test condition of group-V doped devices surpassed Cu-doped CdTe solar cells for the first time. To date, we have certified >22.6% efficiency at NREL, and demonstrated >23% efficiency in-house using NREL measurement protocol. 917 mV was achieved with absorber band gap of 1.39 eV. The gain is largely due to improvement of Voc and FF compared to Cu-doped devices. Engineering the interface between CdTe and ZnTe leads to reduced interface recombination. An optimized selenium profile in part contributed to lower voltage deficit. Other improvements include a wide bandgap metal oxide buffer layer in front of the absorber, *and inserting an optical reflector after the back contact to increase near band-edge QE. In addition, we also demonstrated reduced microscopic non-uniformity via lower As dosage or phosphor incorporation. Nevertheless the benefit on device Voc is yet to be materialized. Pathways for further improvement include enhanced passivation at back contact interface, and reduction of non-radiative recombination in absorber via better activation of group V dopants, reduced potential fluctuations, and identification and mitigation of defects in the absorber.*

2:00 PM *EN02.06.02

From Cadmium-Based to Antimony-Based Thin Film Solar Cells *Alessandro Romeo, Elisa Artegiani, Narges Torabi and Mariyam Mukhtar; Università degli studi di Verona, Italy*

Since the beginning of the 80's of the last century, chalcogenide-based thin film materials have been introduced for low-cost, low-material, highly scalable PV devices. Different materials like $CuInGaSe_2$, $CuInSe_2$, *CdTe, and* Cu_2ZnSnS_2, *have demonstrated good conversion efficiency and good stability. However, the binary alloys like CdTe, are the ones that have shown an exceptional feasibility and scalability for mass production, being the only thin film material in market competition with the high-energy-demanding crystalline silicon cells. In particular, CdTe has reached an efficiency of 22.6% and has demonstrated remarkable robustness, nevertheless still much has to be done for high doping concentration.*

Sb_2Se_3 *or* Sb_2S_3 *are, instead, ceramic-based materials that, with a band gap respectively from 1.2 to 1.7 eV, and with an exceptionally high absorption coefficient, show optimal photovoltaic characteristics. Their combination could bring the first tandem solar cell made with similar absorber materials as in the scope of our ACT-FAST EU project.*

In this work, we will present all the latest developments of the Cd-based and Sb-based solar cells, illustrating their based ceramic window layers and contacts (such as CdS, CdSe, SnO_2*). The latest challenges on* Sb_2Se_3 *and* Sb_2S_3*-based solar cells will be presented.*

2:30 PM *EN02.06.03

Recent Progress in Cd(Se,Te) Photovoltaics from NREL *Matthew Reese[1], Eric Colegrove[1], Joel Duenow[1], Chun-Sheng Jiang[1], Darius Kuciauskas[1], Andrea Mathew[2,1], Deborah McGott[1], Chris Muzzillo[1], Craig Perkins[1], Benjamin E. Sartor[1], Hope Wikoff[1] and Samantha Reese[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States*

The push to improve efficiency in Cd(Se,Te) photovoltaics centers around improving the extracted photovoltage. In 2016, the National Renewable Energy Laboratory (NREL) demonstrated using CdTe single crystals that a new defect chemistry, namely doping with a group V element in place of Cu, was a path to improve voltage while enhancing stability. Since then, the broader community has been striving to implement this in polycrystalline thin films that have been alloyed with Se. Successfully achieving this requires simultaneously improving doping, bulk minority carrier lifetime, and interface recombination by at least an order of magnitude each over historic CdTe:Cu devices. Progress has required a more detailed scientific understanding of the material system and its challenges. This talk will focus on contributions from NREL over the past few years towards this goal. These include modeling to help understand losses in real devices, a technique to expose buried interfaces and how they evolve, characterizations that reveal our material limitations, as well as synthesis strategies to address these in the bulk and contacts. Depending on the schedule of other talks, some more contextualization of this research will also be presented.

Hybrid Solar Cells Comprising Inorganic and Organic Materials Through Vapor Phase Infiltration *Kristina Ashurbekova*[1] *and Mato Knez*[1,2]*;* [1]*CIC nanoGUNE, Spain;* [2]*IKERBASQUE, Basque Foundation for Science, Spain*

The development of inorganic, organic and perovskite solar cells (SCs), has witnessed considerable progress over the past decade. Perovskite SCs, while highly efficient, encounter stability and toxicity concerns. Inorganic SCs outperform their organic counterparts in efficiency and durability but lack mechanical flexibility, motivating exploration of alternative technologies. In contrast, organic SCs offer the desired flexibility, but face the mentioned lower efficiency challenges. Despite the inherent limitations of each SC type, they have their own merits, promising a grand step forward if synergy is achieved. Combining the adaptability of organic SCs with the efficiency of inorganic ones may yield a hybrid versatile alternative. Herein, we are introducing new hybrid solar cell materials by applying vapor phase infiltration (VPI) to polymers.
We present a completely new hybrid materials set obtained after growing Sb_2S_3 and Sb_2Se_3 by VPI inside the bulk and atop of diverse polymers including Poly(3-hexylthiophene-2,5-diyl) (P3HT), poly(triaryl amine) (PTAA), Poly[N,N'-bis(4-butylphenyl)-N,N'-bisphenylbenzidine] (PolyTPD) and Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS). PTAA, PolyTPD and PEDOT:PSS are excellent hole-transporting semiconducting materials, while P3HT is an efficient light absorber in the visible range. Metal chalcogenide light absorbent materials, such as Sb_2S_3 and Sb_2Se_3, have huge potential in photovoltaics owing to the suitable bandgap of 1.7 and 1.3 eV, and high light absorption coefficient above 10^4 and 10^5 cm^{-1}, respectively. For the VPI growth of Sb_2S_3 and Sb_2Se_3, $SbCl_3/H_2S$ and $SbCl_3/(Me_3Si)_2Se$ precursors were used, respectively. The hybridization process was monitored in-situ with a Quartz Crystal Microbalance (QCM). The monitoring allowed studying the saturation behavior of the VPI process and quantitatively controlling the loading of the inorganic precursors into the polymer. Scanning electron microscopy (SEM) showed infiltration in form of Sb_2S_3 and Sb_2Se_3 crystal growth throughout the whole polymer depth. TEM was used to examine the structure of the crystalline phase of the Sb_2S_3 and Sb_2Se_3 grown in the bulk and on top of the polymer.
With the fabricated polymer-inorganic hybrid materials as base, planar p-i-n SCs devices with following structures were fabricated: ITO glass/polymer-Sb_2S_3//Sb_2Se_3 /ETL/Ag and ITO glass/polymer-Sb_2S_3//Sb_2Se_3/perovskite/ETL/Ag. C60/BCP was used as an electron transport layer (ETL). With those devices, a complete photovoltaic characterization of the new set of hybrid materials was done in 16 ITO pins SCs, including the current density–voltage (J–V) characteristic under illumination, power conversion efficiencies (PCEs) and the external quantum efficiency (EQE). The results are very encouraging and offer new solutions for the design of future flexible and highly efficient SCs.

Structure-Property Engineering in Multinary Chalcogenide Semiconductors *David B. Mitzi; Duke University, United States*

Multinary chalcogenides play a vital role in commercial and emerging photovoltaic (PV) and related *photoelectrochemical (PEC) devices. I_2-II-IV-X_4 semiconductors, wherein "I" is Ag or Cu, "II" is a divalent metal or alkaline earth, "IV" is a tetravalent metal and "X" is a chalcogen (generally S or Se) form a particularly interesting branch of emerging solar absorbers, with a target of replacing more traditional systems such as CdTe or Cu(In,Ga)$(S,Se)_2$ that suffer from toxicity or elemental abundance issues. Large efforts have been focused on $Cu_2ZnSn(S,Se)_4$ as an earth-abundant and reduced-toxicity absorber, leading to significant performance improvement. However, similarity of component atom size and preferred coordination gives rise to facile anti-site defect formation, which has limited performance improvement. In this talk we will explore a broader class of I_2-II-IV-X_4 (I = Ag, Cu; II = Ba, Sr, Eu, Pb; IV = Si, Ge, Sn; VI = S, Se) multinary semiconductors, which involve a II atom with significantly larger disparity in atomic radius and preferred coordination. Beyond the more thoroughly studied $Cu_2BaSn(S,Se)_4$, II = Eu systems have been recently identified as providing potentially suitable crystal and band structures for PV/PEC.[1] We have also been extending the II^{2+}-IV^{4+} component of these systems to I^{+}-V^{5+} analogs, to provide opportunity to explore whether a structural tolerance factor approach derived for the II^{2+}-IV^{4+} systems[2] still proves useful for structure prediction, as well as to broaden the prospects for property tunability (e.g., bandgap and defect tolerance). As many of these structures crystallize in non-centrosymmetric space groups and contain heavy atoms (with significant spin-orbit coupling), we also explore the implications for engineering systems with a large degree of spin splitting,[3] of prospective interest for spintronics and as has also been pursued in 2D halide perovskites.[4] If desirable electronic structure tunability associated with a multi-element stoichiometry can coincide with earth-abundant components and control over defect formation, such multinary chalcogenides will provide an interesting path forward in the quest for high-performance, low cost and scalable PVs and other optoelectronic devices.*

4:15 PM EN02.07.03

Fabrication and Analysis of GeSe Thin Film Solar Cells Using Close Space Sublimation Deposition *Bradley G. Lewis[1], Thomas Shalvey[1], Christopher Don[1], Daniya Sindi[1,2], Mounib Bahri[1] and Jon Major[1]; [1]University of Liverpool, United Kingdom; [2]Umm Al-Qura University, Saudi Arabia*

Over the past 6 years, GeSe has emerged as a potential absorber material for thin film solar cells, with a power conversion efficiency (PCE) increase from 1.5% to 6.1% from just over 10 publications on photovoltaic devices worldwide. With well suited base materials properties such as a high absorption coefficient, thin-film carrier mobility over $25cm^2V^{-1}s^{-1}$, intrinsic carrier density of $10^{15}cm^3$ and a direct band gap of 1.3eV, it seems that the main limitation of this material as an absorber is the volume of research focussing on it. With a 2-dimensional orthorhombic Pnma structure, covalently bonded in 2-directions with van der Waals interactions in the other, an optimized deposition method and device structure could offer reduced orientation-dependence on device performance compared with Sb_2Se_3 absorbers. Alongside potentially more favourable electronic properties and stereochemically active lone pairs, this could enable the production of photovoltaic devices that outperform those with Sb_2Se_3 absorbers.

Large single crystals of intrinsic, Cu-doped and Ag-doped GeSe have been produced via a vapour transport growth method and these have been analysed in low and high energy X-ray photoelectron spectroscopy, along with electrical characterisation techniques such as Hall effect.

The majority of higher efficiency GeSe photovoltaic absorbers have been produced via vapour transport deposition, mostly in a 'rapid thermal sublimation' or 'close spaced sublimation' (CSS) based system. The increased performance for this type of deposition had been attributed to a sublimation purification mechanism as a result of high vapour pressure of GeSe and the removal of unwanted Ge and $GeSe_2$ phases. This work focusses on the optimisation of GeSe film growth on both CdS and TiO_2 substrates using a CSS deposition system similar to that used for deposition of high efficiency Sb_2Se_3 and CdTe devices. Alongside it's benefits in reducing parasitic absorption in the device, it is shown that TiO_2 acts as a more optimal window layer choice than CdS for GeSe absorber devices due to the incidence of Cd diffusion during deposition with a CdS window layer, resulting in the formation of CdSe grains in the bulk absorber and a poor interface quality at the junction.
Previous works have utilised an Sb_2Se_3 interfacial layer between the window layer and the absorber to enable higher efficiency devices above 3% PCE. In this work, the role of this layer is found to provide an anisotropic seed layer for growth of GeSe thin films which improves the quality of the thin-film growth.
A range of hole-transport layers (HTLs) have been applied to the device structure and the effect of these on device performance have been studied. The application of a Spiro-O-MeTAD HTL enables the production of Cd-free GeSe Devices with PCE of up to 2.51%.

SESSION EN02.08: Poster Session: Thin Film Chalcogenides for Energy Applications
Session Chairs: Jon Major and Nicolae Spalatu
Tuesday Afternoon, December 3, 2024

EN02.08.01
Optimized Annealing and Patterning of Sb_2Te_3 and Bi_2Te_3 Thin Films for Antenna-Coupled Thermoelectric THz and mm-Wave Detectors *Rumana Zahir, F. Javier Gonzalez, Edgar Nino, Keqi Qin, Kalpathy Sundaram, Masahiro Ishigami and Robert Peale; University of Central Florida, United States*

Antenna-coupled thermoelectric junctions hold potential for THz and mm-wave detection and energy harvesting. These devices require patterned deposition of thermoelectric materials with a junction at the antenna feed, which is heated by radiation-induced currents. Sputtered Sb_2Te_3 and Bi_2Te_3 thin films, ideal for this application, must be deposited over patterned photoresist on a suitable substrate followed by lift-off. Films deposited on room temperature substrates have high resistivity and low Seebeck coefficient. Films deposited on substrates at 175 °C have optimal thermoelectric properties, but such temperatures reflow and carbonize patterned photoresist, which complicates lift-off. This problem is avoided by deposition and lift-off at room temperature followed by an activation anneal. We describe a two-level full-factorial experiment to optimize the annealing conditions. We find that the optimized annealed films have Seebeck coefficients comparable to those obtained by heating the substrate during deposition. Additionally, annealing dramatically reduces the resistivity. Corresponding changes in the electrodynamic properties of the films are revealed by far-infrared spectroscopy. Simulation predicts a mm-wave responsivity of 4V/W for a single Sb_2Te_3-Be_2Te_3 junction coupled to a Ti bowtie antenna on glass substrate. Results of characterization using a backward wave oscillator on fabricated detector devices will be presented.

EN02.08.03
Exploring p-Type Dopants in the Zintl Phosphide AM2P2 Solar Absorbers *Yagmur Coban[1], Zhenkun Yuan[1],*

Andrew Pike[1], Gideon Kassa[1], Muhammad R. Hasan[2], Kirill Kovnir[2], Jifeng Liu[1] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]Iowa State University of Science and Technology, United States

The Zintl phosphides AM2P2 (A=Ca, Ba, and M=Cd, Zn) have recently been proposed as a new class of thin-film solar absorbers because of their attractive optoelectronic and defect properties. Our previous work found that these materials have good p-type dopability and could be used as a p-type absorber layer for p-n junction type solar cells. Using first-principles hybrid functional calculations, we systematically explored potential dopants that could lead to adequate p-type doping in the Zintl phosphides. The potential p-type dopants that we considered span quite a range of chemistry, including alkali elements (Na and K) and group 11 elements (Cu and Ag) for substitution of the A and M sites. We also addressed the dopant self-compensation and compensation by other intrinsic donor defects.

EN02.08.04

Evaluating the Electronic Structure of Cu_2GeSe_3 for Energy Conversion Applications

Philippa Cox, David O. Scanlon and Alex G. Squires; University of Birmingham, United Kingdom

Thermoelectrics offer a promising avenue for sustainable energy solutions by enabling the harnessing of waste heat for power generation. Not only do they have applications in various sectors such as wearable medical devices, aerospace and automotives, but they also provide a reliable and low maintenance power source for remote locations[1]. The success of a thermoelectric is measured by the dimensionless figure of merit. The highest figure of merit achieved to date is 3.1 by hole doped polycrystalline SnSe at 783K[2]. However, there are issues surrounding mechanical fragility and brittleness, as well as concerns around the long-term chemical and thermal stability. It has classically been difficult to dope, causing problems with optimisation of the material. This is also observed in other high performing thermoelectric materials such as Bi_2Te_3[3]. PbTe, another high performer, shows less mechanical and stability problems, however, contains highly toxic elements[4]. As a result, developing new thermoelectric materials is still an important area of research.

Cu_2GeSe_3 has been explored as a thermoelectric for many years, it contains mostly cheap, non-toxic and abundant materials, with good thermal and chemical stability. It has shown poor performance as a pure material with a maximum performance of zT 0.3 but has had a recent resurgence in doped systems because of these benefits with elements such as bismuth and zinc [5,6]. However, little is known about the structure and properties of Cu_2GeSe_3. Once believed to be ordered, Cu_2GeSe_3 has now been shown to be more complex and intriguing[7]. It is essential to comprehensively characterise the Cu_2GeSe_3 endmember to ensure its suitability as an energy material.

This work aims to explore the structure and properties of Cu2GeSe3 for use as a thermoelectric by employing computational techniques such as Density Functional Theory via the Vienna Ab initio Simulation Package (VASP) and Cluster Expansions with Monte Carlo sampling.

Exploring the Electronic Tunability of Transition Metals Intercalated Bi_2Te_3 Nanoplates *Michelle Frasch and Susan M. Kauzlarich; University of California, Davis, United States*

Thermoelectric materials are a potential solution to minimizing waste heat in our society. The material focused on for this study, Bi_2Te_3, is the current state-of-the-art room–temperature thermoelectric material, and doping this material has shown an increase in the thermoelectric unit of merit. Intercalation of transition metals into Bi_2Te_3 provides a new way to design and modify the electric properties. Here, I intercalate Mn and Cu into two-dimensional nanoplates of Bi_2Te_3 while additionally systematically testing to see if other first-row transition metals (Ti, V, Cr, Co, Ni, and Zn) can be intercalated in this manner. These materials are synthesized by a one-pot intercalation route via the polyol synthetic method with characterization utilizing PXRD, SEM/EDS, and SAED via TEM. Creating this synthetic technique to intercalate transition metals into 2D materials would continue to push the field forward, and ultimately work towards producing a high zT thermoelectric material.

EN02.08.06

Enhancing Device Performance of CZTSSe Thin Film Solar Cells with IZO by Controlling Substrate Temperature *Dong Hyun Kang and Jin Hyeok Kim; Chonnam National University, Korea (the Republic of)*

Transparent conductive oxide (TCO) is a material used in various optoelectronic fields such as displays, sensors, automobiles, and solar cells. In these applications, the TCO used as the window layer of solar cells must have high transmittance to transmit light to the absorption layer. TCO must also have good electrical properties to ensure smooth transport of charge carriers. Among various materials, Indium Tin Oxide (ITO) is preferred in various fields because it has excellent electrical conductivity in the visible light region, excellent optical transmittance, low electrical resistance, and wide band gap. However, achieving the high electrical and optical properties of ITO requires relatively high deposition temperatures, which can degrade the performance of the base material. Indium Zinc Oxide (IZO) has been attracting attention as an alternative due to its favorable electrical conductivity, high optical transmittance, and wide work function. Furthermore, IZO can be deposited at low power and low temperature, and it has low absorption at long wavelengths.
In this study, IZO thin films were deposited on soda-lime glass (SLG) using RF magnetron sputtering. The deposition was conducted at temperature RT, 100 °C, 170 °C, 230 °C, and 300 °C, respectively. Especially, the thin film deposited at 170 °C showed a high transmittance of 86.4% and a low sheet resistance of 12.97 Ω/sq in the visible light region. Also, an IZO transparent electrode was applied to the actual $Cu_2ZnSn(S,Se)_4$ (CZTSSe) thin film solar cells (TFSCs) devices as a window layer, and the device parameters and EQE of the solar cells were analyzed systematically. The CZTSSe TFSCs with IZO TCO layer deposited at 230 °C show a power conversion efficiency (PCE) of 6.85%. Surprisingly, the CZTSSe TFSCs without i-ZnO deposited at RT show PCE of 9.83% with V_{oc} of 481 mV, J_{sc} of 30.5 mA/cm^2, and FF of 66.9% respectively.

EN02.08.07

Engineering Ultrafast Photoconductive Response in Two-Dimensional SnS2 Through Metal Intercalation
Sepideh Khanmohammadi[1], Camille Williams[1], Kateryna Kushnir[1], Ronald L. Grimm[1], Kristie J. Koski[2] and Lyubov V. Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]University of California, Davis, United States

Two-dimensional (2D) SnS2 is a layered semiconductor with a band gap in the visible range of spectrum (~ 2.3 eV) and good environmental stability.1 In an earlier study, we reported on transient photoconductivity dynamics in SnS2 following above-gap, 400 nm excitation. We found that photoexcited free carriers have high mobility of 250 ± 10 cm2 V-1 s-1 and the lifetime in the hundreds of picoseconds.2 Here, we demonstrate zero-valent intercalation of various atomic metals into the van der Waals gap of SnS2 can be used to change the lifetimes of optically excited charge carriers. Zerovalent intercalation introduces atomic metals into the van der Waals gap of 2D materials without radically altering the structure or the oxidation state of the host lattice. 3-5 It has been shown to reduce the lifetime and improve the mobility in GeS under near-gap excitation.6
In the case of SnS2, we identify two metals, Cu and Cr, that increase the carrier lifetime. In fact, while all photoexcited carriers become trapped or decay within the first few hundred ps in pure SnS2, SnS2-Cr retains ~ 10% of carriers, and SnS2-Cu ~ 5% of carriers by 0.5 ns mark. At the same time, Fe and Bi intercalation shortens the carrier lifetime. Metal intercalation can thus be used to engineer the properties of SnS2 for its applications in solar energy conversion, where a longer lifetime is beneficial, to high-speed photodetectors, where minimizing the response time is important.

EN02.08.08

Enhancing the Efficiency of CZTSSe Solar Cells by Cation Alloying *Youngrog Kim and Jin Hyeok Kim; Chonnam National University, Korea (the Republic of)*

We can address the serious issues of fuel depletion and climate change that require urgent attention by developing alternative energy sources. Solar energy is a renewable energy that can replace fossil fuel-dependent sources, as it does not produce carbon dioxide or other greenhouse, gases and is environmentally friendly. Up to now, the highest efficiency of CZTSSe thin film solar cells replace with CIGS materials achieved 14.9%, that is lower than the CIGS world record of 23.35%. Therefore, additional research is essential to enhance the efficiency needed for commercialization. We have endeavored to overcome the limitations of V_{oc} and J_{sc} in CZTSSe thin film solar cells via cation substitution. CZTSSe thin films have lower performance than other materials when applied to devices due to problems such as many lattice defects and secondary phase formation. To enhance this Ge and Cd were selected. CZTSSe was doped with Ge and it was replaced with Sn to reduce pinhole and bulk recombination, and CZTSSe was doped with Cd and it was replaced with Zn to promote grain growth and suppress secondary phase formation. CZTSSe thin film solar cells with Ge alloyed enhanced the V_{oc} by 494 mV, and CZTSSe thin film cells with Cd alloyed enhanced the J_{sc} by 36.9 mA/cm^2. As a results, We achieved its highest performance of 10.84%, representing a 20% enhancement compared to the pure CZTSSe device without alloying.

EN02.08.09

CuGaSe$_2$ Semi-Transparent Thin-Film Solar Cells *David Palma[1], Sateesh Prathapani[2], Antonio Arranz[1], José Manuel Merino[1], Raquel Caballero[3] and Christian Kaufmann[2]; [1]Universidad Autónoma de Madrid, Spain; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [3]Instituto de Óptica, CSIC, Spain*

Semi-transparent photovoltaic (PV) devices offer a promising route for integrating solar energy generation into buildings, known as building-integrated photovoltaics (BIPV). Among the various materials under investigation for thin-film PV devices, CuGaSe$_2$ (CGSe) has emerged as a potential candidate due to its band gap energy of around 1.7 eV and stability. However, it is a challenge to achieve high efficiency and high transparency in CGSe based solar cell devices at the same time.

In this work, 750 nm CGSe thin films were deposited via co-evaporation on different substrate configurations. The conventional Mo/SLG, SLG and semi-transparent substrates based on Mo/FTO with thin Mo layers of 7.5 and 30 *nm were used. In the case of the semi-transparent back contacts, a 8 nm NaF precursor layer was evaporated before the CGSe co-evaporation process. A remarkable 70% straight-through transmittance in the near-infrared region was achieved for CGSe deposited on SLG. In previous works, CGSe semi-transparent solar cells showed a transmittance of around 60 % for the same wavelength range [1].*

The influence of the buffer layer on the CGSe final device has been investigated. Currently, CdS, Zn(O,S) and $Zn_{1-x}Sn_xO_y$ *are the main buffer materials used in CGSe solar cells. Larsson et al. [2] reported 1.5 µm CGSe solar cells with efficiencies of 11.9 % when using* $Zn_{1-x}Sn_xO_y$ *and an antireflective coating. Here, improvements in device performance have been achieved by using an alternative buffer layer,* $Zn(O_{0.6}S_{0.4})$*, instead of the conventional CdS. SLG/Mo/CGSe/ZnSO/AZO/Ni-Al solar cell structure yields an open-circuit voltage* V_{OC} *of 944 mV and an efficiency of 7.1%. However, the use of semi-transparent back contact resulted in a* V_{OC} *of 826 mV and an efficiency of 4.0%. The semi-transparent device performance is mainly limited by the FF, suggesting that an improved back interface is necessary. These results highlight the potential of CGSe thin films for BIPV applications, demonstrating that they can achieve both high transparency and substantial photovoltaic performance.*

Cu_2O Hole Transport Layer for Antimony Chalcogenide Solar Cells *Ines Riech[1], Pedro Mijangos-Alonzo[1], Osvaldo Vigil-Galán[2], Roberto González-Castillo[2], Miriam Nicolás-Marín[2] and Milenis Acosta[1]; [1]Universidad Autónoma de Yucatán, Mexico; [2]Instituto Politécnico Nacional, Mexico*

$Sb_2(S,Se)_3$ *has been recognized as a potential absorber layer for photovoltaic devices due to its tunable band-gap in the range of 1.1 – 1.8 eV, high absorption coefficient (≈* 10^5 cm^{-1}*), earth-abundant and non-toxic component, which makes this material a good candidate for low-cost thin-film solar cells. The best* $Sb_2(S,Se)_3$ *solar cell efficiency achieved at the laboratory level in the traditional p-n configuration is lower than the expected theoretical efficiency for these absorber materials. An alternative n-i-p structure configuration has been proposed, considering the quasi-intrinsic nature of the absorber layer. The incorporation of a p-type interfacial layer improves the carrier extraction efficiency. Properly selecting materials for the ETL (n-type semiconductor) and HTL (p-type semiconductor) layers is vital for the solar cell performance. The maximum efficiency reported experimentally was using the FTO/CdS/*$Sb_2(S,Se)_3$*/Spiro-OMeTAD/Au structure. We propose the replacement of Spiro-OMeTAD with inorganic material as an HTL in order to make the solar cell scalable to the industrial level.*
In this work, we investigated the Cu_2O *layer as HTL for* $Sb_2(S,Se)_3$ *solar cells based on the theoretical results reported by [1].* Cu_2O *is a p-type material with an optical band gap between 2.0 - 2.6 eV. Considering that a compatible deposition technique with the underneath absorber layer should be used for HTL, the RF-Sputtering technique at room temperature was used to obtain single-phase* Cu_2O *thin films with low electrical resistivity and good optical properties.* $Sb_2(S,Se)_3$ *compound was synthesized using thermal evaporation and coated by an optimized* Cu_2O *layer. Optoelectronic properties of bilayers, the role of the interface, and bulk passivation were investigated by low-temperature photoluminescence. XPS analysis was performed to evaluate the band alignment in order to ensure the easy transfer of holes in* $Sb_2(S,Se)_3$ *solar cells. Finally, to evaluate the effect of* Cu_2O *thin film as HTL in a device with n-i-p configuration, the first attempts were made to process the FTO/CdS/*$Sb_2(S,Se)_3$*/*Cu_2O*/Au structure. Our findings provide a basic understanding of interfacial engineering in this structure.*

$Zn_{1-x}Sn_xO_y$ Buffer Layer Deposited by Chemical Bath Deposition for Low and Wide Band Gap (Ag,Cu)(In,Ga)Se_2 Solar Cells

Diego A. Garzón[1], Jan Keller[2], Rafael Cerqueira[1], Tobias Törndahl[2], Marika Edoff[2] and Sascha Sadewasser[1]; [1]International Iberian Nanotechnology Laboratory, Portugal; [2]Uppsala University, Sweden

Cu(In,Ga)Se_2 (CIGSe) solar cells with a tunable bandgap stand out as a promising technology for tandem applications. However, challenges arise, particularly in the performance of wide-bandgap CIGSe with a high [Ga]/([Ga]+[In]) ratio (GGI), which exhibits lower efficiency than anticipated, mostly related to losses in open-circuit voltage (V_{oc}). On the other hand, alloying the copper position with silver has shown improvement in the V_{oc}, related with a better conduction band offset between high-Ga (Ag,Cu)(In,Ga)Se_2 (ACIGSe) and the traditional CdS buffer layer, with a maximum PCE of 16.3% for an absorber band gap of 1.43 eV, without antireflective coating and RbF postdeposition treatment. [1]

Addressing the environmental concerns associated with Cd-based buffers, we recently developed a solution-based method for depositing thick ZTO ($Zn_{1-x}Sn_xO_y$) buffer layers by ammonia-based chemical bath deposition (CBD). [2] This method allows for the tuneability of the ZTO bandgap (3.2–3.6 eV) by adjusting the [Sn]/([Sn]+[Zn]) ratio (TTZ). Here, we investigate the suitability of zinc tin oxide (ZTO), as a Cd-free alternative for both low-bandgap CIGSe and wide-bandgap (Ag,Cu)(In,Ga)Se_2 (ACIGSe) solar cells. Best ZTO-buffered devices exhibited competitive power conversion efficiencies (PCE) of 14% and 7% for low-bandgap and wide-bandgap absorbers, respectively. The optimization process revealed distinct optimal tin concentrations for the two absorbers, with 10% TTZ ZTO identified as optimal for the wide-bandgap samples, and 20% TTZ ZTO for the low-bandgap material. A pronounced decline in performance was observed for both materials when higher Sn content buffer layers were used, primarily resulting from losses in open-circuit voltage. These losses in ZTO-based devices might be linked to poor band alignment, providing a plausible explanation for the results obtained in the low-bandgap CIGSe sample. Further characterization of the full devices showed inhomogeneities at the interface between the absorber and buffer that impacts negatively the open-circuit voltage when they occupy most of the interface.

In summary, ZTO-based devices showcased promising photovoltaic performance with average PCE values of (12 ± 3) % [V_{oc} = (520 ± 34) mV; $E_{g,\,CIGSe}$ = 1.03 eV] for low-bandgap CIGSe and (6 ± 1)% [V_{oc} = (0.62 ± 0.03) V; $E_{g,\,ACIGSe}$ = 1.46 eV] for wide-bandgap ACIGSe. This emphasizes the ZTO's potential as a practical and non-toxic buffer layer, deposited by CBD, for diverse CIGSe solar cell applications.

In Situ Characterization of the 2-Stage Cu(In,Ga)Se_2 Formation Process

José Fonseca[1], Carlos J. Tavares[2], Alec LaGrow[3], Cristiana Alves[1], Oleksander Bondarchuk[1] and Sascha Sadewasser[1]; [1]International Iberian Nanotechnology Laboratory, Portugal; [2]Universidade do Minho, Portugal; [3]Okinawa Institute of Science and Technology, Japan

Cu(In,Ga)Se_2 (CIGSe) solar cells offer benefits such as cost-effectiveness, efficient manufacturing processes, *application versatility, and a lower carbon footprint compared to Si photovoltaics. The best-performing CIGSe solar cells and industrial-scale modules are usually deposited through multi-stage processes where the material's composition and temperature are adjusted based on empirical optimization methods. In-depth understanding of the formation process of CIGSe during deposition could enable further power conversion efficiency improvements. Most available studies on the CIGSe formation process have used in-situ X-ray diffraction experiments to follow phase changes during the deposition process. To improve the understanding of the materials processing and ultimately their performance, we conducted a combination of various in-situ experiments during the selenization stage of a sequential deposition process, namely Raman spectroscopy, X-ray diffraction, X-ray photoelectron spectroscopy, and transmission electron microscopy. Special attention is given to phase transformations during the material growth, particularly formation of secondary phases, segregation of elements between the different components, and how this affects the crystallinity. Samples were prepared on glass/Mo substrates by sputtering of a Cu-In-Ga alloy at room temperature with simultaneous supply of Se by evaporation, forming an amorphous CIGSe layer. A Se capping layer was evaporated on top of the CIGSe to provide sufficient Se for the diffusion reaction. In-situ Raman spectroscopy performed during crystallization shows that the* A_1 *vibrational mode of the α-phase of CIGSe starts to appear at 175 °C with a significant increase in intensity above 350 °C. The FWHM of the* A_1 *mode peak decreases until 350 °C indicating an increase in structural ordering in the material. When cooling down, the FWHM further decreases due to a reduction of the phonon-phonon interactions. With increasing temperature, the spectrum shifts to lower wavenumbers as result of the thermal expansion and changes in phonon occupation numbers. After 6 minutes at 600 °C, a decrease in the peak intensity is followed by broadening. In a sample without the Se capping layer, the intensity of the* A_1 *mode peak is lower and only becomes noticeable at a higher temperature of 425 °C. In-situ XRD indicates that CIGSe starts to crystallize above 150 °C with preferential orientation along [112] and that* Cu_2Se *starts to form at 400 °C. Between 200 °C and 400 °C, the crystallite size of (112) CIGSe increases from 7 to 52 nm. For the sample without the Se capping layer, the crystallite size first increases at 200 °C and then again above 350 °C, reaching a maximum size of 50 nm at 600 °C.*

Phase Formation and Microstructural Evolution of Cu_2SnS_3 Thin Films Grown from Environment-Friendly Solutions

Ritika Sharma and Bhaskar C. Mohanty; Thapar Institute of Engineering and Technology, India

Cu_2SnS_3*(CTS)- a ternary chalcogenide compound with earth abundant and eco-conscious elemental composition has captivated a significant research interest due to its promising electrical and optical properties for application in affordable and sustainable devices such as solar cells, IR sensing, catalysis, thermoelectricity etc. Interestingly, CTS has been claimed to manifest three structural polymorphs (tetragonal, monoclinic and cubic) each substantially influencing its electrical as well as optical properties. Hence, the facts mentioned above suggest the thorough investigation of the fundamental properties of CTS along with the assessment of its potential for photovoltaic applications. Now, while the solution based approaches offer seamless and low cost methods of film fabrication, the presence of multiple compounds of varying stoichiometry in the Cu-Sn-S system makes it very difficult to reliably grow single phase CTS with desired properties. So, our key interest was to prepare CTS thin films of desired stoichiometry and structure by employing a single solution comprising of the chloride salts of Cu and Sn and thiourea as sulphur source in 2- methoxyethanol in appropriate ratios and explore its electrical and optical properties. For that the glass substrate was spin coated with the precursor solution followed by intermediate drying. The post-deposition sulfurization configuration (viz. temperature, dwell time, environment, etc.) strongly affects the reaction pathway and the eventual phases, the parameters were systematically varied to find out the optimum conditions to prepare films of desired properties. XRD, Raman spectroscopy and FESEM confirmed that films sulphurized at 550°C with 0.5g of sulphur in flowing argon for 5 mins were phase pure with dense uniform grains. These films exhibited a bandgap of 1.0 eV with p-type conductivity confirmed by hall measurement and high white-light sensitivity.*

Limitations and Prospects of $NaBiS_2$ Nanocrystals in Solar Cell Applications *Fiona Treber, Sara Baserga and Erik Johansson; Uppsala University, Sweden*

The material class of metal chalcogenides has yielded a lot of promising compounds for optoelectronic devices and solar cells in particular. Besides bulk-based thin film technologies, there are also prominent examples of metal chalcogenide nanocrystals employed as solar cell absorber layers such as PbS and $AgBiS_2$.[1–3] They provide the unique opportunity to tune the materials band gap and other optoelectronic properties through changes in the particle size or through surface treatment and passivation, making compounds available or optimizing them for certain applications they would otherwise be less suitable for.[4] But while the aforementioned two examples have shown great potential with solar cell efficiencies exceeding 10% and 8%, respectively,[2,5] developing new material platforms around non-toxic and earth-abundant materials is still crucial for optimal resource management. In that context, $NaBiS_2$ nanocrystals have been identified as an interesting and promising candidate with a high absorption coefficient, stability and a suitable band gap.[6] However, its implementation into solar cell devices so far has proven to be challenging, but at the same time remains a largely unexplored topic.[7,8]

Therefore, the main focus herein is to investigate what has been preventing $NaBiS_2$ nanocrystals from being applied more successfully in solar cells so far, as well as to explore strategies to overcome these issues. We have found that the conductivity of the nanocrystal film and its passivation remains a limiting factor, properties that are closely tied to the ligands employed in the nanocrystalline system. Results from X-ray photoelectron spectroscopy indicate that ligand exchange does not occur as readily compared to similar systems such as $AgBiS_2$ for commonly used passivation agents like TBAI or EDT. Thus, other compounds and strategies are explored and tested to further a better understanding of the surface chemistry of this system to provide new selection guidelines for improved ligand exchange as a basis for successful device implementation.

KCu_3S_2—Synthesis and Optoelectronic Properties of a Potential Absorber Material for Photovoltaics *Faleela V S, Gurudayal Behera, Aftab Alam and Balasubramaniam Kavaipatti; Indian Institute of Technology Bombay, India*

A possible replacement that alleviates the shortcomings of the dominant light absorbers in solar photovoltaics is *synthesized, and its microstructural, electronic structure, and optical properties are investigated. P-type KCu_3S_2 microcrystals are synthesized using the conventional carbonate method. Structural and morphological properties and composition have been determined using X-ray diffraction, transmission electron microscopy, scanning electron microscopy, and X-ray photoelectron spectroscopy. The compound with nominal composition, $K_{0.82}Cu_{2.83}S_2$, exhibits a direct bandgap of 1.68 eV with a hole concentration of 9.18×10^{19} cm^3. Furthermore, DFT calculations confirm the directly allowed electronic transitions and indicate a high optical transition probability, leading to a remarkably high optical absorption coefficient of 10^5 cm^{-1} in the visible region. This yields a theoretical spectroscopic limited maximum efficiency (SLME) of 26.7% for a film of 7 to 10 µm thick of KCu_3S_2, making it a highly promising candidate as a light absorber in single junction and tandem photovoltaic devices. Moreover, the limiting factors, high carrier concentration, and large bandgap (for single junction solar cell) were tuned by doping with Sb and Se.*

EN02.08.16

Enhancement in Thermoelectric Properties of Tellurium Nanowires by Surface Passivation *Iris Nandhakumar[1], Pawan Kumar[2], Syed Zulfiqar Hussain Shah[1,2] and Kedar Hippalgaonkar[2,3]; [1]University of Southampton, United Kingdom; [2]Institute of Materials Research and Engineering, Singapore; [3]Nanyang Technological University, Singapore*

The pursuit of high-performance thermoelectric materials is of paramount importance in addressing energy sustainability and environmental concerns. Here, we explore the multifaceted impact of sulfur passivation in the matrix of tellurium nanowires (TeNWs), encompassing environmental control, thermoelectric properties, and charge carrier mobility. In this study, we present the facile production of TeNWs using an aqueous solution synthesis approach. The synthesized TeNWs were subsequently subjected to surface modification involving sulfur moieties. Our findings demonstrate that sulfur passivation not only effectively safeguards the nanowires from environmental degradation but also significantly augments their thermoelectric properties. Notably, the highest recorded values were achieved at 560 K for passivated tellurium nanowires, exhibiting a Seebeck coefficient of 246 µV/K, electrical conductivity of 14.2 S/cm, and power factors of 86.7 $\mu W/m\text{-}K^2$. This strategy presents a promising avenue for the development of advanced thermoelectric materials for applications in energy harvesting, waste heat recovery, and sustainable energy conversion technologies

EN02.08.17

Defect-Driven Thermoelectric Performance in Disordered Cd-Doped $AgSbTe_2$ *Sabrine Hachmioune[1,2], Alexander Squires[3], Seán R. Kavanagh[4], Chenguang Zhang[5], Jose Recatala-Gomez[5], Maheswar Repaka[2], Kedar Hippalgaonkar[5,2], Michael B. Sullivan[2] and David O. Scanlon[3]; [1]University College London, United Kingdom; [2]Agency for Science, Technology and Research, Singapore; [3]University of Birmingham, United Kingdom; [4]Harvard University, United States; [5]Nanyang Technological University, Singapore*

With an increasing demand for efficient and environmentally friendly energy conversion technologies, thermoelectric materials play a pivotal role in harnessing waste heat for power generation. In this work, we focus on enhancing the thermoelectric performance of $AgSbTe_2$, a well-known high-performance material that has garnered significant attention for its exceptional performance in mid-temperature range applications.[1] Previous works showed the high ZT could be further improved by Cd-doping to achieve a maximum ZT of 2.6 at 573 K.[2] This improvement in performance was attributed to cationic ordering and tuning of the disorder in the material. This study presents a comprehensive experimental and theoretical investigation of the thermoelectric properties of cadmium-doped silver antimony telluride (Cd-doped AST).

Single-phase Cd-doped AST samples were successfully synthesised, exhibiting notably high-power factor values.

Remarkably, a peak power factor of $\sim 20\ \mu Wcm^{-1}K^{-2}$ *was achieved, demonstrating the material's exceptional electrical conductivity. Furthermore, thermal conductivities as low as* $0.5\ Wm\text{-}1K^{-1}$ *were observed at 330 K. This research also investigates the influence of growing under silver and tellurium poor conditions.*

Employing first-principles hybrid-density functional theory (DFT) calculations and techniques like cluster expansion, we elucidate the true ground-state structure of the system and investigate the role of disorder in the system. With this ground-state, we are able to systematically analyse the defect landscape within $AgSbTe_2$*. By quantifying the concentration and distribution of defects, we unveil their effect on the crystal lattice structure and electronic band structure. The impact of Cd-doping on the electronic band structure can then be analysed to understand the underlying mechanisms responsible for the observed changes in thermoelectric performance.*

By understanding the interplay between disorder-induced defects and thermoelectric performance, we aim to pave the way for the design and optimisation of advanced thermoelectric materials for efficient energy conversion applications. The combined experimental and theoretical approach offers a robust framework for the design and optimisation of thermoelectric materials contributing to the advancement of sustainable energy technologies.

EN02.08.18

Organic Solvent Dispersible MXene for Work Function and Interface Engineering of CQD Photovoltaics *Hyung Ryul You and Jongmin Choi; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

Lead sulfide (PbS) colloidal quantum dots (CQDs), are promising optoelectronic materials owing to their size and shape dependent optical bandgap, high absorption coefficients, multiple exciton generation effect, and facile solution processability. With these benefits, recent remarkable advances in CQD solar cells are achieved by tailoring the CQD surfaces and device architecture. The lead iodide (PbI_2) *based surface passivated CQDs (PbS-I) enabled achieving an outstanding air stable CQD devices, and the thiol-passivated CQDs (PbS-EDT) as hole transporting layer (HTL) mediated the band alignment of CQD solar cells efficiently by virtue of their electron blocking ability originating from shallow conduction band edge level* (E_C)*. The bulk homojunction of CQDs via a cascade surface modification method enabled fabrication of thicker CQD layer and reaching the remarkable power conversion efficiency (PCE) of CQD solar cells surpassing 13%.*
Despite these advances in CQD photovoltaics, some as remaining challenges hinder further improvements of CQD solar cell performances. First, the Fermi-level (E_F) *misalignment between lead iodide treated-photoactive PbS CQD (PbS-I) and PbS-EDT* ($E_{F,Iodide}<E_{F,EDT}$) *made hole accumulation in CQD solar cells. In the solar cells, for efficient charge extraction, the energy level relation of* $E_{F,ETL}>E_{F,active}>E_{F,HTL}$ (E_F *of photoactive layer should be lower than that of the electron transport layer (ETL) and higher than that of the HTL) should be achieved. In this regard, the junction of PbS-I photoactive layer and PbS-EDT HTL is undesirable. The* E_F *alignment of* $E_{F,Iodide}<E_{F,EDT}$ *in conventional CQD solar cell forms the depletion region direction opposed to desirable hole flow. Second, the numerous surface cracks of PbS-EDT HTL formed during the solid-state ligand exchange process can permit the direct contact between PbS-I and metal electrode, which is the electron-blocking free junction.*
To address these problems, this work demonstrates a work function and interface engineering strategy for CQD solar cells using polycatechol-functionalized MXene (PCA-MXene). PCA-MXene facilitates its use as a dopant and an interlayer for CQD solar cells via dispersion in organic solvents, used in the CQD solar cell fabrication process.

This is not feasible with conventional water-borne pristine MXene. PCA-MXene, when used as a dopant, tailors the work function of PbS-I CQDs and resolves the chronic problem of an undesirable depletion region direction at the PbS-I/PbS-EDT interfaces. The 2D structure of the PCA-MXene interlayer, inserted in the PbS-EDT/electrode interfaces, effectively prevents metal penetration into the crack sites during the electrode deposition process. Leveraging these benefits, the PCA-MXene integrated CQD solar cells demonstrated a PCE of 13.6%, compared to the reference device PCE of 12.8%. Moreover, the hydrophobic nature of PCA-MXene on the CQD solar cells facilitated the retention of 73% of the initial PCE after 30 hours of thermal aging in 70°C air (with a relative humidity (RH) of approximately 40%), whereas conventional CQD solar cells retained only 59% of the initial PCE.

EN02.08.19

Nickel Intercalation of Two-Dimensional SnS2 for Enhancing Optical Absorption and Tuning Ultrafast Photoexcited Carrier Dynamics *Camille Williams[1,1], Sepideh Khanmohammadi[1], Kateryna Kushnir[1], Ronald L. Grimm[1], Kristie J. Koski[2] and Lyubov V. Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]University of California, Davis, United States*

Two-dimensional (2D) SnS$_2$ is a layered semiconductor with a band gap in the visible range of spectrum (~ 2.3 eV) and high carrier mobility.[1,2] It has been put forth as a potential material for solar energy conversion.[3] Here, we demonstrate that zerovalent intercalation of atomic Ni into the van der Waals gap of SnS$_2$ can change its optical and electronic properties, allowing absorption of light not only in the blue-green but over the entire visible spectrum. We also find that it significantly changes the lifetime of the charge carriers injected over the 2.3 eV gap. In the case of 400 nm excitation, we find that all optically injected carriers are trapped or recombine within 100 ps, while the lifetime of ~ 3x that is observed in pristine SnS$_2$. We hypothesize that Ni introduces a significant concentration of free carriers which enable broad spectrum absorption, while at the same time introducing additional trap states that limit the photoexcited carrier lifetime. Thus, Ni intercalation can thus be used to engineer the properties of SnS$_2$ for its applications in solar energy conversion as well as for other optoelectronic and photonic applications.

EN02.08.20

Characterization of the Electrical Conductivity and Optical Transmittance of MoS$_2$:PEDOT:PSS Environmentally Friendly System *Luis Felipe Almeida[1], Marcos Vinícius Woiski Barcote[1], Matheus F. F. Neves[1], Mauro S. Ferreira[2], Lucimara S. Roman[1], Maiara Bassi[1] and Camilla K. Oliveira[1]; [1]Universidade Federal do Paraná, Brazil; [2]Trinity College Dublin, The University of Dublin, Ireland*

In this study, an aqueous nanocomposite formed from Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)

(PEDOT:PSS) and two-dimensional molybdenum disulfide (2D MoS_2) was investigated. Nanocomposite thin films were produced by varying the volumetric concentration of PEDOT:PSS added in smaller quantities to the 2D-MoS_2 solution and were analyzed using electron microscopy techniques (TEM and SEM), UV-vis spectroscopy and the results showed an increase in the transmittance of the nanocomposite compared to pure PEDOT:PSS. Electrical characterization at ambient temperature revealed an increase of up to two orders of magnitude in electrical conductivity compared to pure PEDOT:PSS, with a maximum at a specific concentration. Measurements of electrical conductivity at low temperatures and the Mott-VRH model indicate that the polymer may be main responsible for charge transport to the nanocomposite. Further theoretical analysis using Kirchhoff's Circuit approach are consistent with experimental data, elucidating possible avenues to explain the observed peak in electrical conductivity values. These results demonstrate the potential of this nanocomposite, which is simply produced from the mixture of the components with the advantage of being used with the most ecological and universal solvent, water, and the possibility to substitute rigid subtrates in different devices.

EN02.08.21

High Electrical Mobility in Indium Selenide Grown by Molecular Beam Epitaxy (MBE) for High Performance Electronic Devices *Anas I. Abutaha, Abdelmajid Salhi, Atef Zekri, Mujaheed Pasha, Ayman Samara and Said Mansour; Hamad Bin Khalifa University, Qatar*

Numerous optoelectronic/electronic applications rely on high-mobility semiconductors to transport charge carriers efficiently and minimize power dissipation. Indium selenide (In_xSe_y), with its excellent electronic properties, emerged as a promising candidate for next-generation electronic devices. However, achieving and optimizing high electron mobility in In_xSe_y films remains challenging since its polymorphic nature. Molecular Beam Epitaxy (MBE) provides a controlled growth environment for synthesizing high quality semiconductors with precise atomic layer control. In this study, we explore the impact of MBE growth parameters, specifically the growth temperature and Se/In flux ratio, on the structural and morphological characteristics of In_xSe_y on Si (001) substrate. Morphological, structural, and electrical characterization techniques were performed to elucidate the impact of the growth conditions on the crystal structure and the electrical mobility of the grown films. The results indicate that both growth temperature and Se/In flux ratio have significant influence on In_xSe_y properties. A phase map was constructed within growth conditions. The formation of single phase (γ-InSe or γ-In_2Se_3) and mixed phases (γ-InSe and γ-In_2Se_3), occurs in a small and large growth window, respectively. All films exhibited n-type behavior with the highest Hall mobility exceeding 2000 cm^2/Vs achieved for single phase γ-In_2Se_3. The sensitivity of the electrical and morphological properties of In_xSe_y to the growth conditions implies the necessity for precise adjustments of the growth conditions to selectively synthesize single phase γ-InSe or γ-In_2Se_3. Our work paves the way for developing wafer-scale indium selenide as a potential candidate material for high-performance optoelectronic/electronic devices.

EN02.08.22

Determining the Dielectric and Piezoelectric Response of SnSe *Joshua Wahl[1], Jonathan R. Chin[1], Marshall B. Frye[1], Qihua Zhang[2], Maria Hilse[2], Stephanie Law[2] and Lauren M. Garten[1]; [1]Georgia Institute of Technology, United States; [2]The Pennsylvania State University, United States*

Tin selenide (SnSe) is a layered chalcogenide which is predicted to exhibit a piezoelectric coefficient greater than conventional lead-free piezoelectrics such as MoS_2 and AlN. However, bulk SnSe forms in the centrosymmetric Pnma structure while piezoelectricity can only occur in non-centrosymmetric crystal structures. Thus, SnSe can only become piezoelectric by breaking the center of symmetry by either scaling the material down to the monolayer limit or inducing stacking faults. In this work, we demonstrate layer control in SnSe down to the monolayer limit with micron scale lateral growth for the determination of the intrinsic piezoelectric response of this *material.*

SnSe films were grown over a temperature range of 250 – 300 °C on (100) MgO by molecular beam epitaxy. X-ray photoelectron spectroscopy shows that films grown using a Se:Sn flux ratio of 1.17:1 or greater exhibit 1:1 Se:Sn stoichiometry. Raman spectroscopy fits to the Pnma phase of SnSe for thick films, with a clear shift in the A^1_g *and* B^1_{3g} *upon scaling down to the monolayer. The monolayer thickness is further verified by atomic force microscopy showing a discrete step height of approximately 0.5 nm per layer. Transmission electron microscopy shows stacking faults in films thicker than 10 monolayers that break the center of symmetry along the basal plane direction of the 2D material, creating a net symmetry breaking that enables piezoelectricity beyond a monolayer or through surface effects. Perpendicular sets of planar top contacts were then deposited onto both monolayer and thick SnSe films for a comparison of the dielectric and piezoelectric measurements. The dielectric response is highly anisotropic and thickness dependent with a minimum tanδ of 0.06 when measured in the dark. The impact of layer scaling on the piezoelectric response was measured through wafer flexure. Overall, this work provides insight into the layer control synthesis and electrical anisotropy of a unique class of 2D materials.*

Synthesis and Characterization of $NaBiS_2$ for Application in Energy Conversion Devices *Ana Paula d. Modesto, Tárcio A. Barros and Francisco C. Marques; Universidade Estadual de Campinas, Brazil*

The use of solar energy in photovoltaic form is considered a promising strategic alternative for green and sustainable development. In this way, many materials have been studied over decades. Perovskites are materials that have aroused great interest in the scientific community for providing efficiencies above 25% [1]. However, these inorganic materials are unstable and do not provide durability to the manufactured devices, in addition to using lead, which is toxic. The new trend is to modify these structures looking for greater stability or to look for non-toxic materials [2]. In addition to perovskites, chalcogenides, kasterites and ternary alloys are potential candidates [3]. In this work we investigated the chalcogenide, NaBiS2, using the hydrothermal route, known as a simple methodology, varying the sulfur precursors. The films were obtained using the spin coating deposition technique. The developed materials were investigated by various XRD, UV-Vis, FTIR, XPS and SEM techniques. The solar cells will be manufactured to evaluate the quality of the materials and verify the potential use of the developed materials.

Evaluation of Annealing Temperature on the Properties of $AgBiS_2$ *Ana Paula d. Modesto, Maria E. Suekuni, Tárcio A. Barros and Francisco C. Marques; Universidade Estadual de Campinas, Brazil*

In recent decades, a form of sustainable energy that has been studied and applied in many countries is solar energy in photovoltaic and photocatalytic forms. Highlighting inorganic semiconductor materials, such as germanium, silicon, oxides, binary compounds and alloys. Some of these solution-processed inorganic photovoltaic materials have stood out due to their reduced manufacturing price compared to conventional *production of photovoltaic materials, such as perovskites [1]. However, these materials generally use heavy metals such as lead. An alternative that is being studied to solve this problem are ternary compounds, materials free of heavy metals. Among them, bismuth silver sulfide nanoparticles are being studied. These nanoparticles have a high absorption range, high mobility and high absorption coefficient [2]. The present work aimed to develop and study the ternary compound $AgBiS_2$, as a light-absorbing layer, obtained through solvothermal synthesis, aiming to study the influence of the annealing temperature when the $AgBiS_2$ powder is subjected to temperatures of 100, 200 and 300 °C [3]. The thin films of this material were obtained by spin-coating deposition, being characterized by XDR, FTIR, UV-Vis, XPS and SEM. The solar cells will be manufactured to evaluate the quality of the materials and verify the potential use of the developed materials.*

Scanning Probe Microscopy Investigation of the Effects of Alkali-Fluoride Post Deposition Treatments on Cu(In,Ga)Se_2 Solar Cells *Deepanjan Sharma[1], Nicoleta Nicoara[1], Phillip Jackson[2], Wolfram Witte[2], Dimitrios Hariskos[2] and Sascha Sadewasser[1]; [1]International Iberian Nanotechnology Laboratory, Portugal; [2]Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg, Germany*

Alkali-fluoride (AlkF) post-deposition treatments (PDT) have led to significant increases in the power conversion efficiency of polycrystalline Cu(In,Ga)Se_2 (CIGSe) solar cells. Nevertheless, a full understanding of their role and impact is not yet established. We used Kelvin probe force microscopy (KPFM) to investigate the local electronic properties of grain boundaries (GBs) for CIGSe absorbers with different AlkF-PDTs. The results show a strong difference in the potential variation across the GBs for samples with different alkali fluorides, which correlates with the open-circuit voltage of reference solar cell devices. The findings suggest that heavier alkali lead to better passivation by reducing the density of charged defects at GBs [1]. However, these results rely on surface potential information collected at the surface of the AlkF-PDT CIGSe, and the electronic structure of grain boundaries in the bulk remains unknown [2]. Here, we explore the nano-scale electronic properties of CIGSe absorbers into the bulk of the layer, by using an emerging conductive atomic force microscopy (C-AFM) tomography method. Highly doped diamond-coated AFM tips are scanned repeatedly across the same area using high tip-load forces of several μN, leading to a tip-induced material removal [3,4]. Simultaneously, the local tip-sample current is recorded. The layer-by-layer C-AFM images finally result in a 3D current volume, reaching deep into the bulk of the CIGSe layer. We present how the C-AFM current signal depends on electronic properties such as doping concentration, bandgap, and electron affinity. Furthermore, we developed a methodology for the quantitative analysis of the C-AFM current signals, in consistency with a mechanical model describing the materials removal. The analysis enables to determine the charge-carrier concentration of individual grains in the polycrystalline CIGSe absorber.

For CIGSe with various AlkF-PDT treatments, we find that a lower efficiency solar cell with a KF-PDT shows a stronger inhomogeneity of charge-carrier concentration, while RbF and CsF lead to narrow distributions at higher charge-carrier concentrations. The charge-carrier concentration and its homogeneity relate directly to the open-circuit voltage of solar cell devices, thereby impacting the device performance. Thus, the success of the AlkF-PDT can be hampered by spatial inhomogeneities in the charge-carrier concentration. Furthermore, analysis of grain boundary currents reveals that they behave similar in the bulk to what is observed near the surface.

Investigation of "Optoiontronic Carrier Dynamics" for Cu(In,Ga)Se_2 Photoelectrode During Water Splitting Reaction Kana Ueda and Mutsumi Sugiyama; Tokyo University of Science, Japan

Photoelectrochemical (PEC) hydrogen production, which utilizes solar energy to split water, is a promising method for green hydrogen production with decarbonization. Chalcogenide Cu(In,Ga)Se_2 (CIGS) is an attractive material for highly efficient photoelectrodes [1], and it has an appropriate bandgap range (1.0–1.7 eV) to use a wide range of the solar spectrum. Hence, it is theoretically capable of generating a photocurrent over 30 mA/cm^2. However, several studies using CIGS as the surface have reported lower photocurrent of the photoelectrodes due to the surface recombination on CIGS photoelectrodes [2]. Therefore, the investigation of the water splitting reaction mechanism using CIGS photoelectrodes is of paramount importance in advancing practical water splitting systems.

In this study, the concept of "otptoiontronics" for photoelectrodes, which focuses on the electron–hydrogen ion interactions, is proposed. During the water splitting reaction using photoelectrodes, both "physical elements (optoelectronics)", such as photocarrier excitation and drift, and "chemical elements (ionics)", such as ionic conduction and electrolysis, occur. Therefore, it is necessary to investigate "optoiontronic (optoelectronics + ionics) carrier dynamics" for photoelectrodes in the water splitting reaction.

In this study, the water splitting reaction mechanism at the interface of CIGS photoelectrode/electrolyte will be investigated, in terms of the "optoiontronic carrier dynamics", via a novel in-situ measurement for CIGS photoelectrodes during the water splitting reaction. The "optoiontronic carrier dynamics" during the water splitting reaction using CIGS photoelectrodes, which is related to electron–hydrogen ion interactions at the interface of the photoelectrode/electrolyte, will be revealed.

The Chemical Conversion of a Thin Mo Sacrificial Layer at the Interface Between ITO and Widegap ACIGSe and Its Impact on GaO_x Formation Angelika Demling[1], Rico Grutzler[2], Cristiana Alves[3], Regan Wilks[1,4], Dimitrios Hariskos[2], Rafael Cerqueira[3], Wolfram Witte[2], Sascha Sadewasser[3] and Marcus Baer[1,4,5]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-

Württemberg, Germany; [3]International Iberian Nanotechnology Laboratory, Spain; [4]HZB, Germany; [5]Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Germany

In (Ag,Cu)(In,Ga)Se_2 (ACIGSe)-based thin-film solar cells, molybdenum is commonly used as back contact. At elevated temperatures during absorber deposition, a $MoSe_2$ interlayer is formed [1], which is responsible for the ohmic contact leading to large fill factors [2]. However, for applications like bifacial devices or top cells of multijunction devices, transparent back contacts are required.

For such purposes, various transparent conductive oxides (TCO) such as ZnO:Al (AZO), SnO:F (FTO), In_2O_3:Sn (ITO), In_2O_3:H (IOH) [3], [4], [5] have been suggested. One major obstacle found in these studies is the formation of GaO_x at the absorber/TCO interface at deposition temperatures above 500°C, which deteriorates the device performance. However, Keller et al. found that moderate amounts of GaO_x might not be detrimental, but thicker layers (several tens of nm) cause Ga depletion towards the back of the absorber, which negatively affects charge carrier separation [5].

One opportunity to reduce the formation of GaO_x at the absorber/TCO interface is the addition of a thin, metallic Mo interlayer, which is thought to be converted into $MoSe_2$ during absorber preparation [6], [7].

In our study, we examine the effect of a thin Mo interlayer on the device performance of solar cells based on an ACIGSe/ITO layer stack. The absorber material is optimized for a large band gap (~1.5 eV), achieved by a high GGI (~0.73), but low AAC (~0.09). While a cell without such an interlayer shows an efficiency of less than 1%, a similar cell with an about 10 nm thick Mo layer deposited on the ITO prior to absorber deposition exhibits an efficiency of 10.6%, with the fill factor being more than tripled. A combination of transmission electron microscopy (TEM) and hard X-ray photoemission spectroscopy (HAXPES) confirms that GaO_x forms at the back contact of both samples, however the layer thickness is significantly reduced upon Mo layer insertion. Analysis of the chemical composition of the interface suggests that the metallic Mo is nearly completely converted to $MoSe_2$ and MoO_x. Since the latter is a prominent material to realize charge carrier selective contacts for holes, we suggest its formation together with inhibiting the formation of GaO_x as an explanation for the drastically enhanced cell performance. These findings may provide crucial insights for the optimization of absorber/TCO interfaces in ACIGSe-based multijunction devices.

Copper Dynamics in Chalcogenides—Effects on Band Gap, Crystal Structure and Thermal Conductivity

Yuxuan Wang[1], Marios Zacharias[2], Stephanie Tarczynski[1], Alan Olvera[1], Brandon Buchanan[1], Zhixiong Yin[1], Ella

Fujimori[1], Heather Hare[1], Yiqiao Huang[1], Yimo Hou[1], Sieun Chae[3], Xiao Zhang[1], Liang Qi[1], Emmanouil Kioupakis[1] and Pierre F. Poudeu[1]; [1]University of Michigan–Ann Arbor, United States; [2]Institut National des Sciences Appliquées de Rennes, France; [3]Oregon State University, United States

Solar and thermoelectric energy conversions are two main approaches to generating renewable energy. Many chalcogenide materials possess superior efficiency for future energy materials: CuInGaSe2 and Cu4TiSe4 are both efficient solar absorbers, while Cu2Se offers superior zT values with Earth-abundant and non-toxic elements. The reason lies in superionic Cu vibrations, which creates the phonon-liquid electron-crystal effect, inhibiting heat transport while maintaining high electrical conductivity. However, accurate characterization of the electronic structure remains a challenge due to the strong effects of polymorphism (local disorder), electron-phonon coupling and phonon anharmonicity. Density functional theory calculations on the high-symmetry structure yield semi-metallic behavior. We address the problem by treating the effects of symmetry breaking and high-temperature anharmonic vibrations utilizing the anharmonic special displacement method (ASDM). We determined the ground-state polymorphous structure and obtained a converged bandgap of 0.9 eV, which is in excellent agreement with experimental values. Further, we applied ASDM starting from the polymorphous structure and investigated the band-gap renormalization as a function of temperature, and found that increasing temperature reduces the band gap by 0.06 eV. We lay out a framework and elucidate how Cu dynamics and anharmonicity impact the electronic properties and electronic properties of Cu2Se.

Moreover, by replacing Cu in the Cu2Se FCC sublattice with Zn, we synthesized single crystals of Cu2Zn3Se4 with Cu ions, Zn ions, and vacancies randomly distributed at the tetrahedral sites, according to XRD data. The unusually large 3/8 tetrahedral site vacancy fraction promotes large cation vibrations and high electrical conductivity. We perform molecular dynamics (MD) simulations and find that, while the high-symmetry structure is thermodynamically unfavorable at 0 K, Cu dynamics stabilize the structure at room temperature. Moreover, we observe local motifs that deviate significantly from the octet rule, yet the time-averaged structure supports the high-symmetry cubic picture with randomly occupied tetrahedral sites. Compared to the MD Mean Squared Displacement (MSD) in Cu2Se, Cu2Zn3Se4 exhibits similar values in Se displacements. Yet instead of a continuously increasing Cu MSD, Cu2Zn3Se4 exhibits a plateau in Cu MSD, showing large Cu vibrations without diffusion between tetrahedral sites. Thus, Cu dynamics can also explain why the measured thermal conductivity in Cu2Zn3Se4 is four times larger than Cu2Se, diminishing its thermoelectric performance.

Toward Highly Efficient Kesterite Solar Cell and Module *Hao Xin; Nanjing University of Posts & Telecommunications, China*

The performance of kesterite $Cu_2ZnSn(S,Se)_4$ (CZTSSe) thin film solar cells is seriously limited by large open circuit voltage deficit ($V_{OC,def}$), mainly due to high concentration of defects within the absorber and at the interfaces. To tackle the defect issues, we first mitigated the absorber intrinsic defects by controlling the reaction path/grain growth mechanism of solution processed CZTSSe absorbers. We found the combination of Cu^+-Sn^{4+} precursors produce kesterite structured precursor film that takes direction phase transformation grain growth without involvement of secondary phases, leading to greatly reduced defect concentration and $V_{OC,def}$. Second, we mitigated the absorber defects by extrinsic Ag and Cd alloying through the unique phase transformation grain growth, which further reduced banding tailing and $V_{OC,def}$. Thirdly, the uniform absorber surface enabled us to investigate the heterojunction interface property of CZTSSe/CdS. We found that the CZTSSe/CdS heterojunction is constructed on a Zn-poor surface due to the dissolution of Zn^{2+} during chemical bath deposition. The occupation of Cd^{2+} on Zn site and re-deposition of Zn^{2+} into CdS creates a defective and lattice-mismatched interface. Low-temperature annealing of the CZTSSe/CdS junction drives elemental di-mixing and thus reconstructed an epitaxial interface, which greatly reduces interface recombination and achieved record efficiency of 13%. The above strategies enabled fabrication of kesterite absorber films with high homogeneity and reproducibility, which encouraged us to make kesterite solar cell modules by series integration through laser (P1, P2) and mechanical (P3) scribing. Characterizations show that the three patterns are well established without observation of metallization. Importantly, benefited from solution process, a thicker absorber is deposited in P1 groove than other area, which reduces lateral charge transport resistance and decreases cell to module loss. By optimization of module structure, kesterite solar cell module with certified efficiency of 10.1% has been achieved with an area of 10 cm^2. Our results push one step forward for this low-cost and environmentally benign thin film solar cell to practical application.

$Cu_2Zn(Sn,Ge)(S,Se)_4$ Wide Bandgap Kesterite for Indoor Photovoltaic Application *Yuancai Gong, Alex Jimenez Arguijo, Sergio Giraldo, Joaquim Puigdollers, Zacharie Jehl and Edgardo Saucedo; Universitat Politècnica de Catalunya, Spain*

Indoor photovoltaic (IPV) cells have the potential to power distributed and remote sensors, actuators, and communication devices, enabling the widespread implementation of the Internet of Things (IoT). Commercial (c-Si, CIGS, CdTe) and emerging (perovskite, organic solar cells) photovoltaic technologies face several challenges for indoor applications, including cost, toxicity, stability, and/or spectral mismatch. In contrast, kesterite materials are composed of earth-abundant, non-toxic elements and exhibit excellent stability, with a wide bandgap tunability between 1.0 eV up to 2.1 eV. This technology has recently achieved certified efficiencies of 14.9% under AM1.5G for the narrow band gap (Se-rich; 1.1 eV) compound and 13.1% for wider bandgap (1.5 eV), demonstrating its high efficiency potential.

In this work, we present the first complete theoretical and experimental study of the behavior of kesterite solar cells under indoor illumination conditions, with different high efficiency devices. First, we will show that the most relevant and mature photovoltaic technology, that is c-Si, expectedly drops the performance in indoor conditions due to its narrow band gap. Hence, the use of wide band gap materials is required for a good performance in indoor conditions. We will show that, under indoor conditions, the wide band gap (S-pure; 1.5 eV) can achieve efficiencies above 20%.

The experimental results demonstrate the excellent optoelectronic properties under low injection conditions, showing that the efficiency of narrow bandgap (12% efficiency in AM1.5G conditions) is practically unchanged with the AM1.5G light intensity down to 0.2 suns. To further support the high potential of kesterite materials for low *injection applications we studied the narrow bandgap device performance under simulated indoor conditions by red shifting the typically used indoor spectra, corresponding to the blackbody emission at 2700K, 3000K, 4000K and 5000K. These spectra can be achieved using a calibrated LED based solar simulator. As predicted from the numerical simulation results, the devices demonstrate an outstanding efficiency over 18% for spectrally shifted conditions, and over 13% at 2700K illumination conditions for wide bandgap kesterite (Eg = 1.7 eV) (Figure 1). These results motivate the development of efficient kesterite solar cells with a wider bandgap, specifically tailored for IPV applications. The indoor performance of the wide bandgap kesterite material has been studied using the same experimental procedure, revealing a performance of above 13% under simulated indoor conditions, consistently with the numerical simulation. The charge carrier extraction is analysed with spectral response (External quantum efficiency, EQE) and the changes induced by indoor light are characterized by performing EQE under dark and indoor illumination conditions. Furthermore, to prevent interface recombination and drastically improve the IPV performance two strategies will be presented: (i) Ge alloying to further widen the bandgap and minimize the spectral mismatch, and (ii) device engineering by using passivation interlayers (e.g. Al_2O_3), adjusting the thermal post deposition treatment conditions or employing other electron-selective contacts (e.g. ZnSnO). Therefore, the pathway for achieving efficiencies over 20% for indoor kesterite solar cells will be presented. These original ideas will set the stage for affordable, bio-safe, and durable indoor solar cells. It will also provide a technical approach for the comprehensive design of other emerging PV technologies.*

11:15 AM *EN02.10.03
Atomic-Layer Approaches Towards 'Extremely Thin' Chalcogenide-Based Photovoltaics—A unique Combinatino of Advantages *Julien Bachmann; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany*

Atomic layer deposition (ALD) and variants are techniques ideally suited to the generation of 'extremely thin absorber' (ETA) solar cells, in which three distinct semiconductors are combined as electron transport (TiO_2, ZnO), light absorption (Sb_2S_3, Sb_2Se_3), and hole transport (polythiophenes, V_2O_5) layers.
(1) ALD can deliver a material quality significantly improved with respect to solution processing, with crystals of 10 µm lateral size obtained in planar films of 50 nm thickness.
(2) It enables one to vary and optimize the thickness of each layer systematically.
(3) It offers the opportunity to engineer interfaces with the use of interfacial layers with extreme thickness sensitivity, on the scale of approximately 1 nm.
(4) It enables conformal coatings of non-planar substrates. Parallel arrays of cylindrical, coaxial heterojunctions decouple the paths for light absorption and charge separation. Ordered monolayers of nanospheres scatter near-bandgap light, enhancing its conversion.
(5) Our extension of ALD to the use of precursors dissolved in the liquid phase ('solution ALD' or sALD) expands the range of materials accessible by ALD. It also provides additional experimental tools and an inexpensive access to ALD.
(6) The recent invention of 'atomic-layer additive manufacturing' (ALAM) circumvents the limitations associated with traditional blanket layering methods, opening the door to rapid prototyping approaches.

11:45 AM EN02.10.04
Optimization of Sb_2Se_3 Thin-Film Solar Cells Grown by Selenization of Sb Layer *Victor Bonal[1], Yudania S. Gonzalez[2], Samira Khelifi[3], Beatriz Galiana[4], Nazaret Ruiz-Marín[5], Fernando Chacón-Sánchez[6], José Manuel Merino[1], Rosalia Serna[6] and Raquel Caballero[6]; [1]Universidad Autónoma de Madrid, Spain; [2]Fundació Institut de Recerca en Energia de Catalunya, Spain; [3]Ghent University, Belgium; [4]Universidad Carlos III de Madrid, Spain; [5]Universidad de Cádiz, Spain; [6]Instituto de Óptica-CSIC, Spain*

Low-dimensional antimony-chalcogenide materials have received an outstanding interest for PV devices in the last *years. They show high stability, low environmental impact, low cost, low carbon footprint and high technological flexibility. In particular, $Sb_2(S,Se)_3$ shows a high absorption coefficient > 10^5 cm^{-1}, allowing to reduce the film thickness to 50-500 nm, band gap energy E_g tuneable between 1.2 to 1.8 eV, and, a much lower melting point than that of CIGSe, CdTe and CZTSSe, requiring lower processing temperatures. Currently, efficiencies above 10% have already been achieved for $Sb_2(S,Se)_3$-based solar cells [1]. The versatility of this material makes it very promising for different PV applications.*

In this work, Sb_2Se_3 thin films have been grown by selenization of evaporated Sb layer on Mo/SLG and SLG substrates. Different growth parameters such as the thickness of the precursor Sb layer, the maximum selenization temperature and Se added during the thermal treatment have been investigated on the device performance. XRD, XRF, AFM, SEM, EDX, TEM and ellipsometry techniques have been used to investigate the compositional, structural, morphological and optical properties of the active layer. Independently from the used growth parameters, all absorbers show an orthorhombic structure with [hk1] preferred orientation, and a compact structure free of pinholes. However, the band gap energy E_g of Sb_2Se_3 is modified by the variation of the absorber thickness, the thinner the active layer, the higher the E_g. The best solar cells with ITO/ZnO/CdS/Sb_2Se_3/Mo/SLG substrate configuration correspond to the Sb layer selenized at 340 C, and, when [Se]/[Sb] ratio is not much higher than 1.6. It is also found that the device performance enhances when the absorber thickness is reduced from 1300 nm to 400 nm. A maximum efficiency of 4.9% (active area) is achieved. An increase in the device performance is expected by optimal combination of all the growth parameters, absorber thickness and a fine control of the Se content.

The limitation of the efficiency is not only given by the absorber quality, but also by other layers that build the photovoltaic solar cells. Here, we investigate the effect of the variation of the CdS buffer layer on the performance of the solar cells. For that, TEM investigation of the interface in completed devices has been carried out. The variation of the chemical bath deposition of CdS has an important impact on the short circuit current density J_{SC} that resulted in an improved efficiency from 3.6% to 5.4%. This enhanced performance is very well correlated with the decreased defect concentration from 3.4×10^{17} cm^{-3} to 7.8×10^{16} cm^{-3}, as determined from DLCP and CV measurements. Further investigation is being performed to define the optimal active layer and heterojunction to enhance the devices performance.

Cu_2SiSe_3—A Defect Tolerant, Earth Abundant Semiconductor with PV and Thermoelectric Applications *Adair Nicolson[1], Lauren Borgia[2], Philippa Cox[3], Alex G. Squires[3], Amy L. Prieto[2], James R. Neilson[2] and David O. Scanlon[3]; [1]University College London, United Kingdom; [2]Colorado State University, United States; [3]University of Birmingham, United Kingdom*

Low-cost, non-toxic and earth-abundant materials are a long-sought after target in the photovoltaics research *community. Initially, chalcogenides were the frontrunners to replace Si as the next generation of thin film solar absorbers, however, the initial promise of CIGS and CZTS has since slowed considerably. In this presentation, I will outline our computational and experimental analysis of Cu_2SiSe_3, which was initially identified due to its simple ternary composition, and the favourable difference in charge and size between the cation species, potentially limiting antisite defects and cation disorder. We find it to have an ideal, direct bandgap of 1.52 eV and a maximum efficiency of 30% for a 1.5 µm-thick film at the radiative limit. Using hybrid density functional theory, the formation energies of all intrinsic defects are calculated, revealing the p-type copper vacancy as the dominant defect species, which forms a perturbed host state. Overall, defect concentrations are predicted to be low and have limited impact on non-radiative recombination, as a consequence of the p–d coupling and antibonding character at the valence band maxima.[1] We also present detailed experimental growth and characterisation investigations, and use cluster expansion methods to explore polymorphism in this system.*

Predicting Two-Dimensional Semiconductors Using Conductivity Effective Mass *Wenjun Zhang[1], Zhikun Yao[1] and Lee A. Burton[2]; [1]Shanghai University, China; [2]Tel Aviv University, Israel*

In this project, we investigate the relationship between the conductivity effective mass and exfoliation energy of materials to assess whether automatic sampling of the electron band structure can predict the presence of and ease of separating chemically bonded layers. We assess 22,976 materials from the Materials Project database, screen for only those that are thermodynamically stable and identify the 1,000 materials with the highest standard deviation for p-type and the 1,000 materials with the highest standard deviation for n-type internal conductivity effective mass tensors. We calculate the exfoliation energy of these 2,000 materials and report on the correlation between effective mass and exfoliation energy. A relationship is found which is used to identify a previously unconsidered two-dimensional material and could streamline the modelling of other two-dimensional materials in the future.

Data-Driven Discovery of Novel Chalcogenides for Photovoltaics *Md Habibur Rahman and Arun Kumar Mannodi-Kanakkithodi; Purdue University, United States*

The efficiency of CIGS and CZTS solar cells is significantly limited by defects arising from cation disorder which could potentially act as nonradiative recombination centers for carriers, reducing the overall efficiency of the solar cells [1-2]. Composition engineering offers a promising approach to discover new semiconductors which in addition to showing attractive optoelectronic properties, are also defect-tolerant [3]. In this study, we explored the chemical space of quaternary A_2BCX_4 and ternary ABX_2 chalcogenide semiconductors where X = [S, Se, or Te], focusing on their thermodynamic stability, optoelectronic properties, and defect behavior, by implementing a high-throughput density functional theory (DFT) workflow. We define the A_2BCX_4 chemical space as A = [Na, K, Rb, Cs, Ag, Cu], B = [Mg, Ca, Sr, Ba, Zn, Cd], and C = [Ge, Sn], and the ABX_2 chemical space as A = [Na, K, Rb, Cs, Cu, Ag] and B = [Al, Ga, In], with each compound simulated in both the Stannite and Kesterite phases.
For a total of 540 compounds, we performed geometry optimization using the GGA-PBEsol [6] functional, and the relaxed geometries were used as input to a hybrid HSE06 calculation with spin-orbit coupling (SOC) to accurately calculate the decomposition energy, defined as the tendency to decompose into competing phases A-X, B-X, or C-X phases. 358 compounds were found to be stable to decomposition, and we performed additional HSE06+SOC calculations to determine their electronic band gaps and spectroscopic limited maximum efficiency (SLME) [5]

based on the computed optical absorption spectra. This eventually led us to a list of 16 stable compounds that show an SLME > 32%, suggesting that they could be highly effective absorbers for single-junction solar cells. Finally, we performed detailed point defect calculations on the top candidates to confirm their tolerance to the spontaneous formation of potentially harmful vacancies, self-interstitials, or anti-sites, as well as the nature of equilibrium conductivity and dopability in a given semiconductor [4].
Finally, we expanded our exploration by training random forest regression (RFR) models for each property using descriptors that one-hot encode composition and phase, and additionally include well-known elemental properties of the A/B/C/X species [7]. Using rigorously optimized predictive models, we made property predictions over > 200,000 hypothetical compositions with cation- or anion-site mixing allowed and established an active learning loop to perform new calculations for iteratively improving the models. This exercise led us to hundreds of new alloys that show low decomposition energy, band gap between 1 and 2 eV, and SLME > 30%, at the HSE+SOC level of theory. Defect calculations are performed on the best candidates to evaluate defect tolerance and dopability. Overall, the integration of high-throughput DFT calculations, RFR models, and defect calculations offers significant insights into the design and identification of new, defect-tolerant materials for solar applications.

Phase Transitions in the $BaZrS_3$ Chalcogenide Perovskite Through Machine Learning Potentials *Prakriti Kayastha[1], Erik Fransson[2], Paul Erhart[2] and Lucy Whalley[1]; [1]Northumbria University, United Kingdom; [2]Chalmers University of Technology, Sweden*

Chalcogenide perovskites, particularly BaZrS3, has gained popularity in the last few years due to its great potential as an alternative lead-free photovoltaic absorber material. This is due to promising optoelectronic properties such as defect tolerance, strong dielectric screening, and light absorption [1]. However, some fundamental material physics, in particular polymorphic phase transitions, have not been explored in detail. Experimental studies have given conflicting results with Raman spectroscopy showing no signs of a phase transition[2], whilst XRD studies show an orthorhombic-to-tetragonal phase transition at 800K [3].

In this talk, we will introduce our machine learning potential model trained on perovskite structures with the neuroevolution potential method [4]. Through molecular dynamics calculations, we heat the experimentally reported orthorhombic Pnma phase and observe a first-order phase transition to a tetragonal I4/mcm phase at 610K. Upon further heating, we observe a second-order phase transition from the tetragonal phase to the cubic Pm-3m phase at 880K. We explain the order of these phase transitions through group-subgroup relationships and Landau theory.

Further analysis shows that the phase transitions are mediated through the M and R phonon modes associated with octahedral tilting, as is typically found in perovskite structures [5]. We analyze all possible Glazer tiltings to show that for the $BaZrS_3$ perovskite only the Pnma --> I4/mcm --> Pm-3m phase transition route is accessible *through heating. We will also show a temperature-dependent XRD pattern to support further experimental studies.*

To end, we will outline how various levels of anharmonicity (harmonic, quasi-harmonic, and fully anharmonic) and exchange-correlation functional (PBEsol and HSE06) impact on our predictions, highlighting some of the subtleties and limitations of each method.

Defect States in Bi- and Sb- Chalcogenides Revealed by Combination of Experimental Techniques and DFT Modelling

Daria Miliaieva[1], Vojtech Nadazdy[2], Mykhailo Koltsov[1], Rokas Kondrotas[3], Cibran Lopez[4,4], Claudio Cazorla[4,4], Malle Krunks[1], Ilona Oja Acik[1] and Nicolae Spalatu[1]; [1]Tallinn University of Technology, Estonia; [2]Slovak Academy of Sciences, Slovakia; [3]Center for Physical Sciences and Technology, Lithuania; [4]Universitat Politècnica de Catalunya, Spain

Understanding the nature of the defects, namely point defects, their formation mechanism and the contribution to the properties is essential for device performance improvement. Shallow-level defects with thermal energy of about k_BT from conduction band minimum (CBM) or valence band maximum (VBM) play the major role in the carrier concentrations and conductivity type determination of the material. In contrast, deep-level defect whose activation energy is much higher than k_BT from CBM or VBM is detrimental to photogenerated carrier lifetime and transport (carrier mobility and diffusion length). These defects result in the trap-assisted Shockley–Read–Hall recombination (dominant non-radiation recombination) in solar cells, which is the primary cause of open-circuit voltage loss (Lian et al., 2021).

In the center of our interest were lone-pair ns^2 cation chalcogenides such as Bi_2S_3 and Sb_2S_3, and their $(Sb/Bi)_2S_3$ alloys (with 0, 10, 33, 50, 67, 90, 100 at% Sb_2S_3 content). Here we present the chalcogenides' density of states (DOS) obtained experimentally by energy-resolved electrochemical impedance spectroscopy (ER-EIS). The information from DOS includes (but is not limited to) VBM, CBM, and the energy distribution of defect states - all obtained in several minutes with a simple setup and application technique. The DOS showed good agreement with previously reported DFT calculations, as well as experimental characterization of the chalcogenides using UPS, UV-VIS, and Hall effect measurements. Namely (i) VBM position is at ~ 5 eV; (ii) optical bandgap is of 1.3 eV and 1.7 eV for Bi_2S_3 and Sb_2S_3, respectively; (iii) the major charge carrier density in Bi_2S_3 is of the order of 10^{18} cm^{-1}. Importantly, DOS from ER-EIS directly provides information on the energy distribution of the defect states in the Bi_2S_3, Sb_2S_3 and their alloys. In Bi_2S_3 only shallow defects at CBM were detected. They might be responsible for the well-known n-type conductivity of Bi_2S_3 (Glatz et al., 1963). In Sb_2S_3, besides shallow defects, ER-EIS also revealed midgap states. It corroborates the PL results, in which a significant decrease in the intensity of radiative recombination in Sb_2S_3 compared to Bi_2S_3, which happens due to deep defects, was detected.

In the series of $(Sb/Bi)_2S_3$ alloys, a gradual transformation of the intraband gap states was observed, namely with increasing Sb:Bi ratio the pronounced DOS band of shallow defects at CBM disappeared, while a distinct peak of midgap states appeared. A comparison between the defect energy distribution and the microstructure was made by comparing the experimental and DFT DOS.

*In summary, by combining **ER-EIS, PL, and DFT calculations it was possible to reveal the energy distribution of the defect states and their nature in Bi_2S_3, Sb_2S_3 and their alloys**, which is crucial for their further application in photovoltaics.*

***Ultrathin Chalcogenide Light Harvesters—Charge-Carrier Transport and Fast NIR Photodetectors** Robert Hoye; University of Oxford, United Kingdom*

Bismuth-based semiconductors have gained increasing attention as potential nontoxic alternatives to lead-halide perovskites [1]. Whilst most attention has been on bismuth-halide-based compounds, there is growing interest in broader families of materials, including chalcogenides, such as ABZ_2 materials (A = monovalent cation; B = Bi^{3+} or Sb^{3+}; Z = chalcogen) [2]. This talk discusses our work on two such compounds: $NaBiS_2$ and $AgBiS_2$.

We show $NaBiS_2$ nanocrystals to have a steep absorption onset, with absorption coefficients reaching $>10^5$ cm^{-1} just above its pseudo-direct bandgap of 1.4 eV. Surprisingly, we also observe an ultrafast (picosecond-timescale) photoconductivity decay and long-lived charge-carrier population persisting for over one microsecond in $NaBiS_2$. These unusual features arise due to cation disorder, with inhomogeneous disorder leading to localised S p states forming that contribute to the formation of small hole polarons [3]. Whilst this severely reduces charge-carrier mobilities, we find that it is still possible to extract charge-carriers in photovoltaic devices, with external quantum efficiencies >50% reached at 450 nm wavelength [4].

The second half of this talk covers our recent work on $AgBiS_2$, which also has high absorption strength, such that films only 50 nm thick are required to achieve adequate light absorption. Given the small bandgap of 1.2 eV, we demonstrate the utility of this material in near-infrared photodetectors. We achieve high cut-off frequencies reaching 0.5 MHz at 940 nm wavelength, along with >1 MHz cut-off frequencies in the visible wavelength range. Through detailed characterisation, we reveal the electronic-ionic transport properties of this material, and how these properties can be controlled to achieve fast NIR photodetectors. Finally, we demonstrate the practical application of these devices for heart beat monitoring [5].

Overall, in this talk, the critical role of cation disorder in these ternary chalcogenide systems is revealed, especially how they influence optical absorption and charge-carrier kinetics.

Additive-Assisted Hydrothermal Growth Enabling Defect Passivation and Void Remedy in Antimony Selenosulfide Solar Cells *Yazi Wang, Seunghwan Ji and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Antimony selenosulfide, $Sb_2(S,Se)_3$, has recently emerged as a promising light-absorbing material due to its tunable photovoltaic properties, low toxicity, and robust environmental stability. However, despite these advantages, the current record efficiency for $Sb_2(S,Se)_3$ solar cells significantly lags behind their Shockley-Queisser limit, especially when compared to other well-established chalcogenide-based thin-film solar cells, such as CdTe and $Cu(In,Ga)Se_2$. This underperformance primarily arises from the formation of unfavorable defects, predominately located at deep energy levels, which act as recombination centers, thereby limiting the potential for performance enhancement in $Sb_2(S,Se)_3$ solar cells. Specifically, deep-level defects, such as sulfur vacancy (V_S), have a lower formation energy, leading to severe non-radiative recombination and compromising device performance. In recent years, my research group has continually improved power conversion efficiency of antimony selenosulfide via fine control of additional Se flux during the absorber preparation, rear surface passivation by post-deposition Se treatment, and tailoring bandgap grading by a hybrid growth approach. Most recently, we introduced thioacetamide (TA), a sulfur-containing additive, into the precursor solution for the hydrothermal deposition of $Sb_2(S,Se)_3$. Our results indicate that the incorporation of TA helps in passivating deep-level defects such as sulfur vacancies and in suppressing the formation of large voids within the $Sb_2(S,Se)_3$ absorber. Consequently, $Sb_2(S,Se)_3$ solar cells, with reduced carrier recombination and improved film quality, achieved a power conversion efficiency of 9.04%, with notable improvements in open-circuit voltage and fill factor. This work provides deeper insights into the passivation of deep-level donor-like V_S defects through the incorporation of a sulfur-containing additive, highlighting pathways to enhance the photovoltaic performance of $Sb_2(S,Se)_3$ solar cells.

9:00 AM *EN02.12.03

Interface Engineering for the Efficient Sb_2Se_3 Thin Film Solar Cell *Feng Yan; Arizona State University, United States*

Antimony chalcogenide (Sb2X3, X=S, Se, Te) thin film solar cells have garnered significant interest due to their optimal bandgap, high absorption coefficient, and earth-abundant constituent elements. Interface engineering plays a pivotal role in optimizing the performance of these solar cells, as the interfaces between different layers critically influence charge carrier dynamics. This talk focuses on the systematic investigation and engineering of interfaces in Sb2X3-based thin film solar cells to enhance their efficiency and stability. By employing techniques such as sputtering, and chemical bath deposition (CBD), precise control over interface properties was achieved. The introduction of buffer layers, passivation treatments, and surface modifications were explored to mitigate recombination losses and improve charge extraction. Advanced characterization methods including X-ray photoelectron spectroscopy (XPS), were utilized to analyze the interfacial properties and their impact on device performance. The findings highlight the critical importance of interface quality and the potential of tailored interface engineering to unlock higher efficiencies in antimony chalcogenide thin film solar cells. This work provides a pathway for further optimization and commercial viability of Sb2X3 solar cells, contributing to the advancement of sustainable photovoltaic technologies.

9:30 AM EN02.12.04

Extrinsic p-Type Doping of Sb_2Se_3 Single Crystals and Solar Cells *Thomas Shalvey and Jon Major; University of Liverpool, United Kingdom*

Antimony selenide (Sb_2Se_3) has garnered significant attention as a photovoltaic absorber material due to its promising characteristics, such as a suitable band gap (~1.2 eV), high absorption coefficient, and abundance of constituent elements. One notable feature of Sb_2Se_3 is its low intrinsic carrier concentration at room temperature, with experimental values as low as ~10^{10} cm^{-3} [1]. Inspection of native defects using density functional theory [2] reveals that the Fermi level remains close to the middle of the band gap irrespective of stoichiometry, and single crystals grown from high purity material is found experimentally to be highly insulating regardless of whether they are grown selenium-rich or selenium-poor [3]. This suggests that intrinsic doping is insufficient for achieving the conductivity required for efficient device performance.

Therefore, the necessary conductivity for functional Sb_2Se_3 devices requires extrinsic dopants, most often in the form of unintentional impurities. These impurities can significantly impact device performance, yet they are seldom identified, never mind studied in detail. In standard device architectures, a p-type absorber layer is typically preferred. However, the reliance on unknown, unintentional impurities frequently results in n-type conductivity. This n-type conductivity, although not always explicitly reported, can be inferred from photoemission measurements and often leads to charge separation via an n-n+ heterojunction [3], which is not optimal for device efficiency.

Efforts to achieve p-type doping in Sb_2Se_3 have been explored in the literature, primarily focusing on group 4A elements such as tin (Sn) and lead (Pb). Tin in particular has received considerable attention due to its position in the periodic table, with one less electron than antimony. However, tin tends is often found in the 4+ oxidation state, whereas the 2+ state is required to increase hole density when incorporated substitutionally onto the Sb site (which is in the 3+ state). At present, there has been little consideration of group 2B transition metal elements, which are more likely to be found in the 2+ state, as potential p-type dopants.

In this work, we investigate the potential of cadmium (Cd) and zinc (Zn) to induce p-type doping in Sb_2Se_3. Our approach involves fabricating sample sets of both highly pure single crystals and full solar cell devices in parallel. This dual-faceted strategy allows us to correlate the electrical properties of the doped material in an idealized material system with the performance in a functioning device stack. After investigating a wide range of dopant incorporation levels, we find that both Cd and Zn can contribute effective p-type doping. Cd appears to be a more promising choice of dopant, producing crystals with low resistivity and apparent doping densities in excess of $10^{16}cm^{-3}$, and can therefore comfortably reach the carrier concentrations required in an absorber layer. Initial device tests have shown a significant improvement in the V_{oc} of thin film solar cells compared to baseline devices prepared using commercially available Sb_2Se_3 which includes Cl as an unintentional impurity, as well as intentionally doped Sn doped Sb_2Se_3 source material. Through this study, we aim to gain a deeper understanding of the impact of Cd and Zn doping on the electrical properties and overall performance of Sb_2Se_3 solar cells, providing insights that could lead to more efficient photovoltaic devices.

Variable Bandgap Antimony Sulfide Selenide Prototype PV Modules Produced by Simplified Chemical Deposition *P.Karunakaran Nair, Yareli Colin Garcia, Brenda Jocabed Rodriguez Vazquez, Priyanka Bamola, Enue Barrios Salgado and M.T. Santhamma Nair; Universidad Nacional Autónoma de México, Mexico*

With an optical bandgap (E_g) of 1.1 eV for antimony selenide (Sb_2Se_3) and 1.88 eV for antimony sulfide (Sb_2S_3), *chemical deposition offers a simple and accessible method to build solar cell structures of CdS/$Sb_2S_xSe_{3-x}$. The bandgap of an $Sb_2S_xSe_{3-x}$ absorber can be changed by varying the value of x from 3 (E_g, 1.88 eV) to 0 (E_g = 1.1 eV) through the addition of increasing quantities of sodium selenosulfate (a selenide ion source) during the deposition, lasting for 180 min at 80 °C. In solar cell structures prepared on fluorine-doped tin oxide, SnO_2:F (FTO)/CdS(80 nm)/$Sb_2S_{2.5..0.5}Se_{0.5..2.5}$(180 nm)/graphite, a solar-to-electric energy conversion efficiency (η) of 5.8% is obtained with open circuit voltage (V_{OC}) of 0.485 V, short circuit current density (J_{SC}) of 24 mA cm $^{-2}$ and fill factor (FF) of 0.52 under air mass 1.5 (AM 1.5G, 1000 W m^{-2}) global-tilt solar radiation. Prototype module of ten series -connected cells with an active area of 9 cm^2 prepared on a 5 cm x 5 cm FTO showed V_{OC} of 4.8 V with maximum power of 50 mW. Further scale-up is illustrated with operational stability of these cells being their hallmark is confirmed. In variable composition chemical deposition (VCCD) of $Sb_2S_xSe_{3-x}$ presented here, the material with a higher E_g facilitates a higher V_{OC} and that with a lower-E_g provides a higher J_{SC} and FF. In previous reports, the variable E_g for the $Sb_2S_xSe_{3-x}$ absorber was achieved via sequential deposition in distinct solutions with different chemical compositions, which made the production costlier and delayed. Overall, the VCCD makes innovation in these solar cells simpler, versatile, reproducible, and accessible to research groups.*

Templated Liquid-Phase Growth of Textured Tin Sulfide Films *Olivia Schneble and Rafael Jaramillo; Massachusetts Institute of Technology, United States*

Tin sulfide (SnS) is a layered semiconductor with a band gap of 1.1 eV that is of interest for thermoelectrics and solar cells. It features non-toxic and Earth-abundant elements, excellent stability, good charge carrier mobility, and strong light absorption. However, the highest reported efficiency for SnS solar cells remains below 5%. This poor performance is likely due to defects introduced during film growth, including sulfur vacancies that are understood to be recombination-active lifetime killers. The layered crystal structure also poses challenges of making thin films that are compact and smooth, especially for high film deposition rate. Continued innovation in the growth and processing of SnS thin films is needed to overcome these material limitations and propel technology development.

Here, we extend the method of templated liquid-phase (TLP) growth to make SnS thin films with strong texturing. TLP growth involves depositing a metal thin film, capping it with a thin dielectric layer, and then annealing the film above its melting point in a reactive atmosphere to form a compound. To make SnS, we deposit a Sn metal film and anneal in H_2S gas. This process has previously been demonstrated to make polycrystalline III-V films with large grain size (e.g., InP), but has not previously been reported for chalcogenides. TLP growth of chalcogenide thin films represents a new opportunity in defect control. The high overpressure of H_2S used during metal-co-compound conversion (here, carried out at atmospheric pressure) suggests that films may form with a much lower concentration of chalcogen vacancies than film made by vacuum processing.

We find that TLP growth of SnS on a-plane Al_2O_3 produces single-phase films with a preferred out-of-plane orientation (i.e., texturing). A thin (50 nm) Sn film converts to a rough SnS film with 100-300 nm islands on top of the film. A thicker (200 nm) film converts to a rougher film with approximately 1 µm islands. SnS films grown from uncapped Sn metal have a fine, needle-like morphology, suggestive of high nucleation density and rapid crystal growth. We demonstrate that control of Sn metal de-wetting and the sulfurization rate are important to producing smooth, uniform SnS films. We report on how growth parameters control grain size, electrical conductivity, photoluminescence, and excited-state lifetime. As time allows, we may also present growth of (Sn,Pb)S and (Sn,Pb)Se alloys, also by TLP, of interest for infrared optoelectronics.

10:45 AM EN02.13.02

Experimental Investigation of Carrier Concentration Control in Nitrogen-Doped SnS Thin Films for Solar Cell Applications *Mutsumi Sugiyama and Taketo Tsuchiyama; Tokyo University of Science, Japan*

Chalcogenide-based tin sulfide (SnS) has attracted significant attention as a promising material for fabricating p-type absorber layers in solar cells. However, the development of high-efficiency solar cells using SnS remains elusive. Although nearly 20 years have passed since SnS was first highlighted for its potential in solar cells, current research on SnS solar cells is at a significant crossroads: "Is SnS truly suitable as a solar cell material?" While SnS possesses favorable material properties for solar cells, such as a high absorption coefficient and reasonable bandgap; however, it faces critical challenges, including the difficulty of defect control and carrier instability. The largely unexplored and complex nature of its material properties is a major hindrance in developing high-efficiency solar cells. Among these properties, understanding the behavior of point defects in SnS is fundamental and indispensable. A critical issue is that the primary acceptor (tin vacancy:V_{Sn}) can have a “deep” acceptor level. Therefore, unlike other chalcogenide solar cell materials, such as CIGS and CZTS, which primarily rely on intrinsic defects for carrier generation, SnS may require intentional doping to perform optimally in photovoltaic devices.

We have investigated the sulfurization growth mechanism of SnS thin films [1], band alignment of SnS and n-type layers [2], and fabrication of SnS solar cells. We have also simultaneously revealed the defect properties of SnS [3,4]. In this study, we focused on controlling the carrier concentration and point defects in SnS via nitrogen (N) doping. Controlling the carrier concentration to tune the electrical properties of SnS by doping it with Na [5] or Ag [6] has been proposed. First-principles calculations on N doping in SnS have theoretically shown that N at S site (N_S) defects can act as acceptor levels [7]. Therefore, carrier concentration can be controlled by intentionally doping N_S defects. However, few reports on carrier concentration control by N-doping exist, and many aspects remain unclear. In this study, the effect of N atoms on SnS thin films will be investigated by reactive sputtering with an N_2-Ar mixed gas and sulfurization to control the carrier concentration and film quality of SnS thin films.

Although SnS is a simple, binary material, it forms complex phases and defects. Therefore, our research focused on experimentally elucidating the properties of doped SnS, rather than relying solely on theoretical simulations, We will be introduced N as a dopant to modify the defect landscape, improve the material properties and achieve better solar cell performance. This approach provides a practical understanding of the effect of doping on SnS and revealing the development of efficient SnS-based solar cells.

Tin Chalcogenide Sn(S,Se) Thin Films of Cubic Structure by Vacuum Thermal Evaporation *Fabiola De Bray Sanchez, M.T. Santhamma Nair and P.Karunakaran Nair; Universidad Nacional Autónoma de México, Mexico*

Photovoltaic absorber materials with a cubic crystalline structure, specifically Sn(S,Se)-CUB, exhibit a direct optical bandgap (Eg) ranging from 1.45 to 1.65 eV. These materials are expected to deliver a light-generated current density of 25 to 30 mA/cm^2 and a relatively high open-circuit voltage (Voc) in solar cells. This performance contrasts with the more commonly known orthorhombic (ORT) polymorphs of SnS or SnSe, which have a bandgap of about 1 eV and are known for experiencing significant Voc deficits. While Sn(S,Se) cubic structures are typically synthesized using chemical techniques, achieving this structure through vacuum techniques has proven challenging until recently. It has now been demonstrated that Sn(S,Se) cubic thin films can be produced via vacuum thermal evaporation (TE) at a substrate temperature of approximately 450°C and a carefully controlled low deposition rate of 3 nm/s. At higher deposition rates exceeding 10 nm/min and/or lower substrate temperatures below 350°C, Sn(S,Se)-ORT films with a bandgap close to 1 eV are formed. The addition of selenium (Se) or tin selenide (SnSe) in small quantities (1-20 wt%) to the SnS powder source in the crucible helps maintain the bandgap of the Sn(S,Se)-CUB thin film within the 1.6 to 1.7 eV range. However, higher selenium content results in SnS-Se-ORT films with a bandgap of 1.3 eV, accompanied by an increase in the p-type electrical conductivity from 10^{-6} (for Sn(S,Se)-CUB) to 10^{-3} Ω^{-1} cm-^{1} (for Sn(S,Se)-ORT). Various strategies are being explored to optimize tin chalcogenide solar cells, with a particular focus on increasing the Voc towards 0.5 V. These efforts are crucial for enhancing the overall efficiency and viability of these solar cells.

Chemically Deposited SnS Thin Film Solar Cells *Fernando Ayala Mato, Luis Arturo López Cruz, P.Karunakaran Nair and M.T. Santhamma Nair; Universidad Nacional Autónoma de México, Mexico*

Sn(II) sulfide exists naturally as a dark brown mineral, herzenbergite, having orthorhombic crystal structure with a = 0.434 nm, b = 1.116 nm, and c = 0.398 nm. In chemically deposited thin films and nanocrystals, a cubic crystalline structure (a = 1.16 nm) having 32 SnS units per cell has also been reported. Thin films of the material deposited by chemical bath method, depending on the temperature and chemical composition of the deposition bath, show either the orthorhombic SnS(ORT), or cubic SnS(CUB) structure with optical bandgaps, E_g, of 1.1 or 1.74 eV, respectively. These films are of p-type conductivity: 10^{-4} $(\Omega\ \mathrm{cm})^{-1}$ for the SnS(ORT) films and 10^{-6} $(\Omega\ \mathrm{cm})^{-1}$ for the SnS(CUB) films. In this work, we report solar cells of both these crystal structures prepared by sequential deposition on glass substrates coated with SnO_2:F (FTO) or indium tin oxide, ITO. We used previously reported chemical baths containing soluble metal complexes and thioacetamide or thiourea to deposit the films of Zn(O, S), CdS, and SnS. The superstrate configuration cells with ITO as front contact, glass-ITO/Zn(O, S)-CdS/SnS(CUB)-SnS(ORT)/Ag, showed V_{OC} of up to 398 mV and J_{SC} of 3.2 mA/cm^2. The cell FTO/Zn(O, S)-CdS/SnS-CUB/SnS-ORT/Au-Ag showed V_{OC} of 430 mV, J_{SC} of 3.2 mA/cm^2, and a conversion efficiency η of 0.6 %. With the addition of a thin layer of chemically deposited Cu_xS film between the SnS(ORT) film and the Ag contact, the current density in the cell increased, resulting in FTO/Zn(O, S)-CdS/SnS-CUB/SnS-ORT/CuxS/Ag, showing V_{OC} of 400 mV, J_{SC} of 14.1 mA/cm^2, and η of 1.52 %. Work is in progress in our laboratory to improve the characteristics of these solar cells as well as on developing solar cells of chemically deposited SnS thin films in substrate configuration. We will present the updated results on these investigations.

Defect Density Quantification in Monolayer MoS2 Using Scanning Helium Microscopy (SHeM) *Aleksandar*

Radic, Sam Lambrick, Nick A. von Jeinsen, Ismail Sami, Yiru Zhu, Vivian Perez, Andrew Jardine and Manish Chhowalla; University of Cambridge, United Kingdom

Sulphur vacancy defects mediate a wide range of optoelectronic properties in MoS2, with precise control of defect density allowing for tuneable optoelectronic devices. However, accurate measurement of defect density in monolayer and few-layer samples poses a challenge due to their small scattering cross-sections to photon or electron probes.Conventional lab-based techniques such as Raman and photoluminescence can infer approximate defect density in micro-scale samples via optoelectronic properties, but they require calibration using stoichiometric beam-line XPS. We introduce an ultra-low energy (~64 meV), non-damaging, lab-based technique to quantify the surface defect density in micron-scale monolayer MoS2. Here we show that a recently developed technique, scanning helium microscopy (SHeM), can be used to directly measure vacancy-type defect density in 2D materials by performing atom diffraction from a microscopic spot. SHeM uses a neutral, inert, and thermal energy probe of helium-4 atoms to measure ordered and disordered atom-surface scattering allowing the level of surface order to be inferred. The presented method enables rapid, non-damaging, and material-agnostic lab-based quantification of defect density in 2D materials, a crucial step towards the wider adoption of 2D semiconductors in devices.

Synthesis of High Quality $SrHfS_3$ Thin Films via Sputtering and Two-Step Annealing *Haolei Hui, Lauren Samson and Hao Zeng; University at Buffalo, The State University of New York, United States*

$SrHfS_3$, in its distorted perovskite structure, has been identified as a direct bandgap semiconductor with a bandgap of approximately 2.4 eV, exhibiting strong green photoluminescence [1][2]. This material's high stability and defect tolerance make it a promising candidate for applications such as LEDs. In this study, we report the synthesis of $SrHfS_3$ thin films using magnetron sputtering with elemental metal targets, followed by CS_2 sulfurization. A significant challenge in sputter synthesis using metal targets is the evaporation of Sr during high-temperature processing, leading to off-stoichiometry and deteriorating film quality. Under normal processing conditions, the off-stoichiometry can even prevent the formation of the distorted perovskite phase. To address this challenge, we employed a two-step annealing method. The first step involves low-temperature annealing in CS_2 to allow interdiffusion of metal cations. The reaction with CS_2 leads to the formation of amorphous $SrHfS_x$. The bonding of Sr cation with sulfur prevents the evaporation of Sr and ensures cation stoichiometry. The second step involves high-temperature annealing to form $SrHfS_3$ and crystallizes it into the distorted perovskite structure. This approach enhances the quality of the films and is beneficial for device fabrication.

***Magnetic Field-Driven Emergent States in Uranium Ditelluride** Nicholas P. Butch[1,2]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States*

Uranium ditelluride is an unusual example of a low-temperature superconductor, whose properties include spin-triplet pairing, a nodal energy gap, and possible nontrivial topology. Under the influence of relatively moderate magnetic fields and applied pressures, additional superconducting phases can be stabilized. The identification of these phases and their underlying interactions is a topic of current research. Perhaps the most dramatic example is a reentrant superconducting phase
that is stabilized in magnetic fields between 40T and over 65T, whose origins defy current theoretical frameworks. In this talk, I will discuss recent experimental developments in the study of these superconducting phases and the related magnetic interactions.

11:15 AM EN03.01.02
***Thermoelectric Properties of UX_2Zn_{20} (X = Co, Rh, and Ir) Compounds** William L. Nelson[1,2], Benny Schundelmier[1,2], Jorge Galeano-Cabral[1,2], Ryan Baumbach[3], Theo Siegrist[1,2] and Kaya Wei[1,2]; [1]Florida State University, United States; [2]National High Magnetic Field Laboratory, United States; [3]University of California, Santa Cruz, United States*

Thermoelectric materials have an intrinsic property that allows for conversion between heat energy and electrical energy. This property can be harnessed as society pursues renewable energy sources and more efficient energy usage. However, owing to the relatively low efficiency seen in thermoelectric devices their use is currently very limited. To overcome this challenge, great efforts have been made in the discovery of novel materials and composites with novel structural and electronic properties. Measurements on crystals in the 1-2-20 family ($YbTM_2Zn_{20}$, TM = Co, Rh, and Ir) have revealed enhanced low temperature Seebeck coefficients [1, 2] which could make them useful materials for thermoelectric devices in cryogenic applications. For these materials, the high figure of merit (ZT) originates from f-electron hybridization and reduced thermal conductivity brought on by the sizeable unit cell and phonon mediated "rattling behavior" within the cage-like lattice. In this work, the effects of *chemical substitution on the f-electron hybridization strength and phonon scattering modes will be investigated by replacing Yb with U. We will report on the detailed investigation on the thermoelectric properties of UX_2Zn_{20} (X = Co, Rh, and Ir) single crystals that were grown in a Zn self-flux.*

11:30 AM *EN03.01.03
***Correlated Electronic States in Uranium Intermetallic Systems Studied on Well-Characterized Single Crystals** Yoshinori Haga; Japan Atomic Energy Agency, Japan*

Uranium intermetallic compounds show various physical properties arising from 5f electron behavior. Because of the larger spatial extent of wavefunctions compared to 4f electrons in rare earths, hybridization with ligand electrons and the application of external fields largely influence their behavior. As a consequence, these compounds are extremely sensitive to small amounts of impurities that modify the local chemical environment around uranium. One prominent example is the sample-dependent behavior of the unconventional superconductivity in UTe_2, where superconductivity is absent in 'low-quality' samples. We have successfully identified the origin of 'impurity' in UTe_2 using precise crystal structure and chemical composition analyses. Then, the crystal growth method was improved to grow high-quality samples. [1,2] On the other hand, it is recognized that local symmetry around the uranium site induces characteristic behavior. It is, therefore, important to develop new compounds with novel crystal structures. Characterization and physical properties of several new compounds, including magnetic compounds with a uranium honeycomb network and a uranium cluster in intermetallic compounds, will be reviewed.

SESSION EN03.02: Spectroscopy of Actinides
Session Chairs: Amey Khanolkar and Kevin Vallejo
Monday Afternoon, December 2, 2024
Sheraton, Third Floor, Huntington

1:30 PM *EN03.02.01
***Counting the 5f Electrons of the Actinides** Tonya Vitova; Karlsruhe Institute of Technology, Germany*

The actinides have a complex electronic structure and, as a result, are amongst the elements with the least understood chemical and physical properties in the periodic table. The occupation and role in covalency of the 5f and 6d orbitals is central to understanding the electronic structure of actinides. Advanced experimental tools, able to obtain deep insights into the electronic structure and binding properties of the actinides, are highly desirable. Here, we present two highly sensitive spectroscopic tools.[1] The first is capable of 'counting' the number of 5f electrons localized on an actinide element. The second is sensitive to the level of covalent character of the actinide-ligand bonding. Both tools are based on the multiplet structure present in actinide M_4 edge core-to-core resonant inelastic X-ray scattering (CC-RIXS) maps.[2] The spectral intensity of different many-body final-state multiplets directly depends on the local many-electron ground-state symmetry including the local 5f spin *configuration and electron occupation. By comparing U M_4 edge CC-RIXS data for total of 21 U, Np, Pu and Am compounds, we theoretically and experimentally demonstrate how this type of spectroscopy can be used to compare the number of 5f electrons across the actinide series or bond covalency for different ligands bound to one actinide element.*

The Revolution in Actinide Spectroscopy Driven by X-Ray Emission *James G. Tobin; University of Wisconsin-Oshkosh, United States*

The advent of new, powerful, highly efficient, multi-component, X-ray monochromators used in the detection of tender x-rays has revolutionized spectroscopic investigations of the 5f electronic structure. All of the new experiments are, in essence, variants of X-ray Emission Spectroscopy (XES), where the improved monochromatized detection plays a key role.

A *In HERFD (High Energy Resolution Fluorescence Detection), the monochromatized XES detection allows the performance of a scattering experiment that devolves into a higher resolution version of X-Ray Absorption Spectroscopy (XAS). It has been shown that the M_4 and M_5 spectra are essentially direct measurements of the j-specific ($5f_{5/2}$ and $5f_{7/2}$) Unoccupied Density of States (UDOS), which can be directly correlated with the UDOS from Inverse Photoelectron Spectroscopy (IPES) and Bremsstrahlung Isochromat Spectroscopy (BIS). [1,2] In this case, ligand field density functional theory calculations of the dioxides of thorium, uranium, and plutonium have been combined with high-energy-resolution fluorescence detection (HERFD) in x-ray absorption spectroscopy and inverse photoelectron spectroscopy (IPES) measurements to provide powerful insight into the underlying composition of the unoccupied 5f electronic structure in these 5f localized systems. Fine structure in the 5f5/2 transitions in HERFD can be directly correlated with the fine structure in the leading edge of the IPES. The shapes, intensities, and systematics in HERFD and IPES are explained in a consistent and rigorous fashion in terms of the j-specific 5f electronic structure.*

B *Similarly, Resonant XES has been demonstrated to be Raman in nature, with a 5f-5f transition, not a simple charge transfer transition (ligand 2p to actinide 5f). [3] In this experiment, X-ray resonant Raman spectroscopy (XRRS), a variant of resonant inelastic x-ray scattering, has been used to investigate the two prototype systems, UF4 and UO2. Both are U5f2 and each is an example of 5f localized, ionic behavior and 5f localized, covalent behavior, respectively. From the M5 XRRS measurements, the 5f band gap in each can be directly determined and, moreover, a clear and powerful sensitivity to 5f covalency emerges.*

C *Finally, the 5f delocalization in U metal has been quantified with the combined 6p & 5f $M_{4,5}$ non-resonant XES, which exhibits strong angular momentum coupling effects. [4] Historically delocalization of the 5f states in the early actinides in general and U metal in particular is significantly important and yet poorly understood. Extant spectroscopic techniques have failed to resolve the situation. Here, it will be shown that x-ray emission* *spectroscopy of the M4,5 levels can provide the needed information, with a distinct difference between the delocalized U metal and localized uranium dioxide and uranium tetrafluoride cases. A peak ratio model, built upon electric dipole selection rules, has been developed and utilized, with quantitative agreement between experiment and theory. Possible expansion to other types of 5f mixing systems will be discussed.*

Charge-density Wave Transitions and Phonon Instabilities in α-U *Volodymyr Buturlim[1], Sabin Regmi[1], Chris Marianetti[2], Michael E. Manley[3], Jason Jeffries[4] and Krzysztof Gofryk[1]; [1]Idaho National Laboratory, United States; [2]Columbia University, United States; [3]Oak Ridge National Laboratory, United States; [4]Lawrence Livermore National Laboratory, United States*

Uranium is one of the only elemental metals in which charge density waves have been observed (the phases are labeled α_1*,* α_2*, and* α_3*). The first transition takes place at 43 K (*α_1*), the second at 38 K (*α_2*), and the last one stabilizes below 25 K (*α_3*). The structure below the transition is complex, consisting of small displacements of the atoms along all three of the orthorhombic axes. Despite the large experimental and theoretical effort, the nature of these transitions is still elusive, but it is believed to be associated with the unique coupling of 5f states, residing in the vicinity of the Fermi level, and the lattice vibrations. Here we present detailed experimental and theoretical studies of low-temperature thermal, thermodynamic, and electronic transport properties of the high-quality single crystals of α-U, across the CDW transitions.*

Growth of ThO_2***,*** UO_2***,*** $U_xTh_{1-x}O_2$ ***and*** CeO_2 ***Single Crystals for Thermal Property Measurements*** *James M. Mann[1], David B. Turner[2], Karl Rickert[3], Timothy Prusnick[3], Amey R. Khanolkar[4], Zilong Hua[4], Stefan Nikodemski[3], Charles J. Reyner[1] and David Hurley[4]; [1]Air Force Research Laboratory, United States; [2]Azimuth Corporation, United States; [3]KBR Inc., United States; [4]Idaho National Laboratory, United States*

High quality single crystals greatly simplify measurements of thermal properties and microstructure defects, especially for complex assessments such as nuclear fuel utility. High melting points, typical of nuclear fuel materials and their surrogates, present a difficult challenge in the synthesis of single crystals for such studies. Materials like UO_2 *and* ThO_2 *that melt at 2865°C and 3390°C, respectively, are beyond traditional melt growth techniques like Czochralski. Therefore, exotic melt techniques including solar furnace, cold crucible, and arc melting have been used to produce crystalline samples. These samples tend to suffer from thermally induced defects, multiple grains, and/or small sample sizes that limit the types of characterization that can be performed.*

Solution growth techniques, including hydrothermal and flux growth, enable the dissolution of refractory materials and recrystallization at significantly lower temperatures.

This talk will focus primarily on the crystal growth of ThO_2, UO_2, $U_xTh_{1-x}O_2$, and CeO_2 as nuclear fuel materials or surrogates. The uranium and thorium bearing oxides were synthesized in supercritical hydrothermal solutions between 650 and 750°C, which is over 2000°C lower than the melting points and thereby avoids thermal defect formation. In these solutions the samples are grown near equilibrium, which further reduces the defects. Under these thermodynamic growth conditions, highly faceted single crystals displaying identifiable crystallographic planes were grown, enabling plane-specific thermal measurements. The CeO_2 single crystals could not be grown in hydrothermal solutions and therefore a Na_2O-B_2O_3 flux was used to produce (111) oriented samples. The crystals spontaneously nucleated on cooler sections of their container's platinum walls as the growth solution was slowly cooled from 1200°C.

The latter half of the talk will discuss the electrical and thermal property measurements of the fuel and fuel candidates before and after irradiation. The crystal samples were irradiated with 2MeV protons at both room temperature and elevated temperature (600°C) to generate desired defect structures such as point detects and dislocation loops. Thermal conductivities of the pristine and irradiated samples were measured in a temperature range of 77-300K using spatial-domain thermoreflectance, and the results were compared to the modeling predictions from density functional theory and Boltzmann transport equations to investigate the scattering mechanisms between phonon-phonon, phonon-electron, and phonon-defect. Important modeling inputs, such as the lattice structure of pristine and irradiated samples and quantitative information of defects, were investigated by using characterization techniques including single crystal X-ray diffraction, Raman spectroscopy, photoluminescence spectroscopy, X-ray fluorescence spectroscopy, Hall, and advanced electron microscopy. This multi-institute effort has provided unique insights into energy transport and defect diffusion of nuclear fuels and fuel candidates in extreme environments.

The Interplay Between Phonon and Magnetic Excitations and Its Impacts on Low-Temperature Thermal Transport in Mixed Uranium Oxides *Saqeeb Adnan[1], Zilong Hua[2], Puspa Upreti[3], James M. Mann[4], David Hurley[2], Michael E. Manley[3] and Marat Khafizov[1]; [1]The Ohio State University, United States; [2]Idaho National Laboratory, United States; [3]Oak Ridge National Laboratory, United States; [4]Air Force Research Laboratory, United States*

The low-temperature anomalous magnetic and thermal properties of uranium dioxide along with its nuclear fuel applications, make it one of the most extensively studied. In this study, we investigate the low-temperature thermal transport properties of uranium-thorium mixed oxide (U-ThO_2) with a wide range of varying thorium concentrations. The thermal conductivity was measured down to cryogenic temperatures using the spatial domain thermoreflectance technique. The interaction between electron spin-waves and magnetoelastic coupling of the electric quadrupoles to phonons results in a unique low-temperature thermal conductivity profile. The presence of magnetic excitation effects above Neel temperature is suggestive of a dynamical Jahn-Teller effect and the phonon-magnon coupling in the paramagnetic phase. The potential interplay between spins and phonons is also captured using high-resolution inelastic X-ray scattering (IXS) measurements. A first principle-based thermal transport model is implemented to isolate the influence of magnetic excitations on phonon lifetime from the experimental results. Analysis of thermal transport and T_{2g} Raman mode behavior indicate two distinct spin-phonon scattering mechanisms regimes. Our results provide new insights into the spin-lattice interaction that dominates the low-temperature thermal transport processes in UO_2 and have implications for the optimization of nuclear fuel materials.

4:15 PM EN03.03.03

Effects of Charge State on Chromium Substitution and Oxygen Vacancy Segregation Energies at Grain Boundaries in Uranium Dioxide *Mack W. Cleveland and Ericmoore Jossou; Massachusetts Institute of Technology, United States*

Uranium dioxide is the main fuel used in light water reactors due to its relative radiation stability, high melting point, and chemical stability. However, fission gas release during reactor operations leads to degradation in thermal conductivity with an associated increase in thermal stresses and swelling. Promoting large grains during fuel sintering slows down fission gas diffusion to grain boundaries and increases fuel plasticity. Transition metal oxide dopants such as chromia are important for tuning this process. Previous work has shown that chromium solubility depends on its charge state, but there is disagreement about what charge states of chromium exist within the bulk versus at the grain boundary. Recent spectroscopic studies of chromia doped uranium dioxide suggest that the charge state of the chromium ion exists in a +3 charge state in the bulk, while a +2 charge state can be found in grain boundaries, challenging previous ab initio simulation work that points to a +2 charge state being energetically favorable in the bulk. To resolve the discrepancies, this work uses density functional theory calculations to identify the relationship between the charge state and the local atomic environment at the grain boundaries. Coincident site lattice grain boundary structures were generated, and chromium substitution energies were calculated while varying the charge state and defect position, allowing the analysis of the charge state's effect on grain boundary segregation energy to inform dopant engineering. This work lays the foundation for a machine-learned interatomic potential to model the chemical behavior of transition metal dopants in actinide oxides beyond the time and length scales that can be modeled by density function theory.

SESSION EN03.04: Advances in Synthesis and Characterization
Session Chairs: Amey Khanolkar and Eteri Svanidze
Tuesday Morning, December 3, 2024

8:45 AM *EN03.04.01

Challenges in Crystal Growth, Structural Characterization and Magnetism of Bulk Actinide Materials *Binod K. Rai[1], Alex Bretana[1], Gregory Morrison[2], Rosalie Greer[1], Krzysztof Gofryk[3] and Hanno z. Loye[2]; [1]Savannah River National Laboratory, United States; [2]University of South Carolina, United States; [3]Idaho National Laboratory, United States*

Actinides, with their unique electronic configurations, are pivotal in advancing research on quantum phenomena and the nuclear industry, promising notable technological breakthroughs. Their 5f-states exhibit dual behavior, involving competing interactions and strong spin-orbit coupling, which manifest in complex magnetic properties like multi-k antiferromagnetic ordering, multipolar ordering, topological superconductivity, and mixed valence states. The intriguing structural and magnetic characteristics of actinide systems are central to scientific inquiry, despite challenges posed by their toxicity, radioactivity, and high reactivity. This presentation will introduce the challenges in crystal synthesis, structural characterization, and magnetic property analysis of actinide oxides. These compounds open new avenues for understanding the unique properties of actinides beyond their typical oxides. The discussion will cover methods for growing less commonly studied actinide telluride and selenide crystals and provide insights into their crystal structures. Additionally, the presentation will explore the challenges associated with delineating the magnetic properties of these materials, aiming to enhance our understanding of *their complex behaviors.*

9:15 AM EN03.04.02

Recent Advances in the Transuranium Compounds Studies at JRC-KA *Jean-Christophe Griveau[1], Éric Colineau[1], Olaf Walter[1,2], Karin Popa[1], Octavian Valu[1,2] and Andries Van Hattem[2]; [1]European Commission, Germany; [2]Delft University of Technology, Netherlands*

Here we report recent studies performed at the JRC-KA (Karlsruhe, Germany) on Actinides based compounds. New devices have been commissioned to perform low temperature measurements on nuclear materials extending fundamental and applied research possibilities and giving access to their thermodynamic, magnetic, electronic, thermal transport properties and especially thermal expansion down to 1.8 K under magnetic field properties. These techniques have supported the examination of re-examination of systems produced in house (Np, Pu, Am based oxides and intermetallic).
We will present results on UO_2 oxides doped by RE (= Nd, La) and Am studies using XRD, heat capacity and magnetization with consideration of the ageing effect induced by 241Am self-heating. Interestingly Americium doping is affectingt magnetic feature of UO_2 the more [1].
Then, we will report on the structural, magnetic and thermodynamic studies of Pu-based perovskite PuAlO3 and PuBaO3 compounds showing intriguing magnetic features (antiferromagnetic at 15 K and ferromagnetic at 164 K ground state, respectively). Both systems present μ_{eff}~0.9 μ_B obtained by a Modified Curie-Weiss law above ordering state in the paramagnetic state in contrary to reported values [2].
Finally, examination of Transuranium Fluoride systems by magnetisation will be reported with tentatively antiferromagnetic ordering developing below 6K.

Thin Film Synthesis of Rare Earth and Actinide Nitrides Using Molecular Beam Epitaxy *Kevin D. Vallejo, Zach Cresswell, Shuxiang Zhou, Volodymyr Buturlim, Sabin Regmi, Brelon J. May and Krzysztof Gofryk; Idaho National Laboratory, United States*

New nuclear energy paradigms require an in-depth understanding of new fuel and cladding materials. Lanthanide- and actinide-based nitride compounds are an understudied group of materials compared to their oxide counterparts, which provide new avenues for nuclear reactor designs. Their 4f and 5f electron shell gives rise to a variety of interesting physics such as unconventional superconductivity. Samarium nitride (SmN) has been recently identified as a material where ferromagnetic order and p-type superconductivity coexist.
Our team will present results on the growth conditions for pure and doped SmN single-crystal thin films using molecular beam epitaxy, and its electronic transport properties as a function of temperature and magnetic field. CeN and UN thin films are also explored. The presence of SmN(111) peaks on (001) substrates indicates an orientation-preference for some material systems. AC magnetic susceptibility studies have shown a range of magnetic behaviors, including paramagnetic and antiferromagnetic. With a potential superconductive transition around ~10 K, SmN and its doping effects on crystal structure and electronic properties are characterized.

Investigating the Thermoelectric Properties of Unconventional Heavy Fermion Superconductor UPt_3 *William L. Nelson[1,2], Benny Schundelmier[1,2], Jorge Galeano-Cabral[1,2], Theo Siegrist[1,2] and Kaya Wei[1,2]; [1]Florida State University, United States; [2]National High Magnetic Field Laboratory, United States*

UPt3 is an unconventional heavy fermion superconductor with multiple low temperature superconducting transitions (550 mK and 500mK) and an enhanced Sommerfeld coefficient of around 430 mJ/mol-K^2 [1]. More recent theoretical work suggests that there may also be a topological aspect to the superconductivity [2]. Given the large Sommerfeld coefficient and the possibility of hybridization between the U 5f electrons and the conduction electrons in the system, UPt_3 shows signatures of being a good thermoelectric material. In this work, powder X-Ray diffraction, Energy-dispersive X-Ray spectroscopy, magnetic properties, resistivity, heat capacity, and thermoelectric measurements are carried out on an arc melted sample of UPt_3. These results will be discussed.

Rara Avis—U^{+5} in Chalcogenides *Anna Berseneva[1,2] and Hanno z. Loye[1]; [1]University of South Carolina, United States; [2]National Renewable Energy Laboratoru, United States*

Chalcogen environments tend to stabilize low oxidation states, thus making the +5 oxidation state in uranium chalcogenides extremely rare: more than 97% of U-containing chalcogenides have oxidation states of U that do not exceed +4. Having one unpaired electron, the magnetism of U^{+5}, $5f^1$, is of significant interest; however, it is underexplored due to a scarcity of examples. This talk arranges around the novel structures of uranium sulfides containing U^{+5}: $Na_2Cu_5US_6$, $Na_3Cu_4US_6$, and $Na_3Cu_4USe_6$; the impact of the uranium oxidation state on the properties will be highlighted. Firstly, I will discuss synthetic challenges to obtain those materials as well as provide support for the uranium oxidation states via bond valence sum analysis and X-ray absorption near edge spectroscopy. Second part of the talk will be focused on the magnetic properties of U^{+5}-sulfides. Magnetic studies on powder and single crystal samples revealed that $Na_2Cu_5US_6$ is an antiferromagnet (T_N = 4.7 K) with anisotropic magnetic behavior. Moving from the $Na_2Cu_5US_6$ framework structure to the related layered $Na_3Cu_4UQ_6$ compositions does not change the magnetic behavior, and bulk measurements on the $Na_3Cu_4UQ_6$ powder showed that it is an antiferromagnet with T_N of 3.4 K (Q = S) and 5.9 K (Q = Se). The magnetic moments derived from the Curie-Weiss law for both $Na_2Cu_5US_6$ and $Na_3Cu_4USe_6$ samples were significantly reduced (1.06–1.08 ��$_B$) and cannot be described by either the spin-only or the total angular momentum models, highlighting the complexity of the interaction between 5f electrons and the ligands. Such a decrease in the magnetic moment can be explained by the covalency contribution of the U–Q bonding, leading to the changes in the electron density of uranium.

11:00 AM EN03.05.03

Thermal Conductivity of UO_2, ThO_2 and U-ThO_2 *Zilong Hua[1], Amey R. Khanolkar[1], Ella K. Pek[1], Saqeeb Adnan[2], Kaustubh Bawane[1], James M. Mann[3], Marat Khafizov[2] and David Hurley[1]; [1]Idaho National Laboratory, United States; [2]The Ohio State University, United States; [3]Air Force Research Laboratory, United States*

Nuclear fuel thermal conductivity directly impacts reactor safety and efficiency. This presentation summarizes our recent research on thermal transport behavior of actinide materials ThO2, UO2, and U-ThO2 in pristine and irradiated states. Through a fundamental analysis of phonon scattering mechanisms, especially with the 5f electron related electron spins and various microstructural defects, we investigate the defect generation and evolution within fuels throughout their service life, and the corresponding influences on their thermal conductivity. These insights will contribute to the advancement of fuel performance codes and pave the way for the development of high thermal conductivity fuels.

11:15 AM EN03.05.04

Understanding Chemical Features of UTe_2 and Their Role in Superconductivity *Eteri Svanidze; Max Planck Institute for Chemical Physics of Solids, Germany*

Unconventional superconductor UTe_2 has attracted much attention since its discovery in 2019. [1,2] *Still, many questions remain regarding the intrinsic crystal structure and its affect on the physical properties. In particular, it has been shown that the crystals of UTe_2 can be grown in several different ways – Te-flux,*[1] *chemical vapor transport,*[3,4] *and salt flux.*[5] *While previous reports*[3,6–8] *have related the differences between T_c, residual resistivity ratio, shape and height of the specific heat anomaly to the particular features of the synthesis route, the complete understanding of underlaying chemical features that cause these differences remains unknown. I will discuss a comprehensive review on the sample-dependence of UTe_2 and provide microscopic insight into the origin of differences, reported so far for this peculiar system.*

Going Beyond Average Structure of Uranium Dioxide Using Neutron Total-Scattering Methods *Lionel Desgranges[1], Gianguido Baldinozzi[2], Henry E. Fischer[3] and Gerry Lander[3]; [1]Commissariat à l'énergie atomique et aux énergies alternatives, France; [2]Université Paris-Saclay, France; [3]Institut Laue-Langevin, France*

Despite a simple fluorite structure, uranium dioxide exhibits original properties, including low temperature AFM order and high temperature predicted superionic conduction. These structural features can be characterized by scattering methods because they induce changes to the long-range average crystalline order. However, their characterization is trickier when they are related to short-range or dynamic phenomena that do not modify the long-range average structure. Total scattering methods are an option for the characterization of short-range and dynamic correlations because they probe the local instantaneous structure and thus can provide information not available by a Rietveld analysis, which describes only a time and space averaged organisation of the structure.

In this talk, we will present the results obtained on UO2 samples by neutron diffraction measured at D4 diffractometer at ILL from 10 to 1300K. We studied the magnetic and nuclear Pair Distribution Functions (PDF) derived from these diffraction data. Two main results will be detailed. Firstly, magnetic correlations at temperatures above TN ranging from 30 to 200K are studied using the so-called "magnetic PDF" that is produced via Fourier transform of the total magnetic diffraction intensity. Just above 30K, no long range magnetic order exists and therefore no magnetic Bragg peaks in the diffraction pattern, but rather broad features of magnetic diffuse scattering which nevertheless lead to sharp peaks in the magnetic PDF(r) that we successfully modelled using the SPINVERT software, allowing to conclude that spin-spin correlations exist above TN up to the fourth nearest neighbor. Above room temperature, only nuclear scattering is significant: the second result concerns the interpretation of the U-O distance anomalies. These distances are smaller than what expected from the average structure model. This feature was interpreted as inelastic contributions of a weakly dispersing transverse phonon branch to the equal-time correlation function, providing an explanation of the oxygen disorder mechanism at high temperature in UO2 (J. Phys.: Condens. Matter 35 (2023) 10LT01) . Recently, we observed a similar effect in CeO2.

9:15 AM EN03.06.02

Phonon Thermal Transport in Uranium Dioxide—A Self-Consistent Perturbation Theory Approach *Shuxiang Zhou[1], Enda Xiao[2], Hao Ma[3,4], Krzysztof Gofryk[1], Chao Jiang[1], Michael E. Manley[3], David Hurley[1] and Chris Marianetti[2]; [1]Idaho National Laboratory, United States; [2]Columbia University, United States; [3]Oak Ridge National Laboratory, United States; [4]University of Science and Technology of China, China*

Computing thermal transport in uranium dioxide (UO_2) remains a formidable challenge for first-principles approache due to the challenges associated with Mott physics. Here we use DFT+U to explore the thermal transport properties, and apply f-orbital occupation matrix control to navigate the many metastable electronic states. Furthermore, irreducible derivative approaches are applied to compute the cubic and quartic phonon interactions in UO_2, with enhanced thermal transport computations by evaluating the phonon Green's function via self-consistent diagrammatic perturbation theory. Our predicted phonon scattering functions and phonon lifetimes at T = 600 K agree well with our inelastic neutron scattering measurements across the entire Brillouin zone, and our thermal conductivity predictions agree well with previous measurements. Nontrivial effects on thermal tranposrt from thermal expansion, interband phonon transitions, and self-consistent contributions are also yielded in UO_2 at high temperatures.

9:30 AM EN03.06.03

Optical Response of Charged Oxygen Vacancies in Wide-Bandgap ThO₂ with GW Correction *Himani Mishra[1], Shuxiang Zhou[1], Linu Malakkal[1], Amey R. Khanolkar[1], David Hurley[1] and Marat Khafizov[2]; [1]Idaho National Laboratory, United States; [2]The Ohio State University, United States*

Experiments suggest that ThO_2 is an optical insulator with a bandgap between 5.0-6.0 eV and the introduction of oxygen vacancy results in an emergence of new optical absorption peak in the visible region of the electromagnetic spectrum. Using a fully ab-initio methodology, we demonstrate how oxygen vacancies effect opto-electronic *properties of ThO_2. The bare energies were calculated using density functional theory, whereas G_0W_0 many-body perturbation theory was utilized to extract the excited-state energies. A coupled electron-hole Bethe-Salpeter equation (BSE) was solved with quasi-particle correction from G_0W_0 calculation revealing the optical signatures of both pristine ThO_2 and ThO_2 containing oxygen vacancies at two different concentrations. Our G_0W_0 calculations reveal that oxygen vacancy at concentration of 1.6 at% reduces the bandgap from 6.6 eV for pristine ThO_2 to 1.06 eV. Consequently, the optical response changes, showing emergence of a new peak at 1.0 eV in the presence of oxygen vacancies, compared to 4.54 eV peak observed in pristine ThO_2 which aligns well with the experimental observations. Furthermore, we investigated the neutral and charged vacancies (+2 charge) within ThO_2 in the G_0W_0 + BSE framework. This comprehensive study of the excited state physics provides valuable insights in to defect physics within ThO_2 and serves as a platform for tuning opto-electronic and transport properties in these materials.*

9:45 AM EN03.06.04
Phonon Anharmonicity Effects at Elevated Temperatures in Actinide Oxides and Surrogates *Amey R. Khanolkar[1], Saqeeb Adnan[2], Md Minaruzzaman[2], Linu Malakkal[1], David Hurley[1] and Marat Khafizov[2]; [1]Idaho National Laboratory, United States; [2]The Ohio State University, United States*

Since thermophysical properties such as thermal conductivity and heat capacity are dictated by lattice vibrations in actinide oxide nuclear fuels, understanding anharmonic interactions of phonons at elevated temperature is crucial for developing accurate predictive tools for fuel behavior at operating temperatures. Raman spectroscopy is a facile means toward studying anharmonic phonon-phonon interactions via changes in the position and linewidth of zone-centered optical phonons with temperature. Here, we investigate the anharmonic behavior of the first-order Raman-active mode in two nuclear fuels (uranium dioxide and thorium dioxide) and a fuel surrogate (cerium dioxide) from room temperature to 1000°C. By examining the temperature-induced changes of the vibrational properties of these fuels/surrogates, the contribution of volume expansion and anharmonic inter-mode coupling to the Raman frequency shift and line width in these systems are reported. Experimental measurements are compared with first principles calculations of phonon dispersion linewidths that account for higher-order phonon scattering processes.

SESSION EN03.07: Characterization, Properties and Performance of Nuclear Fuels
Session Chairs: Zilong Hua and Amey Khanolkar
Wednesday Morning, December 4, 2024
Sheraton, Third Floor, Huntington

10:30 AM *EN03.07.01
Phase-Dependent Properties of Irradiated Metallic Fuels *Assel Aitkaliyeva[1,2], Mitchell Mika[1], Allison Probert[1], Mary Sevart[1], Tiankai Yao[2], Ethan Hisle[2], Tsvetoslav Pavlov[2], Cynthia Adkins[2] and Luca Capriotti[2]; [1]University of Florida, United States; [2]Idaho National Laboratory, United States*

Metallic U-Zr and U-Pu-Zr fuels are being considered for use in fast reactors by Oklo's Aurora, TerraPower's Natrium, and Advanced Reactor Concept's (ARC) ARC-100. The licensing of these new reactors will require comprehensive knowledge of fuel performance and mechanistic fuel performance codes that accurately describe and predict fuel properties. The most prominent irradiation behaviors in metallic U-Zr and U-Pu-Zr fuels (e.g., *constituent redistribution), that set them apart from other fuel forms, depend on key structural features (e.g., phases and porosity) and material properties (thermal and mechanical). Unfortunately, experimental data that captures phase-dependence of material properties is scarce, which prevents us from developing mechanistic physical property models for fuel performance codes. To fill this gap, we examine the microstructure and properties of metallic fuels irradiated in the Experimental Breeder Reactor-II. We will report on the phases and porosity formed within each constituent redistribution region and correlate the microstructure of the fuel with the fuel's thermal and mechanical properties. We compare new findings to historical understanding of constituent redistribution and thermo-mechanical properties, and highlight how modern characterization approaches could help with the development of physics-based models for of these complex fuels.*

11:00 AM *EN03.07.02

Atomic Scale Modelling of the Properties and Behaviour of Oxide Nuclear Fuels *Marjorie Bertolus, Luca Messina, Johann Bouchet, Emeric Bourasseau, Julien Tranchida, Maciej Karcz, Baptiste Labonne, Petra Ospital and Giulia Porto; CEA IRESNE, France*

Ensuring the safety and performance of nuclear reactors requires a comprehensive understanding of the behaviour of nuclear fuels under various conditions. Fuel performance codes, such as the PLEIADES multiphysics platform developed by CEA in collaboration with EDF and Framatome, are essential tools for this purpose. Central to this effort is the precise knowledge of physico-chemical properties across various fuel types, coupled with the formulation of behaviour laws integrating experimental data and modelling results. Leveraging a multiscale modelling approach that starts at the atomic scale, the activities in our laboratory aim at providing input data and laws to the PLEIADES platform. In this context, machine-learning methods are important complementary tools to accelerate traditional methods and facilitate the bridging between the modelling scales.
We will present our activities that make use of a combination of electronic-structure and empirical potential simulations to gain deeper insights into fuel properties and behaviour. We will discuss the development and application of various interatomic potentials for actinide oxides (UO_2, $(U,Pu)O_2$, $(U,Am)O_2$), including machine-learning potentials trained on extensive electronic-structure databases. We will then discuss the investigation of the temperature-dependent and diffusion properties that are crucial for understanding the thermal and irradiation-induced microstructure evolution, respectively. We use the results obtained to provide useful insights on the fuel physical behaviour and experimental measurements. Finally, we will demonstrate how generative machine-learning tools can help accelerating the study of compounds exhibiting chemical disorder, such as mixed actinide oxides.

These activities are included in the PUMMA and PATRICIA projects, which have received funding from the Euratom research and training programme 2019-2020 under grant agreements No 850945022 and 850945077.

11:30 AM *EN03.07.03

Density Functional Theory (DFT) Calculations of Point Defect Properties to Inform Nuclear Fuel Performance Models *David Andersson, Wiiliam Neilson, Michael Cooper, Benjamin Liu, Conor Galvin, Anton Schneider and Christopher Matthews; Los Alamos National Laboratory, United States*

Thermodynamic and kinetic properties of point defects are important for the performance of nuclear fuels in reactors; among others, they influence creep, fission gas release, swelling, densification and thermal conductivity. Being able to predict properties of point defects by density functional theory (DFT) calculations provides an avenue to develop mechanism-based engineering scale simulation codes for fuel performance using a multi-scale approach. In this presentation, DFT methodologies to simulate nuclear fuels will be reviewed. This will be followed by showcasing current applications of DFT to point defect properties of UO_2. For UO_2 the latest DFT methodology *explicitly considers a dispersion correction, spin–orbit interaction, and noncollinear magnetic contributions. The importance of accurate DFT data will be shown by building a point defect model informed by defect energies calculated by DFT and vibrational entropies obtained by empirical potential calculations, followed by predicting point defect concentrations in* $UO_{2\pm x}$ *over a wide range of conditions. Experimental validation is achieved by comparing to experimental data for the deviation of x in* $UO_{2\pm x}$ *as a function of temperature and oxygen partial pressure and to the uranium self-diffusion coefficient for nearly stoichiometric* $UO_{2\pm x}$*. The link between point defect properties and the irradiation response of* UO_2 *is investigated by using the cluster dynamics code Centipede. In addition to the thermodynamic properties, this code captures defect production, self-interactions, sink-reactions, clustering, and kinetic properties governing the response to irradiation. The resulting defect behavior will be connected to in-reactor performance at the engineering scale through diffusion and retention/release of fission gas and creep. The application of similar simulation methodology to other fuel types, such as UN and TRISO fuels, will also be discussed.*

SESSION EN03.08: Actinides for Next-Generation Nuclear Reactor Technologies

ANSTO's Synroc Technology Options for the Treatment of Actinide Wastes from Next Generation Nuclear Reactors *Dan Gregg, Rohan Holmes and Gerry Triani; ANSTO Synroc, Australia*

Future nuclear fuel cycles including the next generation reactors currently being commercially developed will produce actinide wastes that require disposal solutions. As part of the approvals process for these new nuclear facilities, the demonstration of whole of life strategies which provide an ultimate waste disposition pathway is now required by the Nuclear regulator. In any such plan, a key element is treatment of the material into a stable 'wasteform', which can be safely disposed. Therefore, high feasibility solutions for the safe and responsible management of actinide wastes generated from the deployment of new nuclear technologies are essential. However, actinide management is one of the major environmental science challenges of modern society, for example plutonium isotopes have extremely long half-lives (e.g., Pu-239 has a half-life of 24,065 years), are radiologically and chemically-toxic, fissile and require criticality control and safeguards measures. As a result, actinides have a major impact on the risk assessment of any geological repository or disposal scenario.

Synroc technology is uniquely suited to the treatment of actinide wastes as it employs hot-isostatic processing (HIPing) as a consolidation approach where the waste is contained within a canister during consolidation into the final form. Importantly, the technology allows for the production of a range of wasteforms (ceramic, glass, and advanced composite wasteforms such as cermets and glass-ceramics) with the design tailored to maximise actinide immobilization within targeted mineral phases. Such mineral phases are based on natural analogues that have demonstrated their survival in the natural environment over geological timescales where they are impacted by natural processes of alteration and radiation damage. Their study provides a snapshot in time (after millions to billions of years) and therefore demonstratable and predictable long-term chemical and mechanical durability. This presentation will discuss concepts for advanced candidate wasteforms and processing options that use the HIP technology for the immobilization of actinides from advanced reactors and future fuel cycles.

*9:00 AM *EN03.08.02*

Spin Relaxation and Metal–Carbon Bonding in Early Actinide and Lanthanide Organometallic Complexes Probed by Pulsed EPR *Floriana Tuna; The University of Manchester, United Kingdom*

Our comprehension of actinide (An) spin relaxation dynamics and chemical bonds lags behind that of other elements, and will need to improve given the technological as well as fundamental importance of f-block elements [1]. Some key differences in the chemical behaviours of actinides and lanthanides, as well as the differences between different actinides, are ascribed to minor differences in covalency, that is, the degree to which electrons are shared between the f-block element and coordinated ligands [2]. Yet there are almost no direct measures of such covalency for actinides.

This paper will discuss our recent results on studies of early actinide(III) and lanthanide(III) organometallic complexes. Recently we have reported the first pulsed electron paramagnetic resonance (EPR) spectra of actinide (An) complexes with substituted cyclopentadienyl ligands, $[An(Cp^{tt})_3]$ (An(III) = Th(III), U(III); $Cp^{tt} = C_5H_3(^tBu)_2)$, demonstrating that pulsed EPR methods, such as hyperfine sublevel correlation (HYSCORE) spectroscopy, are ideal tools to probe spin densities at the ligand nuclei [2]. This is of great importance because it relates directly to the M-L chemical bond [2]. For $[An(Cp^{tt})_3]$, we found greater spin density on the Cp^{tt} ligands bound to U(III) than Th(III), indicating enhanced covalency for the U(III)-C than Th(III)-C chemical bond, which can be ascribed to the valence electrons residing in the 5f (U) rather than 6d (Th) orbital.

An expansion of this study to the lanthanide (Ln) analogues, $[Ln(Cp^{tt})_3]$ (Ln = Nd, Ce, Sm), has allowed a direct comparison of the valence isoelectronic Nd (III) ($4f^3$) and U(III) ($5f^3$) pair, which is the only comparison available between 4f and 5f M(III) ions that does not require designated radiochemical laboratories. We found the Ln-C bond in $[LnCp^{tt}_3]$ to be predominantly ionic in the sense of minimal transfer of spin density from the 4f to ligand orbitals [3]. We note that HYSCORE studies on a closely related $[Yb(Cp)_3]$ complex, a late Ln complex ($4f^{13}$), showed far more significant transfer of spin density from 4f to Cp ligand, and can hence be described as being "more covalent" in this sense, despite the smaller ionic radius of the Yb(III) ion [4]. This highlights the importance of ligand substituents and Ln ion charge density in controlling the magnitude of 4f metal–ligand interactions, and shows that EPR spectroscopy is a sensitive technique to study these effects.

Equivariant Neural Network Force Fields for 11-Cation Chloride Molten Salts System *Chen Shen[1], Siamak Attarian[1], Mark Asta[2], Izabela Szlufarska[1] and Dane Morgan[1]; [1]University of Wisconsin–Madison, United States; [2]University of California, Berkeley, United States*

Molten salts are a promising class of ionic liquids for clean energy applications, such as nuclear and solar energy.

However, efficient and accurate evaluation of salt properties from a fundamental, microscopic perspective remains challenging. Recently, machine learning interatomic potentials (MLIPs) have emerged as a crucial tool in materials science, combining near ab initio accuracy with the computational efficiency of classical force fields. Standard MLIPs are typically fit to a few chemical species, and recently, there have emerged so-called universal potentials, which often fit 50 or more chemical species. We target a middle ground that treats 10-20 elements with similar chemistry and phases with a goal of achieving almost ab initio accuracy for a large composition space. We describe this type of MLIP for molten salts as a 'SuperSalts' potential. We have developed an efficient workflow to generate such an MLIP for all liquid phase compositions of 11-cation chloride melts, namely LiCl-NaCl-KCl-RbCl-CsCl-MgC2-CaCl2-SrCl2-BaCl2-ZnCl2-ZrCl4. Extensive validations indicate that the SuperSalts potential can predict densities, bulk moduli, radial distribution functions, coordination numbers, potentials of mean force, specific heat capacities, viscosities, and thermal conductivities of multicomponent molten salt systems with near-DFT accuracy, maintaining good transferability across different chemical systems. The fitting uses ~70,000 ab initio training configurations, which is a large training database. However, we believe this SuperSalts potential approach is dramatically more efficient than fitting all the suballoys separately (there are 561 suballoys up to quaternaries (2047 total suballoys)), both in terms of the total number of ab initio calculations required, training time, and human time. The SuperSalts potential also serves as a consistent, validated, one-stop resource. This SuperSalts potential joins other recent results in suggesting a paradigm shift from empirical, semiempirical, and ab initio approaches to a more efficient and accurate machine learning potential approach in molten salt modeling. However, our findings further suggest that a SuperSalts potential could provide a single foundational MLIP for the majority of molten salts of interest.

10:15 AM *EN03.09.01
Machine Learning Generation of Actinide Materials Mingda Li; Massachusetts Institute of Technology, United States

Actinide materials play an essential role in nuclear energy production, and their unique electronic structures, stemming from 5f electrons, provide a rich source for harboring exotic magnetic orderings. These properties hold promising applications in advanced fields such as quantum computing. However, research on candidate materials has long suffered from a data scarcity problem, with discovered actinide compounds representing only a tiny fraction of all possible materials. Additionally, the safety handling requirements of actinide elements pose significant barriers to experimental exploration, emphasizing the need for computation-aided discovery of actinide compounds. In this MRS seminar, we present our latest work using a generative model to discover new actinide, rare-earth, and transition metal compounds with specific lattice type constraints. By augmenting the diffusion process in a diffusion-based generative model, we have successfully generated actinide materials with actinide elements positioned on square, triangular, kagome, and hexagonal lattices. After a multi-staged down selector, additional density-functional theory (DFT) performed on 26,000 generated materials show that half of them are stable to the DFT level. This generative model not only expands the range of potential actinide materials but also *accelerates their discovery, providing a pathway to overcoming the limitations imposed by experimental challenges and data scarcity.*

10:45 AM EN03.09.02

A Density Functional Theory Study of CO Catalytic Conversion on Defected Actinide Dioxide AnO_2 Surface

Shukai Yao, Gaoxue Wang, Enrique Batista and Ping Yang; Los Alamos National Laboratory, United States

Actinide dioxides AnO_2 are the most common forms of nuclear fuels in commercial nuclear reactors. Understanding the surface chemistry of AnO_2 is crucial to the operational safety, efficiency, recycling, and storage of nuclear fuels. Studies have shown that actinide materials could serve as highly efficient catalysts for the activation of H_2, CH_4, NH_3, etc., mainly due to actinide valent 5f electrons characterized by strong electron correlations and various oxides states. However, experimental studies of actinide systems are limited by their elevated safety requirement associated with radioactivity. In this simulation study, we employed first principles atomistic calculations based on density functional theory (DFT) to reveal the catalytic behavior of AnO_2 surface with O vacancies. We observe that O vacancies significantly change the electronic structure of AnO_2 surfaces, and act as the active sites of small molecules adsorption. We will show an example of converting CO, a type of exhaust gases emitted by vehicles on roads that needs to be cleaned for the environmental purpose. We find that the excess electrons on defect sites of AnO_2 enhanced the catalytic activity of CO conversion compared to the pristine AnO_2 surface.

11:00 AM EN03.09.03

Magnetic Excitations of a Nodally-Hybridized Heavy-Fermion Semi-Metal— Application to CeNiSn and UniSn

Peter S. Riseborough; Temple University, United States

We examine the magnetic excitations of an Anderson Lattice Model with a V-shaped pseudogap due to nodal hybridization. The model produces a V-shaped pseudogap in the electron density of states close to the Fermi-Energy, similar to the low-temperature density of states inferred from NMR, break-junction and specific heat measurements on CeNiSn. CeNiSn has been described as a nodally hybridized semi-metal with a finite density of states in the pseudogap. The existence of low-dimensional Fermi-Surface has been inferred from measurements of Shubnikov-de Haas oscillations. The low-dimensional Fermi-surface has been attributed to the existence of metallic surface states, however, photoemission experiments indicate that the Fermi-surface is due to bulk-states. Inelastic neutron scattering experiments also show the existence of a spin-gap and unusual magnetic excitations. The interpretations of the experimental results are controversial. The ALM model with nodal hybridization exhibits degenerate pairs of one-dimensional Fermi-surface located at the center of the pseudogap in accordance with the findings of photoemission experiments. At energies slightly off the Fermi-energy, the constant energy cuts open up and develop into tori with small areas. We calculate the static and dynamic magnetic susceptibilities which show that the system exhibits distinct types of magnetic excitations that compare favorably with the experimentally observed spectra for CeNiSn and UNiSn.

SYMPOSIUM EN04

Phase Change Materials for Energy Conversion and Storage

December 2 - December 5, 2024

Symposium Organizers

Tailoring Chemical Bonds to Design Phase Change Materials *Matthias Wuttig[1,2]; [1]RWTH Aachen University, Germany; [2]Research Center Jülich, Germany*

In applications of phase change materials, one usually switches between the crystalline and the glassy state. In our group, we have been trying to understand and tailor phase change materials for various applications. One challenge we have encountered was a deeper understanding of atomic arrangement and properties of the glassy state of these phase change materials. Glasses are commonly described as disordered counterparts of the corresponding crystals; both usually share the same short-range order, but glasses lack long-range order. Here a quantification of chemical bonding in a series of glasses and their corresponding crystals is performed, employing two quantum-chemical bonding descriptors, the number of electrons transferred and shared between adjacent atoms. For popular glasses like SiO_2, $GeSe_2$ and GeSe, the quantum-chemical bonding descriptors of the glass and the corresponding crystal hardly differ. This explains why these glasses possess a similar short-range order as their crystals. Unconventional glasses, which differ significantly in their short-range order and optical properties from the corresponding crystals are only found in a distinct region of the map spanned by the two bonding descriptors. This region contains crystals of GeTe, Sb_2Te_3 and $GeSb_2Te_4$, which employ metavalent bonding. Hence unconventional glasses are only obtained for solids, whose crystals employ theses peculiar bonds. We can thus employ the map to identify crystals which possess glasses with rather different properties. The map even predicts systematic trends for the property change and speed of crystallization, which helps to tailor the properties of the glasses.
Subsequently, it will be demonstrated that we can also use this design concept to design other classes of functional materials such as thermoelectrics. In particular, we can show how to design optimum dopants for a given thermoelectric material.

11:00 AM EN04.01.02

Expanded Stability and Evidence of a Displacive Phase Transformation in SnSe-PbSe Heteroepitaxial Thin Films

Pooja Reddy[1], Leland Nordin[1], Lillian B. Hughes[2], Anna-Katharina Preidl[1] and Kunal Mukherjee[1]; [1]Stanford University, United States; [2]University of California, Santa Barbara, United States

Phase change materials often transition between amorphous and crystalline states. There are few systems which transition between distinct crystal structures at accessible temperatures, and even fewer which maintain semiconducting characteristics, particularly while retaining semiconducting characteristics rather than shifting to and from an insulating state The PbSe-SnSe chalcogenide materials system is a unique example of both, where a unique interplay occurs between a Sn-rich 2D-bonded layered orthorhombic structure (Pnma) and a Pb-rich 3D-bonded rocksalt structure (Fm3m). These phases have indirect and direct band gaps respectively, and require only a fraction of a unit cell displacement to transform between them [1]. This huge change in bonding results in a large contrast in the electrical, optical, and thermal properties, which can be driven by temperature change and intense light-fields [1,2]. The unusual combination of large property contrast between phases while retaining close proximity in structure has the potential for important phase-change devices, if the bulk two-phase region can be avoided.

Recent developments in PbSnSe have demonstrated a direct transition between the two crystal structures, achieved through high-temperature synthesis (>600 °C) and rapid quenching to stabilize metastable phases [1,3]. In contrast, we have achieved direct low-temperature synthesis (165–300 °C) of epitaxial PbSnSe thin films on GaAs using molecular beam epitaxy (MBE) with an in situ PbSe surface treatment. This approach has significantly reduced the two-phase region, extending the stability of the layered Pnma structure up to $Pb_{0.45}Sn_{0.55}Se$ —beyond the bulk limit near $Pb_{0.25}Sn_{0.75}$ at low temperatures—entirely circumventing the two-phase region [3]. Upon cooling, a single-phase cubic film undergoes a displacive phase transformation to the layered phase, accompanied by notable changes in electronic properties. Cryogenic Hall measurements suggest that this phase transition could facilitate highly doped layered phase PbSnSe films. Moreover, we find that this displacive phase transformation is reversible, with the transformed layered film reverting back to cubic when heated. Additionally, the temperature of this phase transition can be tuned, potentially allowing commercial thermoelectric coolers to leverage these phase-change capabilities.

In addition to expanding the stability of single phase PbSnSe alloys, we access metastable two-phase films of layered and rocksalt grains at compositions of $Pb_{0.50}Sn_{0.50}Se$. And so, we directly probe the microstructure of the 3D to 2D phase transformation by investigating grain boundaries in these two-phase films. Detailed microstructural analysis of these grain boundaries reveals distinct interfaces with specific orientation relationships and strain-relief mechanisms. Importantly, this 3D to 2D transformation occurs laterally with minimal strain. This, in addition to the reversibility of the phase transformation, underscores the potential of the PbSe-SnSe materials system for cyclically operated phase-change devices. The thin film growth method on GaAs not only opens avenues to manipulate the energetic landscape using alloy compositions but also facilitates integration with existing photonic schemes for next-generation phase-change devices.

11:15 AM EN04.01.03

Origin of Polarization in Bismuth Sodium Titanate Based Ceramics

Hangfeng Zhang[1], Marcin Krynski[2], A Dominic Fortes[3], Theo Saunders[1], Matteo Palma[1], Yang Hao[1], Franciszek Krok[2], Haixue Yan[1] and Isaac Abrahams[1]; [1]Queen Mary University of London, United Kingdom; [2]Warsaw University of Technology, Poland; [3]Rutherford Appleton Laboratory, United Kingdom

The classical view of the structural changes that occur at the ferroelectric transition in perovskite structured systems, such as $BaTiO_3$, is that polarization occurs due to the off-center displacement of the B-site cations. Here we show that in the bismuth sodium titanate (BNT) based composition $0.2(Ba_{0.4}Sr_{0.6}TiO_3)$-$0.8(Bi_{0.5}Na_{0.5}TiO_3)$, this model does not accurately describe the structural situation. Such BNT based systems are of interest as lead-free alternatives to currently used materials in a variety of piezo/ferroelectric applications. A combination of high-resolution powder neutron diffraction, impedance spectroscopy and ab initio calculations reveal that Ti^{4+} contributes less than a third in magnitude to the overall polarization and that the displacements of the O^{2-} ions and the A-site cations, particularly Bi^{3+} are very significant. The detailed examination of the ferroelectric transition in this system offers insights applicable to the understanding of such transitions in other ferroelectric perovskites, particularly those containing lone pair elements.

11:30 AM EN04.01.04

Deterministic Steering of Atoms in an Electron Microscope Achieved in the Layered Magnetic Semiconductor CrSBr *Julian Klein[1], Kevin Roccapriore[2], Zdenek Sofer[3] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Chemistry and Technology, Prague, Czechia*

The ability to program physics at the atomic scale into materials is a dream for designing and exploring quantum phenomena on-demand. Although aberration-corrected scanning transmission electron microscopy (STEM) is a strong candidate for this task, achieving deterministic modifications remains challenging. This is due to the need for even higher precision in electron beam control than is currently available, requiring extreme management of distributing electrons in both space and time. Widely studied atomically thin materials, such as hBN, MoS_2 or graphene, are furthermore challenging to manipulate owing to their all-surface nature.

In this talk we will demonstrate the deliberate and repeated atomically precise manipulation of individual Cr atoms in the bulk layered magnetic semiconductor CrSBr [1, 2]. Irradiating an area of multilayer CrSBr with electrons drives a structural phase transformation with Cr atoms becoming mobile and moving into interstitial sites in the van der Waals gap [3]. Leveraging this surprising displacement mechanism, we utilize several beam control strategies we have developed, that can deliver electrons with a positioning precision of sub-20 picometer [4, 5], to control individual Cr atom movement in space and time in multilayer crystals [6]. We show that the precision of our real-time electron beam control enables a quantitative study of displacement kinetics. Using these capabilities, we demonstrate deterministic, repeatable, atom number-conserving and deliberate multi-directional atom steering in a thick specimen (> 10 nm). The approaches and results represent a blueprint towards creating identical optically active spin defects in the solid-state in 2D and bulk materials. This is of strong interest for engineering artificial atomic many-body quantum systems, intentionally controlling physics at the atomic level in materials over microscopic and even macroscopic length scales.

Combining DFTB and Structure-Mapping for the Prediction of Transition Paths in Deactivation of ZnO@Cu Catalysts

Artem Samtsevych, Yihua Song, Christoph Scheurer, Karsten Reuter and Chiara Panosetti; Max Planck Society, Germany

Solid–solid transformations are common in nature and in the aging of functional materials. Understanding the origin of these complex phenomena at the atomistic level is a pre-requisite for the design of long-living active materials. For example, catalysts undergo structural and compositional changes during aging, leading to a decline of their catalytic activity and selectivity. Understanding such transformations is necessary to rationally develop mitigation strategies.

From the energetical point of view, the involved activated processes can be modeled as transitions between basins on a complex, high-dimensional free energy surface (FES). Chain-of-states methods optimize presumed pathways between two structural endpoints on FES towards the minimum energy pathway (MEP), yielding transition state estimates. Using the harmonic approximation to transition state theory (hTST), one can estimate reaction rate constants from the location of saddle points on the FES. However, there are two pitfalls that exist in this scheme that typically limit the extent of accessible spatial and time scales. First, the number of possible transition pathways that must be evaluated grows exponentially with system size and, second, ab initio methods, like density functional theory (DFT), are still too computationally expensive to cover the enormously large region of interest in the configurational space.

The first problem can be solved using advanced techniques for the generation of the initial pathway(s) or, in other words, the mapping of atomic structures onto each other. This can be achieved either by purely geometrical methods (mapping of atomic positions and cells) or by topology-based methods, which map the graphs of interatomic bonds. Both approaches are complementary to each other and generate a diverse set of mappings. The combination of mapping algorithms with the chain-of-states method has recently been merged into a generalized workflow.

To tackle the second problem, we harness the power of machine learning (ML) and incorporate it into an approximate, semi-empirical electronic structure model resulting from Density Functional Tight Binding (DFTB) theory [1]. By doing so, we are able to achieve energetics and electronic properties with an accuracy comparable to DFT at a fraction of the cost. Such an approach is realized by means of DFTB parametrization with a Gaussian Process Regression repulsive potential (GPrep-DFTB) [2].

Previous theoretical and experimental studies have shown that ZnO tends to form a graphitic-like overstructure on a Cu surface (catalytically active system) if it is deposited in thin layers. However, the thicker the ZnO phase grows, the more a wurtzitic ZnO structure, which is catalytically less active, becomes favored [3-5]. We will present the combination of mapping algorithms along with GPrep-DFTB to investigate the phase transformations involved in the aging process in ZnO@Cu catalysts.

SESSION EN04.02: Phase Change Materials, Composites and Application

Session Chairs: Patrick Hopkins and Mary Anne White
Monday Afternoon, December 2, 2024
Hynes, Level 1, Room 108

1:30 PM *EN04.02.01
Phase Change Materials with Tunable Phase Change Properties via Nanocomposite Designs *Haiyan Wang; Purdue University, United States*

Phase change oxides have attracted extensive research interests because of significant functional property changes upon phase change and their potential device applications. In particular, vanadium dioxide (VO_2) has been widely studied as a strongly correlated Mott insulator which exhibits an intriguing metal-insulator switching upon cooling near 340 K (67 °C). The ultrafast and reversible first-order phase transition is coupled with a structural transition from rutile to monoclinic upon cooling. In this talk, a range of VO_2-based nanocomposite designs have been introduced with the goal to tune the phase transition temperature. A broad range of phase transition temperature has been demonstrated from as low as 301.8 K (VO_2– Au) to as high as 360.74 K in VO_2-Pt system. In addition, a unique Li-intercalation process has been introduced to tune the T_c. By controlling the relative potential with respect to Li/Li^+ during the intercalation process, T_c of VO_2 can be effectively and systematically tuned in the window from 326.7 K to 340.8 K. These demonstrations open up new approaches in tuning the VO_2 phase transition towards room temperature device applications and enables future real-time phase change property tuning.

2:00 PM +EN04.02.02
VO_2 for Sensing and Energy Storage *Junqiao Wu, Ruihan Guo, Yuhang Cai and Ravanny Komalig; University of California, Berkeley, United States*

Featuring a thermally driven metal-insulator phase transition (MIT) at 67°C, VO_2 finds potential applications in electronics, optics and thermal management. In our recent efforts, we discovered that the surface conduction of VO_2 is highly sensitive to immersion to aqueous solution of salts. Based on this effect, we develop a high-speed, ion-selective, in-memory sensor that operates without the need for external voltage by leveraging the built-in electric fields in the Helmholtz layer at the VO_2-liquid interface. The in-memory sensor, or memsensor, mimics the neuroplasticity in chemosensory neurons of the model organism Caenorhabditis elegans, and guides a miniature boat to simulate the latter's adaptive chemotaxis in food search. In another application, we exploit the latent heat of the MIT in VO_2 to manage thermal energy dissipation in microelectronics.

Phase Change Materials Application in VR, Soft Robotics and Smart Window *Seung Hwan Ko, Yeongju Jung, Jung Jae Park and Minwoo Kim; Seoul National University, Korea (the Republic of)*

A phase-change material (PCM) is a material which releases/absorbs sufficient energy during phase transition to provide useful heat or cooling. PCMs are generally getting intense attention for thermal energy storage and generation. Besides the traditional energy related application, PCM is expanding its applications to various non-energy related fields. This talk will presents the recent progresses in the applications of PCM in various new fields including (1) virtual reality (VR): a thermo-haptic device that enables the artificial hot and cold sensation in virtual environment, (2) soft robotics: an actuator using large volume deformation during phase change to replace bulky conventional air pump, (3) smart window: a transparency changing devices upon phase change.

3:30 PM *EN04.02.04
Thermal Conductivity and Ultrafast Infrared Spectroscopy to Study the Interplay Among Electron, Phonon

and Interface Scattering of Thin Chalcogenide Films (GST, SiTe and GSST) for Phase Change Memory *Patrick E. Hopkins[1], Kiumars Aryana[1], Eric R. Hoglund[2], Joyeeta Nag[3], Derek Stewart[3], Michael Grobis[3] and Juejun Hu[4]; [1]University of Virginia, United States; [2]Oak Ridge National Laboratory, United States; [3]Western Digital Corporation, United States; [4]Massachusetts Institute of Technology, United States*

Phase change memory (PCM) is a rapidly growing technology that not only offers advancements in storage-class memories but also enables in-memory data processing to overcome the von Neumann bottleneck. In PCMs, data storage is driven by thermal excitation. However, there is limited research regarding PCM thermal properties at length scales close to the memory cell dimensions. Our work first presents a new paradigm to manage thermal transport in memory cells by manipulating the interfacial thermal resistance between the phase change unit and the electrodes without incorporating additional insulating layers. Experimental measurements show a substantial change in interfacial thermal resistance as GST transitions from cubic to hexagonal crystal structure, resulting in a factor of 4 reduction in the effective thermal conductivity. Second, we report on a mechanism to suppress the thermal transport in a representative amorphous chalcogenide system, silicon telluride (SiTe), by nearly an order of magnitude via systematically tailoring the cross-linking network among the atoms. As such, we experimentally demonstrate that in fully dense amorphous SiTe the thermal conductivity can be reduced to as low as 0.10 ± 0.01 W m-1 K-1 for high tellurium content with a density nearly twice that of amorphous silicon. Using ab-initio simulations integrated with lattice dynamics, we attribute the ultralow thermal conductivity of SiTe to the suppressed contribution of extended modes of vibration, namely propagons and diffusons. This localization is the result of reductions in coordination number and a transition from over-constrained to under-constrained atomic network. Finally, we discuss heat transport processes in the quaternary alloy, Ge2Sb2Se4Te, which is one of the most promising material candidates for application in photonic circuits due to its broadband transparency and large optical contrast in the infrared spectrum. Here, we investigate the thermal properties of Ge2Sb2Se4Te and show that upon substituting tellurium with selenium, the thermal transport transitions from an electron dominated to a phonon dominated regime. By implementing an ultrafast mid-infrared pump-probe spectroscopy technique that allows for direct monitoring of electronic and vibrational energy carrier life- times in these materials, we find that this reduction in thermal conductivity is a result of a drastic change in electronic lifetimes of Ge2Sb2Se4Te, leading to a transition from an electron-dominated to a phonon-dominated thermal transport mechanism upon selenium substitution. In addition to thermal conductivity measurements, we provide an extensive study on the thermophysical properties of Ge2Sb2Se4Te thin films such as thermal boundary conductance, specific heat, and sound speed from room temperature to 400 °C across varying thicknesses.

Strong, Scalable and Anisotropic Wood Composites for High-Performance Thermal Energy Storage in Buildings *Bernadette Magalindan[1], Gustavo Felicio-Perruci[1], Yudong Li[2], Kyle Foster[2], Charles Booten[1], Hongbing Lu[1] and Shuang Cui[1,2]; [1]The University of Texas at Dallas, United States; [2]National Renewable Energy Laboratory, United States*

Thermoregulation in America's buildings by heating, ventilation, and air conditioning (HVAC) consumes 11% of the nation's total energy use and emits 309 million metric tons of CO_2 in a single year. A promising solution for energy-efficient thermoregulation is to implement thermal energy storage (TES) in buildings through phase change materials (PCMs) integrated into wood, which is the most used building construction material. Recent efforts have explored the encapsulation of solid-to-liquid PCMs in delignified wood. However, the resulting wood composite is weak due to the removal of lignin, which is the natural binding agent in wood. Additionally, the scalability of delignification methods is limited due to the slow and inhomogeneous permeation kinetics of the chemical treatment. To resolve these issues, we herein report an approach to transform the wood into a microporous, anisotropic, strong, and scalable matrix for PCM encapsulation by selectively removing hemicellulose in wood using a chemical-free, pressurized hot water treatment process that preserves lignin. The exterior of the wood was selectively densified by controlled hot-pressing, enhancing its mechanical strength while allowing high PCM loading within the microporous core of the matrix. Following the PCM infiltration, the composite exhibits a mechanical strength of 51 MPa, comparable to that of natural wood, and achieves a latent heat of 62 J/g for TES. The low-carbon fabrication of the composite in addition to the reduced HVAC-associated carbon emissions enabled by TES holds promise to promote the sustainability of the built environment.

4:15 PM EN04.02.06
A Novel Metal-Wool Phase Change Material for Thermal Energy Storage Applications with Exceptionally High Power Density *Alessandro Ribezzo[1], Saranprabhu Mani Kala[2], Sara Risco Amigó[2], Matteo Morciano[1], Emiliano Borri[2], Luca Bergamasco[1], Gabriel Zsembinszki[2], Matteo Fasano[1], Eliodoro Chiavazzo[1] and Luisa F. Cabeza[2];*
[1]Politecnico di Torino, Italy; [2]Universidad de Lleida, Spain

Phase change materials (PCMs) are widely recognized for their potential in thermal energy storage (TES) systems due to their high latent heat capacity. However, a significant limitation in their practical application is attributed to the low thermal conductivity of the majority of such materials, which is detrimental to the heat transfer rate, particularly during the solidification processes of the PCM. Conventional methods to enhance heat transfer, such as the use of fins, nanoadditives, and metal foams, have demonstrated limited effectiveness, as they are often plagued by issues such as significant volume occupation, segregation tendencies, theoretical versus practical performance gaps, and high production costs. To address these limitations, a novel heat transfer enhancement technique involving the incorporation of metal wool within the TES prototype is proposed. Metal wool consists of metal fibers entangled to form sheets with porosity exceeding 90%, creating a highly conductive three-dimensional path within the PCM matrix. This structure significantly enhances the heat transfer rate and reduces the solidification time, which is the main critical bottleneck in PCM-based TES applications. Moreover, being already present in the market for several applications, metal wools represent a relatively cheap, already available, and flexible solution for PCM-based TES applications, especially for those in which an already built TES tank is available. An experimental campaign was conducted by performing charging and discharging processes of a copper wool-PCM composite, by considering one complete and two partial copper wool patterns within the TES tank. Results demonstrated a substantial reduction in discharging times, ranging from 40% to 80% compared to the baseline case with bulk PCM. The maximum volume increase due to the inclusion of metal wool was less than 4%, ensuring that the same mass of PCM was maintained across all experiments. CFD simulations were performed using COMSOL to complement the experimental work. The comparison between the numerical simulations and experimental measurements was obtained by means of local temperature measurements within the PCM matrix at different locations of the TES tank. A significant challenge in these simulations is the variability in thermophysical properties of the PCM, which are often reported with scattered values in the literature due to differing experimental characterization techniques. These techniques typically involve highly controlled conditions that may not accurately represent mesoscopic application scales. To address this, the CFD model was coupled *with an algorithm to explore the design space of the input parameters, accounting for their variability and enabling a sensitivity analysis to identify key input properties. This approach simplified the numerical model while ensuring accurate representation. The introduction of the copper wool within the numerical simulations required additional parameters to be considered, mainly due to the rough surfaces of the metal fibers and non-ideal contact between metal fibers and PCM, which created a thermal barrier to the heat flux. Validation of the numerical model was achieved for both the baseline case and the complete pattern with minimal discrepancies observed between experimental and numerical PCM (or metal wool-PCM composite) temperature curves over the discharging period. Following validation, the numerical model was used to explore different wool materials, providing a techno-economic overview of their potential impact in practical applications. Furthermore, a comparative analysis was performed between the experimentally tested copper wool and a hypothetical nanocomposite PCM with equivalent thermal performance. Numerical results indicated that a PCM nanocomposite with a thermal conductivity of 2.5 W/mK is required to match the thermal performance of the tested copper wool.*

4:30 PM EN04.02.07

Sustainable Ionanofluids with Silk-Based Carbon Dots for Energy Harvesting and Saving *Tiago A. Duarte[1], Rui F. Pereira[2], Bruno Medronho[3,4], Sílvia C. Nunes[5], Elizaveta S. Maltseva[6], Elena F. Krivoshapkina[6], Alejandro Varela-Dopico[7], Pablo Taboada[7], Lianshe Fu[8], Maria Rute Ferreira Andre[8] and Verónica d. Bermudez[1,1]; [1]Universidade de Trás-os-Montes e Alto Douro, Portugal; [2]Universidade do Minho, Portugal; [3]Universidade do Algarve, Portugal; [4]Mid Sweden University, Sweden; [5]Universidade da Beira Interior, Portugal; [6]ITMO University, Russian Federation; [7]Universidade de Santiago de Compostela, Spain; [8]Universidade de Aveiro, Portugal*

Society has been facing serious global problems associated with world population growth, accelerated industrialization, expanding economies, and rising energy demand. Therefore, heat harvesting, heat storage, heat transportation, heat dissipation, and cooling represent paramount issues.

One way to overcome energy consumption is using the smart city concept. Buildings are the largest energy consumer and one of the largest CO_2 emitters, being responsible for 40% of energy consumption and 36% of greenhouse gas emissions. Windows are known to impact dramatically on the mitigation of the building energy consumption. Smart windows are an attractive technological solution allowing to adjust the sunlight and solar heat inflow in real-time, at the occupant's choice, independently of the geographical location, climate region, season of the year, or building's orientation, thus increasing the building energy performance by minimizing heating and cooling needs indoors, providing more visual and thermal comfort, improving outdoors view, and imparting aesthetic features.

Another niche area where to concentrate efforts is solar energy technology. Due to the unsuitable thermophysical behavior of conventional working fluids, solar thermal and solar photovoltaic technologies have now reached a limit.

Ionanofluids (INFs) may become the next generation of smart energy materials.

A novel INF, composed of glucose-derived carbon dots (CDs) and 1-butyl-3-methylimidazolium chloride ([Bmim]Cl) IL, was introduced [1]. Clean and fast synthesis, yielded a self-standing, water-soluble, viscous, reusable INF with self-improving conductivity, thermotropy around 30-40°C, and ultraviolet-blocking ability. At 36°C a sun-actuated thermotropic (TT) device incorporating a 95% w/w nanofluid aqueous solution exhibited a transmittance variation of 9% at 550/1000 nm, which was amplified to 47/31% via the surface plasmon resonance effect (SPRE).

INFs composed of CDs derived from Bombyx mori silk fibroin (SF) dispersed in a mixture of [Bmim]Cl (IL1) and 1-sulfobutyl-3-methylimidazolium triflate (IL2) were later reported [2]. The syntheses were performed with reaction times of 3, 4, and 5 h, leading to viscous fluids, displaying room temperature emission in the visible spectral range. The INFs demonstrated high heat capacity and thermal conductivity values and converted light into heat efficiently, with photothermal conversion efficiencies of up to 28 %.

Herein SF-based INFs have been incorporated into SF-based films to form the active layer of thermotropic, electrochromic, and all-in-one combined window devices, since SF-doped films present high ionic conductivity and good thermotropic behavior similar to that of the nanofluid aqueous solution.

Insulating Geopolymer Foams Containing Phase Change Materials for Energy-Efficient Building *Zineb Moujoud, Omar Tanane and Abdeslam El Bouari; Hassan II University, Morocco*

The development of eco-innovative insulating materials has intensified to reduce the energy consumption of buildings. Geopolymer foams, characterized by their lightweight structure and high degree of porosity, offer significant reductions in greenhouse gas emissions compared to conventional insulating materials. Incorporating phase change materials (PCMs) into these foams allows them to absorb, store, and release large amounts of energy, which reduces energy consumption and increases the thermal inertia of buildings. Geopolymer foams were produced based on metakaolin through combined peroxide decomposition/saponification foaming method. By weight, 5–15% of PCMs were added to the elaborated geopolymer foams. The produced PCM-geopolymer composites were tested for chemical, physical, and thermal properties. Overall, this study confirms the great potential of PCM-geopolymer composites as sustainable insulation materials for building applications.

SESSION EN04.03: Phase Change Materials for Thermoelectric Applications
Session Chairs: Sang-Kwon Lee and Amin Nozariasbmarz

9:00 AM *EN04.03.01
High Thermoelectric Performance in GeTe-Based Compounds *Takao Mori[1,2]; [1]National Institute for Materials Science, Japan; [2]University of Tsukuba, Japan*

Development of thermoelectric (TE) materials & devices is important, for energy saving via waste heat power generation [1], and as dynamic power sources for IoT sensors, etc. [2]. We are systematically developing novel

principles which can overcome the traditional tradeoffs between the thermoelectric properties, namely to enhance Seebeck coefficient, and selectively lower thermal conductivity, in order to lead to viable high performance TE materials & devices [3 and references therein].
GeTe is an attractive thermoelectric material since it is relatively easy to synthesize and possesses particularly high thermoelectric performance. I will present several of our works and strategies on it. Initially trying to achieve a magnetic enhancement effect, Cr doping was tried in GeTe, and had the serendipitous effect to lower the formation energy of Ge defects. This led to creation of homogenously distributed Ge precipitations and Ge vacancies, coupled with typical band convergence doping to lead to an extremely high figure of merit ZT~2 for a Pb-free material [4]. A high entropy approach of AgInTe2 alloying into GeTe, stabilized the cubic phase, thereby enabling enhanced doping of Bi, leading to the first stable n-type conduction in GeTe [5]. The hidden role of rhombohedral distortion degree on the Ge-vacancy formation energy was revealed and utilized leading to high power factor and average ZT [6]. A combined theoretical and experimental screening of some unusual dopants of GeTe revealed Zr to be an effective dopant [7]. Recently a collaborator work focusing on modifying the charge transfer was able to achieve an exceptional ZT~2.7 [8]. Support from JST Mirai Large-Scale Program (JPMJMI19A1) and collaborators are acknowledged.

Modulation of Crystal Structure and Thermoelectric Properties of GeTe-Based Compounds with Sb and Se Alloying *Cheng-Ruei Wu and Chien-Neng Liao; National Tsing Hua University, Taiwan*

Germanium telluride (GeTe) is a promising thermoelectric material with tunable band structure and transport properties in the middle-high temperature regime. Nevertheless, a rhombohedral-to-cubic phase transition behavior at ~ 700 K raises structural stability concern when implementing GeTe in high-temperature thermoelectric modules. A substantial research effort has been dedicated to electronic band modulation and thermal conductivity reduction through partial cation substitution. Nevertheless, anion substitution in GeTe-based thermoelectrics has received much less attention. The study proposes an entropy engineering approach to stabilize the cubic structure of GeTe-based alloys even at room temperature through high fractions of Sb and Se substitutions in GeTe compounds. In this study, the synthesized GeSbSeTe (GSST-Series) alloys exhibited a single-phase cubic structure, high Seebeck coefficients of 200 – 250 $\mu V K^{-1}$, and extremely low thermal conductivities of 0.66 $W m^{-1}K^{-1}$. The cubic GSST alloy exhibited a $(zT)_{max}$ of 1.24 at 623 K and an averaged $(zT)_{average}$ of 0.82 over the temperature range of 300 – 623 K, which was four times higher than that of the pristine GeTe. The alloys achieve a maximum thermoelectric conversion efficiency of approximately 4.7% at a hot side temperature of 648 K. This work establishes an alternative strategy of manipulating crystal structure and thermoelectric properties of GeTe-based alloys.

Improving the Seebeck Coefficient in Fe_2VAl Material System Guided by Cluster Expansion Computational

Modeling *Tao Fang[1], Wei Chen[2], Russell Taylor[1], Geoffroy Hautier[1], Ian Baker[1] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]Université Catholique de Louvain, Belgium*

Fe_2VAl is a low cost, non-toxic, and mechanically robust promising thermoelectric (TE) material for converting waste heat to electricity. Currently, the Seebeck coefficient and figure of merit (zT) values are comparatively low, which restricts its energy conversion efficiency. From our previous experimental studies, two strategies can be applied to increase the Seebeck. (1) Decreasing the order-disorder phase transition temperature by doping/alloying with other elements, the material will have a higher Seebeck coefficient due to favorable changes in band structures when introducing atomic site disorder. (2) Increasing the bandgap in a finite range can also increase the Seebeck in TE material.

However, experimentally testing the order-disorder phase transition temperatures and band structure with different dopants, stoichiometry and processing conditions is time consuming and low throughput. Theoretical modeling will help greatly in screening for promising candidates. Cluster expansion (CE) is a powerful tool to study the phase transition temperature in an alloy as a function of stoichiometry. Atomic site occupation data shows that the occupation is not 100% even at 1000 K below the L21 to B2 phase transition temperature, which suggest that non-equilibrium processing such as quenching can better preserve the favorable atomic site disorder at the TE working temperature of 300-500 K. By Monte Carlo simulation, the phase transition temperature reaches the maximum when the Al/V ratio is between 1.2 and 1. If we increase the Al composition or V composition beyond this range, the phase transition temperature will decrease, and the Seebeck coefficient will increase. For example, at Al/V=1.3 the order-disorder transition is drastically decreased by 500 K. We also calculated the band structure for the Al-rich and V-rich samples. They both show a finite pseudo bandgap. Therefore, we propose that the uneven distribution of Al and V atoms not only decreases the phase transition temperature, but also increases the Seebeck in Fe_2VAl.

Based on these theoretical predictions, we fabricated the base alloy, Al-rich and V-rich samples and tested the heat capacity and Seebeck coefficient. The trend in temperature-dependent heat capacity matched our calculation quite well in order-disorder transition temperatures, and the Seebeck test confirmed that enhancements in Al-rich and V-rich samples compared to the base alloy. Therefore, our calculation was verified by the experiments. Furthermore, thermal conductivity was decreased due to atomic disorder, which notably improved the zT values.

Our research provides a useful tool to increase the Seebeck coefficient in the Fe_2VAl Heusler alloy. Similar methods to decrease the phase transition temperature, such as external doping or ball milling, can be used to further increase the Seebeck coefficient in the future.

Thermoelectric Materials and Devices for High Power Density Coolers *Amin Nozariasbmarz; Rowan University, United States*

Future advancements in high-power electronics demand robust thermal management methodologies. Thermoelectric coolers (TECs), which operate based on the Peltier effect, present an ideal solution to this challenge. These solid-state TECs offer a lightweight design, a high coefficient of performance (COP), high power density, increased reliability, and flexibility in mounting orientation and shape. In this talk, we will explore the design of TECs for electronics cooling through computational modeling and experimental validation.

Key to optimizing TEC performance is understanding the manipulation of material parameters to influence the scattering processes within materials, thereby decoupling the transport of phonons and electrons. We propose thermoelectric materials suitable for high-power cooling applications. Additionally, critical device parameters *such as device thickness, leg density, and contact resistance are analyzed to determine their impact on TEC performance. Our findings indicate that achieving high cooling power density is possible by enhancing the thermoelectric power factor and optimizing the leg height and packing density of the TECs. Furthermore, scaling TECs and reducing contact resistance have been shown to provide ultra-high cooling power density.*

Thermal Imaging of Thomson and Peltier Effects in Phase Change Materials *Ken-ichi Uchida[1,2]; [1]National Institute for Materials Science, Japan; [2]The University of Tokyo, Japan*

The Seebeck and Peltier effects have been widely studied and used in various thermoelectric technologies, including thermal energy harvesting and solid-state heat pumps. However, basic and applied studies on the Thomson effect, another fundamental thermoelectric effect in conductors, are limited despite the fact that the Thomson effect allows electronic cooling through the application of a temperature gradient bias rather than the construction of junction structures [1-3]. In this talk, we mainly report the observation of a giant Thomson effect that appears owing to magnetic phase transitions [4]. The Thomson coefficient of FeRh-based alloys reaches large values approaching -1 mV K^{-1} around room temperature because of the steep temperature dependence of the Seebeck coefficient associated with the antiferromagnetic–ferromagnetic phase transition. The Thomson coefficient is several orders of magnitude larger than the Seebeck coefficient of the alloys. Using the lock-in thermography technique, we demonstrate that the Thomson cooling can be much larger than Joule heating in the same material even in a nearly steady state. The operation temperature of the giant Thomson effect in the FeRh-based alloys can be tuned over a wide range by applying an external magnetic field or by slightly changing the composition. This findings provide a new direction in the materials science of thermoelectrics and pave the way for thermal management applications using the Thomson effect.
We also report that the thermal imaging of the Peltier effect by lock-in thermography is a powerful technique for easily visualizing phase boundaries in phase change materials.

Solid-State Cooling Based on $TiSe_2$ CDW Phase Transition *Mona Zebarjadi, Md Sabbir Akhanda, Kusal Sachithra Dharmasiri and Despina Louca; University of Virginia, United States*

1T-$TiSe_2$ is a layered semimetal exhibiting CDW phase transition at T_{CDW}=200K. Bipolar transport of electrons and holes is evident in this material at above T_{CDW} and signifies itself in a slow increase in the thermal conductivity with temperature. Simultaneously, the Seebeck coefficient slowly decreases and transitions from electron-dominated transport (negative Seebeck) to hole-dominated transport (positive Seebeck). The resulting small gap opening at the phase transition corresponds to the strong temperature dependence of transport properties during phase change. As a result, we observe a large Thomson coefficient in this material with a peak of 450 μV/K and values larger than 150 μV/K over a 250K temperature range making this sample a potential candidate for Thomson cooling and heat management.

11:30 AM *EN04.03.07

Negative Anomalous Nernst Effect Signals in Mixed-Phase (110)-Oriented FeRh Films Grown on Al_2O_3 Substrates *Sang-Kwon Lee[1], Jae Won Choi[1], Chanho Park[1], Gil-Sung Kim[1], Jung-Min Cho[1], No-Won Park[1], Yun-Ho*

Kim[1], Min Young Jung[1], Seo Hyoung Chang[1], Md Sabbir Akhanda[2], Bellave Shivaram[2], Steven Bennett[3] and Mona Zebarjadi[2]; [1]Chung-Ang University, Korea (the Republic of); [2]University of Virginia, United States; [3]U.S. Naval Research Laboratory, United States

By measuring the anomalous Nernst effect (ANE), which is a result of a spontaneous drop in the transverse voltage driven by the temperature gradient in a magnetic material, over a temperature range of 100–350 K, we observed the ANE thermopower in (110)-oriented FeRh films on Al_2O_3 substrates, with similar magnetic transport behaviors observed for in-plane magnetization (IM) and out-of-plane magnetization (PM) configurations. The temperature-dependent magnetization–magnetic field strength (M-H) curves revealed that the ANE voltage was proportional to the magnetization of the material, but additional features magnetic textures not shown in the M-H curves remained intractable. In particular, a sign reversal occurred for the ANE thermopower signal near zero field in the mixed-magnetic-phase films at low temperatures, which was attributed to the diamagnetic properties of the Al_2O_3 substrate. Finite element method simulations associated with the Heisenberg spin model and Landau–Lifshitz–Gilbert equation strongly supported the abnormal heat transport behavior from the Al_2O_3 substrate during the experimentally observed magnetic phase transition for the IM and PM configurations. Our results demonstrate that FeRh films on an Al_2O_3 substrate exhibit unusual behavior compared to other ferromagnetic materials, indicating their potential for use in novel applications associated with practical spintronics device design, neuromorphic computing, and magnetic memory.

SESSION EN04.04: Phase Change Materials for Thermal Regulations

Nanoscale Polymer Thermal Regulator and Rectifier Based on Solid-State Phase Transition *Sheng Shen; Carnegie Mellon University, United States*

Polyethylene nanofibers with high chain alignment and high degree of crystallinity show a high thermal conductivity at room temperature. However, rotational disorder occurs at a high temperature close to melting temperature, in which the nanofibers switch from the orthorhombic phase to the hexagonal phase with a high-contrast and abrupt thermal conductivity change. Such a solid-state phase transition makes the polyethylene nanofiber intrinsically a thermal regulator. Measurements show a thermal switching ratio in average ~8x with maximum ~10x, which is the highest among solid-solid and solid-liquid phase transitions of all existing materials. Based on the sharp and high-contrast phase transition, an unusual dual-mode solid-state thermal rectification effect is demonstrated using a heterogeneous “irradiated-pristine” polyethylene nanofiber junction as a nanoscale thermal diode, in which heat flow can be rectified in both directions by changing the working temperature. For the nanofiber samples measured here, we observe a maximum thermal rectification factor as large as ~ 50 %, which only requires a small temperature bias of <10 K. The nanoscale thermal regulators and rectifiers open up new possibilities for developing advanced thermal management, energy conversion and, potentially thermophononic technologies.

2:00 PM EN04.04.02
Characterization of Size-Dependent Thermal Properties of Liquid Crystal Elastomer Nanofibers *Jingxuan Wang, Yue Wen and Sichao Li; National University of Singapore, Singapore*

The development of materials with high thermal conductivity and high latent heat offers significant advantages for thermal interface materials (TIMs), ensuring efficient heat transfer and effective thermal regulation in high-performance electronics and other thermally sensitive applications. Soft materials, due to their flexibility and conformability, further enhance these benefits by improving contact with surfaces and reducing thermal resistance. Liquid crystal elastomers (LCEs) are particularly promising candidates for TIM applications as they are soft and exhibit phase change behavior. As polymers, LCEs typically have low thermal conductivity; however, we have overcome this limitation by enhancing the alignment of liquid crystal mesogens through hydrodynamic alignment. To characterize the thermal properties of these aligned LCE fibers, we utilized a custom-built sensitive suspended thermometry platform capable of simultaneous thermal conductivity and specific heat measurements. Using a low-frequency alternating current heating method, we measured thermal conductivity, while high-frequency modulation techniques were employed to determine specific heat. Accurate specific heat measurements require fibers of optimal length: long enough to ensure good fitting sensitivity but not so long that thermal conductance decreases excessively, and radiation loss becomes dominant. Our observations indicate a significant increase in thermal conductivity, measured at 1.44 ± 0.32 W/m-K, attributed to the enhanced alignment of polymer chains in the LCE fibers with diameters in the sub-100 nm range. Additionally, we detected notable energy changes driven by the latent heat during the phase change. These findings underscore the effectiveness of our fabrication method and the superior thermal properties of LCEs as TIMs.

Reversible Thermal Conductivity Modulation in Elastic Polyolefin Fibers Through Phase Change Fillers and Strain Engineering

Duo Xu[1], Buxuan Li[1], You Lyu[1,2], Vivian J. Santamaria Garcia[1,3], Yuan Zhu[2] and Svetlana V. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]Southern University of Science and Technology, China; [3]Tecnológico de Monterrey, Mexico

Thermal switches capable of reversible and rapid thermal conductivity changes are essential for various modern technologies, including electronics, automotive, aerospace, and medicine [1]. These devices play a crucial role in managing heat, which is vital for improving the efficiency and longevity of many applications. However, the performance of current thermal switches is often hindered by limited tuning ratios, slow tuning speeds, stepwise tuning mechanisms, and high material and fabrication costs. This limitation creates a significant demand for new materials and designs that can overcome these challenges.

Among potential material systems for thermal switches, polymers stand out due to their suitability for low-cost mass production, chemical inertness, and the ability to be engineered for high mechanical strength and elasticity. Polymers can be tailored to meet specific requirements, making them versatile for a wide range of applications. Nevertheless, the thermal conductivity of commonly used industrial polymers is restricted to a narrow range of 0.1 to 0.5 W/mK, which limits their effectiveness in thermal management.

In this study, we introduce a thermal switch based on an elastic, mostly amorphous polyolefin-based fiber. This switch exhibits a fast and continuously tunable thermal conductivity change with a switching ratio of 6.5 in the first cycle and 2.312 over 1000 cycles, starting from a base value of 0.426 W/mK through uniaxial tensile stretching, providing a dynamic way to manage heat in various applications. Furthermore, by incorporating a phase-change hydrocarbon material as fillers, the thermal conductivity can be reversibly tuned at its melting temperature of 35°C with a switching ratio of 5.56, which has the potential to enhance the switch's thermal tuning capability further. The employed polymer matrix is thermoplastic, enabling large-scale fabrication via standard industrial low-cost melt-spinning techniques and mechanical recycling at the end of its lifespan, making the production process cost-effective and environmentally friendly.

The thermal conductivity of the polyolefin fibers was measured in situ using the Angstrom method [2], enabling quantitave estimates of the effect of both mechanical deformation of the fiber and a first-order phase transition of a PCM filler. Structural changes in the fibers due to mechanical deformation were characterized using wide-angle X-ray scattering (WAXS) and Raman spectroscopy, revealing that the thermal conductivity change does not result from strain-induced crystallization but from an alignment effect. The change is hypothesized to be due to alignment-induced vibration delocalization, where the population of higher-frequency localized vibration modes decreases. This hypothesis is supported by Raman spectroscopy, which shows a decrease in the relative intensity of localized C-H stretching modes upon fiber stretching. The delocalized modes contribute more to thermal transport in polymers [3], leading to the observed increase in thermal conductivity.

***Reversible Regulation of Thermal Conductivity with Spin State Transitions** Qichen Song[1], Rahil Ukani[1], Vidhya Dev[1], Jinyoung Seo[1], Caleb Stamper[2,3], Jason J. Calvin[1], Dehong Yu[2] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]Australian Nuclear Science and Technology Organisation, Australia; [3]University of Wollongong, Australia*

The capability of regulating thermal transport in solids enables efficient thermal energy storage and heat management. Thermal conductivity in materials with metal-insulator transitions or structural phase transitions undergoes abrupt changes across the transition temperature, yet the thermal conductivity switching ratio is limited. Here we report a new mechanism for regulation of thermal conductivity using spin state transition. We observe a significant drop in thermal conductivity exceeding a factor of 2 in an iron molecular complex upon surpassing its spin state transition temperature, measured by frequency-domain thermoreflectance. As temperature rises, the singlet-to-quintet molecular spin state transition occurs when the ligand field splitting energy becomes smaller than the pairing energy. The occupation of antibonding orbitals weakens both metal-ligand bonds (intramolecular) and hydrogen bonds (intermolecular), leading to lower group velocities of heat-carrying phonons evident from inelastic neutron scattering. In addition to the large thermal conductivity contrast, the minimal volume expansion and high reversibility position the spin state transition an effective mechanism for the temperature regulation of thermal transport.

***Covalently Functionalized Leakage-Free Healable Phase-Change Interface Materials for Thermal Management** Shabas Ahammed Abdul Jaleel, Taehun Kim and Seunghyun Baik; Sungkyunkwan University, Korea (the Republic of)*

Thermally conductive polymer-matrix nanocomposites have received considerable attention for the thermal management of electrical and mechanical devices. The thermal interface material (TIM) fills the inevitable gap between the heat source and sink for efficient heat removal. We have investigated TIMs by employing silver (Ag) flakes and multi-walled carbon nanotubes embellished with Ag nanoparticles (nAgMWNTs) to impart thermal conductivity (κ) due to the intrinsically insulating nature of matrix materials [1, 2]. Phase change material (PCM) has received considerable attention as a matrix material because the solid-liquid phase change increases conformality between mating surfaces, taking advantage of both pad-type and grease-type TIMs [3]. However, the leakage of PCM, low κ, and non-healability have impeded the practical applications of PCM-TIMs. Here we report a leakage-free healable PCM-TIM by covalently functionalizing octadecanol (PCM) with polyethylene-co-methyl acrylate-co-glycidyl methacrylate (polymer) through the epoxy ring opening reaction [3]. The PCM undergoes a semi-crystalline to amorphous phase change, preventing leakage. The nAgMWNTs construct thermal percolation pathways between Ag flake islands, resulting in the record-high thermal conductivity (43.4 W m^{-1} K^{-1}) and low thermal resistance (30.5 mm^2 K W^{-1}), compared with PCM-TIMs in literature [3]. The carbonyl (C=O) and hydroxyl (O-H) groups enable reversible hydrogen bonding, realizing a nearly perfect healing efficiency. Excellent heat dissipation demonstration is carried out [3]. The recent progress in our laboratory will also be introduced including non-oxidizing copper nanoparticles [4, 5] and electron-tunneling transport studies [6, 7]. References: [1] Advanced Materials, 28, 7220 (2016) [2] Small, 17, 2102128 (2021) [3] Advanced Materials, 35, 2300956 (2023) [4] Materials Today, 48, 59 (2021) [5] Advanced Functional Materials, 33, 2304776 (2023) [6] Nature Communications, 11, 2252 (2020) [7] Science Advances, 8, eabn3365 (2022)

Fabrication of High-Performance Thermally Conductive Phase Change Material Composites with 2D Boron Nitride Based Porous Ceramic Network for Efficient Thermal Management *Wondu Lee, Minsu Kim and Jooheon Kim; Chung-Ang University, Korea (the Republic of)*

A Phase change material (PCM) has a great potential for heat energy storage and efficient heat management. However, achieving high performance PCM composites is still challenging because of its low thermal conductivity and weak mechanical properties. In particular, to improve the properties of PCM composite with preserving intrinsic latent heat is most important. In this work, we first simply synthesized a PCM matrix with the highly improved mechanical property, fabricated two kinds of porous ceramic fillers (boron nitride (BN)-cellulose nanofiber (CNF), aluminum nitride (AlN)-CNF) through freeze-casting and carbonization of CNF to form porous structured ceramic filler, and fabricated PCM composites using three kinds of method to maximize the properties of fabricated composites. These strategies resulted in synergistic effects that highly improved the thermal and mechanical properties of the PCM composites.
(i) We synthesized erythritol (ET) grafted bisphenol A (ETBPA) through esterification. The ET grafted on the BPA addressed phase separation between BPA and ET and reinforced the mechanical properties of matrix. The latent heat and mechanical properties were measured according to ratios of ETBPA and leakage test also performed to confirm enhanced thermal stability. As a result, the ETBPA (1.5:1 ratio) showed the latent heat of 297.36 J/g (76% of pure paraffin), the enhanced tensile stress and strain of 241 and 247% comparing pure ET, and no leakage at the melting point of the ET.
(ii) Fabrication of porous ceramic fillers was carried out using BN and AlN through freeze-casting and carbonization of CNF. After that, hybridization of porous ceramic filler (BNCNF, AlNCNF) and raw ceramic filler (BN, AlN) was conducted. The hydrophilic functional group derived from carbonized CNF on ceramic filler improved interfacial interaction between ETBPA and fillers. Moreover, the porous ceramic filler and impregnation of raw ceramic filler formed efficient heat conduction paths along through plane direction in the matrix.
(iii) The PCM composites (ETBPA/BNCNF/BN, ETBPA/AlNCNF/AlN) was fabricated by three kinds of methods:

mixing, hot-pressing, and injection molding. To confirm the effect of our new strategies, we measured thermal, mechanical properties, and heat management performance of composites. As a result, the composite showed ultra-high through-plane thermal conductivity of 13.09 W/mK (2,518% enhancement comparing paraffin), tensile strength of 3.2 MPa (300% enhancement comparing paraffin), and elongation at break of 4.55% (37% enhancement comparing paraffin). Therefore, the new attempts of this study will contribute to the research of thermal conductive PCM composites afterwards.
This newly developed PCM composites with superior thermal and mechanical properties than existing PCM composites would suggest a new insight to study of multifunctional PCM composites.

4:00 PM EN04.04.07
Influence of Moisture on the Performance of the Thermal Energy Storage Systems *Abhishek Siddharth Bhesania[1], Mark Messner[1], Dileep Singh[1], Emin Varghese[2] and Santanu Chaudhuri[2,1]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Chicago, United States*

Thermal energy storage (TES) systems will play an important role in renewable energy grids by storing the excess energy during the daytime and releasing it back into the grid when the demand is high or during the night. The latent heat TES storage systems are promising as compared to the sensible heat TES systems due to their high energy density. $MgCl_2$ is a phase-changing material (PCM) that can be used as a latent heat storage candidate due to its high energy density and high melting point temperature (>700 C). The PCM material is sometimes impregnated in the high thermal conductivity material foam to improve the overall heat transfer through the TES. In the TES facility, moisture infiltration is a problem, and it can cause alteration of the PCM material. The moisture can initiate the hydrolysis reactions and the chlorine released can corrode the storage metal containers. The byproducts of the corrosion will also mix with the PCM, eventually altering its composition and properties. $MgCl_2$ will absorb moisture because of its hygroscopic nature, and thus, its hydrous state will change, causing a change in the bulk property as well.

In this work, we perform heat transfer simulations to analyze the influence of moisture on the thermal performance of the TES system. We first develop a mesoscale representative model of graphite foam impregnated with $MgCl_2$ of different hydrous states and derive its effective anisotropic thermal properties by using homogenization methods in the temperature ranges relevant to the TES operation. This model takes the single-phase properties of each component as an input. The derived properties are fed into the larger-scale heat transfer simulation on the TES system for evaluating the system's performance. This system-level model provides the overall driving forces for degradation models on the lower scales, as well as quantifies the effect that moisture will have on the overall system performance of TES.

4:15 PM EN04.04.08
Evaluation of Ti-Doped Al-Si Phase Change Materials Composites for Effective Use in Thermal Energy Storage and Thermal Management Systems *Joshua C. Mba, Takahiro Kawaguchi, Yuto Shimizu, Melbert Jeem and Takahiro Nomura; Hokkaido University, Japan*

The incessant world energy crisis, and the effects of global warming demand clean and sustainable energy alternatives to generate, store, and save energy for use when needed, curtailing the mismatch between energy demand and supply. Latent heat thermal energy storage (LHTES) using metal alloy-based phase change materials (PCMs) and their composites has attracted a lot of interest because of their ability to absorb, store and release large latent heat during the phase change phenomenon, thus making PCMs one of the important players in energy storage and utilization technologies. Al alloy-based PCMs such as Al-Si and their composites show great potential for LHTES and utilizations. However, efficient applications are constrained by possible liquid leakages,

supercooling (SC), and phase change hysteresis (PCH) etc. Specifically, SC phenomenon and the consequent PCH are major drawbacks against efficient practical utilizations. While PCH is the difference between the melting and solidification temperature, supercooling refers to a condition where PCMs remain in liquid state at a temperature lower than their solidification temperature. It inhibits the crystallization process in PCMs, thereby impeding the PCM's ability to transition from a liquid to a solid phase upon cooling, resulting not only in the non-release of stored heat within the expected temperature range, but also intensifies energy consumption and reduces the efficiency of TES systems. Previously, our group reported the fabrication of PCM composites. Characterized by high heat storage density and high thermal stability, the composite PCMs exhibited large supercooling and phase change hysteresis. So far, suppression of the SC and PCH of Al-Si PCMs and their composites are seldom reported despite the large heat storage density per unit volume, and exceptional thermal stability for practical TES applications. Moreover, Al-Si composite PCMs with enhanced thermal properties promise decarbonation to curb the effects of global warming. Therefore, mitigation of the supercooling phenomenon is highly essential for efficient use of not only PCMs but also their composites. Herein, we present the development of Ti-doped Al-Si MEPCM composites with suppressed SC and PCH.
In the field of metal alloying, it is well known that Al intermetallic compounds such as $ZrAl_3$, B_2Al, *and* $TiAl_3$ *etc. are probable nucleating agents for Al. Moreover, the use of additives as nucleation agents has been proposed to aid in mitigating supercooling. In the light of the foregoing, we first fabricated Ti-doped Al-Si MEPCMs by the adherence of* TiO_2 *nanoadditive and* α-Al_2O_3 *(shell material) to the microcapsules via high-speed impact blending, and heat oxidation treatment. Next, the composite material was fabricated using* α-Al_2O_3 *powder as sintering aids. Mixed powder of the MEPCM (80 vol%) and the binder (20 vol%) were wet-mixed and a small amount of the powder (0.5 g) was added to a die with a diameter of 1 cm and pressed for 1 min at 20 MPa and 25 °C. Cylindrical pellets with a height of approximately 4 mm obtained after pressing were heated from 25 °C to 1000 °C at a rate of 10 °C* min^{-1}. *Following heat treatment, structural and thermal properties of the MEPCMs composites were investigated. The pictorial and SEM images of the Ti-doped Al-Si MEPCM composites show successful fabrication of stable composite materials. Furthermore, using the same sintering aid, we observed approximately 57% and 91% reduction of the inherent SC and PCH of Al-Si MEPCM composites by an addition of 3wt.%* TiO_2. *This stems from enhanced crystallization due to heterogenous nucleation of the formed intermetallic compound,* $TiSi_2$. *The results demonstrate the development of Ti-doped Al-Si MEPCM composite of high latent heat capacity with suppressed supercooling and phase change hysteresis, paving way for effective practical use in thermal management and thermal energy storage systems.*

Physics-Based Model for Accessible High-Throughput Heat Capacity Estimation *Elana J. Cope and Matthias T. Agne; University of Oregon, United States*

The ability to characterize and predict thermal properties of materials is fundamental to enable engineering design of temperature profiles in energy conversion and storage devices, especially in systems undergoing phase transformations as in batteries and some thermoelectrics. In particular, knowledge of the heat capacity is crucial to characterizing thermal evolution in working devices, as it is directly related to the enthalpy change within the material and is intimately related to thermal transport. The ability to accurately model heat capacity from accessible materials information can enable high-throughput engineering design and serve as a basis for advanced materials characterization. In this work, we describe the process for building up a physical model of heat capacity in solids, based in thermodynamics and materials physics, and specifically show how to utilize realistic approximations for the constituent contributions to heat capacity from parameters that are widely accessible (e.g. from Materials Project). This includes using a pre-trained machine-learned model for the vibrational density of states, instead of the widely-used Debye model, in the phonon contribution to heat capacity. Approximating the density of states in this way provides more accurate estimates of heat capacity over a wide *temperature range, as demonstrated for 38 diverse materials. This model for single-phase materials thus provides a starting point for more sophisticated analysis that may consider composite materials and phase transformation kinetics.*

Enhanced Electroactive Phase Content of PVDF Composite Thin Film by Tuning $DyFeO_3$ Nanoparticles

Abhinav Yadav, Sushrisangita Sahoo and Vijaya Rangari; Tuskegee University, United States

The design and development of Poly(vinylidene fluoride) (PVDF) based composites became the hotspot of the material science in recent years due to its promising applications in sensors, wearable portable self-powered systems, actuators. The application potentiality of PVDF can be tailored by improving the electroactive phase content, which can be achieved effectively by adding nanofillers into the pure PVDF. The incorporation of nanofillers not only improves the electroactive phase content, it also useful to enhance piezoelectric, dielectric, electrical conductivity and energy density of PVDF. Herein, we have studied the influence of $DyFeO_3$ (DFO) nanoparticles to improvising the electroactive phase content of the PVDF matrix. The DFO nanoparticles as a filler embedded to PVDF polymer matrix with different concentration (3, 6, 9, 12 and 15 % respectively) were fabricated using the doctor blade set up. For the formation of films, initially the granular Polyvinylidene Fluoride was added in Dimethylformamide (DMF) solvent and stirred at 70 °C for 1-2 h to completely dissolve. We added the filler in a clear PVDF and DMF solution as per the weight percentage and stirred for 24 hr for homogeneous blending of the nanoparticle and PVDF composite. The solution was ultrasonicated for 1 hr prior to the film preparation. The ultrasonicated solution were cast on doctor blade equipment to get a uniform film of DFO-PVDF (DFP). To know about the structural property of DFP composites, the room temperature XRD of DFP films was performed at 5 to 80° diffraction angle range. The crystalline peaks of DFO filler and PVDF peaks completely matched with all DFP composites and it suggests that both (DFO and PVDF) characteristic present in DFP composite films. The peak position at 19.8° and 20.4° diffraction angle corresponding to nonpolar α and polar β-phase and planes associated with these two peaks are (020) and (110)/(200). The electroactive phase analysis was investigated from FTIR measurement. Electroactive phase content calculated with the help of Beer-Lamberts law by considering the 766 and 840 cm^{-1} band corresponding to nonpolar α and electroactive phase (both β and γ phase). The obtained values are 72.86, 77.51, 79.27, 82.36, 83.42 and 83.50 for PVDF, 3, 6, 9, 12 and 15 wt%, respectively. To know about the individual contribution of β and γ phase in electroactive phase we deconvoluted peaks in the range 800 to 860 cm^{-1}. The peak centered at lower wavenumber around 828 cm^{-1} indicates γ phase and the peak at higher wavenumber at 838 cm^{-1} corresponds to the β phase. For all the composites including neat PVDF, the β phase found to be the dominant phase than the other phase. To again confirm the existence of β phase, we carried out the DSC measurement as the γ phase melting temperature is relatively higher than the β phase. From the DSC it is observed the melting peak appeared at ~172 °C, which agrees well with the melting temperature of β phase. So, the prominent peak at 20.4° in XRD, individual phase content analysis through Beer-lambert law from FTIR and DSC melting peak investigation confirmed the improved β phase content in the polymer nanocomposites.

SESSION EN04.05: Poster Session I: Phase Change Materials for Thermoelectric and Thermal Management

Session Chairs: Sunmi Shin and Mona Zebarjadi
Tuesday Afternoon, December 3, 2024
8:00PM - 10:00PM

Thermoelectric Properties and Effective Medium Theory Analysis on the $(GeTe)_{1-x}(InTe)_x$ Composites *SongYi Back[1,2], Jong-Soo Rhyee[2] and Takao Mori[1]; [1]National Institute for Materials Science, Japan; [2]Kyung Hee University, Korea (the Republic of)*

We employed the p-type semiconductor InTe as an extrinsic phase mixing in the GeTe matrix for thermoelectric properties investigations on the $(GeTe)_{1-x}(InTe)_x$ (x=0, 0.02, 0.04, 0.06, and 0.08) composites. We observed notable phenomena that a small amount of InTe has a significant influence on the thermoelectric properties as the primary host matrix in the $(GeTe)_{1-x}(InTe)_x$(x=0.02, 0.04, 0.06, and 0.08) composites. Even for small concentrations of InTe which possess lower thermal and electrical conductivities compared to those of GeTe, the thermoelectric properties of the $(GeTe)_{1-x}(InTe)_x$ (x=0.02, 0.04, 0.06, and 0.08) composites are primarily influenced by the properties of InTe. We systematically elucidated the electrical conductivity of the $(GeTe)_{1-x}(InTe)_x$ (x=0.02, 0.04, 0.06, and 0.08) composites through the application of effective medium theory (EMT). It is found that the effective media of the $(GeTe)_{1-x}(InTe)_x$ (x=0.02, 0.04, 0.06, and 0.08) composites is an asymmetric medium insulator. The addition of InTe into GeTe reveals a significant decrease in total thermal conductivity due to reductions in both electronic and lattice thermal conductivity. Particularly, the decrease in lattice thermal conductivity was attributed to an increase in internal strain within the lattice induced by the addition of InTe. Consequently, the ZT values of the composite significantly increase across all temperature ranges. This study suggests that developing composites is an effective approach for enhancing thermoelectric performance, comparable to elemental doping, and demonstrates the ability to analyze the electrical properties of composite materials using EMT.

EN04.05.02

Investigating the Impact of Resonant Doping on the Thermoelectric Properties of Cubic Ge-Sb-Te Thin Films *Suman Abbas[1,2,3], Bhawna Jarwal[1,3], Thi-Thong Ho[1], Suneesh M. Valiyaveettil[1], Cheng-Rong Hsing[4], Ta-Lei Chou[3], Ching-Ming Wei[1], Li-Chyong Chen[3,3,3] and Kuei-Hsien Chen[1,3]; [1]Academia Sinica, Taiwan; [2]National Central University, Taiwan; [3]National Taiwan University, Taiwan; [4]Chang Gung University, Taiwan*

Germanium Telluride (GeTe) has been extensively studied as a promising lead-free thermoelectric material in its rhombohedral and cubic phases. The rhombohedral to cubic phase transition at ~ 700 K made this material challenging for practical application. Additionally, due to the presence of multi-valence bands and strong anharmonic interactions, the high-temperature cubic phase demonstrates a higher power factor, and lower thermal conductivity, that leads to superior thermoelectric performance compared to its rhombohedral counterpart. In this work, a cubic phase of $Ge_{0.9}Sb_{0.1}Te$ (GeSbTe) was first stabilized at room temperature. Then a simple and effective method was proposed to introduce Indium (In) into the GeSbTe structure. The impact of indium doping was thoroughly examined.It is demonstrated that through a two-step process (thermal evaporation and thermal annealing), indium was successfully and uniformly doped into $Ge_{0.9-x}Sb_{0.1}Te-In_x$ thin films. The gradual increase in doping amount (x= 0.02, 0.03, 0.04, and 0.05) indicated that the indium content can be controlled by adjusting the thickness of the evaporated indium layer. Indium doping had increased the effective mass and electron density in the GeSbTe films, reducing the overall p-type carrier concentration and significantly improving the Seebeck coefficient. Density functional theory (DFT) calculations revealed that indium acts as a resonant dopant in the room temperature cubic phase of GeSbTe. Additionally, due to point defect scattering, the presence of indium suppressed thermal conductivity. Overall, the zT for optimized sample increased to 1.95 at 575 K compared to a zT of 0.58 in pristine GeSbTe film. A higher average zT of 1.12 was achieved in the temperature range of 300-575 K, making GeTe-based materials suitable for near-room-temperature applications.

EN04.05.03

Exploring the Impact of Orthotropic Thermal Conductivity in PCM/Expanded Graphite on Thermal Energy

Storage—A Numerical Study *Narender Kumar and Prodyut R. Chakraborty; Indian Institute of Technology Jodhpur, India*

The exponential expansion of the economy has led to numerous notable adverse environmental effects, hence demanding the adoption of novel and economically viable energy sources. Thermal energy storage, particularly latent heat storage, presents a viable method to address the challenge of variable solar energy supply and industrial waste heat recovery. Phase change materials (PCMs) are recognized for their exceptional efficiency as energy storage materials, owing to their various advantages. These include their potent energy storage capabilities, compact structure, relatively stable temperature absorption and release properties, and the ability to be controlled. The primary limitation, however, lies in their low thermal conductivity. There are numerous ways to enhance heat transfer techniques, such as implementing fins, nanoparticles, composites, metal foams, and metal inserts within PCM to improve conductivity. In recent years, expanded graphite (EG), a modified form of graphite with a layered structure and inter-layer space, has been proposed as a heat transfer enhancement material for PCMs with inherently low thermal conductivity. Compressed expanded graphite (CEG) is formed by compressing EG into required shape with required porosity. CEG stands out for its affordability, high porosity, small pore size (ranging from nano to micro), dense pore distribution, elevated thermal conductivity, and versatility in shaping various geometries but the only challenge is anisotropy with compression. The canter of the present work is to numerically investigate the effect of CEG to overcome the anisotropic behaviour of CEG-based composite PCM. In the current investigation, we are examining the orthotropic thermal conductivity to ensure the even distribution of temperature within the composite material to make uniform melting of PCM in PCM-CEG composite. The overall volume of PCM in the system is kept constant at 85% by volume whereas fraction of remaining volume is CEG. The composite is formed by embedding paraffin as PCM in a rectangular foam system. The PCM composite, initially in solid phase, is subjected to a constant heat flux at bottom, while the other sides are kept adiabatic. This paper numerically analyses the melt fraction and temperature distribution during the melting process by varying the volume concentration of CEG in the composite PCM, comparing it with the non-orthotropic case. With the incorporation of orthogonal thermal conductivity, the melting time experiences a remarkable reduction of 2-3 times compared to the non-orthotropic case. This significant enhancement facilitates precise calculations for determining the optimal amount of compressed expanded graphite (CEG) to incorporate into the PCM-CEG composite, ensuring utmost accuracy in its formulation.

EN04.05.04
Measuring Thermal Conductivity of $NdNiO_3$ Thin Films with Frequency Domain Thermoreflectance *Lucy Nathwani, Anne Ruperto, Grace A. Pan, Abigail Y. Jiang, Dan Ferenc Segedin, Ari Turkiewicz, Charles Brooks and Julia Mundy; Harvard University, United States*

$NdNiO_3$ has attracted attention for its concomitant, thermally-driven metal-insulator and magnetic ordering transitions. This metal-insulator transition is particularly interesting in thin film form, as it can be tuned using epitaxial strain and rare-earth doping [1]. Understanding the thermal conductivity in these $NdNiO_3$ films is necessary before using them in devices or exploring their applications in electronics like thermal transistors or switches. This fundamental understanding of heat transport can illuminate both electron and phonon behavior in these films. Here, we synthesize $NdNiO_3$ films using molecular beam epitaxy (MBE) to create high-quality thin films. We then use frequency-domain thermoreflectance (FDTR) measurements to non-destructively determine the thermal conductivity of $NdNiO_3$ films across the metal-insulator transition [2]. Using FDTR, we observe the low-temperature (~100K) metal-insulator phase transition of $NdNiO_3$ and its hysteresis by measuring thermal conductivity as a function of temperature. We analyze our thermal conductivity data in connection with previous research into the electronic properties of $NdNiO_3$.

Thermal Conductivity and Heat Capacity of Anhydrous $MgCl_2$ and Its Hydrates for Efficient Thermal Energy Storage in Solar and Nuclear Applications

Emin Varghese[1], Abhishek Siddharth Bhesania[2], Santanu Chaudhuri[1,2], Mark Messner[2] and Dileep Singh[2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Using phase change materials (PCMs) in thermal energy storage (TES) systems, particularly for applications in solar panels and nuclear power plants, offers significant improvements in efficiency and energy management. Magnesium chloride ($MgCl_2$) is a promising TES candidate due to its high energy density and high melting point temperature (>700 °C). However, moisture leakage in TES facilities can initiate hydrolysis reactions, leading to the corrosion of metal storage containers. Since $MgCl_2$ is hygroscopic, it absorbs moisture, altering its hydration state. These hydrates, formed under varying moisture conditions, can act as impurities, potentially affecting $MgCl_2$'s storage capacity. While the performance of pure anhydrous $MgCl_2$ is well documented, the effects of different hydrates on its thermal properties are not well understood.

In this study, we perform a computational analysis on anhydrous $MgCl_2$ and its various hydrates; monohydrate ($MgCl_2.H_2O$), dihydrate ($MgCl_2.2H_2O$), tetrahydrate ($MgCl_2.4H_2O$), and hexahydrate ($MgCl_2.6H_2O$); to evaluate changes in their thermal properties across a range of temperatures. Using Density Functional Theory (DFT), we assess their heat capacity (C_p) and thermal conductivity (K), with detailed phonon density of states (DOS) calculations providing insight into the subtleties of their thermal behavior.

Our results show significant variations in thermal conductivity and heat capacity among the different hydrates. The anhydrous form exhibits high thermal conductivity, making it suitable for rapid heat exchange. In contrast, the hydrated forms, which increase in number of water molecules, demonstrate enhanced heat storage capabilities due to their larger C_p values. This study uncovers the stability and formation propensity of these materials under various thermal conditions, often overlooked in conventional studies. By integrating fundamental science, including first-principles calculations and phonon DOS analysis, we provide a deeper understanding of how moisture as an impurity influences the thermophysical properties of $MgCl_2$. These findings guide the application of $MgCl_2$ in the efficient design of TES systems, emphasizing temperature dependence and the role of hydration states in heat storage and thermal transport mechanisms.

EN04.05.06

Improving Refrigeration and Heat Pump Cycles with Time-Modulated Thermal Reservoirs

Ximena S. Carrillo[1], Simo Pajovic[1], Sean Lubner[2] and Svetlana V. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]Boston University, United States

With climate change causing worsening heat waves globally [1], our reliance on air conditioning systems to provide thermal comfort in the engulfing heat has increased significantly, further worsening the climate crisis due to increased energy usage [2]. Thus, working toward improving the efficiency of these systems is critical. Solid-state refrigerants are emerging as highly efficient, environmentally friendly alternatives to conventional vapor-compression refrigeration. These include magnetocaloric materials, which increase or decrease in temperature (heat up or cool down) when adiabatically magnetized or demagnetized, respectively, particularly near a magnetic phase transition (e.g., paramagnetic to ferromagnetic). However, even refrigeration and heat pump cycles based on solid-state refrigerants cannot surpass the efficiency of the ideal reverse Carnot cycle, which itself is unachievable under real world constraints due to non-conservative losses such as friction. The coefficient of

performance (COP) is used to measure how well refrigerators and heat pumps can cool or heat objects, respectively, with higher COP generally meaning better performance. COP is inversely proportional to the difference between the heat absorbed from the cold reservoir and rejected to the hot reservoir ($\Delta Q = Qc - Qh$). Thus, to maximize COP, we can either reject a Qh commensurate with Qc or decrease the temperature difference between the reservoirs, neither of which is always practical or desirable. However, given the nonlinear relationship between COP and ΔQ, a decrement in ΔQ increases COP disproportionately more than an equivalent increment in ΔQ decreases COP. Therefore, if ΔQ is periodically modulated about some average value, the time-averaged COP may be higher compared to the static case. We have developed a theoretical model of a reverse Brayton cycle with a time-modulated Qh, which we use to probe the feasibility of such an improvement to refrigeration cycles. We further propose using magnetocaloric materials as a practical way to periodically modulate the temperature of the hot reservoir and thus Qh via a fast, non-contact, bulk heating and cooling process. Our work points toward exploring new methods to more effectively provide cooling and heating via time modulation, with potential for real-world implementation. *This work is supported in part by ARO MURI (Grant No. W911NF-19-1-0279) via U. Michigan. X. C. gratefully acknowledges support from a direct funding award via the MIT UROP Office. S. P. gratefully acknowledges support from the NSF GRFP under Grant No. 2141064.*

Enhanced Thermal Durability of Microencapsulated Phase Change Material via Shell-Localized Oxide Nanoparticles

Melbert Jeem, Takahiro Kawaguchi, Yuto Shimizu, Kaixin Dong, Tomokazu Nakamura and Takahiro Nomura; Hokkaido University, Japan

Thermal energy storage (TES) is an indispensable technology for enhancing the efficiency and reliability of renewable energy systems, particularly in solar thermal power generation. By harnessing phase change materials (PCMs), TES can effectively store and release thermal energy, thereby balancing energy supply and demand. Among various PCMs, inorganic materials such as metal alloys are favored for their high thermal conductivity and latent heat capacity. However, the practical application of PCMs is often hampered by issues such as supercooling and material degradation over repeated thermal cycles.

Microencapsulated PCM (MEPCM) has emerged as a promising solution to these challenges, offering enhanced thermal stability, ease of handling, and improved durability. Encapsulation involves coating PCM particles with a protective shell, which not only prevents leakage during the liquid phase but also mitigates the adverse effects of thermal expansion and contraction. The choice of shell material is critical, as it must exhibit high thermal conductivity, chemical stability, and mechanical strength. Among various encapsulation materials, α-Al_2O_3 is particularly attractive due to its exceptional thermal and structural properties. However, the immiscibility between α-Al_2O_3 nanoparticles and certain PCMs, such as Sn, poses significant challenges in achieving uniform encapsulation and optimal thermal performance.

This study addresses these challenges by employing a high-speed impact blending (HIB) technique to synthesize Sn@α-Al_2O_3 MEPCMs. The HIB method facilitates the dry synthesis of MEPCMs, ensuring high yield and environmental friendliness. Through rapid rotation and collision, Sn and α-Al_2O_3 particles are blended to form a uniform shell structure. The resulting MEPCMs demonstrate remarkable thermal durability, withstanding up to 100 cycles of melting-solidification without significant degradation. The encapsulation process introduces lattice *defects within the α-Al_2O_3 nanoparticles, creating voids that promote the localization of Sn nanoparticles. This localized Sn, observed as nanosized particles within the α-Al_2O_3 lattice, forms a metastable Sn−Al−O surface that is crucial for the subsequent formation of SnO and SnO_2 nanoparticles during thermal cycling.*

Thermal cyclic tests reveal that the Sn@α-Al_2O_3 MEPCMs maintain their structural integrity and thermal properties over 100 cycles, with the α-Al_2O_3 shell remaining resilient even under ultrafast heating/cooling rates. Differential scanning calorimetry (DSC) measurements indicate that the encapsulated Sn core exhibits a latent heat capacity of approximately 50 $J\ g^{-1}$, which is marginally lower than that of pure Sn due to the encapsulation. The degree of supercooling decreases from 72°C to 61°C after 100 cycles, demonstrating the effectiveness of the SnO and SnO_2 nanoparticles in accelerating the nucleation rate during solidification and thus suppressing supercooling.

Density functional theory calculations provide insights into the electronic states at the SnO_2/α-Al_2O_3 interface, highlighting the role of oxygen vacancies in lattice strain and electron delocalization. The formation of the SnO_2/α-Al_2O_3 interface reduces the energy barrier for Sn nucleation, thereby enhancing the nucleation velocity and contributing to supercooling suppression. The SnO and SnO_2 nanoparticles within the α-Al_2O_3 lattice also act as nucleation sites, promoting faster Sn nuclei formation and reinforcing the shell structure, which stabilizes the latent heat and improves thermal cyclic stability.

Our findings highlight the significance of lattice defects and localized oxide nanoparticles in enhancing the thermal performance of MEPCMs. This study provides valuable insights into the interplay between nanoscale crystal lattice imperfections and their implications for energy storage applications, paving the way for the development of advanced MEPCMs with improved properties and durability.

EN04.05.08

Thermal Regulation of CO_2 Methanation Using Al-Cu-Si Alloy-Based Microencapsulated Phase Change Materials *Kengo Mimura, Cholila Tamszyi, Melbert Jeem and Takahiro Nomura; Hokkaido University, Japan*

CO_2 methanation is an effective carbon utilization technology. It involves synthesizing CH_4 by reacting CO_2, recovered from industrial processes, with H_2 produced from renewable energy sources. However, this exothermic reaction causes significant increase in catalyst temperature, leading to thermal runaway, which can reduce CH_4 selectivity, activity, and catalyst lifespan. Therefore, effective thermal regulation of the reactor is crucial for stable CO_2 methanation.

This study focuses on latent heat storage (LHS) for thermal regulation. LHS uses latent heat from the solid-liquid phase transition of phase change materials (PCM), offering high heat storage density, constant temperature heat input/output, and excellent cycling performance. LHS was expected to maintain a constant reactor temperature at the PCM's melting point during the reaction. An Al-Cu-Si alloy PCM, with a melting point of 520°C, is suitable for thermal regulation within the reaction's operating temperature range of 300−600°C. However, the leakage of PCM in its liquid phase and its high corrosiveness are major challenges and necessitate encapsulation.

Our research group developed a microencapsulated PCM (MEPCM) consisting of a PCM core and an α-Al_2O_3 shell. The α-Al_2O_3 shell enhances thermal and chemical stability, enabling MEPCM use as composite molding and catalyst support. By loading the catalyst onto MEPCM pellets, we fabricated catalyst pellets with integrated heat storage function. The close proximity of the catalyst and PCM at the microscale allows in-situ heat recovery, facilitating passive thermal regulation and suppressing sudden thermal runaway.

In this study, catalysts consisting of Al-Cu-Si alloy-based MEPCM pellets loaded with Ni were prepared and evaluated for thermal regulation and catalytic reaction characteristics in a fixed-bed reactor.

Catalyst pellets were prepared by loading Ni onto 1 mm diameter pellets composed of Al-Cu-Si alloy-based MEPCM (70 vol%), α-Al_2O_3 (20 vol%), and yttria-stabilized-zirconia (ZrO_2-3 mol% Y_2O_3) (10 vol%). A quartz tube with

a 20 mm inner diameter was filled with the catalyst pellets to a height of 100 mm. The catalyst bed was heated to 500°C under Ar flow, and Ni was activated under Ar/H_2 flow for 30 min. The catalyst test was conducted for 30 min under an Ar/H_2/CO_2 flow as the feed gas. Temperatures at 0, 25, 50, 75, and 100 mm (denoted as T_0, T_{25}, T_{50}, T_{75}, and T_{100}, respectively) from the catalyst bed inlet were measured using multi-point thermocouples installed in the catalyst bed to assess the thermal regulation. The product gas was analyzed using Q-mass spectrometry to evaluate the catalysts' reactivity.
The results showed temporary temperature stagnation near the PCM melting point at T_{25}, T_{50}, T_{75}, and T_{100}, with the duration of stagnation increasing towards the catalyst bed outlet. This temperature stagnation demonstrated the thermal regulatory effect of the MEPCM. Near the inlet, most of the CO_2 and H_2 reacted with the catalyst, generating substantial heat. As most of the CO_2 and H_2 were consumed near the inlet, the generated heat decreased towards the latter half of the bed, thereby increasing the stagnation duration towards the exit. These results suggest that MEPCM can effectively regulate the thermal environment of CO_2 methanation.

EN04.05.09
Tuning Phase Transitions in Two-Dimensional Perovskites for Thermal Energy Storage *Emily J. Dalley[1], Leo C. Bloxham[2,1] and Connor G. Bischak[1]; [1]The University of Utah, United States; [2]University of Colorado Boulder, United States*

Two-dimensional metal halide perovskites absorb and release thermal energy as they undergo structural phase transitions, making them promising materials for applications such as barocaloric cooling and next-generation phase change materials. The general structure of these Ruddlesden-Popper (RP) perovskites consists of alternating organic and inorganic layers following the chemical formula A2BX4, where A is a monoammonium organic spacer cation, B is a metal cation, and X is a halide. These RP perovskites undergo solid-solid phase transitions, where the organic cation spacer layer “melts,” while the outer inorganic metal halide layers remain solid. Typically, the thermodynamic properties of these materials depend on the identity of the organic spacer cation, limiting the tunability of their phase transition temperature. However, we show that we can precisely tune the phase transition temperature by alloying the organic cation chains, the metal cations, and the halide anions in Mn- and Cu-based alkyl bromide and chloride perovskites. Using differential scanning calorimetry (DSC), powder X-ray diffraction (PXRD), and temperature-dependent grazing incidence wide angle X-ray scattering (GIWAXS), we interrogate the structural and thermal changes related to the blending and exchanging of the individual components of lead-free RP perovskites. We find that blending different species typically decreases the phase transition temperature compared to the pure phases with the largest depression occurring when blending decylammonium and dodecylammonium copper bromide. Overall, we demonstrate a powerful strategy for precisely tuning the phase transition temperatures of hybrid materials.

EN04.05.10
Ternary Al-Cu-Si Alloy-Based Microencapsulated Phase Change Material for Middle-High Temperature Applications *Yuto Shimizu, Melbert Jeem and Takahiro Nomura; Hokkaido University, Japan*

To achieve a decarbonized society, the utilization of renewable energy and industrial waste heat is essential. High-temperature heat storage and regulation technologies are becoming increasingly important. Latent heat storage (LHS) using alloy-based phase change materials (PCMs) is promising due to their high thermal conductivity and heat storage density. Recent advancements include the development of microencapsulated PCMs (MEPCMs) with Al alloy cores and ceramic shells that address leakage and corrosivity issues. In our previous work, we reported MEPCMs with various melting temperatures using various metals and alloys as cores, spanning a wide temperature range. Among these, Al-Cu-Si MEPCMs with a melting temperature of approximately 520 °C, show potential for large-scale heat storage in power-to-heat-to-power systems. MEPCMs can also be utilized as fine

particles with thermal controllability at specific temperatures, exploiting the ability of PCMs to absorb or release heat at their melting temperature. Particularly, the Sabatier reaction, ammonia decomposition, and next-generation solid oxide fuel cells —key technologies in hydrogen utilization—require heat storage and thermal regulation at around 500 °C. Al-Cu-Si alloy MEPCMs thus hold promise for these applications. However, significant supercooling has been reported in alloy-based MEPCMs for most compositions, including Al-Cu-Si systems. Supercooling is a critical issue in LHS, as it reduces exergy and impairs thermal regulation ability. Therefore, it is essential to investigate and mitigate the supercooling behavior of MEPCMs for LHS applications. In this study, Al-Cu-Si alloy MEPCMs were fabricated, and their structures and melting/solidification behaviors were examined.
Al-26.5%Cu-5.4%Si (mass%) alloy powder (D < 38 μm) was used as the raw material. Initially, 20 g of the powder was added to 300 mL of boiling water containing 16.7 g L^{-1} $Al(OH)_3$, and chemically treated for 3 h to form a precursor sample with boehmite on the alloy surface. This precursor was heated at 10 °C min^{-1} to 1100 °C and maintained for 3 h in an O_2 atmosphere using TG for the thermal oxidation treatment. Sample morphologies were observed using XRD, SEM, and EDS. The melting and solidification properties of the MEPCM were analyzed using DSC, with heating and cooling rates of ±5 °C min^{-1}, and the sample heated to either 700 °C or 800 °C before cooling.
SEM-EDS observations of the sample cross-section revealed an Al oxide layer approximately 1-2 μm thick on the surface of the Al-Cu-Si alloy particles. The XRD pattern of the MEPCM showed alloy phases of Al, Al_2Cu, Si, as well as oxide phases of α-Al_2O_3 and $CuAl_2O_4$, confirming the formation of microcapsule structure with an Al-Cu-Si alloy core and an Al oxide shell. The DSC curves show an endothermic peak at 524 °C during heating, corresponding to the melting of the alloy core, with a latent heat of 235 J g^{-1}. The cooling DSC curve from 700 °C showed an exothermic peak of solidification at 483 °C. Cooling from 800 °C revealed two distinct exothermic peaks at 481 °C and 409 °C. The degree of supercooling defined as the temperature difference between the melting and solidification peaks, was 41 °C during cooling from 700 °C and 43 °C or 115 °C during cooling from 800 °C. This variation in supercooling suggests that higher temperatures may lead to the loss of potential heterogeneous nucleation sites, such as clusters. Furthermore, the differences in exothermic solidification behavior observed in DSC imply variations in the microstructural formation process of the alloy.
Understanding the melting and solidification temperatures is crucial for determining the operating conditions for heat storage and thermal control applications using MEPCM. Future studies shall focus on elucidating the relationship between these solidification processes and the resulting differences in alloy microstructure to enable better control of supercooling within MEPCM.

EN04.05.11

Microencapsulated Phase Change Materials with Hybrid Latent Heat Storage and Oxygen Storage Functions

Keita Tanahashi, Melbert Jeem and Takahiro Nomura; Hokkaido University, Japan

Oxygen plays an important role in reducing CO_2 emissions. Combustion with a high oxygen concentration reduces fossil fuel consumption due to its high reaction efficiency. Furthermore, the combustion support gas of a mixture of exhaust gas and pure oxygen increases the CO_2 concentration in the exhaust gas, reducing the cost of CO_2 separation and capture. However, the current method of producing oxygen using cryogenic distillation has the problem of consuming a large amount of energy.
Oxygen production by the pressure swing adsorption (PSA) process using oxygen storage materials (OSMs) based on redox reactions is expected to be an alternative energy-saving oxygen production method. In this process, oxygen is stored in the OSM under ambient oxygen partial pressure and then released by decompression. During this process, the large reaction enthalpies of the redox reactions (exothermic oxidation and endothermic reduction reactions) change the temperature of the OSM during each reaction (temperature increase and decrease, respectively). These temperature changes occur in the direction of inhibiting each reaction, which greatly reduces the efficiency of PSA.

The use of phase change materials (PCMs) is one excellent way to passively control the temperature change during a reaction without energy input. In this PSA, oxidation and reduction reactions are repeated within one packed bed, so it is expected that the PCM in the packed bed will store heat during the oxidation reaction and release heat during the reduction reaction, ideally maintaining a constant temperature inside the packed bed. We previously developed a microencapsulated PCM (MEPCM) with an aluminum alloy core covered with an alumina shell, which overcame the problems of leakage during melting and corrosion by liquid metal. Therefore, MEPCM is suitable as a material for temperature control in the packed bed.

Preliminary experiments on a mixture of MEPCM prepared by a conventional method and an OSM revealed that alumina on the MEPCM surface diffuses to the OSM surface, reducing the oxygen storage/release reaction rate. To solve this problem, this study aimed to enhance the MEPCM-OSM performance by coating the surface of MEPCM with OSM precursor material and preparing the MEPCM-mixed OSM pellets from it. Since OSMs can also be used as a chemical heat storage material using redox reactions, MEPCM-mixed OSM pellets can be applied as a material that can store sensible heat, latent heat, and chemical heat in energy storage systems that use heat.

The experiment was carried out using Y-doped $Ca_2AlMnO_{5+\delta}$ *(CYAMO) as the OSM and Al-12mass%Si (Al-12Si) as the core alloy of the MEPCM. CYAMO was synthesized from the nitrates of each element as starting materials. CYAMO powder and Al-12Si powder (D < 38 μm) were mixed by High-speed Impact Blending (HIB) to attach CYAMO to the Al-12Si powder. The alloy was then heat-treated in oxygen to encapsulate it. The melting and solidification characteristics of the products were analyzed by TG-DSC. The morphology after HIB and heat treatment was also observed by SEM and EDS.*

The trial on the variation of the peripheral speed during HIB at 40, 60, 80, and 100 m/s showed that a large amount of CYAMO fine particles successfully attached to the surface of Al-12Si at 40 and 100 m/s. Analysis of the melting and solidification characteristics after heat treatment showed that at speeds of 40, 60 and 80 m/s, a heat generation peak due to solidification was observed just below the melting point during temperature drop, while at 100 m/s, supercooling of approximately 35 °C occurred. Since this supercooling is a behavior unique to MEPCM that is not present in bulk Al-12Si, this result suggests successful encapsulation at a peripheral speed of 100 m/s.

EN04.05.12

Design, Synthesis and Test of Paraffine-Petroleum-Nanocellulose-Based Phase Change Materials for Personal Cooling of Closed-Circuit Breathing Apparatus

Zhao Qin; Syracuse University, United States

We aim to integrate molecular modeling and experiments to develop innovative wax and oil-based phase change materials (PCMs) for thermal regulation in Closed-Circuit Self-Contained Breathing Apparatus (CC-SCBA) systems to reduce thermal burden, enhance operational longevity, and improve warfighter efficiency. These PCMs are lightweight, biocompatible, reusable, and regenerative with a tunable and stable transition temperatures. We use theoretical calculation to demonstrate that less than 0.4 kg PCM can regulate the inspired air temperatures for CC-SCBA below 35°C for over four hours with continuous usage, in compliance with NIOSH standards. The material can be recharged after usage. Combining molecular dynamics simulation and theoretical analysis, our study provides the recipe of the PCMs, its synthesis and validate its performance in a climate chamber, as well as its packaging to prevent leakage and ensure compatibility with existing CC-SCBA systems and durability in nearly 100% humidity working environment. This study aims to reduce temperature burden that improve CO2 scrubbing efficiency, reduce health risk, and significantly extend mission duration, providing a crucial tactical advantage in individial operations in extreme conditions.

SESSION EN04.06: Phase Change Materials for Heat Management

Effects of Crystallite Size on the Water Absorption Behavior of Layered Manganese Dioxide for Low-Grade Waste Heat Storage

Hiroki Yoshisako[1,1], Norihiko L. Okamoto[1], Kazuya Tanaka[2] and Tetsu Ichitsubo[1,2]; [1]Tohoku University, Japan; [2]Japan Atomic Energy Agency, Japan

δ-MnO_2 is one of the manganese dioxide polymorphs, which has a layered structure with MnO_2 sheets stacked in the c-axis direction and contains K atoms between the layers, and is generally known to accommodate H_2O molecules in the interlayer space for phase stabilization [1,2]. Our research group has found that these accommodated H_2O molecules (0.5 mol-H_2O per mol-MnO_2) can be reversibly extracted/inserted from/into the interlayer of MnO_2 sheets at approximately 100-140°C under ambient atmosphere via a bulk (de)intercalation mechanism [3]. In terms of the entropy change of H_2O molecules during (de)hydration, we have also clarified that the physicochemical state of H_2O molecules absorbed via the intercalation mechanism is similar to that of the solid phase (ice-like). In accordance with this entropy change, the amount of heat absorption/release associated with the water intercalation reaction is as large as the sublimation enthalpy of H_2O (between ice and vapor). In this way, we have demonstrated that this K-containing layered MnO_2 exhibits a thermal energy density of over 1000 MJ m^{-3} via the water intercalation mechanism. Here, the capacity of accommodating H_2O molecules in δ-MnO_2 is expected to be increased by utilizing the MnO_2 surface as an accommodation site in addition to the interlayer space. This study aims to investigate the effects of crystallite size, i.e., the surface-to-bulk ratio, on the thermal storage properties of K-containing layered MnO_2.

To obtain δ-MnO_2 powders with different crystallite sizes, three synthesis methods were applied: 1) pyrolysis of $KMnO_4$ at 700°C, 2) hydrothermal method at 120°C, and 3) redox method at 25°C. XRD analysis confirmed that all samples have a layered structure, but the crystallite thickness along the stacking direction of the MnO_2 sheets strongly depends on the synthesis methods. The crystallite thickness along the stacking direction estimated by EELS analysis for the redox sample was 10 times finer than that of the pyrolysis one, and correspondingly, the specific surface area determined by BET analysis on the N_2 adsorption isotherm was confirmed to be more than 10 times larger. TG-DTA profiles measured under controlled humidity (70% relative humidity at 25°C) indicated that, in addition to the bulk intercalation mechanism, the sample with fine crystallite size can reversibly adsorb/desorb H_2O molecules also on the MnO_2 surface via the surface adsorption mechanism at low temperature range (25-50°C). As a result, the reversible capacity for accommodating H_2O molecules increased with the crystallite size refinement, reaching approximately 1.5 times higher in the redox sample than in the pyrolysis one. Furthermore, the total amount of heat, which was released at 28°C when the dehydrated samples were exposed to a humid Ar atmosphere (~2.0% H_2O), increased by approximately 1.3 times for the redox sample compared to the pyrolysis one, demonstrating that H_2O molecules reversibly absorbed/desorbed by the surface adsorption mechanism are also useful for heat storage. The hydration enthalpy per H_2O molecule decreased for the finer crystalline sample with increasing surface adsorption ratio, suggesting that the physicochemical state of H_2O molecules adsorbed by the surface adsorption mechanism is closer to the liquid state rather than the solid state. Furthermore, we achieved the enhancement of thermal energy density and the heat storage at room temperature by utilizing two different types of phase change of H_2O molecules by crystallite size refinement.

Combining Phase Change and Thermochemical Processes for Air Conditioning and Long-Distance Thermal Transport *Robert Y. Wang; Arizona State University, United States*

This talk presents my group's work on combining phase change and thermochemical processes to improve air conditioning, dehumidification, and long-distance thermal transport. I discuss our work on Smart ThermOREsponsive (STORE) desiccants, which undergo a hygroscopic-to-hydrophobic phase transition at a lower critical solution temperature (LCST). This LCST phase change facilitates thermochemical processes (water absorption/desorption) and can improve air conditioning/dehumidification performance. Next, I discuss our work on facilitating long-distance thermal transport by combining phase change separation processes (distillation) and reversible thermochemical reactions.

I first present thermodynamic models for air conditioning/dehumidification cycles that use STORE desiccant LCST phase transitions.[1, 2] I examine two classes of LCST materials: LCST polymers which undergo a solid-solid phase transition and LCST ionic liquids which undergo a liquid-liquid phase transition. The LCST regeneration mechanism leads to fundamental advantages relative to traditional desiccants. The performance of traditional desiccants is intrinsically tied to psychrometrics because they regenerate by desorbing gaseous water into a stream of hot dry air. In contrast, the performance of STORE desiccants is intrinsically tied to materials chemistry. STORE desiccants instead regenerate by releasing liquid water through their LCST phase transition. Our modeling work shows that these STORE desiccant cycles can have lower regeneration temperatures and higher coefficients of performance than traditional desiccant cycles.

I next present a thermodynamic model for a "thermochemical heat pipe" that uses reversible liquid-phase endothermic/exothermic reactions to efficiently transport waste heat over long distances. More specifically, the thermochemical heat pipe uses waste heat to both (i) drive the endothermic cleavage of an adduct molecule into two small reactant molecules and (ii) chemically separate the reactant molecules via distillation. The separated molecules are then pumped to their destination where they are combined in an exothermic reaction that supplies heat to users (and chemically reforms the adduct molecule). The adduct molecule is then pumped back to the waste heat source for re-use. Thermodynamic analysis of the system shows that heat transport efficiencies of ~30% are possible when only the thermochemical energy storage component is used. This efficiency can be boosted up to ~70% by incorporating heat exchangers that recover the sensible and latent energy components prior to long distant thermal transport. Pump work analysis shows that thermal transport over thousands of kilometers is feasible when transport is done in the liquid phase.

Phase Change-Related Thermal Property Characterization and Enhancement in Carbon-Based Organic Phase Change Composites *Mingxin Li[1], Xuanjie Wang[1,2], Junhua Shen[1], Dong Zhao[1] and Jie Lian[1,1]; [1]Rensselaer Polytechnic Institute, United States; [2]Massachusetts Institute of Technology, United States*

By utilizing the significant amount of energy absorbed and released during their phase transitions, phase change materials (PCMs) can capture and store thermal energy to fill gaps between supply and demand. Due to their many favorable properties, organic PCMs have gained attention in a wide range of applications. Nevertheless, their inherent low thermal conductivity has limited the direct use of organic PCMs in thermal energy storage (TES). Extensive research has been conducted on enhancing organic PCM thermal conductivity by incorporating high *thermal conductivity materials. Owing to their high thermal conductivity and low density, carbon-based materials have been extensively used for thermal conductivity enhancement in phase change composites (PCCs). Carbon-based organic PCCs, which incorporate highly thermally conductive carbon allotropes and their direct chemical derivatives with organic PCMs, are a group of diverse PCCs with highly promising potential for TES applications. Adequate latent heat and shape stability performances are crucial to the success of the applicational performances of these PCCs. Much empirical research has pushed efforts to enhance these phase change properties, yet a logical understanding of these enhancement efforts based on the thermodynamics and intermolecular interactions of carbon-based organic PCCs has been elusive. In particular, the effect of characterization methods on the evaluation of phase change properties has been largely understudied. This review strives to provide novel physical and chemical insights into latent heat and shape stabilization evaluation processes and enhancement efforts in carbon-based organic PCCs through a detailed review and analysis of recent literature. The review provides an unprecedented comprehension of newly developed PCCs that challenge the traditional understanding that the latent heat of PCCs cannot exceed that of its base PCM. Efforts on phase change property enhancement driven by these new insights have the potential for carbon-based organic PCCs to succeed in a variety of TES applications, including solar-thermal harvesting, thermal management of batteries and electronics, thermoregulating textiles, and infrared stealth and infrared responsive materials.*

Electric-Field-Induced Thermal Switching in a Bulk Ferroelectric Material at Room Temperature *Fanghao Zhang, Shantal Adajian and Bolin Liao; University of California, Santa Barbara, United States*

Electric-field-induced thermal switching has recently garnered increasing attention for thermal management, particularly in antiferroelectric and ferroelectric materials. Previous studies have focused on $PbZrO_3$ thin films and PMN-PT solid solutions to achieve thermal switching. However, the small thermal resistance of thin films limits their practical applications, and the inevitable extrinsic phonon scattering in solid solutions complicates their mechanisms, hindering the understanding of how intrinsic ferroelectric polarization and strain affect thermal transport. In this study, we demonstrate significant thermal switching in a bulk single-crystal ferroelectric material at room temperature. We found that, strain, rather than domain walls, plays the most important role in the change in thermal conductivity in bulk ferroelectrics. By engineering the domain switching mechanism, we successfully achieved reversible thermal switching effect with a high switching ratio driven by an external electric field. This result suggests that ferroelectric materials with strong electrostriction can serve as electric-field-induced thermal switches and domain swithcing engineering can be utilized as an efficient way to achieve reversible thermal switching in ferroelectrics. This work is based on research supported by the U.S. Office of Naval Research under the award number N00014-22-1-2262.

New Metavalent Materials and Why Their Thermal Conductivity is Low *Keivan Esfarjani, Safoura Nayeb Sadeghi, Sree S. Das, Ali Rayat and Mona Zebarjadi; University of Virginia, United States*

Metavalent materials have recently been introduced as a new class of materials with small bandgap, large Grueneisen parameters, polarizability and Born effective charges. Up to now more than a dozen such materials have been identified. They are typically IV-VI materials with rocksalt structure, and have good thermoelectric and phase change properties. In this talk, we present our characterization of metavalency in some new candidate materials such as LaP, and explain why it has lower thermal conductivity than LaBi despite having lighter mass and higher phonon group velocities. To identify new metavalent materials, we have investigated the effect of physical *and chemical pressure (or alloying) on metavalency. In partcular, we looked at the doping of cubic GeTe by In, Bi, Pb and Sb. Such strategies may allow us finding new metavalents and possibly low-thermal conductivity materials for thermoelectric and thermal management applications.*

11:00 AM *EN04.06.06

Advantages of Composite Phase Change Materials *Mary Anne White and John Noel; Dalhousie University, Canada*

Phase change materials (PCMs) can be used to efficiently store thermal energy for later release. Two of the main issues preventing wider PCM use are the need for containment (the phase change is generally solid to liquid), and low intrinsic thermal conductivity, especially for organic PCMs. We have addressed both issues through preparation of novel composite materials: freeze-cast porous ceramics impregnated with PCMs. We have shown that many different freeze-cast materials (alumina, titania, carbon black, alumina/carbon black, chitosan, carbonized chitosan) can be used as matrices for a wide variety of PCMs (fatty acids, PEG, paraffin, esters, sugar alcohols, salt hydrates), to prepare a range of composite phase change materials. The porous ceramic matrix does not substantially influence the PCM melting points, but does control the fill, thermal conductivity and mechanical properties of the form-stable PCM. Different matrices can be used to optimize thermal conductivity, or form stability, or PCM loading, depending on the application.

11:30 AM EN04.06.07

In Situ Measurement of Strain-Dependent Thermal Conductivity in Emerging Functional Materials *Shantal Adajian, Nick Tulshibagwale, Sam Daly and Bolin Liao; University of California, Santa Barbara, United States*

Semiconductor devices and sensors often contend with a range of mechanical stresses or strains. This is particularly pertinent in emerging domains like flexible electronics and thermoelectric devices, which find application in the renewable energy sector and experience these stresses in practical operating environments. The existing body of literature on experimental measurements of the strain dependence of materials are limited and still in the process of refinement. There are no steady-state measurement techniques used to measure the thermal conductivity. The measurements done are transient and performed through either Raman Spectroscopy or the 3w method. Both have limitations in terms of stability and duration of experiments as well as for investigating bulk materials due to geometrical and size constraints. Another critical constraint in transient measurements is that heat diffusion is measured, making it difficult to distinguish the strain dependence of thermal conductivity and heat capacity separately. Whereas in steady state we can have stable and continuous long-duration measurements, bulk material experiments, and can measure the temperature gradient of the material, from which we can directly calculate its thermal conductivity. We demonstrate this by measuring the thermal conductivity dependence on strain of bulk Silicon, GaN and GaAs. This study opens up a potential direction towards controlling thermal conductivity in semiconductors. This work is based on research supported by the U.S. Office of Naval Research under the award number N00014-22-1-2262.

11:45 AM EN04.06.08

Enhanced Thermal Conductivity of Bi-filler Paraffin Composites Using Expanded Graphite and Graphene Nanoplatelets *Thomas Hoke, Yiu Chan and Xi Chen; University of California, Riverside, United States*

Paraffin is one of the most widely used phase change materials (PCMs) for thermal energy conversion and storage. Due to its varied composition, its melting point can be tailored to the application, and its high chemical stability allows for the integration of virtually any filler material in the creation of phase change composites. However, its performance as a PCM is significantly hindered by its low thermal conductivity. In an effort to optimize the increase *in thermal conductivity of paraffin with the least amount of filler, various nanocomposites were synthesized by adding a combination of graphene nanoplatelets (GNP) and expanded graphite (EG) at various ratios and weight fractions. The thermal conductivity of these nanocomposites were measured in the solid phase using the steady state method from 280-300 K. The latent heat of fusion and melting point were measured using a differential scanning calorimeter, and the distribution of fillers was investigated using SEM. We found that hybrid systems using both expanded graphite and graphene outperformed the fillers individually at the same filler fraction. At a low filler fraction of 4 wt.%, the 50/50 hybrid EG/GNP system exhibited above a 700% increase in thermal conductivity, roughly the same increase achieved by adding 8 wt.% GNP, indicating unique thermal transport mechanisms specific to hybrid systems. The thermal conductivity data was analyzed using an effective medium theory (EMT) approach to determine the interfacial thermal resistance. These results indicate that this hybrid system shows far superior performance to other single filler materials such as metal/oxide nanoparticles and carbon nanotubes. The thermal energy storage capacity of the composites were not significantly affected through the addition of the filler materials due to the low weight percentage used to enhance the thermal conductivity of the composite.*

Advanced Characterization of Novel Lithium Rich Layered Oxides with Minimum Voltage Decay *Ying Shirley Meng[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States*

Lithium rich layered oxides exhibit complex phase change behavior in lithium ion battery during charge and discharge. Although this class of materials exhibit extraordinary capacity for storing lithium, the lack of understanding of the phase changes has prevented the wide commercial adoption of this type of cathode. In this talk, I will discuss a few emerging new properties discovered in LRLO oxides - the deployment of advanced characterization tools and computational methods have helped us to gain deep insights on this type of materials.

2:15 PM EN04.07.02

Investigating Lithiation Dynamics in $LiFePO_4$ Cathodes Through Phase Field Modeling and In Situ TEM Analysis *Ahmed Yousfi[1,2,3], Guillaume Boussinot[4], Florent Magaud[1,5], Justine Jean[1,5], Kevyn Gallegos Moncayo[1,5] and Arnaud Demortière[1,5,3]; [1]Université de Picardie Jules Verne, France; [2]Université de Picardie Jules Verne (UPJV), France; [3]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), France; [4]RWTH Aachen University, Germany; [5]Centre National de la Recherche Scientifique (CNRS), France*

Lithium-ion batteries are essential in portable electronics and electric vehicles, offering efficient energy storage. However, their microscopic operating mechanisms are very complex. Understanding the dynamics of lithiation is crucial because it directly impacts battery performance, lifespan, and safety. This study investigates the dynamics of lithiation within these batteries using in situ transmission electron microscopy (TEM) experiments and phase-field simulations, aiming to enhance performance and address existing challenges.
We present an experiment involving an electrochemical liquid cell for in situ TEM in which we can directly observe lithiation/delithiation process using the Dark Field technique. This real-time monitoring provides valuable insights into the fundamental processes occurring during cycling. Furthermore, we aim to evaluate the local displacement

field extracted from the 4D-STEM ACOM (Acquisition of Crystal Orientation Maps) datasets, as the modifications in the lattice parameters of the $FePO_4$ host is induced by the lithium intercalation and necessitating the calculation of the symmetric strain tensor at the LFP/FP interface. By integrating 4D-STEM data treatments and analysis, we can accurately characterize the strain distribution and its influence on the phase transformation dynamics.

To gain a comprehensive understanding of the lithiation/delithiation dynamics and further elucidate the underlying mechanisms, we employ phase field model for simulations. Here, we use an Allen-Cahn type phase-field approach to investigate the phase transition from $LiFePO_4$ to $FePO_4$ cathode crystals in the presence of Li-ion chemical potential difference with the surrounding liquid electrolyte. The solid-solid phase boundary between LFP and FP phases are modeled as a diffuse interface of finite width, and its motion is implicitly governed by the phase field variable Φ which the temporal evolution is described by solving numerically a set of of partial equations. By incorporating the real particle morphology and considering the smoothed boundary method (SBM), our phase field model provides a more realistic representation of the lithiation/delithiation dynamics within $LiFePO_4$ crystals. Initially, we employ a simple 2D model including the chemical free energy and the interfacial free energy with a double-well potential approach. By studying the kinetics of the lithiation/delithiation process within the LFP particle, which follows a one-dimensional Li-ion diffusion along the [010] direction, we observe two distinct regimes known as Surface Reaction Limited and Bulk Diffusion Limited. Our simulations are obtained by varying a parameter which refers to the net rate of insertion parameter.

Furthermore, we extend our model by incorporating the elastic free energy to consider its influence on the phase growth direction and shape during the LFP/FP phase transition within a realistic $LiFePO_4$ single particle morphology. The elastic properties are adjusted using strain maps based on 4D-STEM data treatments and adaptative diffraction image registration.

In conclusion, this research explores the Li-ion insertion mechanisms into $LiFePO_4$ crystals using in situ TEM experiments combined with phase-field simulations. The correlation between the phase-field model and the 4D-STEM results provides valuable insights into the complex dynamics of phase transformations and microstructure evolution, contributing to the understanding of key factors affecting the performance and lifetime of Li-ion batteries. Our approach contributes to the elucidation of the intricate process that drives the dynamics of lithiation inside individual cathode materials during the electrochemical process.

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

3:30 PM EN04.07.03

Designing High-Performance Lithium-Ion Batteries with Core-Shell NMC Morphology *Natalia Firlej[1], Michal Grygiel[1], Magdalena Winkowska-Struzik[1], Alicja Glaszczka[1], Jacek B. Jasinski[2], Michal Struzik[3], Dominika A. Buchberger[1] and Andrzej Czerwinski[1]; [1]University of Warsaw, Poland; [2]University of Louisville, United States; [3]Warsaw University of Technology, Poland*

In the continuous search for portable energy sources, active materials for lithium-ion batteries have come into the spotlight, sparking intensive research into promising cathode materials. Currently, one of the most popular cathode materials for lithium-ion batteries is lithium nickel manganese cobalt oxide, described by the formula $Li(Ni_xMn_yCo_z)O_2$. Its attractiveness lies in its high energy density and relatively cost-effective constituent elements. However, there is no middle ground in NMC composition, as both the electrochemical and safety properties of batteries depend significantly on each constituent element. Increasing the Ni concentration enhances the discharge capacity, making it a promising candidate. However, it also induces thermally triggered phase transitions, negatively impacting cycling retention and structural stability upon long cycling [1]. Recently, a beneficial improvement seems to be creation of a cathode material with gradient structure. This involves having a high nickel concentration in the grain interior and increasing manganese and cobalt content towards the outer part. This arrangement secures the high-capacity nickel-rich core with a stable nickel-poor shell [2]. Both high

discharge capacity, stability, and safety are highly relevant.
This research focuses on developing a synthesis route for core-shell NMC with differentiated nickel content. This significant change in the approach to NMC material synthesis aims to provide high capacity without loss in cycling stability. Moreover, to optimize the effect of increasing material stability, we investigated and cross-referenced shell variants differing in Co/Mn content. Gradient structures with high-manganese outer content are well-known, but initial indications suggest that preparing core-shell or gradient NMC with a Co-rich outer layer results in even better stability. Studies have shown that Co-rich material is more stable than Mn-rich and prevents primary grains from cracking and degradation [3].
The high-nickel core precursors were prepared using the coprecipitation method to form the complex metal hydroxide $Ni_xMn_yCo_z(OH)_2$ *in a Couette-Taylor flow reactor, which allowed for maximum control of the synthesis process. Following this, a method for shell deposition was developed. The resulting core-shell precursors were then annealed to produce the lithiated powders. This careful precursor synthesis strategy and the subsequent calcination of the final product ensured reliable and reproducible results.*
To explore the properties of the materials and conduct a comprehensive analysis of their differences, we employed a variety of methods. Scanning electron microscopy was used to examine the morphologies of the prepared powders both before and after the shell coating step. X-ray powder diffraction allowed to characterize the crystal structure of the prepared materials, providing insight into their crystallographic parameters and phases present. Raman spectroscopy was employed to examine the structural homogeneity core and shell and detect post-synthesis contamination of the material. Moreover, to study the shell creation route and the influence of composition on material properties, we investigated its post-cycling morphology and structure.

A detailed analysis will be presented during the conference. *This work was funded by the National Science Center in Poland through the Sonata 17 programme (No. UMO-2021/43/D/ST5/03094).*

Magnetite Nanoparticle Coating Enables High Voltage Stability in Ni-Rich Cathodes for High Energy Lithium-Ion Batteries *Varad Mahajani and Nikhil Koratkar; Rensselaer Polytechnic Institute, United States*

The widespread application of rechargeable batteries necessitates high-performance and cost-effective solutions. Nickel-rich cathodes such as $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ *(NMC 811) are of great interest in academia and industries given their high theoretical capacity (~ 200 mAh* g^{-1} *for NMC 811) and lower economic and environmental costs associated with the cobalt mining. However, deleterious side reaction on the surface of these cathode active particles inhibits their stable electrochemical cycling performance. These reactions are worsened during high voltage cycling, as the Ni cation in the cathode material experiences an increase in oxidation state, which can lead to Li/Ni cation intermixing. This also triggers phase changes from hexagonal to disordered spinel or even rock-salt structure, resulting in an irreversible loss of active material. Herein, we developed a coating of Magnetite nanoparticles over the micro NMC811 particles using a facile surfactant-assisted strategy using an aqueous medium. A notably higher cycle stability, rate performance, and overall energy density was realized for the coated cathode in a conventional liquid electrolyte system. To prove the versatility of the chemistry, pellet-stacked solid-state cells with* Li_6PS_5Cl *as the electrolyte was deployed and the coated NMC 811 showed superior cycling stability* *than its uncoated counterpart.*

4:00 PM EN04.07.05

Moisture Reactivation of Calcium Sorbents for Long Duration Thermochemical Energy Storage *Lyu Zhou[1], Roma Avhad[1], John Mangum[2], Diwash Dhakal[3], Yi Zeng[2], Katherine L. Jungjohann[2], Simerjeet Gill[3], Judith Vidal[2] and Shuang Cui[1,2]; [1]The University of Texas at Dallas, United States; [2]National Renewable Energy Laboratory, United States; [3]Brookhaven National Laboratory, United States*

Calcium sorbents—mainly composed of calcium oxide and carbonate—exhibit great promise for thermochemical energy storage due to their high working temperatures, high energy density, good thermal conductivity, affordability, and non-toxicity. However, progressive performance degradation over long cycles hinders their practical application. In this study, we investigated the mechanism of performance degradation by studying the microstructure changes of calcium sorbents over multiple cycles, including variations in particle size, crystal size, and surface areas. Our results indicate that calcium sorbents with a larger surface area and smaller crystallite size typically show higher initial carbonation conversion rates, leading to more efficient thermochemical energy storage. Specially, a nano-sized calcium sorbent with a surface area of 12.4 m^2/g and crystallite size of 28 nm displayed an initial conversion rate of 92%, which is significantly higher than the 65% conversion rate in a micro-sized calcium sorbent with a surface area of 0.3 m^2/g and crystallite size of 64 nm. However, nano-sized sorbents exhibited more phenomenal degradation due to the sintering and aggregation, with the conversion rate rapidly dropping from 92% to 18% after 15 cycles. To address this issue, we proposed controlled moisture hydration treatments to reactivate the degraded sorbents. Rigorous studies were conducted to study the effects of hydration degrees on restoring surface area and crystallite size, while thermal analysis was performed to understand the improved degradation performance and overall energy storage performance. By reactivating the degraded sorbents with a hydration degree of 300%, the conversion rate was recovered to 87%, indicating an effective restoration of thermochemical energy storage efficiency. This demonstration of reactivating degraded sorbents offers a promising solution for improving long-duration thermochemical energy storage, benefiting renewable energy harvesting systems such as concentrated solar power plants.

Boosted Thermogalvanic Thermopower upon Solid-to-Liquid Phase Transition *Sangtae Kim[1] and Wonjoon Choi[2]; [1]Hanyang University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)*

Thermogalvanic cells offer scalable low-grade waste heat recovery using tunable electrode-dependent thermopower and electrolyte-dependent thermal conductivities. However, the use of single-phase electrodes thermodynamically curb the entropy difference, limiting the thermopower enhancement. Here, we show that phase transforming electrodes achieve significantly enhanced thermopower using the melting phase transition of bulk Na_xK alloys. Under both temporal and spatial temperature gradients, the electrodes exhibit significantly increased thermopower up to 26.1 mV/K across the melting point and the generated voltages of 261 mV under 10 K temperature gradient. We also show that stabilizing the liquid metal electrode-electrolyte interface plays a critical role in evaluating the thermopower associated with the phase transition. The strategies demonstrated in this work suggest potential design guidelines towards optimizing thermogalvanic cells to specific temperature ranges.

A Dual-Biomimetic Surface with Leaf-Skeleton-Based Hierarchical Structures for Efficient Atmospheric Water Harvesting *Qiyu Chen, Fabian J. Medina and Qing Hao; The University of Arizona, United States*

Atmospheric water harvesting (AWH) is a sustainable strategy to mitigate current freshwater scarcity. Recent *developments lie in regulating surface properties inspired by numerous natural creatures. However, it remains challenging to design a surface capable of fast water capture and directional droplet transport, both of which are essential for efficient AWH applications. Here, we proposed a novel approach for designing the water-harvesting surfaces (i.e., a tailored microstructured surface), inspired by the heterogeneous wettability of the Namib Desert beetle and the hierarchical structures of Ficus religiosa leaf skeleton. Unlike conventional oversimplified structural optimization, our approach directly employs the natural designs of the leaf skeleton to distribute heterogeneous wettability and optimize the structural increments without adjustments. Within the leaf-skeleton-based structure of superhydrophilic* SiO_2*, the superior water-capture capability is enabled by the novel intricate venules within reticulate meshes, which is also the critical factor in facilitating directional droplet transport along the abundant hierarchical veins. The proposed water-harvesting surface has shown exceptional efficiency, demonstrating a 62% increase over pristine* SiO_2*/Si wafers and a 58% increase over pristine Si wafers. Furthermore, the impact of leaf-skeleton-based structure orientation in the open-surface droplet transport is investigated. When most veins are pointing downward, aligned with the direction of gravity, our surface achieves the highest water-harvesting efficiency, showing a 17% increase compared with its horizontal orientation and a 10% increase compared with its flipped orientation. The innovative dual-biomimetic surface structures are expected to have wide applications in other water-related research, such as evaporative cooling of electronic devices.*

Composition Dependent Phase Development of the High Capacity Conversion Cathode, FeO_xF_{2-x} *Kieran McDonnell[1,2], Emily Stec[1], Jordan Sweeney[1] and Eve Mozur[1]; [1]Colorado School of Mines, United States; [2]Haverford College, United States*

Conversion electrodes for lithium and sodium ion batteries are promising due to their high capacities compared to traditional intercalation electrodes, and because their mechanism of charge storage allows for greater compositional flexibility. The complete reduction of the metal upon lithium insertion yields this high capacity and flexibility, but it hinders the regeneration of the starting material. Improving the cyclability of these electrodes requires understanding the phase changes of these electrodes in operando. Iron oxyfluoride (FeO_xF_{2-x}*) is an attractive candidate material because of its high theoretical capacity (885 mAh g-1) and because of iron's natural abundance. We'll discuss how the O:F ratio can also be tuned during synthesis to balance the high capacity of oxides and the high voltage windows of fluorides. Next, we'll investigate how the composition of* FeO_xF_{2-x} *impacts the phase development of the material during battery cycling. To do so, we'll use cyclic voltammetry and pair distribution function analysis of total scattering data to provide electrochemical behavior along with local structure information. Insights from this work will allow for modifications of* FeO_xF_{2-x} *and similar conversion electrodes to improve their cyclability without sacrificing their capacities.*

EN04.08.02
Advanced Neutron Scattering Techniques for Operando Characterization of Phase Change Materials *Yiyang Jin and Hillary Smith; Swarthmore College, United States*

The reversible amorphous to crystalline phase transition in Ge-Se glasses has led to their critical use in applications ranging from heat sensors for real time temperature monitoring to optical media storage. Despite these important applications, our understanding of the dynamical changes occurring across this phase transition remains incomplete. This work describes the development of an operando inelastic neutron scattering technique as an advanced thermal and material characterization tool to study the phase transition in bulk Ge-Se glasses. The operando inelastic neutron scattering technique produces time-resolved information about the phonon vibrational dynamics in these materials transition from amorphous solid to undercooled liquid and crystalline solid. This new technique allows us to capture a phonon density of states in as little as 90 seconds, providing real-time quantitative evaluation of the vibrational entropy in the glass, liquid, and crystalline phases. Aspects of operando neutron scattering data collection and analysis will be discussed alongside new insights into the vibrational dynamics in Ge-Se glasses. Potential for application of this technique to additional phase change materials will also be discussed.

EN04.08.03

Study on Bronze-Rich Dual-Phasic TiO_2 Embedded Carbon Architecture Derived from Ti-Metal-Organic Frameworks for Enhanced Lithium-Ion Storage

Won Seok Yang and Hyung Koun Cho; Sungkyunkwan University, Korea (the Republic of)

Lithium-ion batteries (LIBs) are widely used for energy storage due to their affordability, rechargeability, long cycle life, and high energy density. Currently, graphite, as an anode material, faces limitations in constructing high-capacity LIBs due to its low theoretical capacity (372 mAh/g) and safety concerns. TiO_2 is considered a promising alternative due to its abundance, cost-effectiveness, high discharge voltage plateau, and minimal volume change (<3%). However, TiO_2 has a relatively low theoretical capacity and practical capacity issues, with the actual capacity often lower than theoretical values. Nanostructured TiO_2 has been shown to significantly improve lithium insertion rates to over 75%. Moreover, interest in bronze TiO_2 nanostructures has grown due to their high theoretical capacity of 420 mAh/g. Recently, strategies involving dual-phase nanostructures are anticipated to enhance both capacity and rate capability.

Metal–Organic Frameworks (MOFs), composed of metal elements and organic linkers, have emerged as promising materials for catalysts, electrodes, and energy storage devices due to their porous architecture and catalytic sites. Ti-based MOFs, in particular, can be converted into porous carbon materials containing TiO_2 nanoparticles. This study introduces a novel approach using Ti-based MOFs to create a bronze-rich dual-phase TiO_2 embedded in carbon architecture via a two-step pyrolysis process. During the first pyrolysis step, metal clusters decompose to form intermediate phases, facilitating the synthesis of bronze TiO2 crystals. In the second step, the resulting dual-phase TiO_2 is integrated into a conductive amorphous carbon matrix.

This method demonstrates a specific capacity of 638 mAh/g at a current density of 0.1 A/g and 194 mAh/g at 5 A/g, highlighting the contribution of interfacial storage. Additionally, the proposed bronze-rich dual-phase TiO_2 embedded in carbon architecture derived from Ti-MOFs exhibits stable reversibility at high-rate densities over 6000 cycles.

EN04.08.04

Effect of Artificial Cathode Electrolyte Interphase in High Voltage Operation of $LiCoO_2$ for High Energy Lithium-Ion Battery Application

Endazenaw B. Chemere[1,2,3]; [1]Tshwane University of Technology, South Africa; [2]National Taiwan University of Science and Technology, Taiwan; [3]Dilla University, Ethiopia

$LiCoO_2$ has been a prominent cathode material in LIBs because of its favorable electrochemical attributes, such as good capacity retention, favorable rate capability, and high structural reversibility below 4.2 V Li/Li^+. However, the

available capacity of $LiCoO_2$ electrodes charged to this potential limit (4.2 V) is not more than 140 mAh g^{-1}, which is almost only half of its theoretical limit (274 mAh g^{-1}). Increasing the cut-off voltage of the cathode materials is one of the effective ways to increase the capacity. However, at high voltage operation, its degradation behavior causes it to have poor electrochemical performance and thermal instability. The degradation of highly delithiated $LiCoO_2$ is mainly induced by oxygen vacancy migration and weakening of oxygen-related interactions, which result in pitting corrosion and fault formation on the surface.
In this research, a coupling agent, namely, 3-aminopropyltriethoxysilane (APTES), was grafted onto the surface of $LiCoO_2$ to form a cross-linking structure. Through the aza-Michael addition reaction, an oligomer formed from barbituric acid and bisphenol a diglycidyl ether diacrylate was reacted with the cross-linking APTES to form an artificial cathode electrolyte interphase (ACEI). The highly delithiated $LiCoO_2$ containing the ACEI had considerably less degradation on the surface of the bulk material caused by oxygen release. The formation of the O1 phase was prevented in high delithiation and high-temperature operations. This research revealed that the ACEI reinforced the Co−O bond, which is crucial in preventing gas evolution and O1 phase formation. According to the present results, highly delithiated $LiCoO_2$ containing the ACEI exhibited outstanding cycle retention and capacity at 55 °C as well as low heat capacity release in the fully delithiated state. The ACEI considerably protected and maintained the electrochemical performance of highly delithiated $LiCoO_2$, which is suitable for high-energy-density applications, such as electric vehicles and power tools.

EN04.08.05

Iron-Based Oxides with Tunable Porosity by Organic Acid Etching as Electrode Materials for Lithium-Ion Batteries

Yi-Wei Chang, Hsing-An Chang and Tri-Rung Yew; National Tsing Hua University, Taiwan

With the global increasing demand for energy storage, developing high energy density and safe lithium-ion batteries (LIBs) is critical. Iron oxides are considered promising active materials for LIB anodes owing to their high-capacity, earth-abundance, non-toxicity, and low- flammability. However, iron oxides encounter issues such as poor ionic conductivity, low Columbic efficiency, and severe structural expansion during charge/discharge reactions, hindering their applications in LIBs.

Porous materials are considered potential candidates to buffer the volume variation of LIB anodes during cycling. In this work, iron-based oxides with tunable porosity are formed using a simplified and non-toxic organic acid etching process, which is then applied to anode materials for LIBs. Their electrochemical properties at electrode/electrolyte interfaces are investigated. Furthermore, the etching conditions for iron-based oxides are optimized to improve the cycle-life retention and rate-capability of LIB anodes.

Etched iron-based-oxide powders are mixed with carbon black (Super P), carboxymethyl cellulose (CMC), and styrene-butadiene rubber (SBR) to form an aqueous-based electrode slurry, which is then coated onto a copper foil by doctor-blade casting to form an electrode, followed by baking in a vacuum oven. After battery assembly, galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS) are conducted to analyze the cycle-life retention, Coulombic efficiency, and the impedance reduction of electrodes. Besides, the porosity of etched iron-based-oxide powders is characterized by Brunauer-Emmett-Teller (BET) surface area analyses. Field-emission scanning electron microscopy (FE-SEM) and energy-dispersive X-ray spectroscopy (EDX) are conducted to analyze the morphology and composition of active materials, respectively. This work offers a novel approach to improve the retention and rate-capability of LIB anodes through etching iron-based oxides with organic acid.

EN04.08.06

Oxygen-Defective $TiNb_2O_7$ Anode Synergized with Lithiated Polyacrylic Acid Binder for High-Power Lithium-

Ion Storage *Doosoo Kim, Jong Heon Kim and Hadi Khani; The University of Texas at Austin, United States*

The growing demand for renewable energy necessitates the advancement of high-performance energy storage devices. Lithium-ion batteries (LIBs) are the primary energy storage solutions for portable electronic devices and have become predominant in the electric vehicle (EV) market. The existing LIBs use an organic-based liquid electrolyte and a graphite anode. However, the graphite anode has intrinsic limitations related to power density and safety. These limitations arise because lithium-ion intercalation into graphite occurs at a potential very close to that of lithium plating, especially during charging at high rates and low temperatures, which can lead to capacity loss, reduced cycle life, and safety concerns.

$TiNb_2O_7$ *(TNO) emerges as a promising intercalation-type anode material for LIBs due to its high theoretical capacity (≈ 388 mAh* g^{-1}*) and operating potential (≈1.6 V vs.* Li^+/Li*) - above the decomposition voltage of carbonate-based electrolytes. However, TNO encounters several challenges that require attention for widespread adoption: (i) low electronic conductivity resulting from its wide energy band gap, (ii) time- and energy-intensive synthesis using conventional solid-state methods (typically exceeding 12 hours at 1250 °C), and (iii) the absence of a stable solid electrolyte interface (SEI) layer when discharged to 0.5 V. In our study, we address these issues using energy-efficient and environmentally friendly approaches.*

In this study, we prepared oxygen-defective $TiNb_2O_7$ *(OD-TNO) using an ultra-fast Joule heating method. By introducing oxygen vacancies, the unit cell volume expanded due to partial reduction of* Ti^{4+} *and* Nb^{5+}*, thereby accelerating lithium diffusion into the TNO structure. The transition from* d^0 *to* d^1 *electronic configuration in* Nb^{5+} *(to* Nb^{4+}*) and* Ti^{4+} *(to* Ti^{3+}*) resulted in electronic conductivity in OD-TNO that was five orders of magnitude higher than that of conventional TNO. To form an artificial SEI layer on the OD-TNO particles, we replaced the conventional PVDF binder, which requires the toxic solvent N-methyl-2-pyrrolidone (NMP), with a water-based lithiated polyacrylic acid (Li-PAA) binder. The amorphous nature of Li-PAA not only improved film coverage through hydrogen bonding with surface oxygens in OD-TNO, preventing direct contact between TNO particles and the liquid electrolyte, but also facilitated rapid* Li^+ *transport due to its incorporation of* Li^+ *within the polymer structure. As a result, the Li-PAA binder enhanced both cycle stability and rate capabilities.*

The OD-TNO electrode with a Li-PAA binder exhibits a high initial discharge capacity of ~370.74 mAh g^{-1}*, and remarkable rate capability (~149.40 mAh* g^{-1} *at 10 C). After setting the rate back to 1C, the recovered capacity is 247.12 mAh* g^{-1} *and the capacity remains stable, delivering a capacity of 181.03 mAh* g^{-1} *with a retention of 73.26% at 1C over 800 cycles, demonstrating significantly improved cycling performance. To confirm its practical application potential, a full-cell comprising an OD-TNO anode and a* $LiNi_{0.5}Mn_{1.5}O_4$ *cathode was investigated. The full-cell demonstrates a capacity of 146.5 mAh* g^{-1} *over 100 cycles with a capacity retention of 95.8%. These results highlight the synergetic effect of OD-TNO and Li-PAA as a practical high-energy and high-power density anode for LIBs.*

EN04.08.07

Experimental and Theoretical Investigation of Structural, Electrical and Photocatalytic Properties of (K,Na)NbO3 Lead-Free High Temperature Piezoelectric Ceramic Prepared via Different Synthesis Routes

Manish Saha, Manish K. Niranjan and Saket Asthana; Indian Institute of Technology Hyderabad, India

The $K_{0.5}Na_{0.5}NbO_3$ *(KNN) system has emerged as one of the most promising lead-free piezoelectric over the years. In this work, we perform a comprehensive investigation of electronic structure, lattice dynamics and dielectric/ferroelectric properties of room temperature phase of KNN by combining ab-initio DFT based theoretical analysis and experimental characterization. The solid-state reaction and hydrothermal methods are used to prepare the KNN ceramics, and the effects of grain size on the physical characteristics these ceramics are examined. Therefore, a comprehensive study on the impact of different synthesis techniques on the structural, electrical, and photocatalytic properties of ferroelectric ceramics KNN. The KNN-S prepared by solid-state method* *have significantly larger grain size as compared to that for KNN-H prepared by hydrothermal method. Furthermore, the KNN-S is found to exhibit higher dielectric, piezoelectric and ferroelectric properties as compared to KNN-H. On the other hand, the increased photocatalytic activity is observed in KNN-H as compared to KNN-S. As compared to the hydrothermal synthesis, the solid-state synthesis causes an increase in the relative dielectric permittivity from 2394 to 3286, remnant polarization from 15.38 to 20.41 C/, planer electromechanical coupling factor from 0.19 to 0.28 and piezoelectric coefficient from 88 to 125 pC/N. The KNN-S ceramics are also found to have a lower leakage current density, and higher grain resistance than KNN-H ceramic. The enhanced photocatalytic activity of KNN-H is attributed to relatively smaller particle sizes and larger surface area. The KNN-S and KNN-H samples are found to have degradation efficiencies of RhB solution of 20% and 65%, respectively. The experimental study highlights the importance of synthesis methods and how these can be exploited to tailor the dielectric, piezoelectric and photocatalytic properties of KNN. We assign the symmetry labels to KNN vibrational modes and obtain ab-initio polarized Raman spectra, Infrared (IR) reflectivity, Born-effective charge tensors, oscillator strengths etc. The computed Raman spectrum is found to agree well with the experimental spectrum. In particular, the results suggest that the mode in range ~840-870 cm^{-1} reported in the experimental studies is longitudinal optical (LO) with symmetry. The Raman mode intensities are calculated for different light polarization set-ups that suggests the observation of different symmetry modes in different polarization set-ups. The electronic structure of KNN is investigated and optical absorption spectrum is obtained. Further, the performances of DFT semi-local, metal-GGA and hybrid exchange-correlations (XC) functionals, in the estimation of KNN band gaps are investigated. The KNN bandgap computed using GGA-1/2 and HSE06 hybrid functional schemes are found to be in excellant agreement with the experimental value. The COHP, electron localization function and Bader charge analysis is also performed to deduce the nature of chemical bonding in the KNN. Overall, our study provides several bench-mark important results on KNN that have not been reported so far.*

EN04.08.09

Origin of Irreversible Capacity of Water Intercalation in δ-Type Layered Manganese Dioxide

Norihiko L. Okamoto, Hiroki Yoshisako and Tetsu Ichitsubo; Tohoku University, Japan

K-containing layered manganese dioxide ($K_{0.33}MnO_2$●$0.83H_2O$) has been found to exhibit excellent heat-storage properties, including high environmental integrity, high thermal energy density, fast charge/discharge rates, and good cyclability, owing to a water-intercalation mechanism [1]. The K-containing MnO_2 can reversibly absorb and release 0.50 mol molecules per MnO_2 resulting in a reversible thermal energy density exceeding 1000 MJ/m^3. However, it exhibits irreversible capacity of water intercalation (0.33 mol per MnO_2) in the initial heating/cooling cycle, which limits the reversibly available energy density of the material for the subsequent cycles.

To elucidate the origin of the initial irreversible capacity, we investigated the crystal structure of the layered manganese dioxide in the as-synthesize and heat-treated states by atomic-resolution scanning transmission electron microscopy (STEM) [2,3]. The interlayer K cations in the as-synthesized state are randomly arranged in some of the interlayers because excess water molecules prevent the K cations from occupying the most stable interlayer site (Wyckoff 2c site in space group $P6_3/mmc$). After heat treatment at 250°C, on the other hand, the interlayer K cations occupy every third 2c site in all the interlayers, showing a tripled periodicity along the a-axis direction. This infers that simultaneous occupancy at the 2c site of the K cation and the water molecules cannot be realized, and the heat treatment allows the K cation to move from its metastable position to the most stable position (2c site) in the absence of water molecules at high temperatures. Thus, the ordering of the K cations once occurring without the water molecules during heat treatment hinders the excess water initially included to re-intercalate in the subsequent cycle process. The order-disorder transition of the interlayer cations dominates the water-intercalation behavior in the layered MnO_2. To minimize the irreversible capacity of water intercalation, and hence, to increase the thermal energy density, replacing interlayer K cations with other species and/or optimizing the content of interlayer cations that change the interaction between the interlayer cations and water molecules *will be effective.*

Thin Diaphragms with High Selectivity for Alkaline Water Eelectrolysis Application *Yuho Song[1,2], Jungkyu Choi[2] and Tae-ho Kim[1]; [1]Korea Research Institute of Chemical Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)*

Alkaline water electrolysis (AWE) is well-suited for the mass production of hydrogen from renewable energy sources due to its low installation cost, which results from the absence of precious metal catalysts. However, AWE poses a risk of hydrogen permeation through the diaphragm at low loads, which can increase the concentration of hydrogen in oxygen and potentially lead to fire or explosion. Therefore, a diaphragm with strong gas barrier properties is needed. Additionally, due to the low efficiency of AWE, there is a need for a diaphragm that provides low area resistance [1].

In this study, we developed a thin-film diaphragm that simultaneously exhibits low membrane resistance and reduced gas permeability. To achieve this, we introduced a polymeric additive, which is expected to increase the porosity and strengthen the connection between zirconia(ZrO_2)nanoparticles and the polymer matrix as a binder. The diaphragm was fabricated by dispersing the polymeric additive and polysulfone (PSf) with ZrO_2 in N-Methyl-2-Pyrrolidone (NMP) using a planetary mixer to make a slurry. This slurry was then coated on both sides of a polyphenylenesulfide (PPS) support using a roll-to-roll process. Then, the porous structure was formed using the non-solvent induced phase separation (NIPS) method in a water bath. The diaphragm with polymeric additive (A/PSU-10) exhibited a 14% higher bubble point (5.48 bar), lower hydrogen permeability (less than 5×10^{-12} mol s^{-1} bar^{-1}), lower area resistance (less than 0.10 Ω cm^2), and 24% higher AWE unit cell performance at 1.80V (1.65 A cm^{-2}) compared to the diaphragm using only PSf (A/PSU-0).

To further enhance the gas permeation barrier of the diaphragm, a hydrophilic skin layer based on crosslinked polyvinyl alcohol (PVA) was coated onto the diaphragm, a process was previously developed and reported by our research team [2]. An aqueous PVA solution was air-sprayed onto the surface of the diaphragm, and the resulting PVA layer was crosslinked using glutaraldehyde. The diaphragm with optimized composition and crosslinked PVA skin layer (cA/PSU-10) exhibited a 252% higher bubble point (7.61 bar), lower hydrogen permeability (less than 1×10^{-12} mol s^{-1} bar^{-1}), lower area resistance (less than 0.15 Ω cm^2), and 101% higher AWE unit cell performance at 1.80V (1.49 A cm^{-2}) compared to the commercial diaphragm (Zirfon UTP 500).

Ferroelectric Resonator—An Energy-Efficient Alternative to Heat for Water Extraction *Ikra Iftekhar Shuvo[1,1], Carlos D. Diaz[1], Marvin Christen[2], Michael Lherbette[2] and Svetlana V. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]SmarAct Metrology GmbH, Germany*

Many communities worldwide experience a shortage of freshwater resources, which severely inhibits their land *development and creates harsh humanitarian conditions for their populations. There is a need for atmospheric water harvesting (AWH) technologies that can operate in arid or semi-arid climates or in regions where large-scale installations are impractical for economic or security reasons. However, the state-of-the-art technology has prohibitively high energy consumption due to the high heat of water desorption from AWH materials. We present a novel approach to extracting liquid water from atmospheric water harvesting hydrogels (AWGs) using a 1.5W ferroelectric resonator. Our results show that this method is at least ~5x more energy-efficient compared to the current state-of-the-art, which predominantly relies on heating-induced evaporation. Using commercially available ferroelectric polycrystalline material, we designed, prototyped, and tested a lab-made resonator with a capacitance of 3000 pF, which simultaneously induces mechanical strain and Joule heating in AWGs under an AC voltage. Our work demonstrates that the resonator can achieve quick and efficient water release from polyacrylamide (PAM) AWGs synthesized in our lab, which incorporate lithium (Li) and chloride ions (Cl) as essential elements for their ability to adsorb water molecules from the atmosphere. Further, a complex electronic sensor system was used to sense the mechanical wave produced by the actuator that transmitted through the PAM-LiCl, allowing us to effectively study the influence of moduli and thickness of AWGs to be used with our resonator for effective water extraction. Based on the recent thermodynamic models of sorption-based atmospheric water production with AWGs, the lowest amount of energy recorded so far is 22.5 MJ/kg, whereas our proposed system demonstrated an exceptional efficiency of 4.8 and 5.25 MJ/kg for extracting water from HG-M and PAM-LiCl, representing a paradigm shift in the field of water extraction from AWGs.*

Reversible Dielectric Phase of Highly Crystalline $NiFe_2O_4(111)$ Thin Films with Temperature in X-Ray Photoelectron Spectroscopy (XPS) *Arjun Subedi, Detian Yang, Xiaoshan Xu and Peter A. Dowben; University of Nebraska–Lincoln, United States*

Recently, we observed that $CoFe_2O_4$ and $NiCo_2O_4$ thin film surfaces undergo non-metal to metal phase transition with temperature [1]. These non-metal to metal phase transitions were not observed to be reversible with the temperature. Since the non-metal to metal phase transitions observed for $CoFe_2O_4$ and $NiCo_2O_4$ thin film surfaces are mediated by oxygen vacancies, voltage control of non-volatile states may be possible, making such materials electronically attractive especially if the phase transition is reversible. We have observed reversible dielectric (non-metallic) phase change for the $NiFe_2O_4(111)$ thin film surface region, with temperature in X-ray photoelectron spectroscopy (XPS). Energy shifts of 5 eV, to higher binding energies relative to expected values, were observed in Ni $2p_{3/2}$, Fe $2p_{3/2}$, and O 1s XPS core level spectra at room temperature due to surface photovoltage charging during photoemission. This indicated that the surface of the $NiFe_2O_4(111)$ thin film was highly dielectric (non-metallic) at room temperature. The core level binding energy shifts decreased when the thin film was annealed in vacuum, making the $NiFe_2O_4(111)$ thin film less dielectric or more metallic at higher temperatures. At the temperature of 410 K or above, the observed Ni $2p_{3/2}$, Fe $2p_{3/2}$, and O 1s core level binding energies were found to have negligible or no binding energy shifts from the expected values, thereby establishing much diminished dielectric character or much enhanced metallic character at the surface of the thin film at elevated temperatures. When the thin film sample was cooled down to room temperature, core level binding energy shifts of 5 eV were again observed. Thus,

$NiFe_2O_4$(111) thin films exhibit reversible surface photovoltage charging, and thus are distinct from the very similar inverse spinel thin film oxides $CoFe_2O_4$ and $NiCo_2O_4$. Such a reversible dielectric phase transition, for the surface of $NiFe_2O_4$(111) thin film, was further supported by the reversible Fermi level edge shift of the thin film sample with respect to the Fermi level of the spectrometer. The temperature dependent XPS core level binding energies were found to closely follow a new modified Arrhenius-type model [1], recently proposed. This study also showed that a large number of oxygen vacancies at the surface of the thin film might affect the reversible dielectric properties of the $NiFe_2O_4$(111) thin film and cause partially reversible dielectric phase transition of the thin film surface region with temperature. Low energy electron diffraction (LEED) images of the $NiFe_2O_4$(111) thin film showed that the surface of the thin film was highly crystalline throughout the reversible dielectric (non-metallic) to metallic phase transition of the thin film, thus the creation of a massive number of oxygen vacancies does not normally occur under the experimental conditions. Temperature dependent intensities of LEED gave us effective surface Debye temperature of 249.7 ± 11.1 K. The effective bulk Debye temperature of 629.10 ± 58.22 K and 787.03 ± 52.81 K were estimated using temperature dependent intensities of Fe $2p_{3/2}$ and Ni $2p_{3/2}$ XPS spectra respectively indicating different sites for Fe and Ni. As expected, lower effective Debye temperature was found for the surface region compared to the bulk region of the $NiFe_2O_4$(111) thin film. This work fundamentally provides insights into the material properties during an electronic phase transition of some dielectric oxide thin films and opens a door to non-volatile memory devices utilizing thin film oxides like $NiFe_2O_4$.

8:30 AM EN04.09.02
Water Splitting at the Phase Transition of Ferroelectric Oxide Single Crystals *Irena Spasojevic[1], Ignacio Villar[2], Marti Checa[3], Rajesh Mandal[4], Gustau Catalan[1], Yachin Ivry[4] and Neus Domingo Marimon[3]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]CELLS-ALBA Synchrotron Radiation Facility, Spain; [3]Oak Ridge National Laboratory, United States; [4]Technion–Israel Institute of Technology, Israel*

Ferroelectric surfaces are amazing playgrounds for reduction and oxidation reactions since they permanently accumulate surface charges and fields and show specific electrochemical reactivity as a function of the ferroelectric polarization [1,2,3]. Among surface electrochemical reactions, water splitting is naturally observed on FE oxide surfaces and hence hints at their application not only for water decomposition (i.e. H2 production) but also as new platforms for catalysis. Moreover, the chemical reactivity of the FE surface seems to couple to internal FE polarization via many different mechanisms. This feature opens new opportunities such as ferrocatalysis, that is, to exploit ferroelectric surfaces in catalysis for water splitting since ferroelectric polarization becomes a switch to adjust surface catalytic properties.[4]

Here, I will present a study of the water splitting reactions on ferroelectric surfaces as a function of polarization, obtained from the combination of near ambient pressure XPS analysis and Scanning Probe Microscopy techniques (essentially Piezoresponse Force Microscopy and Kelvin Probe Force Microscopy), and demonstrate the emergence of ferrocatalysis, upon cooling at the paraelectric-ferroelectric phase transition of BaTiO3 single crystals. I'll show how the surface redox activity is coupled to ferroelectricity by several different factors: the polarity of the stray electric fields, the coupling to screening mechanisms and the specific chemical active sites of each surface. In this sense, the potential of ferroelectric materials for pyrocatalytic water splitting applications will be discussed.

Towards a Molecular-Level Understanding of Entropy Changes in Layered Barocaloric Materials via Quasielastic Neutron Scattering *Faith E. Chen[1], Malia B. Wenny[2], Daniel Laorenza[1], Marc L. Descoteaux[1], Boris Kozinsky[1], Craig Brown[2] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]National Institute of Standards and Technology, United States*

Solid-state, barocaloric materials—materials which undergo thermal changes in response to applied pressure—have emerged as a promising alternative to conventional yet environmentally-hazardous hydrofluorocarbon refrigerants. In particular, materials featuring bilayers of long hydrocarbon chains—including hybrid organic-inorganic perovskites and symmetric di-n-alkylammonium salts—have recently been reported to drive sizable entropy changes (> 100 J kg^{-1} K^{-1}) at relatively low driving pressures (< 200 bar). These substantial barocaloric effects arise from the solid-state ordering and disordering of hydrocarbon chains, suggesting that the manipulation of hydrocarbon-disordering thermodynamics is a particularly promising direction for barocaloric material design. Critical to the development of such design principles is an understanding of the molecular mechanisms that drive the entropy changes in these materials—that is, what are the types and ranges of motion that disordering hydrocarbon chains undergo?

Here, we present experimental neutron scattering investigations into the molecular motions of hydrocarbon chains in hybrid perovskites and di-n-alkylammonium salts before and after their respective order-disorder transitions. Supplementing quasielastic neutron scattering (QENS) experiments with machine-learning molecular dynamics (MLMD) simulations, we show that the same length hydrocarbon chain accesses fundamentally different geometries and amplitudes of motion across the order-disorder transition when confined in a hybrid perovskite vs. di-n-alkylammonium salt architecture. In doing so, we establish a molecular basis for understanding why molar entropy changes are nearly twice as large in a di-n-alkylammonium salt than in a hybrid perovskite. Ultimately, this work advances a molecular-level understanding of chain disordering-driven entropy changes and offers insights towards the precise and rational design of barocaloric materials.

Poling Effect on Pyroelectric Effect in Ferroelectric Thin Films *Jun Usami, Yuki Okamoto, Hisashi Inoue, Takeshi Kobayashi and Hiroyuki Yamada; National Institute of Advanced Industrial Science and Technology, Japan*

Ferroelectric thin films offer numerous applications, such as nonvolatile memories, piezoelectric sensors, and actuators. It is also noteworthy that significant pyroelectric and electrocaloric effects have been reported in ferroelectric thin films, providing potential applications to infrared sensors, energy harvesting, and electrocaloric cooling. Electrical poling with DC or AC voltages enhances remanent polarization and piezoelectric coefficient. Although the pyroelectric coefficient also increases with increasing poling voltage [1], its relationship with a degree of poling is not straightforward [2].

Here, we investigate the impact of poling on the pyroelectric effect. In this study, using lead zirconate titanate (PZT) with morphotropic phase boundary composition prepared by sol-gel method, we simultaneously measured the pyroelectric effect and the remanent polarization by varying DC poling time. We measured the pyroelectric current via local AC heating at 220 Hz with a Pt thin film heater stacked on the PZT, and the remanent polarization by applying a triangular pulse at 1 kHz. The results show an increase in both the pyroelectric current and the remanent polarization with increasing DC poling time. With the same poling time, the pyroelectric current increased more rapidly than the remanent polarization did, suggesting the importance of poling in enhancing pyroelectric effects and the significance of direct evaluation of pyroelectric properties.

***Manipulating Phase Transitions in Barocaloric Materials** Jinyoung Seo[1,2], Adam Slavney[1,2] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]Pascal Technologies, Inc., United States*

Solid-state phase transitions are central to the design of advanced responsive materials needed to address a wide range of pressing global challenges. This is particularly relevant in the context of barocaloric effects—thermal changes in a material induced by applied hydrostatic pressure—that are strongest near first-order phase transitions. Barocaloric effects in solids can be used to drive energy-efficient heating and cooling cycles, offering a promising alternative to traditional vapor-compression technologies that rely on potent greenhouse gases. Although critical to realizing the full potential of barocaloric effects, it remains difficult to manipulate the thermodynamics of phase transitions in the solid state, and the microscopic mechanisms responsible for barocaloric effects are not well understood.

In this talk, I will describe recent examples of how barocaloric effects in phase-change materials can be leveraged for sustainable refrigeration. First, I will discuss the new classes of barocaloric materials recently discovered in our laboratory—including two-dimensional hybrid perovskites [1], molecular spin-crossover complexes [2], and dialkylammonium halide salts [3]. I will highlight our efforts to elucidate key molecular factors that govern entropy change, pressure sensitivity, and hysteresis of their barocaloric phase transitions. Second, I will describe a new mechanism for driving barocaloric effects that renders solid-state phase transitions extremely sensitive to pressures. This mechanism leverages the thermodynamic effects of a pressure-transmitting medium on hydrocarbon order–disorder transitions. Specifically, I will show how this mechanism enables barocaloric solids to operate over a wide temperature window at record-low pressures. This approach substantially reduces the cost and power consumption required for operating barocaloric cooling cycles, unlocking the use of solid refrigerants in practical devices. Finally, I will highlight our recent efforts to evaluate barocaloric materials at the system level. I will discuss how direct measurements of cooling performance in a cooling prototype allows us to directly probe the impact of hysteresis on device-level efficiency, cooling power, and cyclability under a variety of driving conditions. Bridging the gap between materials discovery and prototype development, this work represents a crucial step toward the development of barocaloric refrigeration system and provides fundamental insights into thermo-mechanical coupling and hysteresis phenomena in phase-change materials.

***Exploring Entropy Contributions in Colossal Barocaloric Plastic Crystals** Richard J. Dixey[1], Bernet E. Meijer[1], Peter D. Nguyen-Minh[1], Shiqi Gan[1], Shurong Yuan[1], Franz Demmel[2], Naresh C. Osti[3], Anthony E. Phillips[1] and Helen C. Walker[2]; [1]Queen Mary University of London, United Kingdom; [2]Rutherford Appleton Laboratory, United Kingdom;*

[3]Oak Ridge National Laboratory, United States

Barocalorics are materials exhibiting a solid-solid phase transition between high and low entropy phases, which can be cycled by the application and release of pressure, analogous to traditional vapour-compression refrigeration, but without the risks associated with leaking environmentally harmful fluids [1]. This technological potential for "green" cooling and heating drives research to not just discover new barocalorics but also to optimise the relvant properties, such as phase tranistion temperature, adiabatic temperature change and thermal conductivity, which requires a more quantitative understanding of the entropy change.

Orientationally disordered "plastic" crystals, in which the near spherical molecules freeze into position at low temperatures but are free to rotate at high temperatures, can generate extremely strong barocaloric effects associated with the unlocking of the rotational degrees of freedom. This is clearly demonstrated in quinuclidinium salts, in which the near-spherical quinculidinium cation packs with inorganic counteranions into structures analagous to the alkali halides. The quasi-spherical shape promotes vibrational entropy arising from molecular libration, while the deviation from perfect spherical symmetry generates configurational entropy.

We have studied the crystallography of seven quinculidinium salts (with counterions Cl, Br, I, NO$_3$, BF$_3$, PF$_6$ and IO$_4$) and measured the phase transitions using high-pressure differential scanning calorimetry. These materials show solid-solid phase transitions between 290 and 340 K, entropy changes of up to 164 J/K.kg, and barocaloric coefficients dT/dP of up to 60 K/kbar, making them "colossal" barocalorics [2]. The dynamics of the Quin ion have been investigated using Quasi-Elastic Neutron Scattering as a function of pressure, while Inelastic Neutron Scattering has alowed an investigation of the low-frequency librational phonon modes and how the phonon density of states varies across the phase transition relating to the disruption of the hydrogen bonding network. Insights from the data are obtained through classical and DFT molecular dynamics simulations.

9:45 AM EN04.09.07
***Synthetic Design of Barocaloric Materials from the Bottom-Up** Daniel Laorenza and Jarad A. Mason; Harvard University, United States*

The refrigerants in used billions of cooling systems are potent greenhouse gases that inevitably leak into the environment during repair or decommissioning, accelerating the ongoing climate crisis. Thus, we must develop innovative and eco-friendly cooling solutions to regulate temperatures everywhere from our homes to shipments of food and medicine. To this end, emissions-free cooling platforms based on caloric materials have emerged as a viable alternative, wherein the latent heat of solid-solid phase transitions may be used for thermal regulation for heat pump or cooling technologies. In particular, barocaloric materials, which exhibit pressure-induced solid-solid phase transitions, hold great promise as alternative cooling platforms. However, barocaloric materials generally require high operating pressures to realize reversible cooling cycles, hindering their implementation into or alongside existing heating, ventilation, and air-conditioning infrastructure. These high operating pressures typically result from both thermal hysteresis and low pressure sensitivity of such phase transitions.

In this work, we aim to elucidate the underlying structure-property relationships that dictate solid-solid phase transition behavior, namely hysteresis and pressure sensitivity, through systematic molecular variations in layered material platforms, wherein inorganic sheets act to confine alkyl chains that undergo order-disorder transitions. Such variations include changes in interaction strength between the inorganic sheets and alkyl chains (e.g., covalent to electrostatic) as well as the packing density of alkyl chains arising from unique layer templates.

Morevoer, we aim to improve the moisture and thermal stability of these materials through deliberate choice of layer composition and removal of halide ions. Finally, we aim to improve potential scalability through reduction in material cost and synthetic complexity based upon a wide screening of layered material families. The insights gleaned from this investigation aim to guide the design of next-generation, emissions-free cooling based on barocaloric materials.

Multiple Caloric Effects Induced by Phase Transitions of Charge-Spin-Lattice Coupled Transition-Metal Oxides *Yuichi Shimakawa, Yoshihisa Kosugi and Masato Goto; Kyoto University, Japan*

Caloric effects of solids can provide us with highly efficient and environmentally friendly energy systems. The exploration of novel caloric materials is challenging but crucial for the development of future technologies. Some transition-metal oxides containing cations with unusually high valence states show phase transitions to relieve the electronic instabilities. Such compounds often release significant latent heat by the first-order charge transitions. We found that the large latent heat and the corresponding isothermal entropy changes can be utilized through caloric effects by applying pressure (barocaloric effects) and/or magnetic fields (magnetocaloric effects). The A-site-ordered quadruple perovskite $NdCu_3Fe_4O_{12}$ *containing the unusual high valence* $Fe^{3.75+}$ *shows the large entropy change of 84.2* $J\ K^{-1}\ kg^{-1}$ *by the intersite charge transfer transition* ($NdCu^{2+}{}_3Fe^{3.75+}{}_4O_{12} \leftrightarrow NdCu^{3+}{}_3Fe^{3+}{}_4O_{12}$) *near room temperature. This entropy change can be utilized by applying pressure through the barocaloric effect [1]. The analogue quadruple perovskite* $BiCu_3Cr_4O_{12}$ *containing* $Cr^{3.75+}$ *also shows the large entropy change by the charge disproportionation phase transition* ($BiCu_3Cr^{3.75+}{}_4O_{12} \leftrightarrow BiCu_3Cr^{3+}Cr^{4+}{}_3O_{12}$) *at 190 K. Because the charge disproportionation yields a ferrimagnetic phase below the transition temperature, the observed entropy change can be controlled by applying magnetic fields as well as pressure. The compound is thus shown to exhibit the multiple caloric effects [2]. The charge transitions, where the charge, spins, and lattice degrees of freedom are strongly correlated, are crucial for the observed novel multiple large caloric properties [3].*

Hard-Axis Magnetization in Iron Borate Single Crystal *Jacob Pfund[1], Shuai Jiang[1], Weiguo Zhang[2], P. Shiv Halasyamani[2], Michael Susner[3], Volkan Ortalan[1] and Menka Jain[1,1]; [1]University of Connecticut, United States; [2]University of Houston, United States; [3]Air Force Research Laboratory, United States*

Iron Borate ($FeBO_3$) *is a transparent green ferromagnet with a rhombohedral calcite-type structure. It holds great potential for use in magneto-optical devices due to its rare combination of room temperature ferromagnetism and optical transparency. Neutron diffraction studies have shown* $FeBO_3$ *is an antiferromagnet below* $T_N = 348$ *K and exhibits weak ferromagnetism due to Dzyaloshinskii-Moriya interaction, all in the crystallographic a-b plane. However, recent work has shown evidence of c-axis magnetism in* $FeBO_3$ *at low temperatures. In this study, we present structural (bulk and micro), heat capacity, and magnetic measurements of single crystal* $FeBO_3$ *that confirm c-axis magnetization with novel behavior including nontraditional paramagnetism above* T_N*, magnetic hysteresis, and rich magnetic entropy change. A qualitative explanation of these behaviors is proposed, stemming from magnetic frustration due to the interplay of long-range surface anisotropy and magnetic inhomogeneity with strong short-range local antiferromagnetism.*

11:00 AM EN04.09.10

Antiferroelectric $PbZrO_3$ and $PbHfO_3$ Thin Films—Anisotropic Control of Functionalities and Phase Transitions *Seonkyu Shin[1], Milan H. Haddad[1], Yulian Yao[1], Nikhilish Maity[2], Vasily Lebedev[3,4], Kristina Holsgrove[5], Sarah Stock[3,4], Amit Kumar[5], Lewys Jones[3,4], Sergey Lisenkov[2], Inna Ponomareva[2] and Nazanin Bassiri-Gharb[1,1]; [1]Georgia Institute of Technology, United States; [2]University of South Florida, United States; [3]Trinity College Dublin, The University of Dublin, Ireland; [4]Trinity College, Ireland; [5]Queen's University Belfast, United Kingdom*

Antiferroelectrics (AFE) are materials with an antipolar arrangement of dipoles in adjacent unit cells, resulting in an overall, macroscopic null net polarization in absence of applied external fields. However, applying a sufficiently large electric field induces a transition from antipolar to polar, through parallel alignment of the dipoles. At reduction of electric field, the material returns to an antipolar phase in a nonlinear and hysteretic fashion, consistent with a ferroelectric material. The antipolar to polar phase transition (and vice versa) is accompanied in perovskite AFE oxides with development of very large strains, extreme changes in dielectric permittivity, and often negative electrocaloric effects. Hence, these materials are of interest for applications in large force-large displacement actuators, multi-state memories, high power capacitors, negative tunable dielectrics, electrooptic switches, solid state cooling devices, etc.

For many of these applications it is of paramount importance to control the phase transition fields, in order to control the functionalities. Such tuning of the properties has been often achieved by use of precise amounts of A-site and B-site cation doping of peroskite prototypical AFE oxides. However, such doping schemes result in challenging processing of the material, particularly in thin film form for miniaturized applications.

Here we report on facile chemical solution processed lead zirconate, $PbZrO_3$ (PZO), and lead hafnate, $PbHfO_3$ (PHO), perovskite antiferroelectric thin films, deposited on platinized silicon substrates. We show that for both compositions, the transitions fields of the films (antipolar to polar and vice versa) can be modified by close to 2x, through simple selection of preferential growth direction, specifically, leveraging homogenous seed layers of PbO. Films with PbO seed layers resulted in preferential 001-orientation, with Lotgering factors above 90% and those direct deposited on platinized Si substrates showed up to 100% 042 orientation. Although no secondary phase was observed in the x-ray diffraction of the samples, the electron microscopy analysis of the cross-sections revealed presence of residual porosity and possible secondary phases at crystallization interfaces. PHO films' forward transition films were changed in a range from ~250 to ~320 kV/cm through control of the crystallographic orientation, while the same for PZO ranged from ~300 kV/cm to ~650 kV/cm for films of approximately 200 nm in thickness. The 001-oriented films showed a higher energy storage density, and efficiency (16 J/cm^2 and ~75%, respectively) for applied electric fields of ~900 kV/cm) than 042-oriented ones (energy storage density of ~8 J/cm^2 and efficiency of ~70% at electric field as low as 400 kV/cm). Films of mixed orientation showed intermediate energy storage density but reduced efficiencies due to multiple phase transitions due to grains of varying orientation. 001-oriented PHO films showed similar energy storage efficiencies to PZO with values of up to 75%. We will furthremore discuss theoretical basis for such anisotropic behavior as well as the anisotropic electromechanical response (with strains up to 1.2%), dielectric tunability, and approaches to reduce defects.

11:15 AM EN04.09.11

Magnetic Field and Ultrasound Induced Simultaneous Wireless Energy Harvesting Using Magnetoelectric Transducer for Biomedical Implants *Sumanta Kumar Karan, Sujay Hosur, Bed Poudel, Mehdi Kiani and Shashank Priya; The Pennsylvania State University, United States*

Wireless energy harvesting is a promising technology that can be seamlessly integrated into various electronics systems. However, one of the primary obstacles in harnessing wireless power transfer for implantable medical devices is the inherent limitations associated with transducer alignment sensitivity and low power capacity within safety limits. Consequently, there is a pressing need to develop wireless technologies with robust power *capabilities. To address this challenge, researchers have explored the use of magnetoelectric devices based on hard piezoelectric materials. These devices can harvest magnetic fields while adhering to safety regulations when operating in air, liquid, or tissue media. A prototype device, with a volume of 0.075 cm^3 is demonstrated to harvest magnetic and ultrasound energies simultaneously from a single device traveling through liquid/tissue media generating an ultra-high rms power of ∼52.1 mW across input of ∼500 μT rms magnetic field and ∼675 mW cm^{-2} ultrasound intensity, which are below the safety limits prescribed by the IEEE and FDA. This represents an ∼225% improvement compared to individual magnetoelectric systems utilizing a single source under safety limits. The device can recharge a 3 V lithium-ion battery with 1 mA-h capacity at a rate of ∼1.67 mC $^{s-1}$ in porcine tissue. Furthermore, the device has excellent cell viability (85–90%) with limited cytotoxicity and is promising for biomedical implants. These findings demonstrate that the dual energy harvester based on magnetic field and ultrasound intensity has the potential to power wide range of biomedical devices.*

Photomodulated Optical Properties of Twisted Azobenzene Crystals *Terrence M. Hopkins and Stephanie Lee; New York University, United States*

Crystal twisting, a spontaneous phenomenon estimated to occur in one-third of all molecular compounds, introduces mesoscale chirality into organic films. Film of twisted crystals exhibit circular birefringence (CB) and circular dichroism (CD) that arise from directional splaying of linearly anisotropic crystals as they twist about the growth direction. Here we explore the dynamic modulation of CB and CD in twisted crystal films comprising azobenzene photoswitches that undergo trans-cis photoisomerization under ultraviolet-blue light irradiation and cis-trans reisomerization upon green light irradiation or heat exposure. N,N-4-dimethylaminoazobenzene (commonly known as methyl yellow) in particular can undergo photoisomerization in the solid state. Upon photoisomerization from the trans to cis conformation, methyl yellow crystals exhibit a reduction in both linear birefringence (LB) and linear dichroism (LD) due to a reduction in crystallinity. Mueller matrix imaging, a complete polarimetry method to spatial map the LB, LD, CB, and CD of solid-state samples, revealed that a reduction in LB and LD of single methyl yellow crystals resulted in a reduction in the CB and CD of splayed stacks of the crystals. Furthermore, polarization-angle dependent absorption studies reveal the formation of an absorption band not previously reported. The ability to tune optical activity with external stimuli (e.g. UV light) will enable the design of chiroptical sensors, detectors, and waveguides sensitive to circularly polarized light.

2:15 PM EN04.10.02
Maleic Anhydride Copolymer Aerogel with Photoluminescence Characteristics and Its Application in Phase Change Energy Storage *Yue Ru, Dali Gao, Guicun Qi, Lin Lin and Xinrong Li; Sinopec Beijing Research Institute of Chemical Technology, China*

Traditional photoluminescence materials are usually inorganic mixtures of rare earth ions and heavy metal ions as activators, or organic macromolecules with rigid planes and π - electron conjugation systems. However, the scarcity of heavy metal/rare earth resources, biological toxicity, and aggregation induced fluorescence quenching

effects of organic macromolecules often limit the application of traditional luminescent materials in many fields such as biomedicine. Therefore, the research team prepared a series of maleic anhydride alternating copolymers with aggregation induced luminescence properties through self stable precipitation polymerization.
These polymers can also be further controlled by molecular structure to obtain photoluminescent copolymers with special properties. We have developed applications in fields such as anti-counterfeiting fibers and light conversion films based on the special properties of these materials. In the latest work, a new type of polymer aerogel, which can be repeatedly reshaped and reused, has been synthesized and prepared. We use the maleic anhydride group in the molecular chain to carry out functional modification, and then through freeze drying and heat treatment, to prepare hydrophobic polymer (SMI) aerogel, which has high heat resistance and excellent performance. The glass transition temperature and initial decomposition temperature can reach 247 °C and 307.6 °C, respectively. In addition, SMI aerogels also have aggregation induced emission (AIE) Properties. In particular, it is worth emphasizing that it has excellent recoverability, because almost 100% of aerogels can be converted back to be re soluble in ammonia and used for the re preparation of aerogels. Based on its super lipophilicity, we also prepared two kinds of recyclable phase change composite (PCM) aerogels, which can achieve efficient energy storage and cold storage performance. Only 10g PCCM can keep 10ml ethanol solution at 0 °C for 2 hours. More importantly, this PCCM can also achieve recycling and recycling, meeting the needs of environmental protection and resource reuse. Meanwhile, the aggregation induced luminescence properties possessed by this material can be used for temperature detection.

2:30 PM EN04.10.03
Infrared Thermochromic Antennas Composites for Self-Adaptive Thermal Radiators *Francisco V. Ramirez-Cuevas[1], Kargal L. Gurunatha[2], Lingxi Li[3], Usama Zufilgar[3], Sanjayan Sathasivam[4], Manish Tiwari[3], Ivan Parkin[3] and Ioannis Papakonstantinou[3]; [1]Universidad Adolfo Ibanez, Chile; [2]JAIN University, India; [3]University College London, United Kingdom; [4]London South Bank University, United Kingdom*

Passive thermoregulation, the ability of organisms to self-regulate their body temperature, offers significant potential for reducing energy usage in heating and cooling applications. Although engineering thermochromic materials have been explored to achieve this functionality, a technology that integrates large emissivity modulation with scalability, affordability, and versatile end-product designs remains undeveloped. In this work, we introduce infrared thermochromic antennas—non-spherical particles that exhibit a substantial increase (~150 times) in their absorption cross-section with rising temperatures, and tunable across specific spectral regions. We will discuss the critical design parameters, including the morphology, size distribution, and concentration of the antennas, and establish guidelines for creating materials with large hot/cold emissivity switching (~ 0.9). Additionally, by incorporating these infrared thermochromic antennas into polymer matrices or through direct spraying, we demonstrate an adaptable and cost-efficient method for mass-producing passive thermoregulation paints, fabrics, and films. These materials hold potential for diverse applications, such as self-adaptive radiative cooling, thermal sensing, and thermal camouflage.

3:15 PM *EN04.10.04
Optimising Thermal Conductivity in Phase Change Materials and Devices *Robert E. Simpson[1], Jing Ning[2] and Ting Yu Teo[2]; [1]University of Birmingham, United Kingdom; [2]Singapore University of Technology and Design, Singapore*

Chalcogenide phase change materials have been commercialised for optical and electrical data storage applications and they are now being developed for displays, optical neural networks, and optical routing.

Programming these devices is achieved by switching the phase change material between two structurally distinct states—typically an amorphous and a crystalline state are used. The resulting optical or electrical property contrast is then used to represent the data. Although this process is conceptually simple and commercial data storage devices based on this effect are widely available, the programming process requires a substantial amount of energy to heat the phase change material to its melting temperature. Moreover, the device or media must be designed to quench at a rate typically close to 10^9 K/s. Thus, there is a design conflict because on one hand the material must heat efficiently to reach its melting temperature yet on the other hand it must also diffuse heat into the surroundings to enable quenching at high rates.

This presentation will demonstrate how we can use transition metal dichalcogenide 2D films, Van der Waals superlattices, and doping to form efficiently switching phase change material based devices. We show that adding WS2 between the PCM and the substrate produces a thermal boundary resistance effect that can halve the switching energy and also protect the substrate from thermal damage. We also show that doping 3.5% Ti into the Sb2Te3 layers of an Sb2Te3-GeTe phase change superlattice also halves the superlattice thermal conductivity by creating phonon scattering centres in the Sb2Te3 layered structure. Again, the result is a radical decrease in the switching energy.

In summary, by controlling heat diffusion in the phase change material and the interfaces, we can enhance the switching energy efficiency and longevity of phase change materials in data storage and programmable photonics devices.

3:45 PM EN04.10.05

Tunable Plasmonic-GeTe Metasurfaces—From Supercell Plasmonic Mode to QBIC *Xiu Liu, Hyeonggyun Kim, Zexiao Wang, Xinyi Fang, Gianluca Piazza and Sheng Shen; Carnegie Mellon University, United States*

Metasurfaces, engineered photonic structures composed of subwavelength scatterers/emitters (meta-atoms), have revolutionized the precise and dynamic control of thermal radiation, enabling narrowband, directional, and polarized emission properties. A tunability mechanism can then be incorporated to facilitate real-time dynamics, holding significant promise for applications in thermal infrared lighting, sensing, imaging, and energy harvesting. Chalcogenide phase-change materials offer important advantages for achieving post-fabrication tunability in metasurfaces due to their drastic optical contrast, fast switching speed, and long-term stability. In this work, we developed a supercell plasmonic-Germanium Telluride (GeTe) metasurface facilitating versatile dynamics. Rather than using a continuous layer of GeTe, we discretized and incorporated GeTe with gold as meta-atoms. Through supercell design, we can realize a plasmonic mode for ultra-broadband and quasi-bound states in the continuum (QBIC) for ultra-narrowband tunability. Our approach represents a significant advancement in chalcogenide-based active metasurfaces for thermal and infrared photonics.

4:00 PM EN04.10.06

Entropy-Driven Phase Separation in Polymer-Grafted Nanoparticle Blends Thin Film *Akhtar Gul[1,2], Masiuddin Muzzammil Mohammad[1], Abdulmaliq Abdulsalam[1], Alamgir Karim[1], Micheal Bockstaller[2] and Krzyztof Matyjaszewski[2]; [1]University of Houston, United States; [2]Carnegie Mellon University, United States*

Polymer-grafted nanoparticle (PGNP) blends exhibit versatile properties ranging from optoelectronics to gas separation membranes, primarily governed by the composition, morphology, and mobility of the polymers and nanoparticles involved. This study investigates the phase behavior of chemically dissimilar polymer grafted nanoparticle blends, specifically PMMA-SiO2/PSAN-SiO2, and compares them with their linear polymer counterparts, PMMA/PSAN, under similar conditions. We have meticulously examined the phase separation and mixing behavior of these blends under vacuum thermal annealing (VTA). Our findings indicate that grafted polymer blends with specific weight fractions tend to exhibit phase separation, whereas linear polymer blends favor mixing.

This phenomenon is attributed to the higher entropy of mixing in linear polymers compared to grafted polymers, despite both systems sharing identical enthalpic interactions. The study further reveals that high molecular mass PGNPs promote mixing instead of phase separation. This behavior can be explained by the longer chain lengths attached to the particles, which influence the overall morphology and interaction dynamics within the blend. Additionally, variations in weight fractions significantly affect the mixing and demixing tendencies, depending on the molecular masses of the blends. We employed Atomic Force Microscopy (AFM) to prob the surface morphology of the thin films, providing detailed insights into the topographical features and phase distribution. To further analyze the internal structure of the films, we utilized Time of Flight Secondary Ion Mass Spectroscopy (TOF-SIMS). This technique enabled us to obtain depth profiles and compositional maps, shedding light on the distribution of different film components. The TOF-SIMS analysis corroborated the AFM findings, comprehensively understanding the phase behavior in PGNP and linear polymer blends. In addition to AFM and TOF-SIMS, we also employed X-ray Photoelectron Spectroscopy (XPS) to analyze the surface chemistry and composition of the blends. The findings of all these techniques will be presented.

SYMPOSIUM EN05

Electrodes for Chemical and Energy Conversion Technologies
December 3 - December 6, 2024

SESSION EN05.01: Electrocatalytic Materials I
Session Chairs: Tomas Edvinsson and Germán Salazar Alvarez
Tuesday Morning, December 3, 2024
Hynes, Level 3, Ballroom B

8:00 AM +EN05.01.01
Catalysis on High Entropy Alloys *Jan Rossmeisl; University of Copenhagen, Denmark*

The green transition requires discovery and development of new catalyst materials for sustainable production of chemicals and fuels. However, it is difficult to predict a material, which might have a high catalytic activity for a given reaction, therefore the development of catalysts up until now has been driven mainly by trial and error. It *would increase the pace of development, if we could predict a range of promising materials or if we at least could understand the limitations of catalysis. In this context high entropy alloys offer a chemical space of possible materials where the composition can be smoothly varied and where the properties also might vary in a seamless manner. This is good news for catalysis as such a smooth space is easier to explore to determine the interesting regions in composition space. Furthermore, the highly heterogeneous nature of a high entropy alloy surface reveals fundamental effects which are important for chemistry on surfaces in general, but are overlooked in the classic mean field view on catalysis.*

8:30 AM EN05.01.02

Nanostructured Electrocatalysts with Atomically Thin Noble Metal Layers for Chemical and Energy Conversions *Jin Soo Kang; Seoul National University, Korea (the Republic of)*

Owing to the ever-increasing significance of the climate change, there have been various efforts to de-carbonize the energy production and utilization cycles. Electrocatalytic conversion reactions are often playing key roles in many of the relevant processes. For instance, splitting of water are essential for the green hydrogen production, and CO_2 reduction is widely studied to achieve negative emission while producing value-added chemicals and fuels. Meanwhile, these electrocatalysts are often composed of noble metals, which increase the overall cost and bring down the economic feasibility of the whole process. There have been substantial efforts to develop noble metal-free catalysts during the past decades, and noteworthy technological advances have been made. Meanwhile, it is also revealed that complete replacement of noble metal might not be ideal in many cases, as very small amount of noble metals sometimes leads to a massive increase in the overall performance. Based on these understandings, our recent research efforts on development of electrocatalysts with atomically thin noble metal layers on the surface will be introduced in this presentation. By combinations of noble metals and compounds with chemical robustness and conductivity, high active and stable electrocatalysts for various chemical and energy conversion reactions are developed. Guidelines for selection of durable compounds are suggested with regard to the synthesis feasibility and durability, and strategies to simplify the production of electrocatalysts are explored.

8:45 AM EN05.01.03

Expelled Water Diffusion from Buried ITO-Polymer Interfaces for Durable Soft Photocathodes During H_2 Evolution *Eui Hyun Suh and Erin L. Ratcliff; Georgia Institute of Technology, United States*

Electrolyte diffusion through conjugated polymers provides novel opportunities for photo-fuel conversion at polymer-electrolyte interphase in soft photoelectrodes. However, their solar-to-hydrogen (STH) conversion efficiencies and lifespans (STH < 4% for a few hours) lag far behind industrial requirements (STH > 10% for 10 years). In addition to many factors already studied in other organic (opto)electronic devices, electrolyte ingress into the polymers provides novel degradation pathways in soft photoelectrodes. At the interphase, electrodes or charge transport layers under polymers are exposed to the diffused electrolytes and induce unwanted (photo)electrochemical reactions. In this work, we demonstrate surface treatments on a transparent electrode (ITO) control electrochemical reactions at buried ITO-polymer to enhance lifespans of soft photocathodes (ITO/Polymer blend/Pt) during H_2 evolution. By four different experimental sets, we reveal hydroxylated ITO surface electrochemically reacts with diffused water molecules in an acidic electrolyte (0.1 M H_2SO_4 in DI water). This reaction immediately reduces current density at zero potential less than 2% of initial value within 500 s. Transient current and open circuit potential measurements and electrochemical impedance spectroscopy show the electrochemical reaction forms hole traps at the buried interface. Phosphonic acid self-assembled monolayer (PA-SAM) treatment is a key strategy to suppress the side reaction. Hydrophobized ITO surface expels the electrolyte from the buried interface and suppress the side reaction. The photocathodes with PA-SAM-treated ITO *preserve high current density at zero potential for at least 1 h. This work has amplified attention on the chemical treatments at buried interfaces to control electroactivities in soft (photo)electrochemical platforms.*

9:00 AM EN05.01.04

Zero-Gap Electrochemical CO_2 Reduction Cell Under Simulated Diurnal Conditions *Sol A Lee, Harry A. Atwater and Chengxiang Xiang; California Institute of Technology, United States*

We report on the investigation of zero-gap CO_2 electroreduction (CO_2R) cells operating under simulated diurnal conditions, to better understand the real-world dynamical operating characteristics of solar driven electrochemical cells, as compared to the constant current density and constant temperature operating conditions typically employed in a controlled lab environment. Various test modes, including cascade and pulse potential cycling, were employed to gain insights into the impact of diurnal cycling on integrated solar fuel devices. Notably, our findings revealed significant degradation of Cu gas diffusion electrodes (GDEs) during simulated day-night shifts, particularly when subjected to periods with an open-circuit voltage (OCV) operating configuration. Comparative analysis across different pulse cycling modes highlighted that Cu GDEs exhibited reduced selectivity only under OCV conditions with repeated cycles. Further investigation using X-ray tomography at the Advanced Light Source (ALS) on custom-designed membrane electrode assembly (MEA) cells elucidated the formation of salt precipitates during −150 mA/cm^2 operation, with rapid flooding occurring upon reaching an OCV operating point in Cu GDEs. Moreover, the severity of flooding correlated directly with the duration of the OCV condition. These insights provide a deeper understanding of potential degradation mechanisms in zero-gap CO_2R cells under diurnal conditions. Looking ahead, our research aims to explore CO_2 reduction under more complex operational scenarios and establish guidelines for the sustainable operation of solar-assisted electrochemical cells in diurnal settings.

9:15 AM *EN05.01.05

Electrochemical Surface Modification and Characterization of Copper Catalysts *Paula S. Pascual; KTH Royal Institute of Technology, Sweden*

Copper-based materials are promising electrocatalysts for different energy conversion reactions, such as the electrochemical reduction of carbon dioxide (CO_2) or the conversion of biomass-derived aldehydes to produce value-added chemicals. Electrocatalytic reactions are sensitive to the catalyst surface structure, and therefore, finding methods to determine the geometry of the different active surface sites is essential to address the structure-electrocatalytic performance relations. In this talk, I will present our recent results on tailoring the facet distribution of copper with halides. To address the formation of new facets and sites on copper, we use a simple method that consists of recording the lead under potential deposition (UPD) on the modified copper electrodes with cyclic voltammetry technique. We started recording the lead UPD cyclic voltammograms on well-defined copper single facets, providing intense peaks with different potential values for each single facet. Then, we used this data to decouple each facet peak contribution in the lead UPD curves of the tailored copper surfaces. With this work, I aim to find a link between the electrochemical response of copper and structural characterization with, e.g. electron microscopy, which is key to assessing surface structure effects in electrocatalysis.[1-4]

10:15 AM EN05.01.06
Laser-Ironing Induced Capping Layer on Co-ZIF-L Promoting In Situ Surface Modification to High-Spin Oxide–Carbon Hybrids on the "Real Catalyst" for High OER Activity and Stability *Weihao Liu[1], Minghui Hong[2], Yong-Wei Zhang[3] and John Wang[1,4]; [1]National University of Singapore, Singapore; [2]Xiamen University, China; [3]Institute of High Performance Computing, Singapore; [4]National University of Singapore (Chongqing) Research Institute, China*

The development of high-performance, stable electrocatalysts is vital for advancing renewable energy technologies, particularly for the oxygen evolution reaction (OER) in water splitting, a key process for sustainable hydrogen production. Metal-Organic Frameworks (MOFs), with their high surface areas, tunable porosity, and versatile structural design, are promising candidates for catalytic applications. However, MOFs often oxidize and degrade during OER, leading to reduced catalytic activity and stability. Although some traditional treatments, such as high-temperature furnace processes, are used to convert MOFs into other compounds, they still face stability challenges during OER.

This study introduces a novel laser-ironing (LI) technique that forms an in-situ laser-ironing capping layer (LICL) on Co-ZIF-L, one type of MOF with a unique flake structure, preserving structural integrity and significantly enhancing OER performance. Using a low-power laser, the LI method converts the surface of Co-ZIF-L grown on carbon cloth into a LICL composed of higher crystallinity graphitic carbon and Co nanocrystals. This process retains the leaf-like morphology and promotes the formation of OER-active Co_3O_4 nanoclusters during OER. In contrast, Co-ZIF-Ls treated with conventional thermal methods collapse and transform into less active CoOOH.

Density functional theory (DFT) calculations highlight the role of high spin (HS) states of Co ions and a narrowed band gap in Co_3O_4 nanoclusters, which enhance OER activity by facilitating spin-selected electron transport, reducing the energy barrier, and enabling a spontaneous O_2-releasing step, the potential-determining step in CoOOH. The resulting LICL stabilizes the catalyst structure, delivering considerable performance metrics: a low overpotential of 290.16 mV, a Tafel slope of 58.95 mV dec^{-1}, and remarkable stability with a 1.56% increase in current density after 20 hours of high-voltage OER. The high crystallinity carbon in LICL reduces electrical resistance and affects the formation of Co_3O_4 nanoclusters through confinement, resulting in optimized OER kinetics and thermodynamics.

This novel LI method offers a controllable, efficient, and low-cost approach for fabricating high-performance electrocatalysts, addressing the critical challenge of maintaining stability and performance during dynamic electrochemical reactions. Beyond OER, the implications of this research extend to sensors, batteries, and wearable electronic devices, providing a versatile method for surface modification and catalyst design. By combining ultra-high temperatures with an ultra-fast process, LI ensures precise control over surface microstructure, preventing aggregation and preserving the unique morphology of MOFs. This technique addresses significant issues associated with traditional thermal treatments, such as high energy consumption, lengthy processing times, and structural degradation.

Our findings demonstrate that LI-induced LICL provides a stable, high-performance catalyst that undergoes a pseudomorphic transformation during OER, forming CoOOH arrays with retained morphology and enhanced surface area. This transformation, driven by HS state Co_3O_4 nanoclusters, significantly lowers the energy barrier and improves overall catalytic activity.

In conclusion, the LI technique represents a promising advancement in electrocatalysis, offering a novel pathway for designing stable and efficient catalysts. This approach addresses fundamental real-world challenges related to energy conversion efficiency and catalyst durability, making hopeful strides toward sustainable and scalable hydrogen production. Our work contributes to the broader goal of renewable energy development and introduces a transformative strategy for high-precision surface microstructure control.

10:30 AM EN05.01.07

X-Ray Absorption Spectroscopy—A Probe for Electroactive Polymer-Electrolyte Interactions *Jonathan Thurston[1], Shuya Li[2], Qi Sun[3], Luis Kitsu Iglesias[1], Collin Sindt[1], Hong Li[3], Elisa Miller[2], Ann L. Greenaway[2] and Michael F. Toney[1]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States; [3]The University of Arizona, United States*

Semiconducting polymers have sparked interest in electrochemical processes such as catalysis and energy storage due to their strong charge transport properties and ionic conductivity. Despite the importance of polymer-electrolyte interactions in device performance, there is a lack of understanding of the fundamental interphasial interactions that occur between the polymer and electrolyte. In this study, we use X-ray absorption spectroscopy (XAS) and X-ray scattering to study the local atomic electronic and chemical structure of two polymers. We use N2200, a well-studied polymer[1] due to its high crystallinity and charge carrier mobility changes, which has monomeric units consisting of an naphthalene diimide (NDI) with alkyl sidechains coupled with a bithiophene unit, and it's derivative, P90, in which 90% of monomers have glycolated sidechains and 10% have alkyl sidechains, that has recently been introduced for use in aqueous applications.[2]
N2200 and P90 are electrochemically active and have two redox events correlating to the formation of polarons (-1 charge) and bipolarons (-2 charge) during charging that are accompanied by the absorption of counter-cations from the surrounding electrolyte for charge neutralization. We will introduce and discuss results from an operando study in which the polymer charge is held potentiostatically, while measuring its XAS spectra and compare this to ex-situ charging XAS results. Using simulated XAS to assign electron excitation spectra to experimental XAS spectra, we identify polaron/bipolaron localization and how ions incorporate into the film to understand polymer-electrolyte interfacial interactions. Our results show how the atomic environments of polymer change as a function of charge, and we discuss the impact of polymer choice as electrode materials on device performance and operation.

10:45 AM EN05.01.08

Predictive Synthesis of Transition Metal Carbides Catalysts by Thermochemical CO-CO_2 Equilibrium *Sang-Ho Oh[1], Dohun Kim[2], Ji Yong Kim[1], Geosan Kang[1], Jooyoung Jeon[1], Miyoung Kim[1], Dae-Hyun Nam[2] and Young-chang Joo[1]; [1]Seoul National University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

Transition metal carbides (TMCs) have attracted considerable interest because their structure, phase, and polymorph provide highly tunable physicochemical properties. Their unique d-band electronic structures make them suitable for a wide range of electrochemical applications. For example, molybdenum (Mo) carbides are promising candidates for electrocatalysis. Interstitial C in Mo carbides interacts with Mo orbitals and induces lattice distortion, thereby modifying their d-band electronic structures to resemble those of noble metals, resulting in outstanding catalytic activities.

Despite extensive efforts to synthesize nanoscale transition metal carbides, the process remains a significant challenge. Among various transition metal compounds, such as oxides, nitrides, sulfides, and phosphides, metal carbides require the highest formation energy, thus exhibiting the lowest tendency for synthesis. In general, metal carbides are fabricated by carburization with gaseous carbon sources (e.g. methane (CH_4)) or by carbothermic reduction with graphite, inevitably leading to an excessive carbon supply during carbide formation. This can induce the precipitation of graphitic carbon, limiting the processing window for the synthesis and structural control of carbides. Therefore, it is necessary to develop techniques that can synthesize transition metal carbides with various phases and structures in nanoscale.

In this study, we developed a technique for synthesizing various nanostructured transition metal carbides. By introducing a CO-CO_2 gas mixture and utilizing the Boudouard reaction ($2CO (g) \leftrightarrow CO_2 (g) + C (s)$), we supplied carbon to the metal to synthesize carbides. The process was designed by thermodynamically predicting the CO/CO_2 ratio and processing temperature, enabling the synthesis of various transition metal carbides such as molybdenum carbides (α-MoC_{1-x}, β-Mo_2C), tungsten carbides (W_2C, WC), and a niobium carbide (NbC_{1-x}). Additionally, we controlled metal diffusion during the carbide synthesis process to form various surface and internal nanostructures. We used carbon nanofibers as templates to control metal diffusion. We controlled the oxygen partial pressure (pO_2) by predicting the CO/CO_2 redox reaction ($2CO_2 (g) \leftrightarrow 2CO (g) + O_2 (g)$), which is an equilibrium reaction of CO-CO_2. By controlling the pO_2 during the calcination, we selectively induced the combustion of carbon around the metal, thereby regulating the diffusion of the metal. We induced diffusion to the surface during the carbide formation process through stress-relaxation diffusion, resulting in the formation of various surface structures (nanospike, stain, particle, nanoflake). Furthermore, we elucidated the formation mechanisms of the nanostructured carbides, enabling us to control the size, aspect ratio, and amount of nanospikes and nanoflakes. Additionally, by creating pores, we were able to diffuse the metal inward through CO-CO_2 calcination, forming core-shell carbide/C structures.

We analyzed the hydrogen evolution reaction (HER) catalytic performance of nanostructured molybdenum carbides/C nanofibers. The nanospike-Mo_2C/C nanofiber achieved excellent HER performance with 142.6 mV at 10 mA cm^{-2} and 186.0 mV at 50 mA cm^{-2}.

We hope that our predictive synthesis will provide crucial guidance to researchers involved in the synthesis and structural engineering of a wide range of catalysts based on transition metal compounds.

11:00 AM EN05.01.09

Cation Insertion in Polymer Electrodes

Shuya Li[1], Jonathan Thurston[2], Bo Dong[3], Sa Suo[3], Tianquan Lian[3], Michael F. Toney[2], Elisa Miller[1] and Ann L. Greenaway[1]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States; [3]Emory University, United States

Semiconducting pi-conjugated redox polymers have been intensively studied in the field of soft photoelectrochemistry for their ability to enhance polymer conductivity through ion insertion. This study focuses on electrochemical cation doping in n-type polymers P90 and N2200, each comprising alternating naphthalene dicarboximide (NDI) acceptor and bithiophene (T2) donor units. The NDI units in P90 alternately feature heptaethylene glycol (HEG, 90%) and 2-octyl dodecyl (OD, 10%) side chains, while N2200 contains 100% alkyl OD side chains. Considering the Gutmann donor number (DN) of the side chains and the polymer durability in different solvents, we investigated P90 in aqueous and N2200 in non-aqueous systems using spectroelectrochemical techniques and structural characterization to access how varying cation identify affect polymer electronic behavior. Specifically, we explored chloride salts (Li^+, Na^+, K^+, Rb^+, Cs^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+}) in aqueous electrolytes and PF_6 salts (Li^+, K^+, NH_4^+, and tetrabutylammonium (TBA^+)) in non-aqueous electrolytes. We analyzed trends in cation size and valence on the redox properties of the polymers using in-situ UV-Vis spectroelectrochemistry; kinetic Raman spectra showed a significant change to the C=O bond as it generally disappears with C-O vibration rising when potential goes more negative. grazing incidence wide angle X ray *scattering (GIWAXS) confirmed that electrochemical doping drives ions into the crystallites, decreases the crystallinity, and increased the degree of the disorder. This study sheds light on cation insertion effects and their influence on polymer electronic behaviors, crucial for advancing energy conversion and storage applications.*

11:15 AM *EN05.01.10

Conducting Polymer Photoelectrodes—Design Criteria, Interface-to-Interphase Considerations and Durability *Erin L. Ratcliff[1,2]; [1]Georgia Institute of Technology, United States; [2]University of Arizona, United States*

Creating organic semiconductor-based photoelectrodes is not as simple as interfacing optimized organic photovoltaic materials with an electrolyte. In photoelectrodes, charge extraction occurs through the generation of molecular fuels from sunlight (i.e. hydrogen), which are either kinetically limited or mass transport limited. Durable and high performing organic photoelectrodes require balancing the photojunction properties with charge transport, attention to catalytic attachment, and a strong emphasis on mitigating parasitic chemical reactions and resistances.

This talk will consider the implementation and feasibility of highly scalable, π-conjugated polymer materials in photocathodes. Why conducting polymers? The mixed electrical-ionic transport properties present a complex polymer/electrolyte interphase that if understood, could provide control over local environments afforded through synthesis, long-lived charge carrier lifetimes, and flexible, low-cost, and scalable thin film formats which circumvent the shortcomings of inorganic materials (surface states, grain boundaries, challenges in processing, and mechanically unstable platforms).

The realization of all-organic semiconductor systems that capture light energy and convert it into chemical energy requires a detailed understanding of structure-property relationships governing the interconnected dynamics of photo-generation, transport, and electron transfer across multiple interfaces. Dark electrochemical processes must be understood before increasing the complexity via light-matter interactions. The Center for Soft PhotoElectroChemical Systems (SPECS) is an Energy Frontier Research Center focused on the basic science questions that underpin the development of low-cost, robust energy conversion and energy storage technologies based on new organic polymer (plastic) electronic materials. These materials are predicted to fill a critical position in the U.S. energy portfolio, providing for next-generation fuel-forming platforms (energy conversion) and batteries (energy storage) that cannot currently be achieved with conventional (hard) inorganic materials. This talk will focus on increasing complex, multiple interface platforms, towards the goal of photons-to-electrons-to-molecules energy conversion processes for all-polymer photocathodes. A number of emerging in situ/operando spectroelectrochemical and scanning electrochemical cell microscopy approaches will be discussed for this exciting new area of energy conversion.

SESSION EN05.02: Electrocatalytic Materials II
Session Chairs: Mathilde Luneau and Tyler Mefford
Tuesday Afternoon, December 3, 2024

1:30 PM *EN05.02.01

Oxygen Reduction on Organic Mixed Ionic-Electronic Conducting Polymers *Tyler Mefford; University of California, Santa Barbara, United States*

Organic mixed ionic-electronic conductors (OMIECs) are a class of conjugated polymers with tunable electronic and ionic transport properties enabled through polaron-forming ion insertion redox reactions. The energy to form these conductive polaronic states can be controlled through rational design of the polymer backbone to enable predominantly electron/cation (n-type) or hole/anion (p-type) transport. Simultaneously, electrolyte uptake into the bulk of the electrode can be controlled through incorporation of polar/non-polar sidechains. The ability to tune the energy of the redox-active states, the majority charge carrier, and the local reaction environment offers an opportunity to independently optimize activity and selectivity in electrochemical energy conversion processes with a single-phase electrode.

In this talk, I will discuss our efforts to develop these polymers as electrocatalysts for the oxygen reduction reaction. The electronic and chemical origins of reactivity are interrogated through pH-dependent electroanalytical characterization, operando optical and vibrational spectroscopy, charge-transport measurements, and ab initio/microkinetic simulations. The nature of the polaronic states provide a generalized framework to understand pathway selectivity towards the 2-electron H_2O_2 *or 4-electron* H_2O *product and serve as a design principle in developing this emerging class of metal-free electrocatalysts.*

2:00 PM EN05.02.02

Designing New Anodic Hydrogen Peroxide Generation System with Acidic CO2-Mediated Two-Electron Water Oxidation *Kyung Tae Kim, WonIl Choi, Changhyun Lee and Ki Tae Nam; Seoul National University, Korea (the Republic of)*

Hydrogen peroxide (H2O2) has a wide range of applications in various industries, including bleaching, water treatment, and chemical synthesis. However, traditional anthraquinone process for producing hydrogen peroxide is not sustainable, making researchers to explore alternative methods. In this context, electrochemical production of H2O2 is gaining attention. Particularly, unlike the two-electron oxygen reduction that requires gaseous oxygen, the two-electron water oxidation at the anode only needs water. This reaction allows for the conversion of renewable electrical energy into chemical energy in the form of O-O bonding on the electrode surface. However, it faces challenges from the competing four-electron water oxidation reaction, which produces oxygen instead of hydrogen peroxide. Therefore, optimizing the system design, including the selection of appropriate electrode materials and operating conditions, is crucial to improve the selectivity and efficiency of the two-electron water oxidation process.
In this study, we explore an approach to anodic hydrogen peroxide generation by employing an acidic environment facilitated by a carbon dioxide (CO2)-based electrolyte. Using fluorine-doped tin oxide (FTO) as the anode material, we aimed to enhance the stability and faradaic efficiency of hydrogen peroxide production. Our electrochemical analysis results demonstrate that the use of a carbon dioxide (CO2)-based acidic electrolyte system performs as effectively as the previously used basic carbonate electrolyte. This approach resulted in improved stability of the generated hydrogen peroxide and better faradaic efficiency.
Our findings indicate that the carbon dioxide-mediated acidic electrolyte environment achieves production rates comparable to those of traditional carbonate-based systems while offering enhanced stability. This finding provides valuable insights into the design of more effective anodic systems, potentially advancing the commercial viability of electrochemical hydrogen peroxide generation technologies.

2:15 PM EN05.02.03

Unraveling the Dynamic Structures of Active Sites in ZIF-8 Derived Fe-N-C Single Atom Catalysts for Electrochemical Oxygen Reduction Reactions *Prakhar Sharma, Ayanthi Thisera, Beth S. Guiton and Doo Young Kim; University of Kentucky, United States*

Single atom catalysts (SACs) constituting non-noble metal elements offer enormous potential to replacing expensive and rare platinum group metals for electrochemical oxygen reduction reaction (ORR), owing to their superior metal utilization and activity. One promising SAC consists of metal-nitrogen-carbon (M-N-C) motifs where single Fe atom acts as active sites for the adsorption of reactant and the desorption of product. Due to well-defined chemical structure of M-N-C, it is possible to tune the reactivity by modifying a metal center and local environment (e.g., ligands and dopants). The mesoporosity of carbon network provides electrical conductivity and serves as a channel for facilitated mass transport. Despite the great promise, significant barriers exist against the commercialization of Fe-N/C-based fuel cells, including (1) incomplete understanding of active sites and mechanistic pathway, (2) limited site density, and (3) poor electrochemical stability. In this presentation, the synthesis of Fe-N/C SACs derived from a ZIF-8 precursor will be detailed. These Fe-N-C SACs demonstrate excellent ORR activity, comparable to state-of-the-art Pt/C catalyst. The location and distribution of SACs are determined by high-resolution scanning transmission electron microscopy (HR-STEM). Chemical configurations of Fe and N in SACs are probed by X-ray photoelectron spectroscopy (XPS). We further report the detailed analysis of structure and dynamics of Fe active site. Operando confocal-Raman spectroscopy provides valuable information including (i) transient binding of ORR intermediates to active sites, (ii) rate determining step, and (iii) dynamic structure of Fe-N-C active site. Moreover, Nitrite stripping voltammetry was conducted to quantify active site density (SD) and turnover frequency (TOF) in the catalyst. This presentation will elucidate relations between the local environment of active sites and their electrochemical stability.

Catalyzing Electrochemical CO2 REduction to Methanol Yang Shao-Horn, Sunmoon Yu and Davide Menga;
Massachusetts Institute of Technology, United States

Our society is currently facing critical challenges regarding CO_2 emissions and drastic changes in the way we produce energy, chemicals and materials are required in order to tackle global warming. The electrochemical reduction of CO_2 is a key reaction in order to reduce our carbon footprint and a great scientific effort is being made to improve our knowledge and understanding about this complicated process. Recently, cobalt phthalocyanine (CoPc) has drawn tremendous attention due to its capability to electrochemically reduce $CO_2$and CO to methanol (1-6), a key molecule in the chemical manufacturing industry. Because of its well-defined structure, CoPc provides a model platform to understand reaction mechanism and rationally improve the catalytic activity and stability. In our recent work, through kinetic isotope effect studies and electrokinetic analyses, we identified the protonation of adsorbed CHO as the rate determining step (RDS) for CO_2-to-methanol conversion and we showed that the hydration shell of more acidic alkali cations can enhance CO_2-to-methanon kinetics via faster proton-coupled electron transfer (in the order $Li^+ > Na^+ > K^+ > Cs^+$). This conclusion was supported by density functional theory calculations and molecular dynamics simulations. In this contribution, the reaction mechanism of CO_2-to-methanol electroreduction will be discussed, with a particular focus on how proton-coupled electron transfer *kinetics and the stability of reaction intermediates can be tuned in order to maximize the faradaic efficiency for methanol production. Moreover, we will discuss the impact of different reaction conditions on the stability of the CoPc catalyst and possible mitigation strategies will be proposed.*

Operando Characterization of Fe in Doped $Ni_x(Fe_{1-x})O_yH_z$ OER Catalyst *Sergey Koroidov; Stockholm University, Sweden*

*Iron-doped nickel oxyhydroxides, $Ni_x(Fe_{1-x})O_yH_z$, are among the most promising alkaline oxygen evolution reaction (OER) electrocatalysts. Fe plays a key role in enhancing the catalytic activity of the material. Several proposals exist for how Fe might influence OER directly or indirectly; however, there is no general agreement on the exact effect of Fe or its character under operation. In an effort to gain insight into the role of Fe, we have performed DFT-supported operando X-ray spectroscopy studies on $Ni_x(Fe_{1-x})O_yH_z$ electrocatalysts. We have probed spectroscopically reversible changes in the structure and electronic character of $Ni_x(Fe_{1-x})O_yH_z$ as the electrode potential is cycled between the resting (here at 1.10 V_{RHE}) and operational (1.66 V_{RHE}) state of the catalyst material. DFT calculations and XAS simulations on a library of iron structures in various NiO_yH_z environments are in favor of a distorted local octahedral $Fe(III)O_3(OH)_3$ unit at the resting state with the NiO_yH_z scaffold going from **α**-$Ni(OH)_2$ to **γ**-NiOOH as the potential is increased. At the catalytic conditions, a combination of EXAFS and HERFD provides evidence that spectral evolution is associated with the change in p-d mixing (or covalency) between O/OH ligands and Fe leading to local structural change at the Fe site from octahedral to square pyramidal. This surprising result is further supported by XES and theoretical simulation and provides evidence that Fe remains in a formal Fe(III) state under both resting and operational conditions, with spectral changes arising due to potential dependent structural changes in the local Fe environment*

Surface Property Modulates the Proton Transport Dynamics in Porous Oxygen Evolving Electrodes *Zhifei Yan, Rui Sun and Daniel G. Nocera; Harvard University, United States*

Three dimensional porous electrodes, such as those in membrane electrode assemblies (MEA), are widely employed in electrochemical devices due to their high surface area and achievable current density. The highly heterogeneous internal structure and microenvironments make it challenging for experimental mechanistic investigation and effectively managing mass transport in porous electrodes. Here, we developed an operando method employing polymer bound fluorescent sensors (PFS) to directly quantify the internal proton gradient in a porous electrode for oxygen evolution reaction (OER). The results revealed notable pH gradients within OER electrodes in unbuffered electrolyte. Proton transport dynamics was found to be significantly influenced by the proton adsorption properties of the support. This property also increases the stable operation time for an electrodeposited cobalt oxide OER catalyst. The PFS method can be extended to study other variables that *contribute to the microenvironments within porous electrodes, and the role of catalyst support in modulating mass transport may be applicable to many other electrochemical devices including fuel cells and CO_2 electrolyzers.*

4:15 PM EN05.03.04

Catalyst Carrier for PEM Water Electrolysis—Synthesis, Characterization and Processing *Mathias Spree[1], Frederik Kunze[1], Lisa Sagewka[2], Norbert Kazamer[2], Martin Underberg[2], Florian Wirkert[2], Sophie M. Schnurre[1], Michael Brodmann[2] and Tim Huelser[1]; [1]Institut für Umwelt & Energie, Technik & Analytik e.V., Germany; [2]Westfälische Hochschule, Germany*

A necessary precondition for proton exchange membrane (PEM) water electrolysis to become a game-changer in hydrogen industry is the significant reduction of noble metal loading as well as robust electrode manufacturing techniques. Highly specific conductive nanomaterials with high specific surface area offer a huge potential to be used as a supporting material for catalysts in electrode structures. The combination of advanced catalyst deposition technologies for targeted deposition only on the electrically conductive electrode surface and the large surface area of the nanostructured carrier material enables higher proportions of active catalyst surface and thus leads to a reduction in precious metal consumption.

Three different nanostructured support materials for anodes (Titania, doped Silicon) and cathodes (Graphene) have been generated in gas-phase reactors in the pilot plant scale.

We demonstrate the synthesis of sub-stoichiometric Titania nanoparticles and their use as iridium carrier material in PEM technology. For this purpose, blue-coloured Titania particles with oxygen deficiencies are produced in combustion processes, deposited on electrical connection geometries and subsequently laser sintered to nanostructured surfaces under reducing atmospheres. SEM analyses confirm process engineering successes both in laser sintering and in the subsequent galvanic deposition of iridium particles, which are clearly visible on the surface and are confirmed by EDX analyses. Cyclic voltammetry on TiO_{2-x}/Ir - systems clearly proofs an activity of oxygen generation (OER) at 1.25 V and lower slopes of the data in Tafel representation indicate an increased catalytic activity compared to bulk Ir.

Another approach for the generation of nanostructured support materials is represented by the use of highly boron doped silicon particles as support material. Here, Monosilane (SiH_4) and Diborane (B_2H_6) have been used as precursor material to produce degenerated silicon semiconductors. As catalysts laser-based synthesized iridium nanoparticles from a laser ablation in liquids (LAL) and laser fragmentation of microparticles in liquids (MP-LFL) are used. Here, particles sizes of 7 nm and 4 nm are applied. XRD analysis reveals a distribution of Si, Ir and IrO_2 phases in the analyzed samples, both of the last two being well-known for being highly active catalytically. The fact that no compound phases between any of Si, B and/or Ir were observed, shows that no alloying takes place. Cyclic voltammograms recorded with Ir decorated Si:B nanoparticles followed the well-studied Ir oxidation path. The laser fabricated Ir nanoparticles exhibit a smaller size than the commercial ones, creating a higher electrochemical surface area reaching lower overpotential and onset overpotential values while presenting similar Tafel slopes.

Additionally, due to high electrical conductivity graphene is a potential candidate to be used as a support material, too. To address this, we performed eco-friendly synthesis using easily accessible ethanol as precursor material. For this purpose, ethanol is evaporated and subsequently fed through an argon-hydrogen plasma generated by microwave radiation. To investigate the influence of precursor concentration on the material properties, the feeding rate of EtOH is stepwise adjusted from 200 g/h to 800 g/h. TEM, SEM and Raman analysis proof that typical graphene sheets with lowest carbon particle presence are formed almost exclusively at lowest feeding rates, which can be explained by reduced carbon saturation during material formation. In good agreement with material morphology highest specific conductivity $\sigma = 3{,}19$ S/cm with $\rho = 0.23$ g/cm^3 at 100 N/cm^2 is obtained for material with high graphene/particle ratio in a powder conductivity test cell at increased pressures. Measurements on

commercial reference materials show lower conductivities by a factor of 8.6.

4:30 PM EN05.03.05

Probing Nanoscale Electron Transfer and Hydrogen Evolution Reaction at Two-Dimensional Electrodes by Scanning Electrochemical Microscopy *Septia Kholimatussadiah[1,1,1], Mohammad Qorbani[1,1], Yu-Ling Liu[1], Michitoshi Hayashi[1,1], Kuei-Hsien Chen[1,2] and Li-Chyong Chen[1,1,1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan*

Electron transfer plays a significant role in many biological and chemical processes, especially in the catalytic reactions involved in photoelectrochemical energy conversion and storage. Revealing the electron transfer behaviour at the interface of electrode-electrolyte is thus of great importance. Here, we fabricate atomically thin tungsten diselenide (WSe_2) by chemical vapor deposition method and directly map the outer-sphere and inner-sphere electron transfer using Atomic Force Microscopy combined with Scanning Electrochemical Microscopy (AFM-SECM). Using AFM-SECM, the topography of the sample as well as the mechanical, electrical, and electrochemical properties can be simultaneously obtained. AFM-SECM feedback mapping shows layer-dependent electrocatalytic ability of WSe_2 to oxidize the redox species Ru^{2+} back to Ru^{3+}. Moreover, AFM-SECM substrate generation and tip collection mode show layer-dependent hydrogen evolution reaction of WSe_2. Compared with monolayer and bilayer, few-layer WSe_2 shows better stability in electrochemical environment, faster electron transfer, and higher hydrogen production. First principal calculations show that the layer-dependent electron transfer and hydrogen production is highly correlated with the higher electronic density of states and more suitable Fermi level position in few-layer WSe_2 for specific redox reactions. Furthermore, finite element method-based numerical simulations using MATLAB® and COMSOL Multiphysics® are performed to calculate the electron transfer rate constants k^0 and simulate the steady-state concentration gradient. Finally, the electrochemistry at WSe_2 electrode-electrolyte interface is spatially resolved at the nanoscale, and understanding this behaviour will be useful for future electrochemical devices.

4:45 PM EN05.03.06

Rational Design of Earth-Abundant Phosphide Electrocatalysts *Kirill Kovnir; Iowa State University of Science and Technology, United States*

Metal phosphide nanoparticles have been shown to be promising electrocatalysts for the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER). We performed systematic studies of the polycrystalline and facet-selective single crystal of 3d transition metal phosphide electrocatalysts. In-situ studies at SLAC SSRL show that P in phosphide plays an important role in H adsorption. At HER applied bias the surface of the catalysts is reduced, and oxidation of the surface occurs only after the reducing bias is turned off, explaining common ex-situ observation of oxidized surface of the used catalysts. Studies of M_2P (M = Fe, Co, Ni) single crystals show that crystal facets have drastically different reactivity thus paving the way to enhance activity of nanocrystalline catalysts via shape control. Finally, tuning of electronic structure and chemical bonding between M and P sublattices via aliovalent substitution allow to enhance activity and stability of ternary ordered phosphide electrocatalysts.

Computational Design of Boron-Based Electrocatalysts for Reduction of Molecular Nitrogen and Carbon Monoxide towards High Valued Products *Tore Brinck and Huong T.D. Bui; KTH Royal Institute of Technology, Sweden*

Molecular nitrogen and carbon monoxide are weak Lewis bases that are difficult to catalytically activate for electrochemical reduction because of their low Lewis basicities and very strong intramolecular covalent bonds. The most successful catalysts are based on expensive and rare transition metals that typically bind to N2 and CO by a combination of sigma-donation from N2/CO to catalyst and pi-backdonation from catalyst to N2/CO. This donation-back donation mechanism requires access to accessible d-orbitals on the catalysts, and thus catalysts based on main-group elements generally perform poorly. However, we have recently shown that molecules of the general formulas B(SiR3)3 and B(GeR3)3 bind N2 and CO with short and strong bonds, enabling selective activation of the N-N and C-O bonds. The strong bonding has been traced to a unique donation-back donation mechanism where the lone pair density of N2/CO is donated into the empty sp3 orbital on boron and electron density from the B-Si/Ge bonds are donated into the N2/CO pi orbitals. Unfortunately, this type of molecules is difficult to realize by chemical synthesis. Instead, we have suggested that similar binding geometry and local electronic structure can be afforded by doping of silicon and germanium compounds. In particular, boron doped silicene and germane have been shown to catalyze the electrochemical reduction of N2 to ammonia and CO to methanol. Complex multi-active site catalysts are needed to facilitate the selective reduction of CO to the C2-product ethanol. For this reaction boron based bi-atom catalysts, i.e. B-B or B-Cu in silicene, are found to catalyze the electroreduction with low overpotentials. In practice, these catalysts are effective three-atom catalysts as coordination to a neighboring Si plays an integral part of the C-C bond formation. This is in line with our general observation that selective catalysis of complex electrochemical reactions requires catalysts with multi-functional active sites similar to the active sites of enzymes.*

8:45 AM EN05.04.02

Charge and Mass Transfer in Positrodes for Proton Ceramic Electrochemical Cells *Truls Norby; University of Oslo, Norway*

Proton ceramic electrochemical cells (PCECs) comprising fuel cells (PCFCs), electrolysers (PCEs), and reactors (PCERs) require well-conducting electrolytes of mechanical and thermochemical stability as well as electrodes with sufficient electrocatalytic activity at moderate temperatures. Oxide positrodes for PCFCs and PCEs are particularly challenging due to poor surface catalytic activity for the oxygen redox reaction and limited transport of protons due to low concentrations. Current research aims to improve these by, e.g., exsolution of catalytic nanoparticles and optimisation of hydration thermodynamics and microstructure. Studies of polarisation and degradation phenomena require physicochemical understanding of the mechanisms of charge and mass transfer and application of appropriate mathematical models.

The polarization processes at solid-state mixed proton-electron conducting oxide positrodes involves proton-proton charge transfer, proton diffusion in the bulk and on the surface of the positrode, and the surface oxygen-steam electron transfer redox-reaction.

Electrochemical impedance spectroscopy (EIS) enables separation of the different polarisation processes by their capacitances. The proton-proton charge transfer may be expected to follow Butler-Volmer (BV) type kinetics. The mass transfer polarisation of porous mixed conducting electrodes involves coupled diffusion, reaction kinetics, and chemical capacitance that in the simplest case can be modelled as a Gerischer impedance when it polarises the BV charge transfer. This approach for mixed proton-electron conducting (MPEC) electrodes for PCECs follows

essentially all the principles for corresponding mixed ion-electron conducting (MIEC) electrodes for SOECs laid down in what is called the Adler-Lane-Steel (ALS) model. [1,2] Measurements under oxidising conditions and moderate humidities at temperatures (typically > 400°C) where p-type electronic and oxide ionic conductivities in the electrolyte are significant must take the transport numbers of these into account when fitting impedance spectra to avoid major overestimates of the performance and activation enthalpies of proton ceramic positrodes. [3] Individual polarisation resistances measured by EIS under DC bias can be integrated over current to obtain individual overpotential-current curves and help to identify processes and predicting behaviours under operation in fuel cell or electrolyser mode.
We illustrate the models and parameterisation by results for Ba-Ln-Co-based perovskite positrodes on doped $BaZrO_3$ *electrolytes using EIS on 3-electrode button cells as a function of temperature,* pO_2, pH_2O, *and DC bias.*

Charting the Electronic States of Intermetallic Catalysts *Zhengda He and Bin Ouyang; Florida State University, United States*

The electronic structure-based descriptors, such as nth moment theory and DOS similarity, have been widely used to rationalize catalytic performance. However, their effectiveness remains unclear. In this study, we selected intermetallic compounds as a platform to examine the variety of electronic states that can be catalytically active. Utilizing high-throughput density functional theory (DFT) calculations, we enumerated all possible low-index surfaces from the reported intermetallic compounds in the ICSD and Materials Project Database. This high-throughput screening yielded a computational database with over 10,000 surfaces. Based on this DFT dataset, we compared the typical electronic structure-based descriptors with well-known HER/ORR catalysts, such as Pt and Ir, to identify promising new catalysts for HER or ORR. Among all the promising candidates screened, the electrochemical stability of these catalysts is also discussed using Pourbaix diagrams.

9:15 AM EN05.04.05

Protons in Triple-Conducting Perovskites—Concentration, Mobility and Surface Reaction Aspects *Rotraut Merkle[1], Max F. Hoedl[1], Giulia Raimondi[1], Christian Berger[1], Andrew Chesnokov[2], Denis Gryaznov[2], Eugene Kotomin[1,2] and Joachim Maier[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]University of Latvia, Latvia*

Triple-conducting oxides with mobile oxygen vacancies, protons and electronic defects are of fundamental interest, and find application as electrode materials of protonic ceramic electrochemical cells (PCFC, PCEC) operating in an intermediate temperature range 400-600°C. In electrolysis mode, PCECs enable the direct generation of dry, compressed H_2 *with high efficiency.[1]. Compared to* $Ba(Zr,Ce,Acc)O_{3-z}$ *electrolytes, the degree*

of hydration in triple-conducting Ba(Fe,Co,Zn,Y)O_{3-d} perovskites is significantly lower. This is attributed to the high covalency of (Fe,Co)-O bonds, which decreases the basicity of the oxide ions.[2-4]
The experimental determination of proton conductivity or mobility in triple-conducting perovskites is challenging. Proton diffusivities from chemical diffusion experiments and SIMS measurements will be presented.[5] They are complemented by extended DFT and ab-initio MD calculations for $BaFeO_{3-d}$, which analyze also trapping effects.[6] While the overall proton transfer process is similar, the high covalency and redox activity in $BaFeO_{3-d}$ lead also to specific differences compared to electrolyte materials.
The role of protons for the surface oxygen reduction reaction is ambivalent. A certain bulk proton concentration is beneficial for proton transfer from the electrolyte to the extended surface of porous thick-film electrodes. However, triple-conducting perovskites show a high coverage by (dissociatively) adsorbed water even at elevated temperature, which may block catalytically active centers such as oxygen vacancies. Microelectrode measurements of Ba(Fe,Co,Zn,Y)O_{3-d} in different pO_2 and pH_2O did not indicate a contribution of protons before or in the rate determining step of the oxygen reduction reaction so far. Overall, a comprehensive picture of proton stability, mobility and reactivity is derived, which can be employed for further materials optimization.

Harnessing Multi-Scale Modeling for Optimizing Energy Conversion Materials— Integrating Data and Performance Across Scales *Sneha A. Akhade; Lawrence Livermore National Laboratory, United States*

In the ever-evolving field of energy storage and conversion, multi-scale modeling has emerged as an indispensable tool for understanding and optimizing material behavior across different lengths and time scales. This talk will explore the critical importance of integrating stability and performance metrics of catalyst materials accounting for various operational conditions. By examining the behavior of catalyst materials from the atomic level up to the reactor scale, we can predict and enhance their performance in real-world applications. Specifically, the talk will highlight how multi-scale modeling bridges the gap between molecular insights and macroscopic phenomena, providing a comprehensive understanding of catalytic processes. It will delve into how stability under operational conditions is as crucial as catalytic activity, influencing long-term efficiency and economic viability. Furthermore, the talk will address the system-level implications of catalyst design and operation, emphasizing the need for a holistic approach that considers the interplay between catalysts and the broader system in which they function.
At the core of coupling scales is the imperative of data integration and optimization. By seamlessly combining data from different scales, we can create models that not only enhance precision but also drive innovation in catalyst design. This integration allows for the optimization of catalytic processes, ensuring that materials are both high-performing and robust under diverse operating conditions. To summarize, the talk will provide insights into how multi-scale modeling can lead to more sustainable and efficient chemical processes by enabling a comprehensive and optimized approach to material development.

Physically-Based Descriptors of the Nitrogen Reduction Reaction on Transition Metal Nitrides Using Ab Initio DFT *Constantine Athanitis and Bilge Yildiz; Massachusetts Institute of Technology, United States*

Ammonia is one of the most widely produced chemicals in the world due to its use in fertilizers. Around 90% of industrial ammonia production is done through the Haber-Bosch process. Unfortunately, this process accounts for around 1% of total global carbon emissions and 2% of global energy consumption, annually. As a result, researchers have been intensely studying the electrochemical nitrogen reduction reaction (NRR) as a means to directly produce decarbonized ammonia using clean energy.

One exciting class of materials for the NRR is transition metal nitrides (TMNs), which use the Mars-van Krevelen (MvK) mechanism for the reaction. Crucially, the involvement of surface nitrogen vacancies in this mechanism facilitates N_2 activation and dissociation by lowering the associated activation energies. However, current state-of-the-art TMN catalysts still don't achieve the DOE performance targets for Faradaic efficiency and production rates. Therefore, in order to advance beyond current TMN performance, we need a holistic fundamental understanding of what materials properties influence the reaction energetics most strongly. It has been shown that the NRR on TMNs is limited by weak first protonation of the surface nitrogen and weak surface nitrogen vacancy filling by N_2H intermediates. Consequently, our objective is to identify physically-based descriptors for TMNs that correlate with the reaction step energies to elucidate what material properties should be targeted to potentially improve NRR activity. We hypothesize that descriptors relating to the bonding character and strength between the lattice nitrogen and metal species will be most strongly correlated to the limiting step energies. Inspired by the predictive success of the metal d-band center and oxygen p-band center descriptors, this work uses density functional theory (DFT) to study binary rocksalt-structured TMNs and to calculate various physically-based descriptors: metal d- and nitrogen p-band centers, hybridization between nitrogen p and metal d orbitals, and average metal/nitrogen Bader charges.

We find that the energy of the first protonation of a surface nitrogen species is negatively correlated with the average nitrogen Bader charge. Due to the binary nature of these TMNs, this also means that the protonation energy is positively correlated with the average metal Bader charge. Furthermore, the surface nitrogen vacancy filling energy by an N_2H intermediate is found to be positively correlated with the difference between the nitrogen p and metal d band centers (directly relating to orbital hybridization). We also investigate how the material composition of each TMN (approximated by the number of d electrons each metal contains) relates to the descriptors. Our results show that the average metal Bader charge increases with decreasing d electron number, while orbital hybridization decreases. Combining the results from the energetics-descriptor and descriptor-composition correlations, we see that the energetics of the limiting MvK steps on rocksalt TMNs are dependent on the nature of the covalency between the lattice nitrogen-metal bonds.

Overall, our results suggest a promising, accelerated materials design pathway to enhance NRR activity of binary TMNs. By taking advantage of the two unique active sites available in the MvK mechanism (the surface nitrogen species and surface nitrogen vacancies), we can potentially tune the energetics of the two limiting reaction steps independently using different metal species at each site. This strategy can yield more active catalysts, providing a pathway towards viable industrial electrochemical ammonia synthesis.

10:45 AM EN05.05.02

Emergence and Stability of Copper Palladium Nitride Nanoparticles Studied by In Situ XAS and X-Ray Total Scattering *Sani Harouna-Mayer[1], Jagadesh Kopula Kesavan[1], Francesco Caddeo[1], Lian Belgardt[1], Chia-Shuo Hsu[1], Lars Klemeyer[1], Ann-Christin Dippel[2] and Dorota Koziej[1]; [1]Universität Hamburg, Germany; [2]Deutsches Elektronen Synchrotron DESY, Germany*

Transition metal nitrides are an interesting class of materials that attracted great attention recently due to their unique properties. They are potentially useful as electrocatalysts, photoactive materials for solar cells, optical data storage, and optoelectronic devices. Transition metal nitrides are less explored compared to the transition metal oxides. Because the synthesis of transition metal nitrides (TMNs) is highly challenging and often requires high temperature and high-pressure reaction conditions. Furthermore, the TMT nanoparticles are highly sensitive to moisture and transform into oxides. To overcome such issues, a second metal is doped with TMN forming the stable ternary transition metal nitride (TTMN). The doping element and the type of doping such as interstitial or substitutional doping could tune the electronic properties such as varying the bandgap from semiconductors to semi-metallic or metallic-like material.
Here we report a one-pot, low-temperature synthesis of Cu_3PdN nanocrystals using primary amine as a solvent. The in-situ HERFD-XANES on the Cu K-edge reveals the type and structure of the initial metal complex and conversion of metal complex to nitrides. In situ total x-ray scattering measurements, PDF analysis and Rietfeld refinement enables to elucidate the nucleation and growth of the nitride nanocrystals. It also helps to understand the type of doping of the Pd atom in the Cu_3N crystal lattice and the sucessive transformation form Cu3PdN to Cu3Pd.
The synthesized anti-perovskite type structured Cu_3PdN is further characterized with EXAFS, HR-TEM, UV-vis spectroscopy and TGA. Interestingly, the electrochemical measurements show that Cu_3PdN is a good catalyst for the hydrogen evolution reaction (HER). A detailed electrochemical study is being carried out.

11:00 AM EN05.05.03

Grain Boundary Engineering of Mo_2C via Pulsed Laser for Enhanced Hydrogen Evolution *Seok-Ki Hyeong[1,2], Byung Joon Moon[1], Jae-Hyun Lee[2], Sukang Bae[1] and Seoung-Ki Lee[3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Ajou University, Korea (the Republic of); [3]Pusan National University, Korea (the Republic of)*

The production of clean hydrogen using water electrolysis is a crucial element in achieving sustainable energy production and utilization systems. A key challenge in using hydrogen as an energy source is to understand and control the hydrogen evolution reaction (HER) dynamics and develop low-cost and high-performance catalysts suitable. Although noble metal-based (e.g., platinum, iridium, ruthenium) catalysts show good performance in HER, they have limitations due to their high cost and scarcity. As an alternative, transition metal carbides, which are non-novle metals, have been studied extensively due to their good performance, stability, and low cost. Methods such as structural engineering, alloying, and heteroelement doping have been mainly used to improve catalyst performance, but strategies using grain boundaries (GBs), which account for most of the crystal defects in crystals, have not made much progress due to their complexity.
Here, we report pulsed laser-based synthesis method for molybdenum carbide (Mo_2C) with high density of GBs. The method using a laser not only reduces the Mo_2C precursor to a Mo_2C crystal through a photothermal reaction, but can also create crystal defects through fast heating/cooling times.
In particular, we fabricated a Mo_2C film with an ultrahigh GB density of 121.13 μm^{-1} (at 20 μs pulse duration) by systematically controlling the heat accumulation effect depending on the pulse duration of the laser and the thermal properties of material.
Consequently, Mo_2C films with high density of GBs not only enhance the activity by tensile/compressive stresses occurring at grain boundaries, but also provide abundant active sites, resulting in excellent HER catalystic performance (overpotential is 184 mV at 10 mA cm^{-2} and Tafel slope is 78.4 mV dec^{-1}).
In this study, we presented a new strategy to improve the performance of the HER through GBs density control using a pulsed laser.

Quantum Insights into the Energy Storage and Environmental Sustainability *Zhen Jiang[1,2] and Andrew M. Rappe[2]; [1]Northwestern University, United States; [2]University of Pennsylvania, United States*

The current energy crisis and climate concerns urgently require our materials science community to accelerate the discovery and development of more promising materials for designing next-generation energy storage and electrocatalytic systems. The goal of our research has been to employ and develop advanced quantum methods to promote the reactivity and selectivity of renewable energy ecosystems by providing atomic-level understanding.

*In this talk, we will first share our recent efforts on the energy storage front, where theoretical designs on material surfaces and interfaces have been conducted to facilitate the optimization of current lithium-air batteries (LABs).[1] Emphasis is placed on understanding the system dynamics through the implementation of methods including ab initio grand canonical Monte Carlo and enhanced free energy sampling algorithms. Through our computational simulations, we found the selection of aprotic solvents in electrolyte dominates the discharge/charge pathways of LABs. In general, high donor number (DN) electrolytes (such as DMSO) can rapidly transport the discharge products (LiO_2 monomers) away from the electrode surface, thus avoiding the deactivation and passivation of the electrode. To address the issues of environmental pollution, we also recently developed a hybrid microenvironment for highly selective conversion of CO_2 into C_3H_8 by coating imidazole-functionalized (*Im) ionic liquids on solid-state electrodes.[2] The *Im layer is effective to increase the electronic conductivity of solid-state catalyst, meanwhile it strengthens the *CO_2 and *CO adsorption on the catalysts by providing columbic force and hydrogen bonds to form ultimate propane products. In comparison, the pristine Mo_3P (without *Im layer) appears to be a mediocre CO_2RR catalyst, producing significant CO and H_2 as major products. Through designing such a hybrid catalyst with ionic liquids, we open new avenues to find more achievable catalysts for CO_2RR. Overall, our quantum methods and insights open the door for technological advancements in materials to accelerate the development of renewable and green energy.*

Understanding the Enhanced Activity of Pd/CeO_2 in Hydrogen Oxidation Reaction in Alkaline Media

Mathilde Luneau[1,2], Linnéa Strandberg[1,2], Gerard Montserrat-Sisó[1,2], Victor Shokhen[1,2], Henrik Grönbeck[1,2] and Björn Wickman[1,2]; [1]Chalmers University of Technology, Sweden; [2]Competence Centre for Catalysis at Chalmers, Sweden

Palladium supported on ceria (Pd/CeO_2) has recently raised strong interest as an alternative catalyst to platinum on the anode electrode in anion exchange membrane fuel cells[1,2]. The enhanced activity of Pd/CeO_2 catalysts for hydrogen oxidation reaction (HOR) activity in alkaline media has notably been attributed to strong metal-support interactions, but the exact mechanism is still under debate.

In this work, we investigate Pd/CeO_2 thin films with well-defined compositions and structures to gain fundamental understanding of the metal-support interface and its influence on HOR activity in alkaline media. We develop a novel approach combining in situ electrochemical quartz crystal microbalance (E- QCM), ex situ microscopy and spectroscopy, and theoretical calculations to describe the interface between Pd and CeO2.

Pd/CeO_2 leads to expected enhancement of HOR in alkaline media compared to pure Pd. Using E-QCM, we provide new fundamental understanding of the adsorption, absorption, physisorption and desorption phenomena occurring during HOR. We show that on pure Pd thin films, absorption of hydrogen dominates while on Pd/CeO_2 the oxidation/reduction of ceria and adsorption of hydroxyl groups are the dominating phenomena[3].

One of the hypotheses for enhanced reactivity of Pd/CeO_2 in HOR is that CeO_2 – at the interface with Pd - serves as a source of OH groups which react with adsorbed H to form water[4]. With this work, we provide new quantitative evidence that this hypothesis is valid. Strong metal-support interactions are confirmed by TEM, XPS and DFT calculations. An important finding is that Pd atoms embedded in CeO_2 are present on the prepared thin films and could be active sites for hydrogen activation.

This work thus provides strong evidence that the interface between Pd and ceria must be carefully designed to provide synergies and to lead to enhanced reactivity in HOR. Finally, this study underlines the importance of model thin films as appropriate tools to study the interface between metal and supports in situ, during electrochemical reactions.

Coupled Ion-Electron Transfer Reactions—Dynamically-Evolving Electrodes *William C. Chueh; Stanford University, United States*

Most non-metallic electrocatalysts and battery electrodes change composition during operation. This change in the composition directly modifies the kinetics of heterogeneous reactions at the electrode/electrolyte interface, whether it is the lithium intercalation reaction in Li_XFePO_4*, oxygen evolution reaction in* CoO_XH_Y*, or oxygen incorporation in* CeO_{2-X}*. While it is possible to infer the composition of the electrode via electrochemical measurements, knowing the composition at or near the active site is challenging. In this talk, I will present on the development of operando nanoscale microscopy (specifically, X-ray and scanning probe) and spectroscopy to track the dynamic evolution of electrocatalysts and battery electrodes during operation, and how the composition of the active site modifies reaction kinetics.*

2:00 PM EN05.06.02
Time Course of Polymer Electrolyte Electrochemical Cells (PEEC) Hydrogen Evolution Properties with MnIrOx Oxygen Evolution Catalyst *Miyuki Nara[1], Katsushi Fujii[1], Takeharu Murakami[1], Kazuna Fushimi[2], Shuang Kong[2], Ailong Li[2], Takayo Ogawa[1], Ryuhei Nakamura[1] and Satoshi Wada[1]; [1]RIKEN, RAP, Japan; [2]RIKEN, CSRS, Japan*

Hydrogen production using water electrolysis in polymer electrolyte electrochemical cells (PEEC) is an attractive technique for renewable energy storage. The PEEC is known to be relatively strong for input energy fluctuation, thus, it is a suitable technique for fluctuating renewable energy. The electrochemical catalysts of PEEC are Pt for hydrogen evolution in the cathode and IrOx for oxygen evolution in the anode. Since the Ir of IrOx for oxygen evolution is one of the precious metals, reducing the use of Ir is strictly desired. One of the Ir amount reduction methods is the use of the MnIrOx catalyst. The MnIrOx electrochemical oxygen evolution catalyst was demonstrated [1], and the MnIrOx catalyst performance is similar to the conventional IrOx catalyst. Although the MnO_2 *catalyst dissolves into the electrolyte in pH around 2 over 1.8 V [2], the stability of MnIrOx against the voltage was not studied well. The stable voltage or current, and the step rectangular-like voltage applications were applied for the stability evaluation in this study.*
The electrode was 5 cm^2 *area, Pt/C conventional cathode catalyst, MnIrOx (Ir 0.08%) anode catalyst with cation exchange membrane were used for the evaluation. When the stable voltage was applied, the current density decreased. The current density decreasing for the applied voltage of 2.0 V was approaching 15% of the initial value after 400 hrs operation. The voltage increase with constant current operation was not the same as the current decrease with constant voltage operation and was less than 10% for 400 hrs applied. These results show that the degradation processes were different either the voltage or current applied.*
For the rectangular-like voltage applied, the high and the low voltages were 2.0 and 1.43 V, and 2.0 and 0.05 V. The voltage applied time was 30 sec each. The current density at the high voltage applied was rapidly decreased at the

voltage of 2.0 V high and 0.05 V low without the prevent reverse current. In the case of reverse voltage prevention, the current density decreasing rate became milder. The current density became much milder at the voltages of 2.0 V high and 1.43 V low. From these results, the reverse current affects the current decreasing drastically.
The constant current operation, not the constant voltage operation, and the reverse current prevention effectively prevent property degradation.
Part of this work is based on results obtained from a project, JPNP20003, commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

pH Dependence of Bifunctional OER/ORR Electrocatalysis *Evan Z. Carlson[1,2], Md Delowar Hossain[2], Karina Masalkovaite[1], Hendrik Ohldag[3], William C. Chueh[1], Michal Bajdich[2] and Tyler Mefford[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States*

For many important electrocatalytic reactions, activity is known to depend on electrolyte pH in a non-Nernstian manner. Possible explanations for this phenomenon include electric-field effects,[1] decoupled proton-electron transfer,[2] and competing reaction pathways.[3] In this talk, I will discuss our hybrid experimental-computational investigation of manganese oxide's unique bifunctional OER/ORR activity, as well as its anomalous pH dependence. Our model system, α-$K_{0.1}MnO_2$, is among the highest-performing Mn oxide catalysts for both the OER and the ORR, with ORR activity rivaling that of Pt in basic electrolytes.[4] Using a novel grand-canonical DFT approach, we show that a pH-dependent interfacial electric field weakens the adsorption of key OER/ORR intermediates, leading to a non-Nernstian shift in onset potential for both reactions. The material's pH and cation-dependent activity is characterized via rotating ring disk electrochemistry (RRDE), HRTEM, and operando scanning transmission x-ray microscopy (STXM). Understanding the atomic-scale origins of this unique bifunctional activity may help enable higher performing, lower cost regenerative fuel cells and metal-air batteries.

Practical Materials AI for Improving Electrochemical Stability *Joseph H. Montoya; Toyota Research Institute, United States*

The prospect of using AI for materials engineering has inspired a large volume of innovative academic work using unsupervised and supervised machine learning on materials data. However, making materials AI practical, particularly in industrial contexts, has proven elusive for reasons of insufficient data, a disconnect between simulation and real materials, and technical knowledge gaps between materials AI developers and materials science practicioners. In this talk, I will discuss case studies of efforts to develop materials AI tools at the Toyota Research Institute for the purpose of mitigating electrochemical degradation of materials. In that context, I will comment on what has been effective, adoptable by industrial researchers and engineers, and what has proven *less useful. I will conclude by articulating a research strategy informed by these practical experiences, outlining our future efforts towards making Materials AI matter for materials scientists in the real world.*

4:00 PM EN05.06.05
In Situ Fluorescence Detection for the High-Throughput Screening of Oxygen Evolution Catalysts *Daniel J. Zheng[1], Chuhyon J. Eom[1], Rohit Pant[2], Haldrian Iriawan[1], Shuo Wang[1], Hongbin Xu[1], Jiayu Peng[1], Ichiro Takeuchi[2], Yuriy Roman[1] and Yang Shao-Horn[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Maryland, United States*

The oxygen evolution reaction (OER, $4OH^- \rightarrow O_2 + 2H_2O + 4e^-$ in alkaline electrolytes) is common to many sustainable processes critical for decarbonization, including water electrolysis to produce H_2 as an energy carrier, CO_2 reduction to produce liquid fuels and value-added hydrocarbons, and electrolysis of metal oxides to produce pure metals. However, even the most active OER catalysts that have been discovered are at least an order of magnitude less active than oxygen evolving complexes in biological systems,[1] demonstrating the potential that OER catalysts could achieve with the correct choice in materials. With state-of-the-art OER catalysts becoming increasingly complex to improve their activity and stability, the status quo of experimental materials discovery (where Edisonian-like, model system-based, or descriptor-based approaches have dominated past breakthroughs) limits the chemical space that can be effectively explored.[2] These human intuition driven approaches can also lead to biases in how the available composition space is traversed, resulting in systematic exclusions of entire classes of materials.[2] Furthermore, with the recent advent of high-throughput virtual screening methods for materials discovery harnessing the predictive power of machine learning and artificial intelligence (ML/AI), generating high-quality data of material properties at scale is pivotal to ensure accurate and high-fidelity predictions. As such, recent years has seen the emergence of high-throughput experimental methods for the screening and/or testing of a large chemical space (e.g., $>10^6$ unique compositions)[3] that would be intractable to assess using traditional experimental evaluation methods in efforts to discover new materials or provide the large volume of high-quality data necessary and evaluate predictions for ML/AI models.

In this work, we present a custom-built fluorescence-based screening setup for the testing of OER electrocatalysts with a minimum O_2 detection limit of 50 nmols. We demonstrate that our setup can not only evaluate the OER activity of discrete compositional arrays but can also be used to measure the OER activity of continuous compositional gradient films of various facets, allowing for the screening of a vast compositional space and active site motifs with near infinite compositional resolution simultaneously. Through in situ fluorescence intensity kinetic measurements coupled with electrochemical OER, we devised a method to directly relate the measured fluorescence intensity of tested samples with the rate of oxygen evolution. We applied the setup to composition gradient films of $La_{0.6}Sr_{0.4}Co_{1-x}Fe_xO_3$ with (001) and (111) facets and found that a maximum in OER activity is achieved when $x \approx 0.2$, where the most active composition is over 50x more active than that of the least. We further utilized density functional theory calculations of select equi-spaced compositions within the $La_{0.6}Sr_{0.4}Co_{1-x}Fe_xO_3$ gradient to assess the accuracy of the fluorescence setup and demonstrate how such a setup can effectively accelerate both experimental and computational materials discovery workflows for OER electrocatalysts.

Metal Azaphthalocyanine Rare-Metal-Free Electrocatalysts for Oxygen Reduction Reaction and Applications for Energy Devices *Hiroshi Yabu[1,2]; [1]Tohoku University, Japan; [2]AZUL Energy, Inc., Japan*

The development of oxygen reduction reaction (ORR) catalysts to replace rare metals such as platinum group metals (PGMs) has been extensively reported, including inorganic systems like oxide nanoparticles and heteroatom-doped carbons incorporating elements such as nitrogen and sulfur into the carbon framework. Particularly in heteroatom-doped carbons, the FeN_4 structure, where iron ions are coordinated by four nitrogen atoms, has been reported to exhibit high ORR activity. Similarly, heme iron and iron phthalocyanine, which contain FeN_4 structures within their molecules, have garnered attention as ORR catalysts.
Metal azaphthalocyanines (M-AzPcs) are analogs of metal phthalocyanines (M-Pcs) and possess higher solubility in solvents than M-Pcs. We have discovered the AZaphthalocyanine Unimolecular Layer (AZUL) catalyst, which exhibits high ORR activity by molecularly adsorbing Fe-AzPc onto carbon in a solvent. Using a rotating ring-disk electrode (RRDE) to measure over potentials of ORR under alkaline conditions, we found that the AZUL catalyst exhibited comparable performance to the platinum-carbon (Pt/C) catalyst, with the AZUL catalyst showing a lower overpotential at the half-wave potential. Additionally, the turnover frequency (TOF) of the AZUL catalyst was approximately 2.6 times higher than that of Pt/C. For the AZUL catalyst, each molecule adsorbed on the carbon acts as a catalytic active site, whereas, in Pt/C, only the surface Pt atoms of the nanoparticles contribute to the reaction. This suggests that, even with the same weight, the AZUL catalyst exhibits higher ORR activity[1,2].
As applications of this catalyst, we developed a simple zinc-air battery, a tandem zinc-air battery capable of generating over 2V using tandem cells with acid and alkaline electrolytes, and a high-performance, safe metal-air paper battery using AZUL catalyst coated on paper as the cathode[3].
Also, this concept can be applicable to wide variety of electrochemical reactions including water splitting[4], fuel cells, and supercapacitors[5].

Dynamic Surface and Bulk Phase Transitions at the Oxide/Electrolyte Interface During Oxygen Evolution Reactions *Yang Hu and Qiyang Lu; Westlake University, China*

Perovskite-type oxides have gained increasing interest in electrocatalytic water splitting due to their versatile elemental compositions and tunable electronic structures. Recent experimental observations show that perovskite oxide catalysts can experience dynamic changes in both surface and bulk during the oxygen evolution reaction (OER), rather than remaining static [1,2]. Moreover, the composition and/or structure may further evolve, driven by potential-induced changes in ionic defect concentration, which can impact OER activity and stability. However, elucidating the dynamic changes at the electrode solid-liquid interface and the quantitative defect-

potential relationship remains a challenge. Here, with a model system of epitaxial strontium cobaltite ($SrCoO_{3-\delta}$) thin films, we find that $SrCoO_{3-\delta}$ is rather dynamic during OER that shows a bulk phase transition via electrochemically induced oxygen intercalation, as well as a surface transformation towards Co (oxy-)hydroxide via Sr leaching. A toolkit of electrochemical-based methods has been performed to quantify the change of oxygen nonstoichiometry in $SrCoO_{3-\delta}$ as a function of potentials. We further probe the bulk and surface phase transitions including the thickness of the formed (oxy-)hydroxides layer by using operando techniques. Our findings thus provide a reliable experimental framework for investigating surface and bulk transformations in perovskite electrocatalysts and open up opportunities for shedding more insights into the OER activity and operational stability of perovskite electrocatalysts.

***Electronic Modulation Effect of NiCr Layered Double Hydroxide-Based Iridium Single Atomic Catalyst for Oxygen Evolution Reaction** Swayamprakash Biswal; Indian Institute of Technology Delhi, India*

Single atom catalysts (SACs) have shown immense potential in the field of electrocatalysis by effectively modulating the electronic properties of a heterogeneous matrix. Implementation of such cost-effective catalyst systems has become imperative for the facile completion of kinetically sluggish reactions, such as the oxygen evolution reaction (OER). In this study, we report the synthesis of an Ir SAC system stabilized through the surface functionalization of NiCr LDH. With an overpotential of 232 mV and a Tafel slope of 51 mV dec^{-1}, Ir_1/NiCr LDH showed a significant enhancement in the OER performance compared to pristine LDH and the state-of-the-art IrO_2 catalyst. With a Faradaic efficiency of 96.3% and non-depleting OER performance throughout a stability study for 36 h, Ir_1/NiCr LDH exhibited a higher multi-magnitude turnover frequency (TOF) and mass activity compared to IrO_2. Detailed in situ and computational studies illustrated that the suitable binding geometry of Ir sites on the LDH surface and favourable chemical bonding with reactants and intermediates result in enhanced catalytic activity. The atomistic understanding of the subtle influence of SAC coordination on catalytic activities is highly valuable for its strategic design for targeted reactions.

***Engineering the Electronic Effect in Catalytic Materials Towards Electrocatalysis** Chun-Hong Kuo[1,2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]National Synchrotron Radiation Research Center, Taiwan*

To achieve highly efficient water splitting by electrocatalysis, the issue in the conflicting pH conditions in the electrolyte between HER and OER has to be sorted out. In this talk, two stories about modulating the electronic effects in energy materials to improve the electrocatalytic HER performances in alkaline media will be introduced. The first is understanding for the alkaline HER mechanisms over Ni- and Co-based hollow pyrite microspheres, *including NiS_2, CoS_2 and $Ni_{0.5}Co_{0.5}S_2$. The results hold the evidence of the synergistic Ni-Co electronic effect for the improved H_2 evolution by the cooperative analyses upon in-operando X-ray spectroscopies and DFT calculations. The energy barrier in the first step of H_2O adsorption/dissociation in alkaline HER is 0.73 eV and the free energy of the following hydrogen desorption (to form H_2) is only 0.06 eV over the $Ni_{0.5}Co_{0.5}S_2$ surface. They are 1.63 and 1.41 eV for the NiS_2 and 0.91 and 0.21 eV for the CoS_2, less active compared to the $Ni_{0.5}Co_{0.5}S_2$. The second is to improved the sluggish kinetics in the electrochemical hydrogen evolution reaction (HER) in an alkaline medium by introducing the p-conjugated electronic effect from the rationally designed Pt-BINOL hybrid nanocomposites. This protocol led to different geometric nanostructures, including the spheres (Pt-BINOL nanospheres) and lamellar flakes (Pt-BINOL nanoflakes), which allowed fine-turning the d-band states of Pt NPs in the hybrid nanocomposites. In the two kinds of Pt-BINOL nanocomposites, the nanoflakes exhibited a low overpotential (24 mV) at the current density of 10 $mAcm^{-2}$ and Tafel slope (19.1 mV/dec), showing a superior HER efficiency not only much better than the nanospheres and the Pt/C catalyst but also comparable with the HER electrocatalysts in lately literatures. The lowest charge-transfer resistance (R_{ct}) 11.1 Ω and 1.12% of Pt weight loading reveal the Pt-BINOL nanoflakes a type of cost-efficient electrocatalyst in alkaline HER.*

EN05.07.02

Modelling Surface Atomic Structure of Perovskite Oxide La0.6Sr0.4FeO3 Under Realistic Thermodynamic Conditions *Bill Liu, Hao Tang, Filip Grajkowski, Matthäus Siebenhofer and Bilge Yildiz; Massachusetts Institute of Technology, United States*

$La_{0.6}Sr_{0.4}FeO_3$ (LSF) is recognized as a leading perovskite oxygen electrode, widely used in various energy applications, such as solid oxide fuel cells and electrolysis cells. Although catalytic reactions primarily occur on the surface, the specific atomic structures and formation of interfaces at the surface remain unclear. This talk will offer a thorough analysis of the bulk and surface thermodynamics of LSF perovskite oxides through a combination of quantum chemistry calculations and Grand Canonical Monte Carlo (GCMC) simulations. The chemical potentials (μ), essential for surface energy calculations, are determined by selecting a physically meaningful and practical approach within the multi-component chemical potential space. The chemical potentials of the cations, influenced by oxygen partial pressure (P_{O2}), bulk oxygen vacancy concentration (V_O%), bulk cation vacancy concentration (V_M%), and bulk composition (x_{La}/x_{Sr}), are calculated by considering equilibria with relevant reference states. Bulk thermodynamic calculations show the LSF phase diagram regarding decomposition reactions. Within LSF's stable regime, the stable phases under varying oxygen chemical potentials serve as reasonable initial structure guesses for GCMC simulations. These simulations provide insights into the realistic surface and interface structures of LSF under different environmental conditions. Surface segregation of SrO_2, SrO, La_2O_3, and exsolution of Fe is observed at different oxygen chemical potentials. The resulting surface phase diagram highlights the predominance of SrO segregation under ambient conditions. This methodology offers valuable insights into the surface thermodynamics of LSF perovskite oxides, laying the foundation for future research and experimental validation.

Green Synthesis of Magnesium Single Atom Catalyst from Spinacia Oleracea—Chlorophyll Extracts for Sustainable Electrocatalytic Nitrate Reduction to Ammonia *Kanhai Kumar, Pragyan Tripathi, Gokul Raj and Karuna Kar Nanda; Indian Institute of Science Bengaluru, India*

Single atom-based catalysts (SACs), due to their exceptional electrocatalytic behavior, have been explored for numerous applications such as oxygen reduction reaction, thermo-catalytic CO_2 reduction, and other catalytic activities. Ammonia is one of the most used chemical compounds, and its electrochemical synthesis is a promising alternative due to its simple, cost-effective, and selective tunability towards the synthesis. Single-atom electrocatalysts utilizing comparatively low metal mass loading with exceptional activity could be a better approach to maximize ammonia production. Herein, we report a practically viable magnesium SAC (MgNxC) for the promising reduction of nitrate to ammonia. The catalyst was prepared by green leaf extracts of Spinacia oleracea via simple one-step pyrolysis. We optimized their synthesis temperature to scrutinize the effect of SAC formation and their variation on the catalysis efficacy. MgNxC650 catalyst, as anchored on a defective graphitic matrix, exhibits the best-optimized potential of -0.58 V vs RHE, having faradaic efficiency of 81.5±2.9% and a yield rate of 392.5±41.2 μmol h^{-1} $mg^{-1}_{cat.}$ with excellent repeatability. A comprehensive study of the nature of heterojunction formed at the reactive interface of MgNxC catalysts was carried out by Mott-Schottky analysis to probe the band structure of the intrinsically induced metal-semiconductor junction in the MgNxC catalysts, followed by the parameters like flat band potential and carrier density correlation were analyzed. DFT is employed to optimize the most stable reactive site and various reaction pathways for favorable nitrate reduction with probable reaction intermediates. Combinedly, our work reflects the simple, cost-effective, and convenient way to synthesize SACs. Moreover, it provides clear evidence that chlorophyll moieties could be used as a template to prepare metal catalysts singly anchored on the graphitic carbon matrix.

EN05.07.04

Controlling Catalytic Activity of Electrode Materials *Carlos Herreros Lucas, Melanie Guillen-Soler, Lucia Vizcaino Anaya, Glenn Murray, Mehtap Aygun, Jose M. Vila Fungueiriño and Maria del Carmen Gimenez Lopez; Universidade de Santiago de Compostela, Spain*

Large scale production of hydrogen from water electrolysis has become of great interest in recent years as a green energy source, but its viability is hindered by the long term activity of the system used as electrocatalyst. The most widely used electrocatalyst are based on precious metal nanoparticles, which are highly active but not very durable as they tend to degrade over time.

To improve the durability of the electrocatalysts, an attractive strategy is the development of materials that can undergo a chemical and/or structural reconfiguration in a reversible way during the electrochemical measurements.

In this work, we showcase the enhanced durability of a novel electrocatalyst by modulating its electrocatalytic response. Consequently, the synthesized electrocatalyst material can be reversibly activated and deactivated, tuning its performance at will in a simple manner. Moreover, this unique behaviour was observed to evolve and adapt through successive switching cycles.

EN05.07.05

Effect of Surface Microstructure and Chemistry on Nanoparticle Exsolution in Perovskite Oxides—Optimizing Nanocatalyst Design *Juanita Hidalgo[1], Ruipeng Li[2], Filip Grajkowski[1], Florian Schrenk[1], Iradwikanari Waluyo[2], Adrian Hunt[2] and Bilge Yildiz[1]; [1]Massachusetts Institute of Technology, United States; [2]Brookhaven National Laboratory, United States*

Catalysts are crucial in advancing energy conversion and storage systems, particularly in electrochemical reactions. A recent advance in this field has been the synthesis of self-assembled metal nanoparticles through a process known as “exsolution.” Exsolution involves the in-situ growth of metal nanoparticles anchored to a host oxide, with perovskite oxides typically serving as the parent oxide in this process. Perovskites are important as they *provide electron and ion conductivity, which is key in energy-related applications like solid-oxide fuel and electrolysis cells (SOFC/SOEC). [1] To fundamentally understand exsolution mechanisms, epitaxial single-crystal films are used to eliminate the effects of polycrystalline structures and grain boundaries. [2] However, comparisons between thin films and bulk (e.g., pellet) samples are not always one-to-one, primarily because differences in stoichiometry influence exsolution.[3] Additionally, perovskite surfaces are central in the electrochemical reactions in SOFC/SOECs. [4] Therefore, it is important to thoroughly analyze and understand the structure and chemistry of these surfaces and their effect on exsolution to control nanoparticle formation. The detailed mechanisms underlying exsolution at the surface are not yet fully understood, and there is limited knowledge about the surface structure, which hinders the controlled development and design of these nanocatalysts. [1,5]*

In this work, we use advanced surface-sensitive characterization tools to investigate how surface microstructure and chemistry influence the formation of nickel (Ni) nanoparticles from the exsolution of $La_{0.5}Sr_{0.5}Ti_{0.94}Ni_{0.06}O_3$ *(LSTN) perovskite thin films. We analyze the microstructure of near-single-crystal films on a single-crystal strontium-tin oxide (STO) substrate and polycrystalline films on yttrium-doped zirconium oxide (YSZ) and silicon (Si) substrates, separately. By using grazing-incidence wide-angle scattering (GIWAXS) we analyze the crystal structure at the top surface with a penetration depth of approximately 10 nm. We observe that polycrystalline films on YSZ, which exhibit a preferred orientation of the (110) out-of-plane and high crystallinity, lead to an increased density and surface area of exsolved nanoparticles. In contrast, polycrystalline LSTN on Si shows lower crystallinity and higher disorder, resulting in significantly less exsolved Ni from the LSTN. We hypothesize that a high degree of preferred orientation and crystallinity facilitates cation diffusion, resulting in more Ni^0 nanoparticle formation. Further, we use grazing-incidence small-angle X-ray scattering (GISAXS) to observe and calculate the size of the exsolved nanoparticles. To study and quantify the surface chemistry, we employ in-situ near-ambient-pressure X-ray photoelectron spectroscopy (NAP-XPS). By analyzing the Ni 3p peak in XPS, we track the in-situ reduction of Ni from Ni^+2 into Ni^0. Establishing correlations between surface chemistry and nanoparticle properties is crucial for controlling exsolution surfaces tailored for specific electrochemical reactions in SOFC/SOECs.*

A-Site Cation-Control in Ruddlesden-Popper Perovskite Anode for Boosting Exsolution of Fe Nanoparticles and Formation of Oxygen Vacancies for High-Performance Direct-Ammonia Solid Oxide Fuel Cells

Jungseub Ha, Junil Choi and Won Bae Kim; Pohang University of Science and Technology, Korea (the Republic of)

Direct ammonia solid oxide fuel cells (DA-SOFCs) present a promising pathway for efficient energy conversion for green ammonia utilization. However, challenges such as nitridation and agglomeration of Ni-based anodes have restricted their widespread application. This study explores the application of A-site cation control by partially substituting Sr with Ba in the Ruddlesden-Popper (RP) perovskite. This substitution enhances exsolution of Fe nanoparticles and formation of oxygen vacancies by inducing the lattice expansion in the crystal structure, thereby improving ammonia decomposition and the overall electrochemical performance of DA-SOFCs.
The incorporation of Ba into the RP lattice modifies the crystal structure, facilitating metal nanoparticle exsolution and increasing basic properties of anode material. These modifications are crucial for enhancing nitrogen

recombination and desorption during ammonia decomposition, thereby maintaining active catalyst sites and improving resistance to the nitridation of exsolved Fe nanoparticles. This study focuses on the in-situ exsolution of Fe nanoparticles and the partial Ba substitution, both of which significantly enhance catalytic activity and electrochemical performance while improving durability under operational conditions.
Advanced characterization techniques, including X-ray diffraction with Rietveld refinement and high-resolution electron microscopy, were employed to elucidate the lattice changes and phase transitions induced by partial Ba substitution in the A-site of RP perovskite. These modifications promote the exsolution of Fe nanoparticles, which are essential for enhancing the electrochemical activity. Electrochemical assessments demonstrate that the novel $La_{1.2}Sr_{0.4}Ba_{0.4}Mn_{0.4}Fe_{0.6}O_{4-\delta}$ *with exsolved Fe nanoparticles (R-LSBMF) as an anode material achieves nearly complete ammonia decomposition at 650 °C and maintains this activity over extended periods, indicating excellent durability. The in-situ reduced LSBMF, combined with GDC* ($Ce_{0.9}Gd_{0.1}O_2$) *as a DA-SOFC anode, exhibits a maximum power density of 1.019* $W\ cm^{-2}$ *and a notably low ohmic resistance of 0.154* $\Omega\ cm^2$ *at 800 °C.*
This research advances the understanding of A-site cation substitution in RP perovskite anode materials and highlights the potential of RP perovskite with exsolved metal nanoparticles for high-efficiency and durable DA-SOFC anodes. Furthermore, it demonstrates the practical feasibility of using ammonia as an effective and sustainable fuel for SOFCs, driving the technology towards eco-friendly energy solutions. The exceptional catalytic and durability features of the R-LSBMF anode material pave the way for the commercialization of DA-SOFCs, which is crucial for addressing global environmental challenges.

EN05.07.07

Improving the Performance of High-Temperature PEMFC with Patterned Catalyst-Coated Ion-Pair Membrane

Sohee Kim, Sanghyeok Lee and Segeun Jang; Kookmin University, Korea (the Republic of)

In high-temperature polymer electrolyte membrane fuel cells (HT-PEMFCs), the catalyst-coated membrane (CCM) method has many advantages, yet it remains underexplored for constructing membrane electrode assemblies (MEA) due to challenges with phosphoric acid (PA) doping. This study presents a novel MEA design featuring a patterned membrane for HT-PEMFCs using the CCM technique. The MEA incorporates a PA-doped ion-pair membrane and an electrode with protonated phosphonic acid ionomer applied via direct-decal transfer. To enhance the benefits of the CCM approach, we developed a membrane with an inverted-pyramid structure through a solvent-assisted patterning process, which involves partially dissolving the membrane surface with an aprotic solvent spray to reduce stiffness. The PA-doped patterned membrane in the CCM showed superior decal transfer efficiency, improved PA capillary infiltration, and minimized PA loss during compression. The enhanced 3D interlocking structure increased interfacial adhesion strength and the electrochemically active surface area compared to traditional MEAs with catalyst-coated substrates and flat CCMs. The patterned CCM also demonstrated the lowest oxygen transport resistance due to morphological modifications of the grooved electrode. These advancements resulted in the patterned CCM achieving a high performance of 680 mW cm^-2 at 160°C in dry H2/air.

EN05.07.08

Understanding Polymer-Ion Interactions for Improved OMIECs

Guanchen Wu[1], Hang Yu[1], Sachetan M. Tuladhar[1], Adam Marks[2], Iain McCulloch[3], Piers R. Barnes[1] and Jenny Nelson[1]; [1]Imperial College London, United Kingdom; [2]Stanford University, United States; [3]University of Oxford, United Kingdom

Organic mixed ionic-electronic conductors (OMIECs) are soft electronic materials that can solvate and transport ions as well as electronic charges, and are of interest for applications such as sensing, electrochromics, catalysis and energy storage, often using aqueous electrolytes.[1] OMIECs offer a high degree of flexibility in their structure and function which allows them to be customized for specific applications. However, it is difficult to disentangle *how different factors, such as the polymer chemical structure, ion type and electrolyte influence the properties of the OMIECs such as their transport properties, capacity and stability under electrochemical cycling. A common strategy to investigate polymer-electrolyte interactions is systematic variation of the polymer side chains.[2, 3] In this work, we go further and investigate the effect of varying side chain structure, electrolyte concentration and ion type in order to probe the mechanism of electrochemical doping in a series of oxybithiophene based p-type polymers. We show that introducing hydrophobic groups on to the polar side chains influences redox performance, specific capacity, rate capability, swelling behaviour of the polymers. Interestingly, the choice and concentration of electrolyte strongly modulates the behaviour of the polymers. With the help of in situ characterization methods, we observed an anomalous swelling trend of one polymer that is controlled through choice of electrolyte. We interpret this unusual swelling phenomenon in terms of the interactions between polymer and both anions and cations and will discuss how electrolytes choice may impact the electrochemical performance of OMIECs.*

Improved Selectivity of Linear α-Olefins on Facilitated Transport Membranes— Experiment and Theory *Suim Lim[1,2], Jung Hyun Lee[1] and Kanghoon Yim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Sogang University, Korea (the Republic of)*

Linear alpha olefins (LAOs) such as 1-hexene and 1-octene are experiencing a continuous increase in demand as value-added petrochemical feedstocks. Due to the high energy consumption associated with separating LAOs from their mixtures using distillation and extraction methods, there is a pressing need for more efficient separation approaches, such as membrane technology. Here, we develop facilitated transport membranes containing Ag nanoparticles for the separation of 1-hexene from n-hexane. These membranes exhibit high selectivity at ambient temperature and high downstream pressure due to specific interactions with TCNQ-activated Ag nanoparticles. We use density functional theory (DFT) to investigate the activation of Ag surfaces by TCNQ. We examine changes in the surface charge density of Ag depend on TCNQ coverage and calculate atomic charge differences through Bader charge analysis. Furthermore, we compute the adsorption energies of n-hexane, 1-hexene, 2-hexene, and 3-hexene on the Ag surface with various TCNQ coverages, and confirm the impact of carbon bonding on adsorption. These results demonstrate that the facilitated transport membrane has enhanced separation performance.

EN05.07.10

C3 Product Formation from CO_2 by Br-Bridged Dinuclear Cu(I) Complex Electrocatalyst *Keita Sekizawa, Naonari Sakamoto, Soichi Shirai, Takamasa Nonaka, Takeo Arai, Shunsuke Sato and Takeshi Morikawa; Toyota Central R&D Laboratories, Inc., Japan*

Molecular metal complex catalysts are highly tunable in terms of their CO_2 reduction reaction (CO_2RR) performance due to their flexible molecular design. However, metal complex catalysts face challenges in their *structural stability, and it has not been possible to synthesize high-value-added C3 products due to their inability to perform C–C coupling. In this presentation, we show a CO_2 reduction reaction catalyzed by a Br-bridged dinuclear Cu(I) complex. The Faradaic efficiency was found to be ~50% for C2 products and 12% for propanol at 1.8 V vs Ag/AgCl. Using operando XAFS analysis, we confirmed that during the CO_2RR, the metal complex structure is maintained without forming Cu metal. Operando spectroscopic analysis for the CO_2RR with $^{13}CO_2$ and using surface plasmons enabled the identification of intermediates important for C3 formation. Investigations using DFT calculations revealed a mechanism that can explain both the operando measurements and energetics. The results suggest that the catalyst produces C3 products by forming an intermediate species via C–C coupling between two Cu centers and flexibly varying the distance between them.1) To the best of our knowledge, previous examples of a molecular catalyst that generates C3 products from CO_2 have remained elusive. The achievement of C–C coupling by the CO_2RR in a metal complex that can freely adjust the electronic state of the reaction center and the reaction environment while maintaining its structure may be a major step towards the selective synthesis of higher value-added multi-carbon products.*

Electrochemically Assisted Deposition of Nanoscopic SiO_2 Plugs Reduces Hydrogen Crossover in Sub-Micron Thick Proton-Conducting Oxide Membranes

Jesse S. Dondapati[1], Lucas Cohen[1], William Stinson[1], Sampada S. Mahajan[1], Matthew Weimer[2] and Daniel Esposito[1]; [1]Columbia University, United States; [2]Forge Nano, United States

Production of green H_2 via polymer electrolyte membrane (PEM) electrolyzers (~ \$3.4 - \$12 per kg) remains significantly expensive compared to the blue H_2 produced by steam methane reforming process (~ \$1 - \$3 per kg). Per- and polyfluoroalkyl substances (PFAS) membranes also known as nafion membranes (nafion-117 is ~178 µm-thick) are crucial for polymer electrolyte membrane (PEM) electrolyzers, because they provide high stability and proton (H^+) conductivity (0.08 − 0.12 S cm^{-1} at 50 °C).[1] However, PFAS materials have significant environmental impact and are listed as forever chemicals. Alternatively, a sub-micron or an ultrathin SiO_2 based proton-conducting oxide membranes (POM) can be deposited on electrodes encapsulating the catalytic interface using techniques like atomic layer deposition (ALD) and spin-coating.[2] Sub-micron POM are 2 to 4 orders thinner in magnitude compared to conventional nafion membranes. This enables a drastic decrease in membrane resistance, which allows for electrolyzer operations at much higher current densities and consequently with high efficiency.[1,2] However, occurrence of nanoscopic defects in the form of pinholes or cracks on the sub-micron thick POM can lead to undesirable permeation of H_2 across the membrane, which is also a safety issue. Unfortunately, submicron thick SiO_2 based POM fabrication are prone to formation of these defects.[3] In this work, we demonstrate electrochemically assisted deposition of nanoscopic SiO_2 plugs into the defects of atomic layer deposition (ALD) sub-micron thick (250 nm) SiO_2 POM overlayer. The reported process effectively plugs the pinholes and cracks that are acting as highways of H_2 crossover. Selective deposition of plugs at defective locations is verified by Scanning electron microscopy (SEM) images, Raman spectroscopy, Energy-dispersive X-ray spectroscopy (EDS) and X-ray photoelectron spectroscopy (XPS). It was further electro-analytically supported by SECM measurements at identical defect locations before and after administering nanoscopic plugs. ALD SiO_2 Membranes modified with SiO_2 plugs decrease H_2 permeation by > 99% compared to unmodified membranes. Additionally, electrochemical impedance spectroscopy (EIS) measurements showed that the "plugged" membranes still possess the desirable H^+ conductivity (> 0.12 S cm^{-1}) and electronic resistivity (~120 mΩ cm^{-2}).

EN05.07.12

The Effect of Particle Size on the Oxygen Reduction Reaction Activity of Carbon-Supported Niobium Oxide-Based Nanoparticle Catalysts

Naoki Shinyoshi[1], Satoshi Seino[1], Yuta Hasegawa[1], Yuta Uetake[1], Takaaki Nagai[2], Ryuji Monden[2], Akimitsu Ishihara[2] and Takashi Nakagawa[1]; [1]Osaka University, Japan; [2]Yokohama National University, Japan

One of the alternatives to platinum catalysts for the cathode of polymer electrolyte fuel cells is transition metal oxide-based catalysts, such as TiO_x, ZrO_x, and NbO_x. Although these catalysts have been considered for their potential because of their high chemical stability under acidic conditions, their low oxygen reduction reaction (ORR) activity requires significant improvement. A contributing factor to this low activity is the poor conductivity of oxides. To improve this, it is believed necessary to control the crystal phase, the size of the oxides, and the local conduction paths near the oxide particles. Generally, it is difficult to separate and discuss these factors independently, making it unclear which factor is the most influential. In this study, niobium oxide nanoparticles with significantly different sizes were synthesized using either the irradiation method or impregnation method for the preparation of catalysts precursors, followed by heat treatment. Here, we report on the comparison of ORR activity, focusing on the differences in the size of the niobium oxide nanoparticles in the catalyst.

The irradiation method is a simple one-pot process, in which a glass vial containing ultra-pure water together with conductive carbon nanopowder and metal source ($Nb_2(C_2O_4)_5$) are irradiated with gamma-ray from a cobalt-60 source. The impregnation method places conductive carbon nanopowder and the metal source in ethanol, followed by a drying process to obtain the sample. Thus-prepared composite nanoparticles, acquired in powder form, were used as precursors. Polyacrylonitrile was added and the mixture was heat-treated in an ammonia atmosphere to prepare the catalyst. It is expected that polyacrylonitrile will be graphitized upon heat treatment, forming local conduction paths near the oxide particles.

These samples were characterized by the techniques of TEM, XRD, and LSV. When the precursor prepared by the irradiation method was heat-treated, TEM observation revealed that the Nb-based nanoparticles on the surface of the carbon support had a particle size of 7 nm. Following heat treatment of the impregnation-prepared precursor, the size of the Nb-based nanoparticles on the surface of the support was 13 nm, indicating that each method of precursor preparation successfully produced Nb-based nanoparticles of different sizes. In both cases, XRD showed diffraction patterns corresponding to niobium oxynitride. Additionally, composition ratios of niobium oxynitride determined from Vegard's law, assuming NbO_xN_{1-x}, were consistent regardless of the precursor preparation method.

These catalytic activities were evaluated using Linear Sweep Voltammetry in an acidic medium, based on the open circuit potential in oxygen and current density. After heat-treating the irradiation-prepared precursor, the open circuit potential and current density were slightly higher compared to the impregnation method; however, no significant difference was observed. Using a model based on several assumptions, it was suggested that the dominant factor affecting ORR activity is not the size of the metal oxide nanoparticles, but the length of the local conduction paths near the oxide nanoparticles. The present study revealed that the ORR activity in niobium oxide nanoparticle catalysts does not significantly depend on the size of the oxide nanoparticles.

EN05.07.14

Performance and Characterization of Sustainable Pine-Based Biochar-MnO_2 Hybrid Electrodes for Supercapacitors *Thomas Sadowski[1,2], Max Martone[1,2], Vanessa Adamski[1,2], Andriy Grynyk[1,2], Kaleb Roman[1,2], Jeremy Turpin[1,2], Rahul Singhal[3,2] and Christine Broadbridge[1,2]; [1]Southern Connecticut State University, United States; [2]Connecticut State Colleges and Universities Center for Nanotechnology, United States; [3]Central Connecticut State University, United States*

Supercapacitors are seen as a critical energy-storage device in a diversifying global energy landscape that is becoming increasingly reliant on intermittent green sources. In addition to offering power densities far surpassing traditional lithium-ion batteries they can be fabricated from materials that are less problematic from an environmental and human rights perspective. Among this class of devices, so-called hybrid architectures are of particular interest due an increased energy density arising from combined electrostatic (electric double-layer capacitance, EDLC) and electrochemical (pseudocapacitance) charge storage mechanisms. At present, the best performing devices utilize nanoscale carbons and noble-metal oxides for EDLC and pseudocapacitance, respectively. Alternative materials, while not as energy dense, open the possibility of more sustainable energy storage. For example, MnO_2 is an attractive pseudocapacitive material due to its natural abundance, low-toxicity, and facile synthesis routes while biochar, produced through the pyrolysis of biomass, generates fewer emissions and is predicted to present lower health risks than conventional carbon-based EDLC materials. Furthermore, the fabrication of biochar is carbon negative, and significant opportunities exist to engineer the morphology through rational choice of biomass precursor.

In this study, the performance of pine-based biochar-MnO_2 hybrid electrodes of varying initial biochar concentrations, synthesized using the same one-pot method, were investigated. The electrode surface area was quantified by BET surface analysis and the structure and composition using x-ray diffraction. The supercapacitive performances were investigated using cyclic voltammetry ranging from 3-200 mV s^{-1} as well as galvanostatic charge-discharge tests at 0.5, 1.0, and 2.0 A/g. This data, along with scanning and transmission electron microscopy data, provides insight on the structure-property-performance relationship for these composite material systems. Characterization indicates that nanocrystalline MnO_2 is synthesized that largely mixes with the microporous biochar to create a composite with varying levels of homogeneity. Electrochemical results indicate that the hybrid electrode specific capacitance is maximized at lower initial biochar concentrations.

EN05.07.15

Oxygen Dimerization and Lattice Instability in Perovskite Oxide *Andrew Akbashev; Paul Scherrer Institute, Switzerland*

I will discuss how lattice oxygen redox and chemo-mechanical coupling in a perovskite electrocatalyst develops upon intercalation of O^{2-} under OER conditions. We employ high-resolution resonant inelastic X-ray scattering (RIXS) to detect the oxidation state of oxygen and show that the emergence of oxygen dimers depends on the transition metal. Our study suggests that the oxygen dimerization originates from an intrinsic lattice instability that develops inside the electrocatalyst upon extreme oxidation.

EN05.07.16

Electrode Junction Effect for Enhanced Carrier Dynamics in Water Motion-Induced Electricity Generation
Yong Hyun Cho and Youn Sang Kim; Seoul National University, Korea (the Republic of)

Water motion-induced energy harvesting has emerged as a promising approach to generating renewable electricity through the interaction between nanostructured two-dimensional materials and water. Despite growing interest, understanding the complex solid-liquid interfacial phenomena remains inconclusive mainly due to a lack of analytic approaches and interpretations regarding the nanoscopic interfacial regions, hindering practical advancements in energy harvesting efficiency. Herein, novel analytical approaches to water-induced charge carrier movement in semiconductors are proposed. Specifically, we employ various metal electrodes on reduced graphene oxide (rGO) to investigate its unique carrier density modulation behavior where the water contact region undergoes semiconductor-type inversion. The semiconductor type was confirmed through Hall effect measurements, and observations of I-V curves across wet and dry regions revealed a demonstration of diode characteristics. As semiconductor properties change in response to water interactions, the electrode junction effects also undergo ohmic/schottky contact reversal adjustment. Therefore, asymmetric electrode configurations were deposited on wet/dry regions to optimize carrier dynamics. By asymmetrically arranging metal electrodes at both ends of the rGO membrane, we observed significant enhancements in open-circuit voltage (Voc) and short-circuit current (Isc), reaching up to 1.05 V and 31.6 μA, respectively which is more than twice the voltage and 20-times the current compared to that of the rGO without the electrode deposition. These findings underscore the potential of customized electrode configurations on two-dimensional nanomaterials to enhance the efficiency and applicability of water motion-driven energy harvesting technologies.

EN05.07.17

Probing Cu Surfaces During Carbon Monoxide Electroreduction Using Operando Ambient Pressure X-Ray Photoelectron Spectroscopy (AP-XPS)

Sergey Koroidov and Bernadette Davies; Stockholm University, Sweden

There has been a great wave of effort in recent years towards developing CO_2 and CO electroreduction technologies, in order to address the critical issues of climate change and our dependence on fossil fuels. Fundamental to our understanding of these complex processes are techniques that allow the evolution of the catalytic interface to be tracked under realistic conditions, and in real-time. Ambient pressure X-ray photoelectron spectroscopy (AP-XPS) is a powerful technique for studying catalytic interfaces. It allows the chemical state of the catalyst to be tracked along-side the evolution of catalytic intermediates and products, as well as being sensitive to a broader range of chemical species than other spectroscopic techniques. Despite recent successes in adapting AP-XPS to the study of electrochemical interfaces via the dip-and-pull method, it has not yet been used to study the CO_2 or CO reduction reactions. In this work, we examine a Cu(111) and Cu(100) single crystal surface during the alkaline CO reduction reaction (CORR) using operando dip-and-pull AP-XPS. We reveal insights into the structure selectivity and mechanism of the CORR on these surfaces. Further, we provide an outlook for dip-and-pull AP-XPS as a method for studying the CORR and CO_2RR.

EN05.07.18

Inhibiting Carbonate Adsorption over Ni(OH)2 by Introduction of Pd for Stable Urea Electrooxidation

Nijita Mathew; JNCASR, India

Urea-assisted water electrolysis has emerged as a promising and energy-efficient alternative to conventional water splitting, thanks to its low potential requirement of just 0.37 V—an impressive 860 mV less than the 1.23 V needed for traditional water splitting. In an alkaline medium, the electrochemical oxidation of urea produces CO_2, H_2O, and N_2. $Ni(OH)_2$ has proven to be an effective catalyst for this reaction. However, the process faces challenges due to the sluggish kinetics of the 6-electron transfer and the non-spontaneous desorption of carbonate (CO_3^{2-}) molecules from the catalyst surface, leading to high overpotential and active site poisoning. These issues significantly affect the long-term stability of the catalyst.

To overcome these challenges, we have electrodeposited Pd onto $Ni(OH)_2$. The addition of Pd provides extra sites for the adsorption and activation of urea molecules, resulting in a marked improvement in stability up to 300 hours with negligible decay. The introduction of Pd also reduces the overpotential by 40 mV compared to $Ni(OH)_2$ alone, achieving 1.33 V for a current density of 10 mA cm^{-2}. Furthermore, the decrease in the Tafel slope and charge transfer resistance indicates enhanced reaction kinetics. In operando spectroscopic studies reveal that electrodeposited Pd effectively prevents the poisoning of Ni sites during urea electrooxidation, thereby enhancing the overall performance of the catalyst.

Catalyst Structure Design for Enhancing Hydrogen Fuel Cell Performance *Keonwoo Ko, Jiho Min, Yunjin Kim, Sourabh Chougule, Khikmatulla Davletbaev, Abhishek Chavan, Beomjun Pak, Hyelim Park and Namgee Jung; Chungnam National University, Korea (the Republic of)*

As climate change intensifies, hydrogen fuel cells have garnered attention as next-generation energy conversion devices. Polymer Electrolyte Membrane Fuel Cells (PEMFCs) are prominently applied in transportation, power generation, and hydrogen fuel cell vehicles due to their eco-friendliness, solid electrolyte, and high power density. However, PEMFCs encounter significant performance degradation in real-world operating environments. Numerous research efforts have addressed these issues, but solutions still need to be improved, and the fundamental resolution of these challenges still needs to be discovered. This study aims to provide an integrated solution by designing a catalyst that encapsulates platinum nanoparticles within a multifunctional carbon shell, offering protective and molecular sieve functions. In the PEMFC operating environment, the carbon shell significantly mitigates membrane electrode assembly (MEA) degradation by preventing platinum nanoparticle agglomeration and dissolution and enhancing catalyst selectivity. Furthermore, incorporating high-performance, high-durability metal-organic framework (MOF) materials aims to improve the active metal nanoparticles and the overall catalyst performance. This catalyst design is anticipated to be a promising strategy for maintaining PEMFC performance and maximizing its lifespan.

EN05.07.20

Selective Removal of Micropores and Defect Healing in Carbon Supports Using Polyaromatic Hydrocarbon Molecules for Enhanced Durability of PEMFCs *Seunggyun Han and Han-Ik Joh; Konkuk University, Korea (the Republic of)*

Recently, with the aggravation of global warming, sustainable energy storage and conversion technologies have received attention as alternatives to fossil fuel combustion engines. Proton exchange membrane fuel cells (PEMFCs) are regarded as one of the most promising candidates because of their zero carbon dioxide emissions and rapid conversion response. However, the high cost of catalysts, primarily due to the use of platinum and its *insufficient durability, hinders their commercialization. In particular, carbon corrosion that occurs during the start/stop cycles of PEMFCs significantly deteriorates the performance by not only corrosion of the carbon support but also CO poisoning and Pt detachment. To address this issue, many researchers have attempted to use highly graphitic carbon synthesized by heat treatment at high-temperature treatment as a catalyst support. However, the dispersion of Pt nanoparticles decreases with increasing temperature due to the reduction of surface roughness and loss of anchoring sites such as defects and micropores, leading to the detachment of the nanoparticles during the cell operation. Hence, a breakthrough technology is needed to realize defect-free carbon support with sufficient anchoring sites.*

In this study, we synthesized the carbon supports at temperatures below 200°C using polyaromatic hydrocarbon molecules (PAMs) extracted from the petroleum pitch. The structural and electrochemical properties of as-synthesized carbon supports were then investigated. Our composite carbon support with PAMs (C-PAMs) showed a lower I_D/I_G *ratio in Raman spectroscopy and a larger basal plane (*L_a*) compared to the pristine carbon support, whereas it exhibited similar 2-theta and* L_c *values in XRD results. This indicated that the addition of PAMs into the carbon supports is more effective in healing vacancies and defects in the basal plane than in promoting graphitization. Interestingly, the electrochemical surface area (ECSA) of 20 wt% Pt/C-PAMs was reduced by only 35.0% after 60,000 cycles of the accelerated durability test (ADT), while Pt/C catalyst experienced about 50% loss in ECSA relative to its initial value. In addition, the former and the latter showed a decrease in half-wave potential of 10 mV and 33 mV, respectively. Remarkably, micropores with a diameter of 2 nm in C-PAMs significantly decrease compared to the pristine carbon support, suggesting the selective removal of these micropores due to the electrostatic interaction between the PAMs and the micropores. Consequently, a single-cell prepared using the Pt/C-PAMs catalyst demonstrated outstanding performance in the region of mass-transfer limitation. Therefore, this suggests that our selective and fine control of micropores and defects could facilitate the realization of highly active and durable electrocatalysts at lower temperatures.*

EN05.07.21

Highly Active and Stable ORR Electrocatalysts with Ultra-Low Content of Platinum Derived from Metal-Organic Framework *Uhyeok Son, Jongyoon Lee, Seunggyun Han, SeonYeong Lee and Han-Ik Joh; Konkuk University, Korea (the Republic of)*

Proton exchange membrane fuel cells (PEMFCs) have emerged as promising candidates for the next generation of energy sources due to their pollution-free power generation, high energy density, and abundant hydrogen fuel supply. However, the sluggish kinetics of the oxygen reduction reaction (ORR) necessitates the use of platinum (Pt) catalysts, significantly increase the overall cost of PEMFC stacks. To enhance the efficiency and cost competitiveness of PEMFCs, it is crucial to develop highly active and durable ORR electrocatalysts containing ultra-low amount of Pt.

In this study, ultra-low Pt-cobalt (Co) alloy catalysts were synthesized using core-shell Zeolitic Imidazolate Frameworks (ZIFs). The internal Zn-ZIF (ZIF-8) facilitated the formation of a hollow structure during carbonization, significantly enhancing the porosity of the catalyst. The Co derived from the external Co-ZIF (ZIF-67) was alloyed with 5 wt% Pt, resulting in the high activity of the catalyst. Additionally, the catalyst exhibited a graphitic structure due to the catalyst-induced graphitization of Co during the carbonization and alloying process, thereby increasing its durability.

In a half-cell system, the catalyst achieved a half-wave potential of 0.916 V and a mass activity of 0.191 A/mg_{pt}*, with the half-wave potential decreasing by only 12 mV after 100,000 cycles. Remarkably, in a single-cell system, the MEA employing this catalyst with an ultralow Pt loading of 0.04* mg/cm^2 *demonstrated a high peak power density of 1.380* W/cm^2 *and a mass activity of 0.197* A/mg_{pt}*. Furthermore, the MEA retained 56% of its initial mass activity, with a peak power density of 0.623* W/cm^2 *after 30,000 square wave cycles based on the protocol of the Department of Energy. Therefore, we believe that the ultra-low loaded Pt-Co alloy catalyst derived from core-shell*

ZIF-8@ZIF-67 promotes the interaction with oxygen molecules and lowers the activation energy barrier for the ORR, making it a promising solution for more efficient and cost-effective PEMFCs.

EN05.07.22

Improved Oxygen Reduction Reaction Performance of PGM-Free Catalyst Through Change in Surface Structure

Yunjin Kim, Keonwoo Ko, Beomjun Pak, Hyelim Park, Sourabh Chougule and Namgee Jung; Chungnam National University, Korea (the Republic of)

Over the past decades, extensive research and development have been conducted to replace platinum group metal (PGM), the key material for oxygen reduction reaction (ORR) catalysts, with various non-platinum and carbon-based catalysts. However, non-platinum nanoparticle catalysts have faced significant commercialization barriers due to their lower ORR performance compared to commercial platinum catalyst and their severe dissolution issues in acidic electrolytes. In this context, M-N-C (M = 3d-transition metal) catalysts, which disperse transition metals at the atomic level, have shown considerable promise due to their substantial performance in both acidic and alkaline electrolytes, making them attractive candidates. Also, recent studies have reported that the M-Nx structures on the surface of M-N-C catalysts exhibit electron withdrawing/donating effects depending on the type of core metal or doped elements. Based on these, we have developed novel PGM-free catalysts with anchoring M-Nx structures onto carbon shells of non-platinum metal nanoparticles. As a result, we confirmed the enhancement of the catalytic performance by controlling the electron withdrawing/donating effects between the core metal and the M-Nx sites of the carbon shell. Therefore, we expect these results significantly contribute to the development of novel PGM-free catalysts for fuel cells.

EN05.07.23

Design Principles of Nickel-Based Alloy Catalysts for Ammonia Decomposition

Yeongjun Yoon and Kyeounghak Kim; Hanyang University, Korea (the Republic of)

Ammonia (NH_3) decomposition is extensively studied for clean hydrogen production and direct ammonia fuel cell (DAFC) due to its high hydrogen storage capacity and existing infrastructure. However, current ammonia decomposition proess poses several challenges. Primarily, Ruthenium (Ru) catalysts are highly effective for ammonia decomposition, but their limited supply and high cost hinder their commercialization. Consequently, nickel (Ni) catalysts are being considered as a cost-effective alternative for ammonia-based hydrogen production and anode catalyst for DAFC. To further improve the catalytic activity of Ni catalysts, Ni-based alloy catalysts with other metals are a promising approach. This study employs density functional theory (DFT) calculations to investigate the catalytic activity of 3d transition metals (Ni, Co, Cu, and Fe) and their potential alloys.
According to DFT analysis, the key elementary reaction steps of overall ammonia decomposition are NH_x-H bond scission ($NH_x^* \rightarrow NH_{x-1}^* + H^*$) and N+N recombination ($N^* + N^* \rightarrow N_2^*$). We found that nitrogen binding energy ($E_{ad}(N)$) acts as a key descriptor for predicting the activation energies of these elementary steps, showing a volcano-like relationship between the experimentally observed catalytic activity and the DFT-calculated $E_{ad}(N)$. This relationship indicates that $E_{ad}(N)$ can be used to fine-tune the catalytic properties of the materials to achieve optimal performance.
DFT results showed that Fe-Ni alloy catalyst exhibited a comparable catalytic activity to pure Ni catalyst. Therefore, we anticipated that a Ni-Fe alloying system, incorporating the relatively inexpensive Fe element into Ni, could be a potentially cost-efficient catalyst. To further optimize the composition of Ni-Fe system, we conducted DFT calculations and revealed the relationship between Fe concentration in the Ni-Fe system and $E_{ad}(N)$. Based on this correlation, we identified a $Ni_{0.64}Fe_{0.36}$ composition predicted to have an optimal $E_{ad}(N)$ value on the volcano plot. Experimental validation also confirmed that the $Ni_{0.64}Fe_{0.36}$ catalyst exhibited higher catalytic performance compared to that of pure Ni.

To extract the fundamental descriptor for $E_{ad}(N)$, we additionally performed DFT-based electronic structure analysis and found that as the d-band filling (f_d) of the metal surface increases, the M-N bonding interaction weakens and the anti-bonding interaction strengthens, leading to a decreased $E_{ad}(N)$. This understanding allows us to design catalysts with tailored electronic properties for optimizing their performance. Based on these results, we concluded that f_d can be a powerful descriptor for predicting $E_{ad}(N)$, thereby acting as a useful and fundamental descriptor to predict the catalytic activity of Ni-based alloy catalysts for ammonia decomposition for hydrogen production and DAFC anode. Our findings offer valuable insights for optimizing Ni-based alloy catalysts for efficient hydrogen production and DAFC anode through ammonia decomposition, potentially leading to more cost-effective and sustainable hydrogen economy.*

Zn Content Determines the Electrocatalytic Activity of Scrab Brass Towards CO_2 Reduction into Value-Added Fuels

Ibrahim M. Badawy, Ahmed M. Ismail, Ghada Khedr and Nageh K. Allam; The American University in Cairo, Egypt

The electrocatalytic reduction of carbon dioxide (CO_2RR) into value-added fuels is a promising initiative to overcome the adverse effects of CO_2 on climate change. Most electrocatalysts studied, however, overlook the harmful mining practices used to extract these catalysts in pursuit of achieving high-performance. Repurposing scrap metals to use as alternative electrocatalysts would thus hold high privilege even at the compromise of high performance. In this work, we demonstrated the repurposing of scrap brass alloys with different Zn content for the conversion of CO_2 into carbon monoxide and formate. The scrap alloys were activated towards CO_2RR via simple annealing in air and made more selective towards CO production through galvanic replacement with Ag. Upon galvanic replacement with Ag, the scrap brass-based electrocatalysts showed enhanced current density for CO production with better selectivity towards the formation of CO. The density functional theory (DFT) calculations were used to elucidate the potential mechanism and selectivity of the scrap brass catalysts towards CO_2RR. The d-band center in the different brass samples with different Zn content was elucidated.

EN05.07.25

Insights into Electrochemical Nitrate Reduction with Cu Single Crystals in Alkaline Electrolytes

William T. Phillips, Owen Doyle and Joseph DuChene; University of Massachusetts Amherst, United States

The electrochemical nitrate reduction reaction (NitRR) is an alternative to wastewater treatment, allowing for the conversion of NO_3^- and NO_2^- into NH_3 which can be used to supplement NH_3 formation from the Haber-Bosch process. Cu is a promising material for NitRR catalysis, reaching high rates and Faradaic efficiencies for NH_3. While Cu performs well, there are fundamental gaps in our understanding of which properties are responsible for Cu's activity. The activity of Cu single crystals has been thoroughly studied in acidic environments, but few studies have investigated the NitRR on Cu single crystals in alkaline electrolytes. To bridge this gap, we have utilized Cu single crystals to determine the most active low-index facet for the reduction of NO_3^- to NO_2^- and the subsequent reduction of NO_2^- to NH_3. To gain more insight into the structure-function relationship, we further investigated the kinetics and thermodynamics to determine which reaction steps are rate-limiting for each surface. This study has provided facet-specific mechanistic insight into the NitRR. These results will help advise toward optimal nanoparticle shape of Cu-based catalysts for the NitRR as well as providing a fundamental understanding of which catalyst attributes we should consider for further catalyst refinement.

EN05.07.26

Fabrication and Characterization of Membrane Electrode Assembly with Nanoalloy Catalysts of Ultralow Platinum Loading for PEM Fuel Cell Application

Zeqi Li, Dominic Caracciolo, Dong Dinh, Guojun Shang, Craig

Mu, Jin Luo, Susan Lu and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States

Fuel cells are promising electrochemical devices for clean energy hydrogen conversion where the membrane electrode assembly (MEA) with platinum catalysts plays a critical role in achieving high efficiency and performance. We have been developing nanoalloy catalysts by alloying platinum with other transition metals which exhibit high electrocatalytic activity for oxygen reduction reaction. A key challenge is to demonstrate high performance and durability of the MEA with the catalysts in PEM fuel cells. In this presentation, recent findings on the fabrication and characterization of MEAs with ultralow loading Pt, aiming at optimizing Pt utilization, reduce cost, and enhancing performance. Advanced synthesis techniques were used to achieve precise control of Pt loading for the nanoalloy catalysts on carbon support materials in the MEA. In addition to standard electrochemical techniques, atomic force microscopy (AFM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM) were employed to assess the structural changes of the MEAs before and after the fuel cell operations. Fuel cell performances were correlated with the structural characterization and theoretical simulation results. The MEAs with selected nanoalloy catalysts and ultralow loading of Pt were shown to exhibit enhanced catalytic activity in comparison with those of conventional high-loading MEAs, highlighting their potential for reducing the cost for mass commercialization of fuel cell technologies.

EN05.07.27

Characterization of Multimetallic Nanoalloy Catalysts in Proton Exchange Membrane Fuel Cells *Dominic Caracciolo, Zeqi Li, Zhipeng Wu, Dong Dinh, Guojun Shang, Megan Barber, Niko Vidakovic, Ylith Peck, Jessica Tao, Gary Han, Jin Luo, Susan Lu and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States*

The understanding of control factors of the performance of multimetallic nanoalloy catalysts in proton exchange membrane fuel cells (PEMFCs), a vector for alternative clean energy conversion, is critical for the optimization of membrane electrode assembly design and fabrication. We have been investigating different wet-chemical and solid-state synthesis routes for the preparation of Pt and/or Pd-alloyed transition metal catalysts towards achieving enhanced voltage-current performance and durability. Key to the investigations is the correlation of the phase structures of the nanoalloys with the electrocatalytic properties in the PEMFC. In this presentation, recent results from using in-situ high-energy x-ray diffraction (XRD) to characterize the phase structures and monitoring fuel cell performance of the nanoalloy catalysts in PEMFC to determine the durability will be discussed. Examples of Pt and Pd alloyed with Cu, Ni, Fe, etc. will be highlighted. The effect of dealloying and realloying processes on the PEMFC performance and electrocatalytic durability will be discussed. Both DFT-based theoretical modeling and AI-driven data processing and simulation are used for assessing the experimental results for better understanding the composition-performance relationship of the multimetallic nanoalloy catalysts in fuel cells.

EN05.07.28

Development of Metal-Supported Solid Oxide Electrolysis Cell Using Small Diameter Particles as Cathode Material *Daisuke Moritomo, Rikuya Miyazaki, Yoshino Ikeda, Daiki Teshima, Hiroki Takasu and Yukitaka Kato; Tokyo Institute of Technology, Japan*

As global warming progresses due to increased carbon dioxide emissions, a carbon-neutral energy system called the Active Carbon Recycle Energy System (ACRES) has been proposed [1]. In ACRES, CO2 emitted from industrial processes is captured, converted into carbon resources using zero-carbon energy, and reused cyclically. ACRES has a particularly high compatibility with the ironmaking process called iACRES (smart steelmaking process based on ACRES) and has been investigated so far. In iACRES, the CO2 produced in the ironmaking process is collected *and then reduced into carbon monoxide (CO) electrically according to Equation 1. Finally, the CO is used again as a reductant in the iACRES process, thus achieving a carbon-neutral ironmaking process.*

$CO_2 \rightarrow CO + 0.5O_2, \Delta H = 283\ kJ\ mol^{-1}$ *(1)*

A promising candidate for CO2 conversion technology is using a solid oxide electrolysis cell (SOEC), which can directly electrolyze CO2. SOEC usually uses ceramic materials such as yttria-stabilized zirconia (YSZ) or Ni-YSZ as supports. However, ceramic-supported SOEC (CS-SOEC) are vulnerable to thermal shock and lack strength. Therefore, when aiming for application to actual industrial processes, there was a problem in that the cell area could not be widened larger. To address this issue, metal-supported SOEC (MS-SOEC), a new next-generation cell that uses metal as a support, is being considered[2]*. The use of a metal support guarantees the strength of the cell and is expected to increase the cell area. Also, the addition of metal as a support makes it possible to make each ceramic layer of the SOEC thinner, reducing the amount of expensive ceramics used, which is expected to be beneficial not only in terms of strength but also in terms of material cost.*
We have been developing MS-SOEC using a mesh made of thin metal wires as a support[3]*, and we successfully demonstrated the basic principle of CO2 electrolysis at 800 °C by preparing a 2 cm diameter MS-SOEC coin cell. The next investigation is needed to improve the electrolysis performance by adjusting the cell reaction layers. In this report, to improve the cathode of MS-SOEC, a two-layered cathode structure was investigated by using NiO-YSZ particles with different diameters for thermal spraying.*
The MS-SOEC used in the experiments were prepared by forming each ceramic layer on metal wire mesh placed on a porous metal support of 20 mm diameter by a thermal spraying method. The SOEC structure mainly consists on the substrate: anode | electrolyte | cathode | diffusion barrier layer, which are $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$*(LSCF), YSZ, NiO-YSZ,* $La_{0.6}Sr_{0.2}Ca_{0.2}CrO_3$ *(LSCC) respectively. The ceramic layer was formed under several different conditions using thermal spraying (thermal spraying by TOCALO Co.,Ltd). For the two-layered structure of the cathode, a coarse NiO-YSZ layer was introduced in the first layer to ensure gas diffusion, and a slightly dense layer was introduced in the second layer to enhance contact with the electrolyte. The CO2 electrolysis performances of the fabricated MS-SOEC at 800°C were evaluated by electrochemical and gas analyses. In the CO2 electrolysis experiment, MS-SOEC with the two-layer cathode reached 235 mA/cm2 at 800 °C and 1.6 V. In addition, an electrochemical polarization of this MS-SOEC was analyzed by electrochemical impedance spectroscopy at 300 mA, and it was confirmed that the electrode-related polarization was reduced by about 10 % by the introduction of the double-layered cathode. Although further studies to improve the electrolytic performance of MS-SOECs are still needed for practical applications, these results are beneficial for the future development of MS-SOEC.*

Investigating the Effect of Different Fluorides on the Synthesis and Electrochemical Properties of the $Ti_3C_2T_X$ MXene

Vinícius d. de Souza, Luís F. da Silva, Rafael K. Nishihora and Sydney F. Santos; Universidade Federal do ABC, Brazil

MXenes is a family of 2D compounds (carbides, nitrides and carbonitrides) that hold enormous potential for several technological applications, particularly in energy conversion and storage due to their unique combination of structures and chemical bonds [1]. For instance, MXenes demonstrated with efficiency in hydrogen evolution reaction and high capacitance. Despite their potential uses, producing these materials with high quality lamellas efficiently exfoliated and delaminated is a challenging task. Moreover, it is essential to develop environmentally *friendly routes of exfoliation and delamination of the precursor MAX phase to obtain MXenes with adequate properties since the classical routes involve the use of concentrated fluoridric acid solutions, resulting in generation of hazardous wastes. In this study, we investigated new synthesis protocols for producing the* $Ti_3C_2T_x$ *MXene from the* Ti_3AlC_2 *MAX phase. The HF etchant was replaced by HCl and LiF solution following the MILD synthesis protocol [2]. Further, we investigated the combination of LiF with other fluorines with larger ionic radii, NaF and KF. To analyze the effect of the synthesis protocol on the MXene produced, an extensive set of characterizations was performed including XRD, SEM, XPS, HR-TEM. In addition, the electrochemical properties of the obtained MXenes were characterized by EIS and Cyclic Voltammetry. The obtained results indicated that all routes produced MXenes with good structural features and a remarkable sensitivity of the electrochemical properties with the fluorines used.*

Electrosynthesis of Unusual Nonfcc Palladium Hydride Nanoparticles *Jaeyoung Hong and Xiao Su; University of Illinois at Urbana-Champaign, United States*

Intercalation of hydrogen into the palladium atomic layers during the growth of Pd nanoparticles can lead to the synthesis of unique palladium hydride phases. Here, we discover an unusual nonfcc palladium hydride nanoparticle, a structure that is not face-centered cubic (fcc), formed through coreduction of water molecules and Pd ions in solution. Crystal structure determination based on atomic electron tomography points to potential triclinic unit cells, indicating the presence of more than one nonfcc phase with some of those being a stack of loosened and distorted close-packed layer of atoms. The probability of finding nonfcc phase in single crystalline particles varies depending on the number and distribution of contact area with other particles. Roughly half of the isolated and one side-coalesced single crystal particles exhibit nonfcc structure while fcc dominates multiple sides-coalesced single crystals as well as polycrystal particles, which suggests a coalescence-induced phase transition from a nonfcc to a stable fcc structure due to the metastable nature of the nonfcc phases. While hydrogen is proven to be a key component for the synthesis of the nonfcc structure, given the limited formation of the unusual phase in H_2 *gas bubbling system, the proposed electrochemical approach can be a promising platform for the in situ creation and study of metastable nanomaterials.*

EN05.07.33

Uncovering Performance Improvements of Ni/GDC Anode for Low Temperature SOFC—DFT Study *Taejin Lim and Kyeounghak Kim; Hanyang University, Korea (the Republic of)*

Low-temperature solid oxide fuel cells (SOFCs) offer several advantages, such as improved material stability and operating cost reduction. However, achieving optimal performance and commercial viability requires overcoming various challenges. One significant issue with commonly used electrode materials is the decrease in catalytic activity at low temperatures. Ceria-based anodes are renowned for their robust thermal stability and facile redox ability, thereby contributing to their excellent performance. To further improve these abilities, doping ceria with *lanthanide elements such as Gd or Sm enhances ion conductivity and facilitates the creation of oxygen vacancies. Recently, nickel catalysts supported by gadolinium-doped ceria (Ni/GDC) have shown superior performance to conventional Ni-YSZ electrodes. However, the specific reasons behind this improvement still remain unclear. Therefore, we performed DFT calculations to explore the key factors contributing to the catalytic performance of Ni/GDC. According to DFT studies, oxygen vacancy formation plays a crucial role in explaining intrinsic electronic conductivity. Since easier oxygen vacancy formation (represented by the low oxygen vacancy formation energy (E_{ovf}) in DFT calculations) results in high electronic conductivity, this is expected to further improve the reaction activity. Through E_{ovf} calculations for Ni/GDC, we confirmed that oxygen vacancies form more easily near the Gd sites compared to the Ni or Ce sites. This indicates that near the Gd sites serve as active sites, facilitating electron transfer and reactions. The key finding is that introducing Ni onto the GDC increases the exposure of electronically conductive Gd on the surface. This enrichment of active Gd sites is expected to enhance the catalytic activity, as revealed by the segregation energy calculations. The DFT-predicted enhancement in catalytic activity was validated by experiments. These findings help to overcome low catalytic activity issues in low-temperature SOFC electrodes and contribute to the commercialization of cost-effective electrodes.*

EN05.07.34

Dynamic Hydrogen Bubbling Templated AgSn@ SnO_x Electrocatalyst for Selective Electrochemical CO_2 Reduction—Adjusting the Binding Energy of the HCOO* Intermediate *Nageh K. Allam; American University in Cairo, Egypt*

*A facile electrochemical synthesis of 3D hierarchical porous AgSn@SnO_x core–shell catalysts has been demonstrated as efficient candidates for CO_2 reduction to formate. The AgSn@SnO_x (30 s) catalyst showed excellent selectivity towards formate (FE_{HCOOH} = 96% ± 4.90; j_{HCOOH} = −10.5 mA cm^{-2} at −0.9 vs. RHE) with negligible HER activity. Tafel analysis and adsorption affinity studies suggest that AgSn@SnO_x (30 s) has faster reaction kinetics and the lowest adsorption energy, implying the formation of oxygen vacancies under cathodic conditions, which stabilize $^*CO_2^{\cdot -}$ radicals and achieve lower binding energy. DFT calculations showed that the AgSn@SnO_x core–shell structure accelerates the formation of formic acid by modifying the binding energy of the HCOO*intermediate. Additionally, this structure improved the faradaic efficiency of C_1 production by suppressing the competitive hydrogen evolution reaction (HER), which is considered the main side reaction in the CO_2RR. The AgSn@SnO_x catalyst stands out as one of the most efficient electrocatalysts for CO_2 reduction to formate, when compared to other formate-selective electrocatalysts. It demonstrated superior performance in terms of formate partial current density and formate faradaic efficiency. All in all, AgSn@SnO_x core–shell catalysts showed great potential for efficient CO_2 reduction to formate, which could have significant implications for sustainable energy production.*

EN05.07.35

Enhanced Oxygen Evolution Reaction and Zinc-Air Battery Performance Enabled by Chiral-Induced Spin Selectivity and Cobalt-Doped Nickel Oxide *Young Sun Park, Jeongyoub Lee, Hyungsoo Lee, Juwon Yun, Chan Uk Lee, Subin Moon, Soobin Lee, Sumin Kim, Junhwan Kim and Jooho Moon; Yonsei University, Korea (the Republic of)*

The imminent demand to alleviate the global warming and considerable consumption of fossil fuel have promoted development of sustainable energy conversion systems such as rechargeable Zn–air batteries (ZABs) due to their superior energy density, excellent safety, and abundancy of Zn source. However, sluggish reaction kinetics of oxygen evolution reaction (OER) as well as low conductivity of generally exploited low-cost oxygen evolution catalysts have been challenges for developing competitive ZABs. Although ruthenium and/or iridium noble catalysts have been utilized because of their superior catalytic activity for OER, the high cost as well as efficiency loss derived from the electrochemical decomposition of active sites could pose a serious problem. Therefore,

rational strategies to boost the OER catalytic activity of earth abundant catalyst, which is stable under severe anodic condition, are essential for the advanced rechargeable ZABs.
Herein, we report a distinct approach using cobalt-doped nickel oxide (Co-NiO) with a chiral structure, obtained by a one-step hydrothermal process. Cobalt doping raises the conductivity as well as active site density of the catalyst, while the chiral structure triggers chiral-induced spin selectivity (CISS), which could boost the kinetic rates of OER by modulating the spin states of electrons to be aligned in a specific direction. The parallel alignment of spin configurations of electrons facilitates the production of triplet oxygen ($^3O_2$), which is generated in a lower energy state than the singlet oxygen state ($^1O_2$), mitigating the overpotential for OER. Accordingly, our chiral Co-NiO-based electrode exhibited OER current density of 10 mA cm^{-2} at 1.58 V versus the reversible hydrogen electrode, outperforming both achiral Co-NiO as well as undoped NiO. Furthermore, chiral Co-NiO-based rechargeable ZAB delivered a high open-circuit potential (1.57 V), low charge/discharge overpotential (0.79 V), and excellent operational stability for 100 h. Our findings represent a prominent pathway for the advancement of high-performance ZAB using low-cost OER catalyst mediated by CISS and hetero-atomic doping.

EN05.07.36

Electrolyte-Polymer Interactions in Electrochemically Doped π-Conjugated Materials *Megan R. Brown[1], Joel H. Bombile[1], Chamikara Karunasena[2], Zhiting Chen[2], Anton Perera[1], Erin L. Ratcliff[3], Jean-Luc Bredas[2] and Chad Risko[1]; [1]University of Kentucky, United States; [2]The University of Arizona, United States; [3]Georgia Institute of Technology, United States*

Electrochemically doped π-conjugated polymers (CP) are central materials in several emerging applications, including in electrochemical energy storage and solar fuel generation (i.e., chemicals from sunlight). In these systems, electronic transport is dependent on the motion of polarons, which act as charge carriers in the CP. Here we assess how the local nanoenvironment impacts polaron properties including the surrounding dielectric environment and presence of nearby counterions from the supporting electrolyte. Density functional theory (DFT) and time-dependent density functional theory (TDDFT) are used to determine polaron characteristics in the model n-type CP poly(NDI2OD-T2). Additionally, we perform molecular dynamics (MD) simulations to investigate the interphase of poly(NDI2OD-T2) with an electrolyte solution being perturbed by an electric field. A detailed characterization of this swelling behavior is vital for the design of CP materials that maintain functional performance under operational conditions.

EN05.07.37

Vertically Aligned Transition Metal Dichalcogenide Nanowires as Efficient Electrocatalysts for Hydrogen Evolution Reaction *Hyeonkyeong Kim and Youngdong Yoo; Ajou University, Korea (the Republic of)*

Quasi-one-dimensional (1D) transition metal dichalcogenides (TMDCs) can have novel electronic, optical, and mechanical properties due to the quantum confinement effect. In particular, quasi-1D TMDCs can possess high conductivity and abundant active sites, making them promising candidates for hydrogen evolution reaction catalysts. However, the direct synthesis of vertically aligned quasi-1D TMDCs remains challenging. Here we report on the direct synthesis of the TMDC nanowires vertically aligned on a conductive substrate through a sequential chemical vapor deposition method. The vertically grown TMDC nanowires have numerous active sites and have high stability, so they exhibit excellent catalytic performance for hydrogen evolution reaction, including a small Tafel slope and excellent long-term stability. We believe that our results provide a good strategy for generally fabricating vertically aligned TMDC nanowires for efficient electrochemical catalysis.

Decarbonizing Industrial Biodiesel Wastewater Treatment Through Electrified Glycerol Oxidation Coupled to Waste CO_2 Conversion into Methanol

Kyungho Kim and Joshua Jack; University of Michigan, United States

Introduction

Biodiesel has huge potential to displace petrochemical fuels but its production generates a large amount of wastewater that challenges the economic viability of the whole process. Glycerol is the major component of biodiesel wastewater and can be electrochemically oxidized at low redox potentials, enabling plants to efficiently co-valorize abundant wastewater and CO_2 into useful products. We explored the catalytic activity of non-noble metallic Ni as an anodic material and elucidated interfacial fouling during short- and long-term operations for sustainable waste glycerol valorization. This study will provide insight into fit-for-purpose modification strategies of Ni for glycerol oxidation based on a detailed understanding of the anodic behavior of Ni.

Materials and Methods

Synthetic crude glycerol as an anolyte was constructed to simulate a real crude glycerol matrix from biodiesel production. All electrochemical experiments and analyses were performed using a potentiostat in a flow cell with two chambers separated by an anion exchange membrane. Commercial Ni foam, Pt gauze, and Hg/HgO electrode were used as an anode, cathode, and a reference electrode, respectively. Liquid products were analyzed with HPLC and IC. FTIR was adopted to characterize the anodic surface.

Results and Discussion

Catalytic activity of Ni in an alkaline medium - Cyclic voltammetry (CV) of Ni foams was performed in different solutions. In 0.3 M KOH, NiOOH formation followed by oxygen evolution reaction (OER) was observed in the forward scan while NiOOH reduction to $NiOH_2$ was found in the reverse scan. When 0.1 M glycerol was co-present, a surge of current due to glycerol oxidation reaction (GOR) was found in the forward scan. The absence of the NiOOH reduction peak in the reverse scan confirmed the characteristic catalytic behavior of Ni for GOR in an alkaline condition. Importantly, GOR was found to be a promising alternative to OER saving approx. 300 mV in the potential window of CV.

Ni with high selectivity toward formate - Anodic valorization of glycerol was performed for 30 min at varying anodic potentials ranging from 500 ~ 900 mV in a solution of 0.3 M KOH and 0.1 M glycerol. High Faradaic efficiency (73 - 77%) and selectivity (~ 90%) toward formate at 500 - 700 mV emphasized that Ni may not need further modification when formate is a target value-added product.

Sign of surface accumulation during GOR - After short-term GOR operation at different anodic potentials, Ni foams were recovered, rinsed with deionized water, and analyzed for CV in 0.3 M KOH (i.e., no external glycerol addition). All used Ni generated oxidation currents larger than Ni oxidized only in 0.3 M KOH without glycerol, indicating surface coverage initiation by glycerol and/or intermediates.

GOR efficiency worsened by surface deposits - GOR operation was extended to 24 hrs to examine the impact of surface accumulation. Glycerol concentration continuously declined but charge consumption estimated based on it substantially surpassed actual charge consumption, suggesting a non-electrochemical glycerol loss. FTIR spectrum progression suggested surface inactivation initially driven by intermediates followed by glycerol.

Conclusion

Non-noble metallic Ni without any modifications can be used as an anode with a high formate selectivity for glycerol oxidation. However, surface deposition may originate from the rate-limiting intermediate oxidation such as *glyceraldehyde and glycerate. Ni surface covered by these intermediates can significantly hinder catalytic GOR by promoting glycerol adsorption on the surface irrelevant to GOR. Therefore, Ni modification to alleviate bottle-necking intermediate reaction steps may be a key for stable glycerol valorization.*

8:15 AM ^EN05.08.02

Bimetallic Electrocatalysts for Electro-Oxidation of Alcohol-Based Chemicals *Daniel Martin-Yerga; University of Jyväskylä, Finland*

Transitioning from fossil to renewable resources is essential for advancing clean energy technologies and creating a sustainable chemical industry. The current reliance on fossil resources for producing carbon-based platform chemicals presents significant environmental challenges. Inedible biomass offers a promising renewable carbon source. Biomass-derived chemicals often contain oxidizable hydroxyl groups, such as those found in alcohols, hydroxy acids, and carbohydrates. Electrochemistry provides an ideal approach to converting these chemicals into valuable building blocks, leveraging green chemistry principles such as compatibility with aqueous media, operating under near-ambient conditions, and eliminating the need for external oxidizing agents. Furthermore, these oxidation reactions are highly relevant for renewable energy applications, including fuel cells and energy-efficient hydrogen production. Despite these opportunities, the electrochemical oxidation of biomass-derived chemicals is still an emerging field, particularly in understanding electrocatalytic interfaces for these reactions. Developing catalysts with high activity, selectivity, and stability is essential for advancing sustainable chemical (electro)synthesis and clean energy conversion.

In this contribution, I will present our research on the electrocatalytic oxidation of various alcohol-based chemicals. We focus on bimetallic electrocatalysts that offer several advantages over monometallic materials. Our investigation covers fundamental aspects using model primary alcohol compounds such as methanol and ethanol, as well as practical biomass-derived chemicals such as glycerol, organic hydroxyacids and carbohydrates. I will discuss the multifaceted challenges and prospects of bimetallic electrocatalysts for oxidizing these chemicals, including insights into structure-activity relationships and strategies to enhance activity, counteract catalyst deactivation, and modify reaction selectivity. Our work sheds light on how the chemical and structural properties of bimetallic electrocatalysts can be tuned to enable the sustainable electrosynthesis of chemicals from renewable biomass resources, opening new avenues in this field.

8:45 AM EN05.08.03

Enhanced Urea Electrooxidation Reaction by Synergistic Nickel and Cobalt Mixed Oxides/Hydroxides Catalyst *Tongxin Zhou[1], Sathya N. Jagadeesan[1], Lihua Zhang[2] and Xiaowei Teng[1]; [1]Worcester Polytechnic Institute, United States; [2]Brookhaven National Laboratory, United States*

Hydrogen emerges as a promising and sustainable energy resource; however, its production faces limitations due to the sluggish kinetics of the oxygen evolution reaction (OER, 1.23V) during the water electrolysis. As a potentially superior alternative to the OER, the urea oxidation reaction (UOR) presents a lower theoretical potential when integrated into the electrolytic cell to replace OER. Extensive research has focused on nickel-based catalysts for their high activity in facilitating the UOR and cost-effectiveness compared to noble metals based electrocatalysts. However, the UOR reaction mechanism and UOR-active phases of Ni-based electrocatalysts still remain ongoing debates.

In this study, we investigated a series of Ni/Co electrocatalysts for UOR, including mixed-phase hydroxides and oxides and single-phase oxides. We found that the synergistic effect between Ni and Co enhanced UOR activity, showing decreased onset potential, fast reaction kinetics, and good selectivity against OER, outperforming Ni and

Co monometallic compounds (e.g., NiO, NiOOH, Co_3O_4) and benchmark commercial Pd catalysts. We also found that Ni^{2+} and Co^{3+} species at low anodic potential showed plausible UOR activity and selectivity. While Ni^{3+} formed at high anodic potential showed much enhanced UOR activity, it also accounted for unwanted OER, evidenced by staircase voltammetry electrochemical measurements, synchrotron X-ray absorption and X-ray diffraction, and XPS analysis. This work highlights the importance of valence details and crystalline phase to obtain highly active and selective UOR electrocatalysts and provides a leap forward in understanding the design of high-performance and selective UOR electrocatalysts.

9:00 AM EN05.08.04

Biomimetic Nucleotide-Graphene Hybrids for Electrocatalytic Oxygen Conversion— Quantifying Biomolecule Mass Loading *Arantzazu Letona Elizburu[1,2], Marina Enterría[1], Alex Aziz[1], Silvia Villar Rodil[3], Juan Ignacio Paredes[3], Javier Carrasco[1,4] and Nagore Ortiz-Vitoriano[1,4]; [1]CIC energiGUNE, Spain; [2]University of the Basque Country, Spain; [3]Instituto de Ciencia y Tecnología del Carbono – INCAR, Spain; [4]Ikerbasque, Basque Foundation for Science, Spain*

The development of new technologies is required to promote the transition from fossil fuels to sustainable and environmentally friendly resources. In this context, metal-air batteries are being studied as an alternative to resolving future energy demands and environmental issues due to their high theoretical energy density. However, the chemical conversion based on the Oxygen Reduction and Evolution Reactions (ORR and OER) that take place in the cathode is limited by sluggish kinetics and high overpotentials. Currently, the most widely used catalysts are noble metals such as iridium, platinum and ruthenium; however, they have several drawbacks such as high cost and low availability. Moreover, the discovery of materials capable of catalyzing both ORR and OER reactions (bifunctional) is crucial for improving the efficiency in energy generation and storage technologies.

Nucleotides are metal-free, small and natural molecules composed of a pentose sugar, a nitrogenous heterocyclic nucleobase and a phosphate group. They act as enzyme cofactors in the mitochondrial electron transfer chain by undergoing reversible oxidation/reduction reactions. Hence, nucleotides could be used as catalysts in the metal-air cathodes to mimic efficient biological processes and overcome the kinetic challenges currently encountered in these devices. But as these biomolecules are not conductive, it is necessary to support them on a conductive surface to be used as battery electrodes. In this work,[1] biomimetic electrocatalysts are prepared by liquid adsorption of aromatic nucleotides by π-π interaction in the large and conductive surface area of electrochemically exfoliated graphene.

The determination of catalyst loading and dispersion is relevant when assessing the catalytic activity of catalysts. However, quantifying the loading of non-conventional electrocatalysts is still an underexplored topic in literature. Different characterization techniques have been therefore combined herein for estimation of both the loading and dispersion. In addition, Rotating Disk Electrode (RDE) has been used to analyze the catalytic activity of bare graphene and a riboflavin mononucleotide (FMN)/graphene hybrid. Even though both studied materials presented similar activity towards ORR, the hybrid material achieved higher turnover frequency (TOF, $1.50x10^{-2}$) and lower Tafel slope (151 mV dec^{-1}) than graphene, which displayed values of $1.81x10^{-4}$ and 295 mV dec^{-1}, respectively. Thus, the presence of the nucleotide seems to improve the catalytic activity for OER. In addition, both the catalyst loading and the catalytic activity results have been corroborated by Density Functional Theory calculations. In summary, the methodology here developed will pave the way for the discovery of new bioinspired electrocatalysts by 1) proposing sustainable preparation of biomimetic electrocatalysts and 2) filling the existing gap in the characterization of metal-free organic catalysts.

Upcycled Polystyrene-Derived Carbon-Bound Platinum Alloy Catalysts for Enhanced Durability in Fuel Cells

Young Jun Lee; Korea Institute of Science and Technology, Korea (the Republic of)

Proton exchange membrane fuel cell (PEMFC) technology demands the development of highly active and durable catalysts while minimizing platinum (Pt) usage to lower costs. In this study, we present a scalable method for synthesizing carbon-bound catalysts by upcycling polystyrene (PS) polymer. Our technique employs solvent-based hyper-crosslinking to create a hierarchically porous structure in a single-step process. The resulting PS-derived carbon support, loaded with Pt, features a mesoporous structure that enhances mass transport within PEMFCs, even at a low Pt loading of 0.05 mg_{Pt} $cm^{-2.}$ *This catalyst demonstrates exceptional durability, maintaining 92.1% of its initial power density after 30,000 cycles, attributed to its carbon-bound structure and robust catalyst-support interactions. In comparison, commercial Pt/C retains only 35.8% of its power density after the same number of cycles. This method provides a cost-effective and sustainable way to convert PS polymer into durable cathode materials for PEMFCs.*

Electrode Materials as Key for the Success in Electro-Organic Synthesis

Siegfried Waldvogel[1,2]; [1]Max Planck Institute for Chemical Energy Conversion, Germany; [2]Karlsruhe Institute of Technology, Germany

The direct use of electrochemistry for the generation of reactive intermediates can have major advantages towards conventional synthetic strategies. Compared to the action other sustainable approaches such as photochemistry, the overall energetic balance is superior and allows easily scalable conversions. Less or no reagent waste is generated, and new reaction pathways are accessible. In order to exploit the electricity driven conversions for synthetic purposes and to install unique selectivity two modern approaches will be outlined:

1) For reaching larger scale in electrochemical conversions, the formation of high-performance oxidizers is an option. By the given versatility a broad applicability is targeted. The key here are boron-doped diamond anodes.

2) Several unique molecular entities require for their installation large amounts of reagents, when using electrochemical tools this can be achieved almost waste-free. This is of particular interest when complex molecules are desired.

The working horse to identify suitable electrolytic conditions is the electrosynthetic screening approach. This strategy gives also rise to fast optimization and subsequent scale-up. For technical realization of electrosyntheses carbon electrodes play a crucial role ranging from diamond to highly isostatic graphite carbon allotropes. For reductive conversion leaded bronzes as planar or foam-type cathodes can be employed.

***Electrocatalyst and Interfacial Engineering for Ammonia Synthesis via Nitrate Reduction Reaction** Feng-Yang Chen[1,2] and Haotian Wang[1]; [1]Rice University, United States; [2]Stanford University, United States*

Electrochemically converting nitrate ions, a widely distributed nitrogen source in industrial wastewater and polluted groundwater, into ammonia represents a sustainable route for both ammonia fuel synthesis and wastewater treatment. However, the reaction environments in current lab-scale tests are still far from practical conditions for generating ammonia from natural wastewater. Here, we first report a high-performance Ru-dispersed Cu nanowire catalyst that delivers an industrial-relevant nitrate reduction current while maintaining a high NH_3 Faradaic efficiency. This high nitrate-reduction catalytic activity enables over a 99% nitrate conversion into ammonia while still maintaining an over 90% Faradaic efficiency. Next, we report a three-chamber solid electrolyte reactor design and couple this with cation shielding effects for an efficient nitrate reduction reaction without supporting electrolytes. With this interfacial engineering strategy, we can realize a cation shuttling from the middle layer back into the cathode chamber to boost the nitrate reduction selectivity. This electrode interface and reactor system can deliver high ammonia Faradic efficiencies (> 90%) at practical current densities (> 100 mA cm^{-2}) under an industrial wastewater level of nitrate concentration (2,000 ppm), enabling high-purity water effluent and pure $NH_3(g)$ as products, with no need for any electrolyte recovery processes.

10:45 AM EN05.09.02

***Improve Stability and Selectivity with Sulfur-Derived SEI for Li-Mediated Nitrogen Reduction for Green Ammonia Production** Chaeeun Lim and Kijung Yong; Pohang University of Science and Technology, Korea (the Republic of)*

Ammonia is a major compound widely used for commercial, and agricultural purposes and has recently been considered as the hydrogen carrier. Specifically, the annual consumption of ammonia reaches 200 million tons, demonstrating its significance. However, ammonia has been produced from the Haber-Bosch process, high temperature (400-500 °C), and pressure conditions (up to 200 bar), leading to many environmental (~1.4% of global CO_2 emissions) and energy-related (~1% of global energy use) issues.

Lithium-mediated nitrogen reduction (Li-NRR) is considered the most feasible method for obtaining production quantities distinct from impurities. It utilizes the low electronegativity of Li to break the strong triple bond of nitrogen. The mechanism of Li-NRR has three steps: 1) lithium plating, where Li metal is deposited; 2) lithium nitridation, where Li reacts with nitrogen and forms lithium nitride (Li_3N*); and 3) protonation, where lithium nitride reacts with a proton donor (such as ethanol) and finally produces ammonia. For this cyclic mechanism to perform robustly, the properties of the Solid Electrolyte Interphase (SEI), which is formed by decomposition of the electrolyte during lithium plating (the first step) at the electrode interface, must be controlled during reaction. It could determine not only diffusivity of reactants like nitrogen but also uniformity of lithium plating, finally selectivity of ammonia production in Li-NRR. Furthermore, chemical stability and mechanical strength of the SEIs are related with the electron-consuming decomposition of SEI during lithium plating involving stability of the whole reaction. Thus, electron insulating, ion-permeable and mechanically robust SEI is needed to promote Li-NRR.*
*In this study, we investigate sulfur-derived SEI in Li-NRR for the first time. Dimethyl sulfide (DMS) was chosen as the sulfur source due to its simple chemical structure. DFT calculation also shows DMS has lower LUMO energy levels than other components of the electrolyte. Thus, it reduced well to form sulfur-derived SEI. The addition of a small amount of DMS to the electrolyte altered the physicochemical structure of the SEI with *Li_2SO4* and *Li_2S* resulting in improved lithium-ion conductivity and mechanical strength. The sulfur-derived SEI led to a more uniform and large lithium deposition and changed the morphology of the SEI from a vertically oriented film-like structure to a net-like structure. The study demonstrated that the sulfur-added electrolyte maintained a more stable cell potential during longer times (20 hours) than the base electrolyte (10 hours). This indicates that the introduction of sulfur enhances the overall stability in Li-NRR, enhancing energy efficiency. Similarly, the electrolyte decomposition decreases in the sulfur-added electrolyte. In addition, the sulfur-added electrolyte achieves higher ammonia production and Faradaic efficiency (390 ± 50 µg *cm^{-2} h^{-1}*, 46 ± 6%) than the base electrolyte (305 ± 34 µg *cm^{-2} h^{-1}*, 36 ± 4%). Modifying the SEI through sulfur addition shows promise in improving the Li-NRR process.*

11:00 AM EN05.09.03

Correlation Between Li Solvation and the Interfacial Chemistry for Enhancing Lithium-Mediated Electrochemical Ammonia Synthesis *Haldrian Iriawan, Antonia Herzog, Nicole Ceribelli and Yang Shao-Horn; Massachusetts Institute of Technology, United States*

Ammonia (NH_3*) is a cornerstone chemical in modern society, primarily used as fertilizers (80%) and as the source of N in all synthetic chemicals. Ammonia production, being the largest in the chemical industry, exceeds >170 million metric tons annually, relies on the 100-year-old Haber Bosch process which operates at elevated temperatures (>450 °C) and pressures (>100 bar)[1]. The harsh operation conditions not only make it among the "Big Four" industries that release half of the industrial emissions in the world, but also demands a large-centralized infrastructure whose prohibitive capital cost renders ammonia inaccessible in many developing countries.*

*Electrochemistry provides a key advantage as it allows to drive chemical transformations at milder conditions and using renewable feedstocks. As the only reliable system to date[2-3], the Lithium mediated electrochemical *N_2* reduction to ammonia (LiNRR) in a non-aqueous electrolyte has emerged as a promising candidate. In LiNRR, the activation of molecular nitrogen (*N_2*) is preceded by the electrochemical deposition of metallic lithium in an organic solvent, which then reacts with *N_2* and undergoes protonation to release *NH_3*. Progress in recent years aimed at improving the faradaic efficiency, energy efficiency and long-term stability have been achieved via changing the salt [4-5] and proton donor compositions, which have been correlated with the structure and composition alterations of the Solid Electrolyte Interphase (SEI). However, the understanding of which lithium salts and electrolyte compositions are optimal for LiNRR is unclear and scattered across different groups, owing to the* *different experimental conditions. More importantly, fundamental understanding of the interplay between N_2 reduction, parasitic reactions and speciation at the interface that drive efficiency and system instability is lacking.*

In this study, we aim to draw a comprehensive connection between lithium solvation structures, its implications on SEI formation, and the corresponding ammonia faradaic efficiency and electrode stability of LiNRR. A variety of lithium salts and compositions in Tetrahydrofuran and Ethanol were employed to evaluate their efficacy for ammonia synthesis under the same transport conditions. Physical descriptors to probe Li^+ solvation structure were quantified via electrochemical Li/Li^+ redox characterization and vibrational spectroscopy of the bulk electrolytes. Our study revealed a clear correlation between the extent of Li+-anion & Li+-solvent pairing, NH_3 faradaic efficiency and the degree of parasitic reactions. We also bridged the connection between bulk electrolytes and LiNRR performance through the post-mortem electrode characterization via Raman and Nuclear Magnetic Resonance (NMR) spectroscopy. Such techniques shone light into the distinct SEI chemistry engendered by solvent-rich vs anion-rich Li solvation as well as the different degrees of ethanol participation in SEI formation. An order-of-magnitude improvement in faradaic efficiency can be obtained at the optimal electrolyte composition compared to the state-of-the-art ClO4 or BF4 electrolytes. By drawing a comprehensive connection between ammonia efficiency against bulk and interfacial descriptors, we could reveal the fundamental origin of different NH_3 synthesis performances in different electrolytes which will aid in engineering stable interfaces, resulting in a long-lasting, high-performing system for practical applications.

Polarisation Effects at Metal/Support Interfaces Transcend Reactivity Constraints in Oxygen Electrocatalysis *Tej Choksi, Asmee Prabhu, Kah-Meng Yam, Lavie Rekhi, Bryan C. Lee and Luan Q. Le; Nanyang Technological University, Singapore*

Platinum-based catalysts are widely used for the Oxygen Reduction Reaction (ORR) in fuel cells, metal-air batteries, and electrolyzers due to their excellent electrocatalytic activity and stability. However, platinum's high cost and scarcity have led to extensive efforts in alloying platinum with other transition metals and nano-structuring the Pt surface. Experimentally synthesizable, rationally designed, supported metal films on various earth-abundant carbides and nitrides have the potential to exceed the theoretical maximum for ORR and achieve high activity and stability with low Pt usage. In this study, we selected (111) surfaces of nonmagnetic 2D and 3D metal carbides and nitrides (TiC, TiN, VC, VN, CrN, NiC, NiN, MoC, MoN, and WC), and adsorbed mono- and bilayers of Pt, Ag, and Au epitaxially and as moire patterns. We assessed the thermodynamic and electrochemical stability of 200+ films and evaluated their ORR catalytic activity through a limiting potential analysis using the computational hydrogen electrode model. The OOH vs OH* scaling relation deviates from the bond order conservation slope of 1 (seen across unsupported metals, alloys, and single-atom catalysts). This deviation in slope results in the ORR limiting potential volcano peak shifting upward by >0.15 V, relative to the unsupported metal catalysts. These deviations in slopes are attributed to modulations in the metal film's reactivity by electronic metal-support interaction (EMSI) and strain. The computational analysis explains the superior stability and performance of experimentally validated Pt/TiWC catalysts. Furthermore, we identify at least 10 heterostructures with higher limiting potentials than Pt (111), including Pt/CrC with the highest at 0.93 V. We perform a detailed electronic structure analysis on these heterostructures to rationalize their increased limiting potentials relative to*

Pt (111) and qualitatively explain these deviations in scaling slopes from bond order conservation rules. Tuning the reactivity of the metal film via its interaction with the underlying support opens a wide material space for designing high-performance ORR catalysts with reduced precious metal loading.

On the Influence of pH and Potential on the Selectivity of Electrochemical CO_2 Reduction *Reza Khakpour[1], Kari Laasonen[1] and Michael Busch[2,3]; [1]Aalto University, Finland; [2]Luleå University of Techology, Sweden; [3]Luleå University of Technology, Sweden*

Electrochemical reduction of CO_2 to CO or even post CO products is of central importance for energy storage and conversion. Unfortunately, this reaction suffers from high overpotentials and low selectivity. Specifically, the formation of hydrogen rather than more desirable CO_2 reduction products is a major problem. A promising class of catalysts for CO_2 reduction are single atom catalysts (SACs) which consist of a single metal atom embedded into graphene.[1,2] These materials are known to be selective for the generation of post-CO products like methane, methanol or even formaldehyde.[1-5] Recent studies even suggest that products containing more than 1 carbon atom may be formed over SACs.[4,5]
It is well established, that the experimentally observed product distribution is strongly affected by pH and applied potential.[3,4] However, the underlying mechanistic origin of the changes in selectivity are still poorly understood. In this contribution we will present a complete reaction mechanism for the electrochemical CO_2 reduction and the competing hydrogen evolution reaction over transition metal phthalocyanine complexes obtained from density functional theory (DFT) modeling.[3,5] Taking advantage of this mechanism we will explore the origin of selectivity for different products and establish a fundamental understanding on how proton concentration and potential influence the product distribution and catalyst activity.

Mechanistic Insights into Low Overpotential Pathways for Electrochemical CO_2 Reduction to CH_4 on Pure and Doped MoS_2 Edges *Dhruv Lal[1], Tanmay Konnur[1], Anand Mohan Verma[1], M Shaneeth[2] and Ananth Govind Rajan[1]; [1]Indian Institute of Science, India; [2]Vikram Sarabhai Space Centre, India*

The electrochemical reduction of carbon dioxide (CO_2) has received considerable attention from the scientific community for its promising applications in the selective production of useful hydrocarbons, such as synthetic natural gas, i.e., methane (CH_4). In the field of extra-terrestrial exploration, it can enable the conversion of metabolite CO_2 as well as that present in the Martian atmosphere into CH_4, which can be used as fuel. In this work, *we investigate vertically aligned 2H molybdenum disulfide (MoS_2) and its edge-doped alternatives as heterogeneous electrocatalysts for the reduction of CO_2 using density functional theory (DFT) calculations. Via a comprehensive reaction pathway analysis, we show that the edges of MoS_2 offer a significantly low overpotential of 0.62 V for CO_2 reduction to CH_4 as compared to a value of 0.86 V on copper, a prominent electrocatalyst. Furthermore, by screening 8 dopants (Al, Co, Cr, Cu, Fe, Mn, Ni, and Rh), we find that Al-doped MoS_2 yields CH_4 at a remarkably low overpotential of 0.41 V, owing to a different potential-determining step (PDS) (*COOH -> *CO) as compared to the PDS on pure MoS_2 (*CO -> *CHO). Other promising dopants include Ni and Rh, offering overpotentials of 0.58 V and 0.62 V, respectively, for CH_4 production. Investigation of the competing hydrogen evolution reaction (HER) reveals that, while the CO_2RR is significantly more favorable on Al-doped MoS_2, the HER outcompetes CO_2RR on pure, Ni-doped, and Rh-doped MoS_2. Mechanistic insights obtained by comparing various reaction pathways (via *COOH/*HCOO and *CH_2/*CH_3OH) are complemented by density of states and charge density difference calculations, which rationalize the favored mechanism on each catalyst considered. Overall, our thorough, DFT-based mechanistic investigation of CO_2 reduction on pure and doped MoS_2 presents Al-doped MoS_2 edges as a promising material for the thermodynamically facile electroreduction of CO_2 to CH_4.*

2:15 PM EN05.10.03

Unraveling Surface Reconstruction of Copper Alloy Catalysts During CO_2 Electroreduction in Gas Diffusion Electrode-Based Electrolyzers *Intae Kim[1], Gi-Baek Lee[1], Sungin Kim[1,2], Hyun Dong Jung[3], Seoin Back[3], Jungwon Park[1,2], Dae-Hyun Nam[4] and Young-chang Joo[1]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of); [3]Sogang University, Korea (the Republic of); [4]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

The electrochemical CO_2 reduction reaction (CO_2RR) has attracted significant interest for the long-term storage of intermittent renewable energy and net-zero carbon emissions. For economic profitability, electrocatalyst design is necessary for selective production of value-added multi-carbon (C_{2+}) chemicals. In CO_2RR electrocatalysts, various heteroatoms have been arranged in Cu to steer the reaction pathway toward specific C_{2+} products. However, surface reconstruction-induced atomic rearrangements change the initial alloy active sites during CO_2RR and prevent steering the reaction pathway in the intended direction. For the synthesis of efficient CO_2RR electrocatalysts, it is necessary to understand catalyst reconstruction behaviors. It is reported how reconstruction changes the morphology, facets, and oxidation state of mono-metallic catalysts during CO_2RR. However, for alloy catalysts, it is more challenging to elucidate the reconstruction mechanism due to chemical complexity of multi-elemental system. Furthermore, most reconstruction studies were conducted in conventional H-cell with low-rate CO_2RR. Therefore, the knowledge gained from the mechanism studies is difficult to apply directly to the practical reaction conditions, where gas diffusion electrodes (GDEs) are inevitably introduced for rapid CO_2 mass transport. Herein, we present a universal principle for understanding and predicting the reconstruction of metal alloy catalysts during CO_2RR in GDE-based electrolyzers. Through thermochemical computation, we constructed a thermodynamic elemental map using oxophilicity and atomic miscibility between Cu and heteroatoms (X) as descriptors to systematically analyze the reconstruction behaviors of Cu alloys. By categorizing Cu-X alloys into four sections, we selected Ag, Fe, Zn, and Pd as representative X elements to investigate the reconstruction behaviors. Cu-X catalyst layers were fabricated on polytetrafluoroethylene (PTFE) fiber-based gas diffusion layers (GDLs). Cross-sectional transmission electron microscopy (TEM) with a focused ion beam (FIB) enabled to observe the changes in atomic arrangement and elemental clustering over the catalyst surface after CO_2RR. As a result, we confirmed that alloying immiscible X with Cu (X: Ag or Fe) induced the growth of Cu-rich nanoparticles with lattice defects; in contrast, alloying miscible X with Cu (X: Zn or Pd) maintained the atomically flat surface and homogeneous element distribution. Furthermore, real-time structural analysis revealed that the dynamic evolution of adparticles occurred via the dissolution-redeposition mechanism with the coalescence of the particles during CO_2RR. With density functional theory (DFT) calculation, we elucidated that miscibility and adsorbate-modulated *oxophilicity are the determining factors in the evolution of adparticles. Furthermore, we demonstrated a strong correlation between reconstructed surface structure and *CO spillover efficiency, controlling the selectivity of ethanol (C_2H_5OH)/ ethylene (C_2H_4) as well as C_2/C_1 products. Finally, we developed a methodology to control the reconstruction behaviors in operando condition. This enabled a dramatic improvement in C_2H_5OH selectivity and its structure-performance relationship is discussed.*

2:30 PM EN05.10.04

Enhanced Performance of Molecular Electrocatalysts for CO_2 Reduction by Cations *Keita Sekizawa, Shunsuke Sato, Soichi Shirai, Naonari Sakamoto and Takeshi Morikawa; Toyota Central R&D Laboratories, Inc., Japan*

Electrocatalytic carbon dioxide (CO_2) reduction using water is the key to artificial photosynthesis systems designed to produce fuels. The performance of the electrochemical CO_2 reduction reaction has improved dramatically in recent years, with current densities of 1 A/cm^2 or higher being achieved using gas diffusion electrodes. On the other hand, high voltages are used to achieve high current densities, which leads to the problem of extremely low efficiency in converting electrical energy into chemical energy. In addition, high voltages are required in PV-EC systems combined with solar cells, and expensive GaAs-based space solar cells are needed. The catalysts used in these reaction systems are mainly noble metals such as Au and Ag, and there are few reported cases of complex catalysts. This is because complex catalysts, while stable in H-type cells immersed in solution, are not as durable as metal catalysts when used in gas diffusion electrodes, as they are deactivated within a few hours.[1]
We have succeeded in using the effect of carbon and alkali metal cations to drive a Mn complex, which is not normally driven as a catalyst, as a CO_2 reduction catalyst even in an aqueous solution.[2] We have shown that this effect is also effective for other complex catalysts, and we consider it essential for the CO_2 reduction reaction. Here, we focus on the reaction environment around the catalyst at the gas diffusion electrode. There are no alkali metal cations around the catalyst. Therefore, in order to improve the CO_2 reduction performance, we investigated the possibility of introducing alkali metal cations such as K^+ into the carbon layer of the gas diffusion electrode. As a result, we have successfully developed a new Co complex catalyst electrode for reducing CO_2 to CO with high selectivity (>95%), high energy efficiency (~70%), and high durability (>1 week) at 100 mA/cm^2. [3] In this presentation, we will discuss the details of researching the new electrocatalytic system using cations effects in carbon layer.

The Role of Surface Roughening in Improving the Selectivity of Copper for CO_2 Electroreduction *Joakim Halldin Stenlid[1,2,3], Joseph Gauthier[4], Martin Head-Gordon[5], Alexis Bell[5] and Frank Abild-Pedersen[3]; [1]KBR Inc., NASA Ames Research Center, United States; [2]Stanford University, United States; [3]SLAC National Accelerator Laboratory, United States; [4]Texas Tech University, United States; [5]University of California, Berkeley, United States*

Electroreduction of CO_2 (eCO_2RR) has emerged as a promising alternative for production of renewable fuels and important commodity chemicals such as ethylene and ethanol. Despite decades of research efforts, Cu remains the only metal-based catalyst capable of producing significant amounts of desirable multicarbon (C_{2+}) products. However, further improvement is needed for industrial feasibility. It is known that roughened copper-based electrocatalysts surfaces exhibit enhanced selectivity towards C_{2+} products during electroreduction of CO_2. This poses a challenge for modeling efforts aiming to rationalize the enhanced selectivity. In this work, we use an innovative modeling approach to investigate roughened copper surfaces derived from cuprous oxide on structures *of 100x100 nm^2 size with atomic resolution and accuracy compared to density functional theory (DFT). We combine semilocal DFT (RPBE) in VASP, effective medium theory (EMT), and linear scaling relationships via the recently proposed alpha parameter scheme to investigate the site-resolved catalytic selectivity of copper sites. Electrode potential-dependence is included via the use of the VASPsol implicit solvation and a grand canonical potential approach. The approach allows us to investigate the effect of varied macroscopic roughness on the intrinsic catalytic activity of copper by comparing surfaces exposed to simulated sputtering and electropolishing, respectively. The study highlights i) the challenge for designing improved copper catalysts for CO_2RR with monodisperse active site selectivity, ii) the need for careful experimentation when comparing to theory, and iii) the limitations and opportunities of macroscopic roughness in controlling atomic scale activity.*

Electrodeposition as a Versatile Tool for the Fabrication of Electrocatalysts CO_2 Electroreduction and Glycerol Oxidation *Teresa Andreu[1], Martí Molera[1], Mohamed Amazian[1,2] and Maria Sarret[1]; [1]Universitat de Barcelona, Spain; [2]Plating Decor Recubrimientos SL, Spain*

Carbon dioxide reduction reaction (CO2RR) is a key technology for the chemical industry in a highly electrified energy scenario. To achieve its economic feasibility, it is necessary to reduce the electrolyzer operating voltage. To this end, replacing the sluggish anodic oxygen evolution reaction (OER) with the glycerol oxidation reaction (GOR) is an interesting approach that also offers the opportunity to upcycle a low-value product.

Besides the need to develop eficient and selective catalysts, the fabrication routes should be easily scalable. In this context, we present electrodeposition as an effective and versatile tool to obtain thin film layers of electrocatalysts on metal foams and microporous layers of gas diffusion electrodes (GDE).

In this contribution, it will be presented the recent efforts of the group in the development of coupled systems. On one hand, AuCu, CuIn alloys were succesfully deposited on GDEs and tested in continous flow towards the CO2RR employing different electrolytes. The results show that the presence of halides in the catholyte can avoid the undesirable hydrogen evolution reaction and favor the formation of carbon monoxide or formic acid, an effect that is enhanced by the use of binary alloys. On the other hand, NiCo layered double hydroxides and AuIn alloys were deposited on nickel foams to perform the electroxidation of glycerol, with an electrode potential reduction of 0.2 to 0.5 V with respect to the OER reaction. Results show an strong the depence of the operating conditions in the product distribution, being feasible to obtain C3 products (DHA or lactic acid) under continous flow of the electrolyte. Finally, both half reactions have been coupled in a continous flow reactor at operating current densities up to 200 mA cm^{-2}.

This work has funded by project CO2GLY (PID2022-138491OB-C33) funded by MICIU/AEI /10.13039/501100011033 and by FEDER, UE. M.A. thanks Pla de Doctorats Industrials de la SUR de la Generalitat de Catalunya (2021DI20) and M.M. thanks Ajuts Joan Oró per a la contractació de personal investigador predoctoral en formació (FI) (2024 FI-1 00421), both granted by Agència de Gestió d'Ajuts Universitaris i de Recerca (AGAUR).

Electrosynthesis of Ethylene Glycol Coupled with CO_2 Capture *Rong Xia and Edward Sargent; Northwestern University, United States*

Ethylene glycol is a $25B/year commodity chemical, used mainly as a precursor to polyethylene terephthalate (PET) and as antifreeze, responsible for the emission of 46 MMt CO_2/year. Its present-day production via *thermocatalytic ethylene oxidation leads to a carbon intensity of ~ 1.2 CO_2eq per tonne of ethylene glycol. Electrochemical systems for ethylene oxidation have, to date, suffered from high voltages. To reduce voltage, we sought to build a membrane electrode assembly (MEA)-based system; but observed that a high pH gradient across the membrane causes hydroxide counter-migration, and – when we measured local pH at the membrane-catalyst interface – we found that this resulted in an unfavorable microenvironment for anodic ethylene oxidation, accounting for low FE in MEA studies.*

We sought a cathodic reaction that would serve as a sink for pH-increasing hydroxide. Carbon capture demands a local flux of OH^-, and we pursued therefore this reaction on the cathode.

We report as a result the anodic transformation ethylene-to-EG (94% Faradaic efficiency) coupled with cathodic CO_2 capture (91% carbon capture efficiency with CO_2 concentrations ranging from 1% to 10%). An integrated system, operating at full cell voltage 1.8 V and current density 100 mA cm^{-2}, captures 0.75 tonnes of CO_2 for every tonne of EG produced. The electrified system requires 12.7 GJ compared to 22.6 GJ/tonEG for thermocatalytic ethylene oxidation. This approach offset the substantial carbon footprint of the fossil fuel-derived ethylene feedstock, leading to an estimated carbon intensity of 0.13 tonCO_2eq/tonEG, compared to the 1.2 tonCO_2eq/tonEG global average for ethylene glycol today.

Catalyzed Porous Electrodes for CO2 Conversion to Multicarbon Organics at High Single Product Selectivity and Low Over-Potential *Tao Xu; Northern Illinois University, United States*

The conversion of carbon dioxide (CO2) to value-added multi-carbon (with two or more than two C-C bonds) organic compounds by electrocatalytic reduction of CO2 provides a promising and value-added route to mitigate the greenhouse gas emission. Here, I present a family of porous carbon electrodes embbeded with transition and non-transition metals with varying sizes ranging from single atoms to few atom clusters. These porous carbon electrodes electrocatalytically reduce CO2 to C2 and C3 liquid organic compounds with high single-product selectivity at relatively low potentials. The reaction mechanism is extensively studied by Operando synchrotron X-ray absorption techniques and kinetic isotope effect to identify the dynamic evolution of the catalytic center. It is stunning to reveal that atomically dispersed catalytic metal atoms aggregate to few-atom clusters under reductive potentials and depending on the redox potentials of the metals, oxygen atoms can also involve in the catalytic center. In addition, the supporting substrates exhibit a profound nano confinement effect that also impacts the reaction pathways towards C-C coupling. Our work renders atomistic and quantum mechanical level understanding in the reaction coordination for electrochemical CO2 reduction reaction to a versatility of value-added organic compounds.

Novel Geometries for In-Flow Electrodeposition Enable More Selective and Stable CO2 Electroreduction Catalysts *Erin Heeschen, Harish Reddy Maddikunta, Yilmaz Arin Manav, Benyamin Davaji and Magda H. Barecka; Northeastern University, United States*

To hasten the transition towards carbon neutrality, we look to the promising pathway of industrial-scale CO_2 electroreduction towards profitable chemicals. Large, cheap, uniform electrodes must be reliably produced to implement this technology, preferably through methods already adopted in the industry, such as electroplating. Most popular approaches for applying metal catalysts in CO_2 electroreduction primarily utilize electrospraying methods. However, electrospraying is more challenging to scale and prone to imperfections in the catalyst deposition process. Nonuniform catalyst deposition is detrimental to CO_2 electrolysis, resulting in uneven current density and inconsistent reaction rates across the electrodes, thus creating less efficient systems and reproducibility issues.

Instead, we propose a flow reactor for the uniform electroplating of catalysts onto an electrode and provide a scalable, one-step procedure to synthesize a copper electrode with the C2+ faradaic efficiency similar to the faradaic efficiency achieved using multi-step, resource-intensive methods.
Additionally, while the industry has adopted electrolyzers/flow cells on a small scale, improvements to cell designs must be made for widespread implementation. To address this issue, we use a 3D printable electrolyzer to plate copper onto carbon paper for CO_2 reduction towards ethylene in flow. 3D-printed electrolyzers are cheap, quick to print, and can be customized for more optimized flow field geometry, enabling the development of a wide variety of flow plate geometries to increase electrolyzer efficiency and control over systemic variables.
Here we investigate four different flow plate geometries and analyze their impact on catalyst plating uniformity during electrodeposition of copper via SEM. Simulations of fluid flow through each geometry were conducted using ANSYS FLUENT and validated with benchtop experimentation to determine the optimal specific electrodeposition flow conditions to enable consistent copper plating uniformity.
The impact of copper catalyst uniformity on CO_2 electrolysis efficiency towards ethylene in flow is also explored using a gas diffusion electrode system. By finetuning the process of electrodeposition in flow, the GDE system experienced an enhancement of the selectivity towards specific products and mitigated selectivity loss over time. Achieving these two improvements is an important stepping stone on the way to introduce CO_2 electroreduction on scale.

Hierarchical Conductors Unlock Scaling of ePTFE-Based CO_2 Conversion Electrodes *Simon Rufer, Michael Nitzsche, Sanjay Garimella, John Lake and Kripa K. Varanasi; Massachusetts Institute of Technology, United States*

Gas Diffusion Electrodes (GDEs) for electrochemical CO_2 conversion must maintain robust hydrophobicity to prevent flooding, while also ensuring high conductivity to minimize ohmic losses. Conventional GDEs are limited by intrinsic material tradeoffs: carbon paper is highly conductive but floods easily, while expanded PTFE (ePTFE) is flooding resistant but non-conductive. Though many of the most promising systems to date demonstrate high conversion selectivity with ePTFE GDEs, their lack of through-plane conductivity has limited electrode sizes to just ~5 cm^2. We devise a finite element model which captures the ohmic losses and associated variations in product distribution across ePTFE electrodes which then informs rational electrode conductivity requirements. We then present our Hierarchically Conductive GDE architecture (HCGDE) which employs microscale conductors woven within an ePTFE membrane to overcome the size limitation, achieving C_{2+} Faradaic efficiencies of ~75% for electrodes as large as 50 cm^2. Our approach can be broadly applied to scale any electrode, independent of catalyst chemistry and morphology.

Co-Exfoliated Noble-Metal Chalcogenide/Graphene Hybrids for Electrocatalytic Water Splitting *Ilias-Panagiotis Oikonomou[1,2,3], Apostolos Koutsioukis[1,2], Thomas Brumme[3], Axel Zuber[4], Michelle P. Browne[4], Zdenek Sofer[5], Thomas Heine[3,6] and Valeria Nicolosi[1,2]; [1]Advanced Microscopy Laboratory, Advanced Microscopy*

Laboratory, Crann & Amber Centers, Ireland; [2]Trinity College Dublin, The University of Dublin, Ireland; [3]Technische Universität Dresden, Germany; [4]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [5]University of Chemistry and Technology, Prague, Czechia; [6]Center for Advanced Systems Understanding (CASUS), Germany

Two-dimensional (2D) materials and their heterostructures have been proven effective in energy applications such as energy storage (supercapacitors, batteries) and catalysis. Among them, Pt-based Transition Metal Dichalcogenides (TMDs) have been reported to have promising performance in Hydrogen Evolution Reaction (HER) [1]. However, their use remains limited mainly due to the high cost of using Pt. In this work, we will fabricate graphene-based hybrid heterostructures with different Pt-based TMDs. Graphene hybrids are also potential candidates for HER [2], and through their use, the amount of Pt can be reduced while tuning physical properties and catalytic behavior. Density functional theory calculations imply a strong interaction between the graphene and PtX_2 (X = S, Se, Te) heterostructures, much larger than the interaction of MoS_2/graphene heterostructure. A band-gap opening was observed in all cases. Calculating the adsorption energy of H_2 molecules in different adsorption sites of heterostructures implied a promising performance in water splitting. The hybrid nanostructures were fabricated with a single-step liquid-phase co-exfoliation procedure, which is a cost-effective procedure that also offers the possibility of industrial scalability [3],[4]. The fabricated hybrid inks presented an improved yield and long-term stability over a year, in comparison with the isolated dispersions of graphene and PtX_2. Transmission and scanning-transmission electron microscopy (TEM/STEM) observations revealed the morphological features of the exfoliated flakes, with graphene to be decorated with the Pt-based TMDs. STEM-EDX mapping confirmed the presence of all involved elements in all cases. UV-vis and Raman spectroscopies revealed the optical properties of the hybrid systems, which are modified concerning the individual materials. Finally, the performance of 2D inks in HER was evaluated, resulting in lower overpotential values. A comparative study was conducted on the effect of different chalcogen on the hybrid structures.

Enhancing Water Splitting Activity of NiFe Hydroxide by Introducing Mn Dopant and Hierarchical Structure and Its Application on Anion Exchange Membrane Water Electrolyzer

Sehun Oh, Hyogyun Roh and Kijung Yong; Pohang University of Science and Technology, Korea (the Republic of)

Anion exchange membrane water electrolyzer is attracting attention recently as an alternative for traditional industrial-scale green hydrogen production using alkaline water electrolyzer (AWE). Improving both intrinsic and extrinsic activities of non-noble metal catalysts is essential to raise AEMWE performance to commercial levels. In this study, hierarchical Mn-NiFe@WO_x is newly synthesized as bifunctional water splitting electrocatalysts, through a simple two-step process: thermal evaporation and electrodeposition. Mn-NiFe@WO_x consists of 1D-WO_x nanowire and 2D-Mn doped NiFe nanosheet array (NSA). The WO_x NW provides extended surface area and works as a stable and efficient charge pathway to Mn-NiFe NSA, improving extrinsic activity. The ultrathin 2D Mn-NiFe NSA grown on WO_x NW has heterostructure consisting of the metallic Mn-NiFe alloy core and Mn-NiFe hydroxide surface. Doped Mn dramatically enhances the intrinsic HER activity of NiFe NSA by increasing the *conductivity and the electrochemical surface area and also improves the intrinsic OER activity by modifying the electronic structure of Ni and Fe. Additionally, the metallic core in NSA efficiently transports electrons to active NiFe hydroxide on the surface.*

As a result, our hierarchical Mn-NiFe@WO$_x$ electrocatalysts shows excellent water splitting activities, requiring extremely low HER overpotentials of 18 and 197 mV to achieve -10 and -500 mA cm^{-2}, respectively and low OER overpotentials of 236 and 320 mV to generate 10 and 500 mA cm^{-2}, respectively. In addition, Mn-NiFe@WO$_x$ is applied to the overall water splitting (OWS) system, Mn-NiFe@WO$_x$ || Mn-NiFe@WO$_x$ requires 1.52 and 1.8 V to generate 10 and 500 mA cm^{-2}, respectively. AEMWE is also demonstrated by using Mn-NiFe@WO$_x$ as bifunctional electrodes. In 1 M KOH, the AEMWE cell achieves 1.83 V at 1 A cm^{-2} and operates stable for 300 hours at same operating conditions. Our work presents effective strategies to enhance the AEMWE performance using non-noble metal catalysts.

EN05.11.03

Titanium-Based Nanoparticles from the Gas-Phase as Catalyst Carrier on Anodes for PEM Water Electrolysis—Synthesis, Characterization and Processing

Martin Underberg[1], Mathias Spree[1], Frederik Kunze[1], Lisa Sagewka[2], Norbert Kazamer[2], Florian Wirkert[2], Michael Brodmann[2] and Tim Huelser[1]; [1]Institut für Umwelt & Energie, Technik & Analytik e.V., Germany; [2]Westfälische Hochschule, Germany

In near future, hydrogen will play an important role as an energy carrier. Produced from water by electrolysis with renewable energy, hydrogen has the potential to act as a climate-friendly and CO2-free alternative for energy applications and chemical industry. Since renewable sources like photovoltaic or wind turbines generate fluctuating energy, dynamic operation conditions are required for electrolyzers of the future. Proton exchange membrane water electrolyzers (PEMWE) can handle these dynamics. However, efficiency losses from high anodic overpotential and the use of expensive critical raw materials (CRM) like Iridium with limited availability hinders the commercial use on large scale. The long-term stability of low-cost components is under investigation and seems limited, hindering their use. Corrosion issues from the acidic cell environment and high electrode potentials still necessitate CRMs for the anodic electrode to prevent passivation of the porous transport layer (PTL). Recent studies show strategies to reduce the amount of iridium. Here, electrically conductive nanostructured ceramic materials with implemented oxygen deficiencies and high specific surface area act as carrier material for the catalytic iridium nanoparticles.

In this work, a novel approach to obtain advanced PEMWE electrodes based on conductive titanium oxides and carbides as catalyst support is described. Using an optimized electrode structure with graduated porosity and electrochemical catalyst deposition, a significant decrease of the required amount of iridium is achieved, which results into reduced material costs in comparison to state-of-the-art PEMWE electrodes.

Particle synthesis takes place in gas-phase processes by thermal decomposition of the precursor titanium tetraisopropoxide (TTIP). Two different approaches are being pursued here: sub-stoichiometric titanium oxides are produced by means of spray flame synthesis and composite materials of titanium oxide and titanium carbide are produced in a microwave plasma process. The advantages of these gas-phase synthesis processes are continuous operation, reproducibility and high product purity. The products are characterized by BET (specific surface area), XRD (crystal structure) and electron microscopy (shape and size distribution).

A commercially available microstructured titanium sintered material serves as basis for the porous transport layer (PTL) of the manufactured electrode. Dispersions consisting of either TiOx or TiC in a carrier liquid are applied to this structure using a spraying process. A following laser sintering process of the nanomaterial coated PTL results in a mechanical and electrical bonding of the nanoparticles- on the microstructure, which exhibits a significantly higher specific surface area compared to uncoated PTL. To stabilize and generate oxygen deficiencies or electrically conductive crystallite structures the laser-sintering is performed under inert- or reducing gas atmosphere. To deposit Iridium catalysts on these surfaces galvanic deposition is performed. The electrical *conductivity and bonding are verified by measuring the contact resistance and performing impedance spectroscopy of the prepared electrodes. The achievement of a finely structured and mechanically bonded surface is examined using electron microscopy. The evaluation compares the effects of different powders on the electrode properties. With all samples it is possible to maintain the fine structure and at the same time produce a mechanically stable and electrically conductive layer. Successful catalyst deposition and suitability as an anode in the PEMWE with reduced catalyst loading is exemplified.*

EN05.11.04

MXene-Based Nonstructural Composite for Oxygen Evolution Electrocatalysis in 1 M H_2SO_4 Md Zaved H. Khan and Md. Romzan Ali; Jashore University of Science and Technology, Bangladesh

There is a continuous high demand for an effective electrocatalytic-oxygen evolution reaction (OER) to mitigate energy crises by offering renewable energy sources. Metal oxide and metal carbide are well-regarded electrocatalysts for water splitting; however, they produce sluggish reaction kinetics and require higher energy to launch the OER reaction. The transitional metal carbide MXene and earth-abundant metal oxide show good catalytic performance overcoming potential barriers by enhancing reaction kinetics. Therefore, MXene (TiC2Tx) coupled earth-abundant metal oxide nanocomposite (Zn0.92Cu0.04Ni0.02O2) based electrocatalyst for OER is presented in this work for the first time. TiC2Tx enhances electroconductivity, offers a large surface area, increases the number of active sides of the electrocatalyst, and enhances the electrocatalytic performances. A simple hydrothermal method was used for the fabrication of the electrocatalyst Zn0.92Cu0.04Ni0.02O2@MXene. The proposed electrocatalyst exhibits an extremely low overpotential of 169.5 mV at 10mAcm-2 and long-term stability (higher than 10 hours) in an acidic condition in 1M H2SO4 solution. This work demonstrates a facile and effective strategy to boost the electrocatalytic performance of OER in an acidic medium, aiming to design efficient and cost-effective electrocatalysts.

EN05.11.06

Porous Catalyst Layers for PEMWEs via Electro-Spraying—Achieving Optimal Three-Phase Boundary and Superior Electrolysis Performance Jongyoon Lee and Han-Ik Joh; Konkuk University, Korea (the Republic of)

The efficiency of polymer electrolyte membrane water electrolysis (PEMWE) is crucial for realizing green hydrogen production. Since the multiphase complex electrochemical reaction takes place at the three-phase boundary (TPB) in the electrode, the electrochemical kinetics are highly related to the structure and morphology of the electrode. In particular, oxygen and hydrogen bubbles generated during water electrolysis significantly hinder the efficient contact between the electrode and water, lowering the active surface area. In this study, we fabricated porous electrode layers via electrospray and investigated the effect of the ionomer content on the efficiency and durability of PEMWE. Furthermore, the formation of the TPB as a function of the content of ionomer was observed through SEM and measurement of electrochemical accessible surface area. In the single-cell test, our electrode using commercial electrocatalysts exhibited outstanding electrolysis performances of 5.3 A/cm^2 at 2.0 V and 3.2 A/cm^2 at 1.8 V. These values are the highest reported compared to recent studies [1-8]. In addition to porosity, the ionomer content affected the hydrophobicity and contact resistance between electrode and membrane. Using a simple porosity control technique, the performance of PEMWEs can be improved by over 60%. Therefore, our systematic study on the role of optimal three-phase boundary formation in electrodes is expected to open a new era for the green hydrogen economy.

EN05.11.07

Exceptional Electrocatalytic Hydrogen Evolution—Untapped Potential of Using Cation Distribution in Spinel $CoFe_2O_4$ Nanosheets as an Activity Descriptor Aya K. Gomaa and Nageh K. Allam; The American University in

Cairo, Egypt

Exploring cost-effective and efficient electrocatalysts for the hydrogen evolution reaction (HER) is essential for realizing green energy technologies such as water electrolyzers and fuel cells. To this end, identifying descriptors that determine the activity of the employed catalysts would render the process more efficient and help to design selective catalytic materials. Herein, cation distribution (δ) is presented as the activity descriptor for the HER of $CoFe_2O_4$ spinels. A one-step hydrothermal synthesis method is demonstrated for the fabrication of flower-shaped spinel $CoFe_2O_4$ nanosheets on Ni foam at various pHs with different cation distribution. The XPS and Raman analyses revealed the cation distribution of Co and Fe as the main factor determining the catalytic activity of the material. This has been confirmed both experimentally and computationally. The catalyst with the largest δ (0.33) showed as low as 66 mV overpotential at -10 mA cm^{-2} with exceptional stability for 44 hours of continuous electrolysis in 1 M KOH. Our study demonstrates cation distribution as a catalytic activity descriptor of spinels for HER.

EN05.11.08

Facile Surface Treatment of Industrial Stainless Steel Waste Meshes at Mild Conditions to Produce Efficient Oxygen Evolution Catalysts

Aya K. Gomaa, Nageh K. Allam, Basamat Saif and Ghada Khedr; The American University in Cairo, Egypt

Herein, the ability to convert waste stainless steel (SS) 316L meshes into highly efficient and durable oxygen evolution reaction (OER) catalysts is demonstrated. The process involves surface treatment of previously anodized SS meshes in different gaseous atmospheres. The activity of the resulted electrocatalysts varies as-anodized SS annealed in oxygen (ASS-O_2) > anodized SS annealed in hydrogen (ASS-H_2) > anodized SS annealed in air (ASS-Air). The ASS-O_2 showed an impressive low overpotential of 280 mV at the benchmark current density of 10 mA/cm^2, which is 120 mV less than that of the as-received SS (SS-AR), and a low Tafel slope of 63 mV dec^{-1} in 1 M KOH. These findings have also been asserted by the estimated electrochemical active surface area, electrochemical impedance spectroscopy analysis, Mott–Schottky analysis, and the calculated turnover frequency, affirming the superiority of the ASS-O_2 electrocatalyst over the ASS-H_2 and ASS-Air counterparts. The high activity of the ASS-O_2 electrocatalyst can be ascribed to the surface composition that is rich in Fe^{3+} and Ni^{2+} as revealed by the X-ray photoelectron spectroscopy analysis. The simple method of anodization and thermal annealing in O_2 at moderate conditions (450 °C for 1 h) lead to the formation of a SS mesh-based OER electrocatalyst with activity exceeding that of the state-of-the-art IrO_2/RuO_2 and other complex modified SS catalysts. These results were also confirmed via density functional theory calculations, which unveiled the OER reaction mechanism and elucidated the d-band center in different SS samples with different oxygen content. The presence of oxygen moved the d-band center closer to the Fermi level in the case of ASS-O_2, explaining its superior activity.

EN05.11.09

Ultralow Ru Nanoparticles Dispersed on Co@C Hollow Nanoprisms Derived from ZIF-67 for Highly Efficient Hydrogen and Oxygen Evolution Catalysis

Abdulwahab A. Salah[1], Nabilah Al-Ansi[2] and Qasem A. Drmosh[1,3]; [1]King Fahd University of Petroleum and Minerals, Saudi Arabia; [2]Northeast Normal University, China; [3]King Fahd University of Petroleum & Minerals, Saudi Arabia

Ruthenium (Ru), known for its cost-effectiveness and excellent hydrogen evolution reaction (HER) performance in alkaline environments comparable to platinum (Pt), encounters significant challenges due to irreversible nanoparticle aggregation during synthesis, which diminishes its efficiency in hydrogen production. Zeolite imidazolate frameworks (ZIFs) have been widely utilized as templates, precursors, and substrates for synthesizing complex hollow structures in various energy-related applications but typically have poor performance for HER due *to their low electrical conductivity, limited active sites, and high band gap, which hinder efficient electron transfer and catalytic activity. In this study, we benefitted from the surface features of Co@C hollow nanoprisms (HNP) derived from ZIF-67 to facilitate the dispersion of Ru nanoparticles, addressing the challenges associated with both Ru and ZIF-67-based materials. In 1 M KOH, the synthesized RuCo@C HNP with an optimal Ru mass ratio of 2.38% exhibits exceptional hydrogen evolution reaction (HER) performance, characterized by a low overpotential of 29 mV to achieve a current density of 10 mA cm*$^{-2}$ *(*η_{10}*), a Tafel slope of 39.31 mV dec*$^{-1}$*, a high turnover frequency (TOF) of 3.83 s*$^{-1}$ *at* η_{200}*, and excellent stability over 50 h. Moreover, under the same conditions, this electrocatalyst demonstrates a relatively low* η_{10} *of 266 mV for the oxygen evolution reaction (OER) with a Tafel slope of 45.22 mV dec*$^{-1}$*. The outstanding performance is attributed to the synergistic interaction between Co and Ru, along with the benefits of the hollow prism structure, which enhances surface area and facilitates hydrogen adsorption/desorption. This study presents an accessible synthesis technique for preparing hollow structures using ZIF composites, offering significant potential for energy applications.*

EN05.11.10

Magnetic Field Driven Dynamic Reorganization of Electrocatalytic Interface for Sustainable Enhancement in Oxygen Evolution

Jayeeta Saha; Stockholm University, Sweden

The ever-increasing worldwide energy crisis and environmental pollution problems call for the need to develop an effective technology for providing production of a clean alternative to fossil fuel to ensure energy sustainability. One of the cleanest and carbon-neutral fuels is hydrogen (H_2*), a promising substitute for fossil fuels. Currently the major source for* H_2 *(~95%) is produced by steam reforming of methane resulting in* CO_2 *emissions, which is called grey* H_2*. In 2022, 94 million tonnes of grey* H_2 *are produced globally using fossil fuels, which is a significant source of greenhouse gas emissions.*

It is important to produce H_2 *from renewable source without carbon generation, which is often referred to as green hydrogen. Electrocatalytic water splitting offers a sustainable and economic solution to the global energy crisis due to the utilization of cheap, abundant, and renewable water as a feedstock without producing any carbon footprint.*

In electrocatalytic water splitting, water splits into hydrogen (H_2*) and oxygen (*O_2*) with the application of voltage in an electrolytic cell. For the advancement of the efficiency of overall water splitting, modification of electrocatalysts, electrolyte and addition of external energy sources like temperature, solar energy is done. An additional energy source, which can be implemented in such electrocatalytic reaction without hampering the established electrocatalytic setup, is the magnetic energy. By using the disc magnet with the magnetic field of 100-200 mT, the water splitting process can be kinetically enhanced.*

Magnetic nanoparticles of transition metal-based phosphides are synthesized to act as an electrocatalyst in saline water under magnetic field. Ferromagnetic NiCoFeP and NiCoP, which are synthesized and used as an electrocatalysts for oxygen evolution reaction (OER), in presence of magnetic field aligned perpendicular to the electric field. A device is built where a regular cell, containing electrodes modified with magnetic nanoparticles, is equipped with commercially available Neodymium disk magnets. It is shown, that the current density is higher when the magnetic field is 200 mT, comparing to the 100 mT magnetic field in chronoamperommetry study. This suggests the higher rate of the O_2 *generation due to enhanced magnetic field in saline electrolyte, to replicate the sea water. The effects associated due to the magnetic field on the electrocatalytic pathway are (a) magneto-hydrodynamic effect, (b) spin selection, and (c) magneto-resistance. Lorentzian movement helps in diffusion of reagents and detachment of gas bubbles, therefore improving mass transport. In OER process, the reaction proceeds through the formation of OH with anti-parallel spin of the transition metal centres. In the presence of a magnetic field the anti-parallel spin on metal centres got realigned in the same direction, facilitates the formation of the* O_2*.*

EN05.11.11

Synergistic Enhancement of Water Splitting Performance Using Metal-Organic Framework-Derived Ceria-Based Nanocomposites—Synthesis, Performance Evaluation and Stability Prediction with Machine Learning

Sagar Delekar; Shivaji University, Kolhapur, India

The quest for sustainable and efficient energy solutions has led to significant interest in photoelectrochemical (PEC) water splitting, a promising approach for hydrogen production. The present investigation addresses this challenge by designing advanced photoanodes using metal-organic frameworks (MOFs)-derived ceria nanobars (CeO_2 NBs). These photoanodes are further modified with Zn-dopant, reduced graphene oxide (rGO), and graphitic carbon nitride (g-C_3N_4) to enhance their PEC performance. Initially, bare CeO_2 NBs and Zn-CeO_2 nanocomposites (NCs) are synthesized through the calcination of respective MOFs. Subsequently, simple sonochemical treatment is employed to fabricate ternary Zn-CeO_2/rGO (ZCR-3) NCs with 1 wt. % rGO content. On the other side, g-C_3N_4/CeO_2 NCs are developed using a similar methodology. The incorporation of rGO, g-C_3N_4, and Zn^{2+} ion doping aims to improve the conductivity, stability, and charge transfer efficiency of CeO_2 NBs, leveraging the synergistic effects of the combined materials. Characterization of the high surface area and increased oxygen vacancies in ZCR-3 NCs and gC20 NCs is conducted using N_2 adsorption-desorption isotherms and electron spin resonance (ESR) analysis. These physicochemical properties are critical for enhancing the PEC performance. To fabricate the NCs-based photoanodes, a binder-free brush coating method is utilized, followed by a thorough evaluation of PEC performance through various electrochemical techniques. The ternary ZCR-3 NCs-based photoanode demonstrates an exceptional current density of 2.228 mA/cm2 at 1.23 V vs. reversible hydrogen electrode (RHE), surpassing the performance of Zn-CeO_2 NCs and bare CeO_2 NBs by nearly 2 and 6 times, respectively. Furthermore, binary g-C_3N_4/CeO_2 NCs with 20 wt.% CeO_2 NBs (gC20 NCs) exhibit a significantly enhanced current density of 0.460 mA/cm2 at 1.23 V vs. RHE, outperforming bare g-C_3N_4 (0.195 mA/cm2) by 2.3 times. Additional enhancements are observed with ternary gC20/TiO_2 (gCT50) and gC20/ZnO (gCZ50) NCs, achieving current densities of 1.810 and 1.440 mA/cm2, respectively. These improvements are attributed to the increased donor densities, reduced charge transfer resistances, efficient charge transport, and enhanced charge separation and injection efficiencies within the NCs. The stability of these photoanodes under prolonged water splitting conditions is also evaluated, employing a machine learning-based recurrent neural network (RNN) with a Long Short-Term Memory (LSTM) algorithm to model their performance. The results indicate that the integration of rGO and g-C_3N_4 with MOFs-derived CeO_2 nanostructures offers significant potential for developing efficient and stable photoanodes. In conclusion, this study underscores the efficacy of organic-inorganic hybrids in creating high-performance photoanodes, paving the way for advancements in PEC water splitting and sustainable hydrogen production. The findings highlight the potential of these innovative materials to contribute to the development of next-generation energy solutions.

EN05.11.12

Understanding Structure-Performance Relationship of Nanoarray Structured Anodes in Water Electrolysis

Chenxin Deng and Puxian Gao; University of Connecticut, United States

Nowadays, to achieve carbon neutrality and utilize excess electricity generated from various energy systems, researchers in both industry and academia have made extensive efforts to explore a wide array of electrochemical reduction reactions for generating value-added chemicals and products from various green and renewable feedstocks such as water, biomass, and biogenic CO_2. Such electrocatalytic reduction reactions include hydrogen evolution reaction (HER) through water electrolysis, CO_2 reduction reaction (CO2RR) to hydrocarbons, nitrogen reduction reaction (NRR) to ammonia, and others. All these half-cell electrocatalytic reduction reactions attract significant attentions as they help produce desired products while reducing the carbon footprint, however, it should be noted that oxygen evolution reaction (OER) as the anodic reaction is commonly used as the pairing half-

cell electrocatalytic oxidation reaction in order to achieve charge neutrality. With OER only requiring water as a source, it potentially could be applied for massive production. However, oxygen evolution is a complex 4-electron transfer reaction which suffers from sluggish reaction kinetics. As a result, a higher voltage than the theoretical voltage for water splitting (overpotential) is required to have the OER reaction occurred in a real scenario. Compared to expensive and scarce noble metal oxides such as RuO_2 and IrO_2, which are considered as the best catalysts for OER, nickel, as one of the earth-abundant metals, and its compounds also demonstrate excellent catalytic activities and stability in an alkaline environment. Here, a synthetic process based on anodic aluminum oxide (AAO) template is devised and presented to fabricate nickel-based nanowire array structured electrodes, which have been demonstrated to readily reduce the overpotential for the OER and increase the catalyst stability. The array electrode's spacing/porosity, dimensionalities, and orientation alignment are tuned as well as electrolyte temperature and concentration to investigate the electrocatalytic OER mechanism and the relationship between nanoarray structure, electrolyte environment, and the demonstrated performance. Optimum nanoarray structure configurations are established for achieving better electrochemical activities while retaining the structure and chemical durability of the catalysts.

Graphenylene-Based Single Atom Catalyst for Green Hydrogen Production from Water Electrolysis

Caique C. de Oliveira and Pedro A. Autreto; Universidade Federal do ABC, Brazil

The transition to clean and renewable energy sources is crucial for mitigating climate change. However, providing clean and renewable energy is challenging due to the intermittent nature of some sources like solar and wind, demanding flexible and scalable technologies for clean energy production and storage. Green hydrogen, produced by water electrolysis, is a promising alternative due to its high energetic density, neutral carbon footprint, and versatility in energy harvesting applications[1]. Nonetheless, its production in the electrochemical Hydrogen Evolution Reactions (HER) is hindered by the need for efficient, abundant, and low-cost catalysts as an alternative to the scarce and expensive noble metal-based materials. Carbon-based two-dimensional nanostructures offer high surface area, chemical stability, and the possibility of tunning electronic properties, offering a pathway to tailor catalytic activity[2]. Specifically, using single metal atoms as active sites (Single Atom Catalysts, SACs) can effectively promote catalysis while minimizing metal usage and maximizing atomic efficiency. In this work, we apply first-principles calculations based on Density Functional Theory (DFT) to investigate the catalytic activity of Graphenylene (GPY) within the Computational Hydrogen Electrode (CHE) model[3] framework. Our results show that Sc, Ti, Mo, Zr, Pt, Ni, and Co GPY-based SAC are promising for HER catalysis achieving $|\Delta G_H| < 0.1$ eV, while pristine GPY exhibits weak hydrogen binding ($\Delta G_H = +0.83$ eV). The enhancement in the catalytic activity is attributed to the promotion of charge transfer and the formation of bonding states between the metal and the hydrogen intermediate modulating the free energy of adsorption. This work contributes to the development of new carbon-based catalysts providing fundamental insights on the catalytic properties from the atomistic perspective.

Properties and Potential Applications of Two-Dimensional Diamond-Like Si_4X_2 (X = B, Al, or P) in Energy

Conversion and Storage *Bruno Ipaves[1], João F. Justo[2], James M. de Almeida[3], Lucy V. C. Assali[2] and Pedro A. Autreto[1]; [1]Universidade Federal do ABC, Brazil; [2]University of São Paulo, Brazil; [3]Center for Research in Energy and Materials, Brazil*

In 2004, scientists exfoliated graphene, sparking extensive research into two-dimensional (2D) materials with various physical properties ever since. Additionally, these materials' properties can significantly alter through doping with diverse types of atoms and by integrating with different 2D systems [1, 2]. 2D systems hold potential for applications in numerous areas, thus prompting considerable interest in investigating and understanding the properties of doped 2D structures. Accordingly, we examined the properties of diamond-like silicene nanosheets (bilayers and trilayers) doped with boron, nitrogen, aluminum, and phosphorus atoms [3]. There is limited literature on three-layer doped silicene systems, and our work identified four new nanosheet systems, namely ABC-Si_4B_2, ABC-Si_4Al_2, AA'A''-Si_4P_2, and ABC-Si_4P_2, exhibiting intriguing physical properties and promising applications. Furthermore, we have already demonstrated that ABC-Si_4Al_2 shows promise as a candidate for anodes in alkali ion batteries (AMIBs), particularly for sodium and potassium ion batteries [4]. Finally, our current results highlight the potential of diamond-like Si_4P_2 systems as efficient photocatalysts for water splitting.

Improved Catalytic Activity in Dual-Doped $LaCoO_3$ for Oxygen/Hydrogen Electrocatalysis *Mohamed E. Hilal[1], Seyfettin B. Sanli[2,2], Sander Dekyvere[1], Gulhan Cakmak[2,2], Hussein A. Younous[1], Francis Verpoort[1] and Berke Piskin[2,2]; [1]Wuhan University of Technology, China; [2]Mugla Sitki Kocman University, Turkey*

Electrocatalysts based on perovskite oxides with a chemical formula ABO_3 have been extensively investigated to replace noble metals in oxygen reactions. Different elements can occupy on both A and B sites allowing their properties to be controlled and compositional diversity to be achieved. They have advantages on relatively catalytic activity, low cost, and diversity in compositions. Moreover, the ability to synthesize different compositions with wide-range production methods also attracts attention as an advantage. In this study, $LaCoO_3$ was chosen considering its prominence activity toward OER [1,2] for dual-doping strategy to improve its catalytic activity. Calcium and manganese were used for dual doping for A and B sites, respectively. The influence of this strategy was examined on the structural, morphological, and electrochemical properties of doped $LaCoO_3$. $La_{0.9}Ca_{0.1}Mn_{0.1}Co_{0.9}O_3$ (LCMC9119), $La_{0.8}Ca_{0.2}Mn_{0.2}Co_{0.8}O_3$ (LCMC8228), $La_{0.7}Ca_{0.3}Mn_{0.3}Co_{0.7}O_3$ (LCMC7337), and $La_{0.6}Ca_{0.4}Mn_{0.4}Co_{0.6}O_3$ (LCMC6446) perovskite-oxides which were synthesized via Pechini method. LCMC8228 showed significant improvement in oxygen evolution reaction (OER) at 10 mA cm^{-2} was 1.59 V, being upgraded by 70 mV in alkaline media in comparison to pristine LaCoO3, respectively. Likewise, LCMC8228 exhibited overpotential of 1.63 V at 10 mA cm^{-2}, then held a stable potential of 1.96 V at 50 mA cm^{-2} comparatively to Pt/C prepared electrodes which is a highly improvement in overall catalytic activity than the original perovskite LC.

Accelerating Electrocatalytic Hydrogen Evolution with Ferroelectric Bismuth Ferrite Nanostructures

Astita Dubey, Ignacio Sanjuán, Corina Andronescu and Doru C. Lupascu; Universität Duisburg-Essen, Germany

The high overpotential and Tafel slope of an electrocatalyst significantly limits its effectiveness in energy conversion. To mitigate this issue, optimizing defects and dopants is crucial for developing efficient and environmentally friendly catalysts. Interestingly, ferroelectricity in catalysts like bismuth ferrite (BFO) has a profound impact on their catalytic properties, particularly for water treatment applications.[1] We utilize the electrocatalytic functionality of ferroelectric-doped bismuth ferrite ($BiFe_{0.95}X_{0.05}O_3$; where X = Mn, Co) nanoparticles (NPs) for the hydrogen evolution reaction (HER). The electrocatalytic activity of the pristine nanoparticles undergoes a revolutionary enhancement with the substitution of mono-, di-, and tri-valent cations. Our strategic doping at the Bi and Fe sites results in a significant reduction in the kinetic overpotential required for HER.
We observed that these engineered catalysts exhibit higher HER activity in alkaline media compared to acidic conditions.[2] This reduction in overpotential in doped NPs is attributed to multiple factors: enhanced local ferroelectricity, decreased charge transfer resistance, increased specific surface area, a wide distribution of pore sizes, particles with abundant active facets, and the introduction of dopants as new active sites on the surface. Additionally, the presence of optimized surface defects, oxygen vacancies, and increased microstrain in these NPs further contributes to the reduction in overpotential and Tafel slopes. We demonstrate that modifying the active sites at the Bi site drastically improves electrocatalytic performance, underscoring the promising future of ferroelectric-catalysts in energy conversion applications.

Low-Cost Green Hydrogen—Scalable Hybrid Electrode System for Controlled Nucleation of OER Catalysts

Emilly C. de Brito Dorneles and Magda H. Barecka; Northeastern University, United States

Green hydrogen plays a key role in the sustainability transition: it can be used as a renewable fuel, chemical building block, or an energy storage vector. Water electrolysis, powered by renewable energy, is currently the most promising method for green hydrogen production on an industrially relevant scale(1). Among different types of electrolysis, alkaline reactors hold the promise of enabling the use of low-cost anion exchange membranes (AEM) and abundant catalysts such as Nickel (Ni), yet the energy efficiency and stability of those catalysts are too low to make green hydrogen economically competitive(2). To address this problem, we focused on one of the major sources of energy loss in hydrogen electrolyzers – sluggish oxygen evolution reaction (OER). Here, we report an abundant, cheap, energy-efficient, and stable Ni/NiFe catalyst for alkaline water splitting synthesized in a "Hybrid Electrode" electrochemical system. We deployed electroplating as a synthetic procedure, since it has already been adopted in the industry to synthesize diverse catalysts. To increase the electroplating efficiency for the challenging OER reaction, we hypothesized that by carefully controlling the nucleation mechanism(3), we could *achieve a more uniform deposition of the target co-catalyst (Ni and Fe and Ni foam) resulting in a higher current density at lower overpotentials. Our work shows how to achieve this control by rationally designing the counter electrode used in the electroplating step. Through chronoamperometry analysis, we identify and optimize the regimes in which crystal nuclei formation and growth occur. As a result, we achieved better controllability of the electrodeposition process and a significant increase in the current density of the OER catalyst. Using 1M potassium hydroxide solution (KOH), a milder concentration than what is currently used in the industry (5-10 M KOH), we achieved 167 mA/cm2 at 1.6V applied against an Ag/AgCl electrode. Previous literature reports on Ni-based catalysts reported max. 100 mA/cm2 with the same energy efficiency(4,5), confirming that our nucleation control strategy can significantly enhance the electrocatalytic performance. While using conditions closer to these deployed in the industry (7M KOH), we recorded up to 500 mA/cm2 at 0.7V (against Ag/AgCl), at only 25°C - a temperature significantly lower than what is used in the industrial electrolyzers. High current densities obtained for a wide concentration of the electrolytes and low temperatures enable a broad application of the "Hybrid Electrode" synthesis systems. This synthetic procedure could be used for the development of more efficient and cost-effective anode materials not only for water splitting but also systems of Carbon Dioxide (CO2) electro-reduction to valuable products such as syngas and ethanol as well as for anodic electro-oxidation of glycerol and other liquid waste products(6).*

Strategies to Promote Accurate Gaseous Product Quantification for CO_2RR at Industrial-Relevant Current Densities

Raissa Ribeiro Lima Machado[1,2], Bright Nsolebna Jaato[1,2], Ignacio Sanjuán[1,2] and Corina Andronescu[1,2]; [1]Universität Duisburg-Essen, Germany; [2]Center for Nanointegration Duisburg-Essen - CENIDE, Germany

Anthropogenic CO_2 emissions are the primary drivers of global warming and climate change.[1] The electrochemical reduction of CO_2 (CO_2RR) offers a green alternative for mitigating CO_2 emissions while producing valuable fuels, chemicals, and feedstocks for the chemical industry.[2,3] The simultaneous electroreduction of CO_2 and H_2O to form syngas (H_2/CO) is particularly promising, with tunable syngas ratios (H_2/CO) between 0.3 and 3 meeting the requirements of various downstream processes.[2,4] Using a NiO_x/Ni-N-C catalyst, syngas formation can be achieved at industrially relevant current densities (> 200 mA cm^{-2}).[1,2] Accurate quantification of CO_2RR products at high current densities is essential for evaluating reaction selectivity and efficiency. In this study, we emphasize the importance of optimizing gas product quantification via online gas chromatography to ensure accurate Faradaic efficiencies (FEs) for H_2/CO syngas. We explored the effects of gas quantification on FE using a gas diffusion electrode comprising NiO_x/Ni-N-C on H23C8 carbon paper (Freudenberg, from Quintech) in a flow cell electrolyzer (1 M KOH). Our initial results at a current density of -300 mA cm^{-2} showed a suboptimal syngas ratio of 0.24 and a total FE of 64.5% (j_{CO} = -156 mA cm^{-2}), with a noticeable gap attributed to product quantification challenges at this current density. To address this, we optimized experimental conditions, including calibration for linearity in H_2/CO formation and product dilution with N_2. These adjustments successfully brought H_2/CO products into the linear *range of the gas chromatograph calibration, with total FEs approaching 100% up to a remarkable current density of -900 mA cm^{-2}. At -300 mA cm^{-2}, the total FE reached 94.9%, with a superior j_{CO} of -251 mA cm^{-2}. The highest H_2/CO ratio of 1.77—suitable for hydrocarbon synthesis via Fischer-Tropsch or alcohol synthesis—was achieved at -500 mA cm^{-2}. These compelling results underscore the importance of reporting reliable and accurate CO_2RR data, enabling more consistent comparisons with previous and future studies.*

Nanostructured NiO-GDC Anodes for Improving Solid Oxide Fuel Cell Performances

Federica Rigoni[1], Hicham Helal[1], Stefano Botticini[1], Dario Zappa[1], Hadjer Hakkoum[1], Daniel Chua[2], Pooi See Lee[3] and Elisabetta Comini[1]; [1]Università degli Studi di Brescia, Italy; [2]National University of Singapore, Singapore; [3]Nanyang Technological University, Singapore

Solid Oxide Fuel Cells (SOFCs) are efficient electrochemical devices that directly transform chemical energy into electrical energy through electrochemical reactions, offering a clean means of energy conversion, and they have attracted increased attention due to their potential to lower operating temperatures, which is crucial for advancing the widespread application of SOFCs. Since the power output of a SOFC is closely related to the electrochemical performance of the electrodes, nanostructuration of the anode increases the surface-to-volume ratio of the three boundary conditions where the reactions take place. In this work, the preparation and characterization of nanostructured anodes based on nickel oxide and gadolinium-doped ceria nanowires (NiO-GDC NWs) are proposed. The NiO-GDC NWs were synthesized by Vapor-Liquid-Solid growth technique, and they have been systematically investigated by scanning electron microscope (SEM), X-ray diffraction (XRD), and Raman spectroscopy. Functional characterization of the power output of the fuel cell performance together with Electrochemical Impedance Spectroscopy (EIS) analysis were carried out at different temperatures and for different fuel flows of hydrogen and air. The results obtained at 800 °C with an H2 and air flow of 100 sccm and 200 sccm respectively, showed an Open Circuit Voltage (OCV) of 1.06 V and a power density of 300 mW/cm2. The energy conversion efficiency of SOFCs can reach up to 60-80% in theory. This is because it is not limited by the Carnot cycle, as no combustion is involved in the SOFC process. SOFCs have other benefits such as low emissions, long-term stability, and relatively low cost. SOFCs are considered a sustainable energy source: when supplied with hydrogen and oxygen, they produce electricity through an electrochemical reaction between hydrogen and oxygen. Enhancing the anode performance by means of nanostructuration can lead to improved SOFC electrochemical performance. The electrochemical reaction in the anode takes place at the three-phase boundary (TPB), which refers to the area where the electrolyte, the electron-conducting metal phase, and the gas *phase intersect. Lengthening the TPB will boost the electrochemical reaction and enhance the anode's performance. Currently, researchers are exploring the application of nanomaterials in SOFC technology as a potential solution to enhance its performance. It has been demonstrated that reducing the grain size of the electrode results in an increase in TPB length, particularly when the grain size of the electrode is below 2 μm. In NiO-GDC NWs anodes, through the reduction of NiO and GDC grain sizes to the nanoscale, the interfacial areas between NiO and GDC are significantly magnified. Consequently, this augmentation extends the length of the TPB, leading to enhancement in the electrical performance of the anode. After the systematic investigation (by SEM, XRD and Raman spectroscopy) on the growth parameters which lead to a good NiO-GDC NWs morphology and composition, the NiO-GDC NWs were grown on a commercial single-electrode button cell (with cathode only) to explore the cell and its electrochemical behavior. A comprehensive analysis of the results indicates that the NiO-GDC NWs exhibit promising potential as an anode for SOFCs. Ultimately, this study reports the synthesis and performance of NiO-GDC NWs based SOFCs, with a careful investigation on the morphology and composition of the NWs using SEM, XRD and Raman techniques. Finally, NiO-GDC NWs were grown directly to a commercial single-electrode button cell for the evaluation of the electrochemical performance. Overall, the preliminary results suggest that NiO-GDC NWs show considerable promise as an anode material for SOFCs.*

Advancing Multiscale Modeling Approaches to Examine the Physicochemical Characteristics of Organic Mixed Ionic and Electronic Conductors *Nolan C. Lok, Joel H. Bombile, Megan R. Brown and Chad Risko; The University of Kentucky, United States*

The continued advance of bioelectronic and electrochemical energy storage and conversion applications requires materials that efficiently transport both electrons and ions. Organic mixed ionic and electronic conductors (OMIEC) have emerged as a promising class of soft conductive materials for these applications. Developing a deep physicochemical understanding of OMEIC behavior is complicated by the intricate interplay of semiconductor morphology, which changes as a function of swelling by the electrolyte, electronic properties, and ion transport. Here we use density functional theory (DFT) calculations to investigate the conditions under which bipolarons form, as opposed to maintaining two (or more) isolated polarons, revealing the impact of counterion size and spacing along a polythiophene homopolymer chain on the preferred charge-carrier state. We also implement a molecular dynamics (MD) modeling framework for polymer-based OMIEC, highlighting a boost in performance. This work lays the foundation for future developments of multiscale OMEIC models.

EN05.11.21

Theory-Driven Synthesis of Tungsten Titanium Carbide MXene for Hydrogen Evolution Electrocatalysis

Anupma Thakur[1], Wyatt Hiighland[2], Brian Wyatt[1], Nithin Chandran B S[1] and Babak Anasori[1]; [1]Purdue University, United States; [2]Indiana University-Purdue University Indianapolis, United States

Tungsten (W) based-MXenes are of particular interest as they are predicted to have overpotentials close to Pt-based catalysts in hydrogen evolution reaction (HER), making them candidates for a more sustainable clean energy application. However, the incorporation of W into the MXene structure has proven difficult due to the calculated instability of its hypothetical precursor $M_{n+1}AX_n$ phases (W_2AC and W_3AC_2). In this study, we present the theory-driven synthesis of a tungsten titanium carbide, $W_2TiC_2T_x$, derived from a modified covalently bonded nanolaminated double transition metal carbide ternary carbide $(W,Ti)_4C_{4-y}$precursor. We confirm the atomistic out-

of-plane ordering of W and Ti, using density functional theory, Rietveld refinement, and electron microscopy methods. Our results indicate the importance of W and Ti ordering and defects in the successful synthesis of $W_2TiC_2T_x$. Additionally, the W-rich basal plane endows $W_2TiC_2T_x$MXene with a remarkable electrocatalytic HER performance with the lowest HER overpotential (~144 mV at 10 mA/cm^2) for a MXene under acidic conditions over other $W_{1.33}CT_x$ MXenes (~320 mV) and Mo_2CT_xMXenes (~190 mV). In this direction, more efforts on the continuous exploration of W-containing MXenes with low overpotentials are noteworthy toward the clean energy applications due to their highly active basal plane.

EN05.11.22

First-Principles Study of the Structures and Redox Mechanisms of Ni-Rich Lithium Nickel Manganese Cobalt Oxides

I-Ta Hsieh[1], Yuqin Wu[1], Bin Li[2,3] and Yue Qi[1]; [1]Brown University, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Tennessee Knoxville, United States

To reduce the cobalt (Co) content in lithium-ion batteries, Ni-rich (high-Ni) lithium nickel manganese cobalt oxides (NMC) are pursued as one of the next-generation cathode materials. The critical challenge associated with Ni-rich lithium nickel manganese cobalt oxides (NMCs) is understanding the electronic structure changing during delithiation. The redox activity in Ni-rich NMC is a complicated phenomenon. First, the transition metal (TM) ions in high-Ni NMC cathode are multi-valent, suggesting they could have oxidation states other than 3+ at the fully discharged state. Then the sequence of losing electrons becomes a competition between the electron occupancy on different TM-d and O-2p orbitals. To theoretically explore the electronic structure evolutions, need a deep understanding of the representative structures in modeling. However, there is still debate on the crystal and electronic structures of the baseline, $LiNiO_2$. The widely accepted parent structure of NMCs, $LiNiO_2$ with R-3m symmetry, conflicts with the renowned JT activity and the experiment-measured conducting behavior.

In this work, Density Functional Theory (DFT) calculations were performed to provide a theoretical understanding of Ni-rich NMC. First, it was found that the commonly used R-3m structure for $LiNiO_2$ is metallic, contrary to the experimentally reported mix-conducting behavior. By comparing the four different space groups, R-3m, C2/m, $P2_1/c$, and P2/c, P2/c with charge disproportionation of Ni^{2+} and Ni^{4+} is the most energetically stable and semiconducting structure of $LiNiO_2$, which can serve as a parent structure of Ni-rich NMCs, offering insights into the redox mechanisms. Therefore, the atomic structures of representative Ni-rich NMC were built by partially replacing Ni with Co or Mn in the P2/c $LiNiO_2$ to form $Li_xNi_yMn_zCo_{1-y-z}O_2$. Additionally, by comparing the lattice structure evolution during delithiation with experimental observations, the P2/c-based Ni-rich NMC agrees well with the characteristic anisotropic response in the in-plane and out-plane lattice parameters as a function of lithium concentration. During delithiation, lattice parameters a and b decrease while the c-axis first expanses in the early stage of delithiation and rapid shrink, characterized as the H2–H3 phase transformation with further Li-extraction.

In fully lithiated (x=1.0) P2/c-based high Ni content NMC (y>0.5), the oxidation state of all Mn ions becomes 4+, while Co ions still maintain 3+, and part of the Ni^{4+} ions become Ni^{3+} to compensate for the charge. Upon delithiation, the local environment shows more variation of the charge states on the TM ions. The average oxidation on each TM follows a sequence of losing electrons that starts from Ni^{2+} to Ni^{3+}, then oxidizing Ni^{3+} and Co^{3+}, while Mn^{4+} remains electrochemically inactive till x=0. Additionally, by observing the trend of the changing in the oxidation state of TM ions in the experiment and DFT calculations, a general relationship for the oxidation state change in each TM as a function of x (the stage in delithiation) is derived and shows agreement with both modeling and experimental data.

This work confirmed the representing structure of Ni-rich NMC, elucidated the sequence of electron loss during *charging, and provided a general relationship for the oxidation state change on each transition metal, offering a theoretical approach to get insights into the defects and oxidation in NMC cathodes. The procedure provides a systematical investigation of the electronic structures changing in NMCs during delithiation.*

Insights into the Bulk Structure and Redox Chemistry of Li_2NiO_3—A Lithium Rich Nickel Oxide Cathode Material

Madhulika Mazumder, Alex G. Squires and David O. Scanlon; University of Birmingham, United Kingdom

The advancement of Li ion batteries in energy storage technologies fosters the need to develop high performance cathode active materials that assure impressive energy densities with prolonged cyclability and low expense. Nickel oxides have garnered significant interest in this regard owing to accessible high voltages and capacities and ready availability of nickel[1]. An unavoidable caveat with Ni rich systems is their susceptibility to structural instabilities that propel degradation during the battery charge-discharge cycles.

Amongst several promising compounds in the Li-Ni-O chemical space, we focus on Li_2NiO_3 or $Li[Ni_{2/3}Li_{1/3}]O_2$ – the most Li rich member in the $Li_{1+y}Ni_{1-y}O_2$ solid solution, inspired by recent reports highlighting its synthesizability and attractive first cycle capacity [2,3]. It does, however, suffer from a quick capacity fade which has been attributed to anionic redox and oxygen release.

As the anionic sublattice is of high significance in layered oxide materials, it is imperative to devise a correlation between oxygen redox and the bulk structure of Li_2NiO_3[4,5]. Structural uncertainties are manifested in the form of oxygen deficiencies ($Li_2NiO_{3-\delta}$) and Ni/Li mixing, as observed from ICP analyses and neutron powder diffraction studies[2]. While the oxygen deficiencies influence the Ni oxidation state and hence the underlying electronic structure, the cationic site disorder results in an imperfect honeycomb ordering leading to stacking faults. Employing a systematic computational approach,[6,7] with hybrid Density Functional Theory studies, our work probes the defect configurational landscape in $Li_2NiO_{3-\delta}$. It reveals the importance of an accurate representation of the bulk structure at the charged and partly lithiated states, as a keystone for possible routes of structural transformation and draws a connection between the evolution of electron holes and the reversibility of oxygen redox.

Enhancing Energy Storage in Supercapacitors: A Synergistic Approach Using Co-MOF and Carbon Nanotube Composites

Priti A. Mangrulkar[1], Deepa Bailmare[2] and Abhay Deshmukh[2]; [1]Ramdeobaba University, India; [2]R.T.M. Nagpur University, India

Metal-organic frameworks (MOFs) have garnered significant attention as promising electrode materials for energy storage systems due to their high surface area, tunable structure, and abundance of active sites. In this study, we investigate the synergistic effect of cobalt-based MOFs (Co-MOFs) and carbon nanotubes (CNTs) in enhancing electron transport, while maintaining the conductivity and porosity of the composite material. The Co-MOF@CNT composite was synthesized using a reliable electrochemical deposition technique, with layer-by-layer casting on a conductive nickel foam substrate. The integration of CNTs within the Co-MOF matrix enhances electron transfer and provides structural reinforcement, thereby improving the electrode's overall stability and increasing its cycle life. The hybrid material exhibited a high specific capacitance of 1294.54 F/ g at a current density of 2 A /g in a three-electrode cell configuration. Additionally, the electrode demonstrated excellent cyclic stability, retaining 80% of its capacitance after 10,000 cycles.
An asymmetric supercapacitor device based on the Co-MOF@CNT composite was fabricated, operating in a voltage range of 0–1.0 V in a 2M KOH electrolyte. The composite structure significantly improved energy density, durability, and longevity with the device exhibiting exceptional cycling stability; retaining 94.23% of its capacitance after 100,000 cycles. This study presents an effective strategy to enhance the performance of supercapacitors by utilizing the synergistic properties of Co-MOFs and CNTs, offering a pathway for the development of high-performance energy storage devices with extended cycle life and high energy density.

EN05.11.25

Electrochemical Conversion of Biomass Derived 5-Hydroxymethylfurfural into 2,5-Furandicarboxylic Acid Using Copper Cobalt Mixed Bimetal as an Efficient Electrocatalyst *Muthumariappan Akilarasan, Ayu Wahyuni, Muhammad Nawaz Tahir and Wasif Farooq; King Fahd University of Petroleum and Minerals, Saudi Arabia*

The conversion of 5-hydroxymethylfurfural (HMF) into 2,5-furandicarboxylic acid (FDCA) is a crucial step in the production of bio-based chemicals, serving as a sustainable alternative to petroleum-derived products. Therefore, in this study, we synthesized mixed metals (Cu & Co) based electrocatalysts using hydrothermal method. The synthesized catalysts were annealed at elevated temperature (600 °C) under inert conditions. The prepared catalysts were extensively characterized using X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM), and Raman spectroscopy to determine their structural, morphological, and vibrational properties. The characterized catalysts were evaluated for their catalytic performance for the electrochemical conversion of HMF into FDCA. Electrochemical performance was assessed using linear sweep voltammetry (LSV) for both the oxygen evolution reaction (OER) and HMF oxidation reaction (HMFOR). The results demonstrated that HMFOR occurred at a notably lower potential of 1.37 V vs. RHE at a current density of 25 mA cm^{-2}, compared to the OER, which required a higher potential of 1.63 V vs. RHE to achieve the same current density. The Tafel slope for HMFOR was calculated to be 72 mV dec^{-1}, indicating efficient catalytic kinetics. Further testing in an H-type electrochemical cell with a Nafion membrane separator revealed an impressive HMF conversion rate of 98.64%, an FDCA yield of 95.42%, and a Faradaic efficiency of 96.7%. These findings highlight the potential of CuCo mixed metals-based composites as highly efficient catalysts for the sustainable electrochemical conversion of HMF to FDCA, contributing to the advancement of green chemistry.

EN05.11.27

Rational Design of a New N-modified Nickel Foam with Superior Electrocatalytic Conversion of Nitrate to Ammonia *Yi Wei and Jong-Sung Yu; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

Electrocatalytic reduction of aqueous nitrate to ammonia has emerged as a sustainable and practical approach in combining water treatment and ammonia fertilizer synthesis. In this study, we developed a new N-modified NiF from commercial NiF. Our unique approach induces key characteristics such as high electrochemical surface area (ECSA) and N-rich surface. These induced properties lead to superior performance for the modified NiF *compared to the pristine NiF in electrocatalytic nitrate reduction reaction (NO_3RR) to ammonia. The modified NiF achieves a high current density of 2.0 A cm^{-2} at a potential of only 0.067 V vs RHE with a Faradaic efficiency (FE) of 92.7% and a yield rate of 146 mg h^{-1} cm^{-2} at elevated temperature. Such an outstanding yield rate is more than 160 times higher than that of commercial NiF. Moreover, the thermal-enhanced electrocatalysis system shows remarkable stability, low interference resistance, and a favorable energy consumption for nitrate reduction reaction. Complementary in situ analyses indicate that the significantly superior relay of active adsorbed *H generated on the surface of modified NiF facilitates the electrocatalytic hydrogenation of N-based species in the process of $^*NO_3 \rightarrow {}^*NO_2 \rightarrow {}^*NO \rightarrow {}^*N \rightarrow {}^*HN \rightarrow {}^*H_2N \rightarrow {}^*NH_3$. The new strategy aims to provide the rational design of a newly modified structure on the NiF to serve as the future direction for NiF-based materials for practical electrodes with high performance.*

SESSION EN05.12: Photoelectrocatalysis

8:00 AM *EN05.12.01
Dynamic Nature of Electrodes for Solar Cells and Catalysis *Tomas Edvinsson; Uppsala University, Sweden*

Solar cells and catalysis are two important applications in the field of renewable energy where the performances of the materials in these systems are influenced by the efficiency and stability of the electrodes. Here, we highlight the importance of understanding the dynamic processes in eeloctrodes, such as ion migration and electrochemical reactions and surface restructuring, and how these phenomena can influence the overall performance of the systems. Lead halide perovskites have emerged as a promising class of materials with exciting optoelectronic properties, making them promising candidates for next-generation optoelectronics. The detailed electronic structure and photo excited charge density response in the excited state are here important to describe and optimize lead halide perovskites under operation (1,2). Experiments from photoinduced Stark-effect experiment as well as corroborating theoretical investigations using both ground state and time-dependent density-functional theory (TD-DFT) are presented show that the excess energy after thermalization under blue-light illumination is large enough for overcoming the activation energy for iodide migration and can thus trigger ion movement and vacancy formation [2,3]. Here, a dipolar A-site cation would decrease the energy of defect formation, but instead impede defect migration [4] and also affect the excited state response and subsequently enhanced optoelectronic properties [5, 6]. In an extension, the results give rationale for using dipolar A-site cations and mixed halide perovskites to decrease halide migration and the mechanistic origin of reported stability issues under blue and UV-light illumination. We present electrode materials reaching certified conversion above 26% solar-to-electricity power conversion.

In the field of catalysis, we show that serial interconnected photo-absorbers are cost-effective solution to the spectral mismatch problem. Taking losses due to charge carrier separation and overpotential for catalysis into account, the maximum solar-to-hydrogen (STH) efficiency for a series interconnected solar splitting device is 24.6 %, compared to 32.0 % for an optimum double junction tandem device. Applying modified Cu-In-Ga-Se2 (CIGS) within the approach al-lows harvesting of photons up to 1200 nm in the solar spectrum and convert this energy into solar fuel beyond 10% STH efficiency. We will also outline how operando Raman spectroscopy can be utilized to unveil Fe-Ni based electrocatalyst reformulations into the active catalyst phase and their structural integrity and *how machine learning can guide us towards compositional choices in high entropy alloy catalysts.[7,8]*

Antenna-Reactor Plasmonic Electrocatalyst for Alkaline Ammonia Electrolysis *Jeongwon Kim; Ewha Womans University, Korea (the Republic of)*

Ammonia electrolysis represents a significant advancement over traditional water electrolysis, offering a more energy-efficient route for on-site hydrogen production with an operational voltage of only 0.06 V compared to 1.23 V required for water electrolysis. Despite the potential advantages, the widespread adoption of ammonia as a hydrogen source has been significantly hindered by the low durability and rapid deactivation of catalytic sites due to unavoidable poisoning dynamics during the electrolysis process. Here, we discovered the novel plasmon-driven surface dynamics with an antenna-reactor hybrid catalyst model. This configuration leverages localized surface plasmon resonances (LSPRs) to rejuvenate active sites selectively, ensuring continuous operation and a substantial enhancement in the electrocatalytic activity and stability under practical conditions including wastewater environment. Significantly, our findings demonstrate a high average ammonia removal efficiency of 92% over 210 hours, with an assessed hydrogen production cost of $6.45 per kg_{H2}*, nearing the economic feasibility threshold necessary for widespread adoption.*

8:45 AM EN05.12.03
How Synthesis Conditions Define the Quality of the Perovskite Oxide Electrocatalysts *Nagaarjhuna Arumuga Kani[1,2] and Andrew Akbashev[2]; [1]ETH Zürich, Switzerland; [2]Paul Scherrer Institute, Switzerland*

Rationalizing synthesis conditions in perovskite oxides is difficult due to the complex interplay of several factors such as precursor size and composition, presence of doping elements and formation of metastable intermediate phases. In our study, we track morphological and chemical state of La0.8Sr0.2CoO3-δ particles on the meso- and nano-scale as a function of time and temperature using transmission electron microscopy (TEM) and scanning transmission X-ray microscopy (STXM). We explore the entire transformation of the electrocatalyst particles, from the precursor state to the formation of nanoparticles and eventual growth into mesoscale agglomerates. Our experiments show how the initial compositional non-uniformity first translates into intermediate phases and then results in the formation of the perovskite phase. Importantly, we notice that the segregation of Sr shows up already at 800°C and is temperature-dependent. Our results indicate that the range of possible temperature/time used in the solid-state synthesis is much narrower than previously assumed when a higher quality of the oxide material is required.

9:00 AM *EN05.12.04
Advancing Semiconductor-Based Photoelectrodes for Artificial Photosynthesis *Francesca M. Toma;*

Helmholtz-Zentrum Hereon, Germany

Photoelectrochemical cells (PECs) offer a promising route for converting sunlight into energy-dense and high-value chemicals (e.g. hydrocarbons, hydrogen) via CO2 reduction, water splitting, and nitrate reduction. However, challenges related to the performance and stability of catalysts and semiconductor-based photoelectrodes within complex electrochemical environments necessitate detailed microscopic understanding.
This talk will present the use of advanced correlative characterization techniques, such as Kelvin Probe Force Microscopy (KPFM) and operando Spectroscopic Ellipsometry (SE), to assess photoelectrode surfaces with nanometer precision. For example, using TiO2 thin films deposited by Atomic Layer Deposition (ALD) as a model system, we uncover insights into surface potential evolution and carrier dynamics. A major hurdle in achieving high efficiency is probing the interplay between local morphology and charge carrier dynamics. We demonstrate how time-dependent KPFM can precisely correlate local morphology with optoelectronic properties and degradation mechanisms.
We will also report on the novel catalytic microenvironments to enhance the stability and reaction selectivity of (photo)electrocatalytic materials. We will show examples based on Cu2O, halide perovskites, and ZnTe, and discuss the impact of the semiconductor/electrolyte interface on performance and selectivity.
These advanced techniques can aid detailed understanding of complex catalytic architectures and enable the design of more efficient photoelectrodes, thus advancing sustainable energy production and climate change mitigation.

Hybrid Molecular Materials for Energy Applications Antoni Llobet Dalmases; *Institut Català d'Investigació Química, Spain*

The replacement of fossil fuels by a clean and renewable energy source is one of the most urgent and challenging issues our society is facing today, which is why intense research is devoted to this topic.[1] Nature has been using sunlight as the primary energy input to oxidize water and reduce CO_2 to generate carbohydrates (a solar fuel) for over a billion years. Inspired but not constrained by nature, artificial systems can be designed to capture light and oxidize water and reduce protons or other compounds such as CO_2 to generate useful chemical fuels. One of the key aspects for the efficient design of useful devices for the making solar fuels is the understanding and mastering of the catalysts involved in both the anodic and cathodic reactions. The talk will describe the initial developments up to the state of the art, of molecular catalysts and their anchoring on conductive and semiconductive surfaces. The latter is crucial for the generation of powerful hybrid molecular anodes and cathodes for the production of solar fuels.[2]

The Swiss Army Knife of Electrodes—Pillar[6]arene-Modified Electrodes for Molecular Electrocatalysis over a Wide pH Range *Jan Bühler, Helena Roithmeyer and David Tilley; Universität Zürich, Switzerland*

Molecular catalysts can be immobilised on common electrode materials, including metal oxides, through various methods such as physi- or chemisorption. However, systems which are stable across a wide pH range are uncommon. Typically, each electrochemical transformation requires a specifically tailored system to ensure strong catalyst binding and high activity. In aqueous media, combating hydrolysis is crucial to enable catalysis under strongly acidic and basic conditions. One method to achieve this is the functionalisation of mesoporous indium tin oxide electrodes with the macrocyclic host molecule pillar[6]arene (PA[6]). These electrodes exhibit stability within a pH range of 2.4–10.8 and can be equipped with electrochemically active ruthenium complexes via host-guest interactions for various oxidation reactions. Benzyl alcohol oxidation is used as a model reaction in acidic media, while ammonia oxidation is performed to evaluate the system's performance under basic conditions. PA[6]-modified electrodes show catalytic activity for both reactions when complexed with different guest molecules. Due to the stable binding of PA[6], they can be reused after degradation of the catalyst by a simple reabsorption procedure. Moreover, the system can be employed to perform successive reactions in electrolytes with varying pH, allowing the same electrode to be utilised in multiple different electrocatalytic reactions.

10:45 AM EN05.13.02

Microenvironment Manipulation via Enzyme-Inspired Ligand Engineering Boosting Fatty Alcohol Electrocatalytic Oxidation *Ruiqi Du, Rui Jia, Zemao Chen, Bingjie Yuan and Yi Cheng; Tsinghua University, China*

Alcohol electrocatalytic oxidation represents a promising green method for producing carboxylic acid products. Additionally, it serves as a viable alternative to the oxygen evolution reaction (OER), contributing to reduced energy consumption in water electrolysis and improving the economic feasibility of hydrogen production. In the realm of electrocatalyst, nickel hydroxide ($Ni(OH)_2$) stands out for its low cost and excellent electrocatalytic activity, widely applied in the electro-oxidation of short-chain alcohols such as methanol and ethanol. However, the electrocatalytic oxidation of long-chain fatty alcohols, which offers higher added value, remains a significant challenge. The extremely low solubility of long-chain fatty alcohols in aqueous electrolyte results in a low concentration of accessible reactants on the catalyst surface, thereby restricting reaction rates due to mass transport limitation.

In natural enzyme, the active center is typically surrounded by the second coordination sphere where specific ligand groups can modulate the local microenvironment near the active center. This arrangement enhances the affinity between reactants and the active center, consequently accelerating reaction rates. Building upon this concept, our work investigates nickel-based metal organic frameworks (Ni-MOFs) as material platform designed to mimic enzyme microenvironments. Ni-MOFs were prepared through the assembly of nickel metal ions and highly tunable carboxylate organic ligands via solvothermal methods. Ex-situ X-ray photoelectron spectroscopy (XPS) analysis indicates that Ni-MOFs undergo reconstruction under anodic reaction conditions, transforming into $Ni(OH)_2$, which is considered as the actual catalytic active species. Notably, Raman spectra and attenuated total reflectance infrared spectroscopy (ATR-IR) reveal that some carboxylate ligands persist in the second coordination sphere after the reconstruction.

Through modulating the carboxylate ligand hydrophobicity, we create a hydrophobic microenvironment that facilitates the local enrichment of fatty alcohols at active sites. This strategy significantly boosts the activity and selectivity of fatty alcohol electrocatalytic oxidation while mitigating competitive OER. Experimental findings demonstrate that Ni-MOFs outperform pure $Ni(OH)_2$ for the electrocatalytic oxidation of the model substrate octanol, achieving a more than five-fold increase in octanoic acid yield and a Faradaic efficiency exceeding 85%. The enzyme-inspired ligand engineering strategy proposed in this work lays the groundwork for designing efficient electrocatalytic oxidation catalysts and holds promise for application in various electrocatalytic reactions involving water-immiscible reactants.

11:00 AM EN05.13.03

Pt-Ni-Ru Nanoframes as a Bifunctional Catalyst for MOR and HER *Patrick J. Deegan, Erin Jiang, Stella Wang, Eduardo Lezama, Kira Shulman and Yoora Cho; Binghamton University, The State University of New York, United States*

Platinum catalysts exhibit outstanding performance in clean energy applications, such as water splitting and fuel cells. Unfortunately, their widespread use is limited by the scarcity and high price of Pt. To overcome these challenges, Pt-alloy catalysts have been extensively studied with the aim to reduce Pt content while improving the catalytic performance. On the other hand, nanoframes (NFs) have been proven to be effective catalytic platforms because of the large surface area generated by their fully open structure. In this report, we generated ternary alloy NFs by introducing Ru into Pt-Ni nanocubes. These nanocubes showed a phase segregation feature where Pt was segregated on the edges and diagonals, and Ni was distributed evenly. The solid cubes were hollowed out through galvanic replacement between Ru^{3+} and the segregated Ni component. Ru deposited on the edges because of the Kirkendall effect and alloyed with the segregated Pt, forming the framework. These Pt-Ni-Ru NFs were applied to the methanol oxidation reaction (MOR) and hydrogen evolution reaction (HER), showing boosted performance for both applications. These findings not only suggest the Pt-Ni-Ru ternary alloy NFs as a bifunctional catalyst but also provide insight for developing improved storage and conversion systems for clean energy.

11:15 AM EN05.13.04

Elucidating Intrinsic and Extrinsic Effect on Electrochemical Oxidation of Alkene in Aqueous Solutions *Tae Gyu Yun[1], Sarah Wells[1], Boqiang Chen[1], Younghwan Lim[2] and Alexis Grimaud[1]; [1]Boston College, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Electro-oxidation of alkenes powered by renewable sources offers a promising pathway for producing target chemicals. However, to compete with well-established, energy-intensive processes that utilize high temperatures and/or high pressures, selectivity and yield must be perfectly controlled. This can only be achieved through a deep understanding of reaction pathways and reaction intermediates. Recent studies on propylene oxidation have shown that various chemicals, such as propylene glycol, propylene oxide, acetone, and acrolein, can be produced depending on the conditions, including applied potential and pH of the solution. However, few studies have been conducted at high anodic potentials, where a significant amount of oxygen evolution reaction can occur. In this research, we first investigated the mechanism of propylene oxidation to propylene glycol on Pd-based catalysts within a high-potential range in acid media aqueous solutions, exploring the effects of oxidation state, substitution and local coordination on the yield, selectivity and kinetics of the reaction. We found that the faradaic efficiency (FE) peaks at 1.4 V (RHE) for metallic Pd, while it increases to 1.6 V (RHE) for other materials, including PdO and Pt-doped PdO, before higher anodic potentials, where the OER becomes dominant. Interestingly, although cyclic voltammetry (CV) and X-ray absorption spectroscopy revealed that the Pd surface is oxidized at potentials where the FE is at its maximum, Pd shows a much lower FE (23% at 1.4 V) compared to PdO (56% at 1.6 V). This suggests *that the structural differences between PdO and the oxide layer formed on Pd play a crucial role in electrocatalysis, guiding us through the design of novel Pd-based oxide catalysts with enhanced activity, including Pt-doped PdO that shows FE of 67% at 1.6 V vs. RHE. Operando attenuated total reflection Fourier transform infrared (ATR-FTIR) spectroscopy was then employed to elucidate the reaction mechanism and intermediates, demonstrating the crucial role played by oxo-intermediates in the reaction. These results gathered in acidic conditions were then compared to those collected in neutral conditions, where propylene oxide is found as major product but in very limited amount (maximum FE of 13% was measured for Pt-doped PdO catalyst). This major discrepancy when compared to previous reports using Pd-based catalysts in neutral conditions shines the light on the extreme sensitivity of this reaction to experimental conditions. Our study provides insights into the propylene oxidation behavior in different media and emphasizes the significant impact of crystallographic coordination of active sites on electrolysis efficiency.*

11:30 AM *EN05.13.05

Electrocatalytic Syntheses with Interfacial Control *Anna Wuttig; The University of Chicago, United States*

Synthesis driven by renewable electricity offers a sustainable, scalable, decentralized, and energy-efficient route to furnish value-added products. As electrocatalytic reactions occur at the interface between solid electrodes and liquid electrolytes, designing selective reactions requires methods to study this interface and predict how changes in its structure affect reaction outcomes. In this talk, I will disclose two recent discoveries from my group using in-situ spectroscopy, electrochemical analyses, and simulations to unravel the catalytic interfacial structure and guide reaction development. First, we have found that carboxylates bind to oxide electrode surfaces, enhancing the selectivity for non-Kolbe oxidation to alkenes by suppressing the parasitic oxygen evolution reaction. Second, we have uncovered a paradigm that deploys catalytic electrode surfaces to develop reductive fragment-based electrophile coupling reactions. The addition of Lewis acids pre-organizes the surface, enabling a carbon-centered radical (obtained via electrocatalytic activation) to efficiently add to the carbonyl. Our studies lay a foundation to develop sustainable synthetic methodologies by tuning the interfacial structure at catalytic, reusable electrodes at the molecular level.

SESSION EN05.14: Organic Electrosynthesis II
Session Chairs: Alexander Giovannitti and Helena Lundberg

1:30 PM *EN05.14.01

Advancing Sustainable Nylon Production Through Electrosynthesis—Elucidating Reaction Mechanisms at Electrode Interfaces and Enabling Bio-Derived Polymers *Miguel A. Modestino; New York University, United States*

The chemical industry, particularly organic chemical manufacturing, is a significant contributor to global greenhouse gas emissions, with traditional processes relying heavily on fossil fuels and operating under energy-intensive conditions. Transitioning to electrosynthesis offers a promising path for integrating renewable electricity and accelerating the decarbonization of large-scale chemical processes. This is especially relevant in the production of Nylon 6,6, a crucial polymer reliant on adiponitrile (ADN) as a key precursor.
Our research focuses on two critical aspects of sustainable ADN production: (1) improving the performance and

understanding of the electrochemical hydrodimerization of acrylonitrile (AN), one of the largest electro-organic reactions practiced in industry, and (2) optimizing the electrochemical synthesis of ADN from biomass-derived precursors.

In the first approach, we investigate the role of tetraalkylammonium (TAA) salts as supporting electrolytes in the electrochemical hydrodimerization of AN. By manipulating the molecular size and concentration of TAA ions, we observed improvements in ADN selectivity and production efficiency, primarily influenced by the mass transport of organic reactants to the electrical double layer (EDL). Combining an electrochemical flow cell with attenuated total reflection Fourier-transform infrared (FTIR) spectroscopy revealed that TAA ions significantly increase the local concentration of AN near the electrode, correlating with improved ADN selectivity. Kinetic isotope effect (KIE) studies and electron paramagnetic resonance (EPR) spectroscopy provide insights into the reaction mechanism, suggesting that hydrogen transfer to AN is a rate-determining step and that ADN production partially occurs through the coupling of free AN radicals in solution.

In the second approach, we propose a sustainable pathway utilizing renewable glutamic acid from protein waste hydrolysis. Glutamic acid is transformed into 3-cyanopropanoic acid (CPA), followed by ADN synthesis via Kolbe electrolysis. Our study employs a hierarchical electrochemical reaction engineering strategy, combining high-throughput experimentation with detailed studies to identify optimal conditions and elucidate factors controlling reaction pathways. Results show that platinum electrodes favor ADN formation, while graphite electrodes promote AN production. Under optimized conditions, a Faradaic efficiency of 40% towards ADN at current densities up to 500 mA cm-2 is achievable.

The guidelines obtained from these studies apply to various electrochemical decarboxylation reactions and AN electrohydrodimerization, informing the development and optimization of sustainable electro-organic manufacturing processes in the chemical industry.

2:00 PM *EN05.14.02

Electrochemical Biomass Depolymerization—Can Complex Catalysts Trigger High Product Selectivity?

Adam Slabon; Universität Wuppertal, Germany

Replacing crude oil as the primary industrial source of carbon-based chemicals has become crucial for both environmental and resource sustainability reasons. In this scenario, wood arises as an excellent candidate, whilst depolymerization approaches have emerged as promising strategies to unlock the lignin potential as a resource in the production of high-value organic chemicals. So far, catalysts for the electrochemical biomass depolymerization have been regarded as somewhat static catalytic systems with a focus on bulk or thin-film electrodes, whereas nanoparticle catalysts for the electrochemical CO2RR or water splitting have been demonstrated in the recent to undergo significant shape and size evolutions under operation conditions [1]. Taking electrochemical lignin depolymerization as a showcase, recent studies have been focused on bulk electrodes of carbon, nickel and copper, but the heterogeneous nature of chemical linkages, e.g. C-O or C-C, makes it challenging for bulk electrodes to achieve high selectivity for specific bond cleavage [2,3]. This talk will investigate complex electrocatalysts, such as nanoscopic catalysts, metal borides, and single atom catalysts for electrochemical depolymerization of lignin. Catalyst stability will be also elucidated based on TEM and in operando methods using X-ray absorption spectroscopy (XAS) [4].

Tailoring the Active Oxygen Species in the Electrochemical Oxidative Coupling of Methane to Suppress Deep Oxidation *Filip Grajkowski, Bill Liu, Subhash Chandra, Sanaz Koohfar, Dongha Kim, Georgios Dimitrakopoulos and Bilge Yildiz; Massachusetts Institute of Technology, United States*

Ethylene (C_2H_4) is a crucial industrial product with a broad range of applications such as the manufacturing of plastics. Commercial C_2H_4 production involves the steam cracking of ethane/naphtha, resulting in ~1.5-3 tonnes of CO_2 released for every tonne of C_2H_4: this makes C_2H_4 production the second-biggest contributor to industrial CO_2 emissions globally. A promising route to low carbon C_2H_4 production is the oxidative coupling of methane (OCM)[1] which can directly convert CH_4 into C_2H_4. Unfortunately, this OCM approach is severely limited by significant "deep oxidation" where CH_4 is instead combusted to CO/CO_2 and H_2O. To improve the C_2 (C_2H_4 and C_2H_6) selectivity and yield of OCM, recent works have integrated OCM activity into solid oxide electrolyzers. In this electrochemical OCM (EOCM) approach, O^{2-} ions from the cathode are transported to the anode where they oxidise CH_4 to yield the desired C_2 products. While the initial results are somewhat promising,[2] it is unclear what active oxygen species are involved in the activation of CH_4 and how these active oxygen species then affect the overall reaction selectivity.

In this work, we first adopt the model titanate-based mixed ionic-electronic conductor $La_{0.3}Sr_{0.7}TiO_3$ (LST30) as an anode material for EOCM. We demonstrate that by coupling the EOCM reactions to oxygen evolution at the anode surface, we can increase the C_2 selectivity of the system by >3x relative to the baseline performance of LST30. We rationalize this observation by hypothesizing that the oxygen intermediates produced as part of the oxygen evolution reaction are also OCM-active and therefore enable the selective oxidation of CH_4 into C_2 products. We can thus utilize this insight into the nature of the OCM-active oxygen species to further tune the reaction selectivity. Since it is known that the OCM selectivity is limited by deleterious reactions of C_2H_4 with the surface oxygen species,[3] herein we attempt to suppress these reactions by changing the surface binding strength of these oxygen species. We use the well-established O 2p-band model for oxides[4] to tune the oxygen binding strength: doping $SrTiO_3$ with Ta to form $SrTi_{1-x}Ta_xO_3$ can therefore allow us to monotonically shift the O 2p-band down and thus increase the oxygen binding strength. By exploring this family of materials, we demonstrate that the C_2H_4/C_2H_6 ratio can be significantly manipulated along this series, highlighting that the oxygen binding strength changes the relative rates of the C_2 oxidation reactions. To complement this, we utilize ab initio density functional theory (DFT) calculations and we confirm that the binding strengths of the active oxygen species can be significantly increased using Ta-doping, providing a materials-based approach towards altering the selectivity of the EOCM process. Overall, our general materials design strategy enables us to target electrode surfaces with optimal oxygen binding strengths to favor CH_4 activation while also suppressing the deep oxidation reactions, providing a pathway towards EOCM systems with enhanced C_2 selectivity.

Water Oxidation Catalyst Enables Highly Selective Electrochemical Baeyer-Villiger Oxidation *Yu Mu[1], Boqiang Chen[1], Hongna Zhang[1], Muchun Fei[1], Tianying Liu[1], Alexander J. Miller[2], Paula L. Diaconescu[3] and Dunwei Wang[1]; [1]Boston College, United States; [2]University of North Carolina at Chapel Hill, United States; [3]University of California, Los Angeles, United States*

The Baeyer–Villiger oxidation of ketones is crucial for producing esters but traditionally requires difficult-to-handle peroxides. Electrochemical methods can use water as the oxygen source but often suffer from low selectivity due to poor control over oxidation processes and reactions occurring away from the catalytic site. We proposed improving its selectivity by utilizing surface-anchored species for the reaction. We report in this work the application of a known water oxidation catalyst, iron oxide (Fe2O3), for the synthesis of ε-caprolactone with ca. 99% selectivity as a benchmark example of Baeyer–Villiger oxidation through electrochemical OAT with H2O as the oxygen donor. Mechanistic studies revealed that surface hydroperoxo intermediates (M-OOH) are key for promoting nucleophilic attacks on ketone substrates. By confining reactions to the catalyst surface, we limited competing processes such as dehydrogenation and hydroxylation, leading to high selectivity. Kinetic studies and spectroelectrochemical characterizations confirmed the surface-initiated nature of the reaction. This discovery adds nucleophilic oxidation to the tools available for electrochemical organic synthesis.

Proton Activity and Pathway in Aqueous Organic Redox Flow Battery Electrolyte *Wei Wang; Pacific Northwest National Laboratory, United States*

Aqueous soluble organic (ASO) redox-active materials have recently shown great promise as alternatives to transition metal ions employed as energy-bearing active materials in redox flow batteries for large-scale energy storage because of their structural tunability, cost-effectiveness, availability, and safety features. However, development so far has been limited to a small palette of organics that are aqueous soluble. This presentation will use fluorenone as an example to showcase how a natively redox-inactive molecule can be tuned to possess two-electron redox reversibility through hydrogenation and dehydrogenation. The modified fluorenone molecules demonstrated high energy density and recorded stable cycling. Furthermore, research has shown the unique chemical-electrochemical coupled redox reactions mechanism; thus, the system rate capabilities can be improved by incorporating suitable hydrogen acceptors that regulate the proton pathway for faster kinetics.

Electrochemical Flow Systems for Stationary Energy Storage and CO_2 Capture *Michael J. Aziz; Harvard University, United States*

Organic-based aqueous flow batteries have been developed with the goal of rapid scaling to cost-effectively store electrical energy from intermittent renewable sources for use when the wind isn't blowing and the sun isn't shining. Redox-active organic molecules in aqueous solution can reversibly bind CO_2 directly in one redox state and release it in the other. The same molecules can swing the pH by undergoing proton-coupled electron transfer, thereby enabling CO_2 capture by hydroxide. Recent progress in the development of active materials and cell designs will be reported.
Modest areal power densities in both of these applications, caused in part by mass transport limitations within the cell stack, limit system performance. A detailed understanding of mass transport and electrochemical activity within the porous electrode would benefit all electrochemical flow systems. We use operando fluorescence microscopy to image the fluid flow velocity field and molecular concentration fields using fluorescent tracer particles and redox-active organic molecules respectively. The molecular fluorescence signal is converted to a local measure of the state of charge with sub-pore-scale resolution. We are using this quantitative electrochemical fluorescence microscopy technique to gain insight into the influence of the electrode architecture on electrochemical-flow processes and, ultimately, to guide the development of high-performance electrodes for redox flow based electrochemical systems

Molecular Engineering towards Low Cost, High Energy Density Aqueous Reodx Flow Batteries with High Stability *Dawei Feng; University of Wisconsin-Madison, United States*

An increasing amount of renewable energy sources is being integrated into the electric grid in the US and globally. However, as intermittent wind and solar power begin to constitute more than a quarter of grid energy production, significant energy storage technologies must be employed to mitigate the imbalance between energy production

and demand. To meet emission targets in an economically viable manner, low-cost, grid-scale energy storage solutions are essential.
This talk will describe our efforts in developing a new generation of inexpensive redox-active species for redox flow batteries (RFBs) that offer extraordinary energy density and cycling stability. Our approach involves identifying the critical requirements for organic molecular redox couple and electrolyte design in RFBs and developing the simplest yet most effective synthetic routes to produce redox-active molecules with the desired performance.

4:00 PM *EN06.01.04
Eutectic Electrolyte Platform for Next-Generation Electrochemical Energy Storage *Guihua Yu; The University of Texas at Austin, United States*

In pursuit of next-generation electrochemical energy storage (EES) systems, though many researchers focus on the design of new chemistries and structures for high-capacity and stable electrode materials, the electrolyte also plays an essential role in enabling the successful function of these new electrode materials and chemistries. Discovery of new electrolytes is urgently needed to keep up with the rapid growth of EES, particularly redox flow batteries (RFBs) for grid-scale energy storage.
Benefiting from strong yet tunable intermolecular interactions between different components, eutectic electrolytes emerge as a promising platform to advance EES systems as they possess attractive functionalities that conventional electrolytes do not have, such as highly concentrated systems, non-flammability, high degrees of structural flexibility, and good thermal and chemical stability, leading to greatly enhanced energy density of EES, as well as potentially lower cost and ease of preparation.
In this talk, I will first introduce different mechanisms that guide the formation of eutectic electrolytes and discuss their structure–property relationships and ion transport mechanisms. I will then discuss recent progress on exploration of both metal- and organic-based eutectic electrolytes in next-generation EES with focus on RFBs, and conclude with further thoughts on the remaining challenges and potential research directions in this area.

SESSION EN06.02: Organic Flow Batteries II
Session Chairs: Ellen Matson and Pan Wang
Tuesday Morning, December 3, 2024
Hynes, Level 3, Room 307

8:00 AM EN06.02.01
Automated Determination of Concentration-Dependent Redox Properties for Redox Flow Battery Materials
Rebekah A. Duke-Crockett[1,2], Siamak Mahmoudi[1,2], Aman P. Kaur[1,2], David Eaton[1,2] and Chad Risko[1,2]; [1]University of Kentucky, United States; [2]Center for Applied Energy Research, United States

The development of redox flow batteries (RFB), a promising answer for the energy storage challenges associated with intermittent renewable energy sources, hinges on a deep understanding of the complex physicochemical interactions among the solvent, electrolyte salt, and redox-active molecules within the RFB. To advance our understanding of these systems, we developed a robotic platform designed to automate the study of redox flow battery chemistry. This system integrates our ExpFlow software with a versatile modular robotic hardware infrastructure, allowing for precise, reproducible electrochemical experimentation. The electrochemistry platform automates the execution and analysis of cyclic voltammetry (CV) and chronoamperometry (CA) electrochemical procedures to quantify descriptors such as oxidation potential, diffusion coefficients, and conductivity. When *validated with well-known electroactive systems, the system yields results that closely align with established literature values. We employed this automated system to analyze the effects of varying concentrations of the redox-active molecules (e.g., 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO)) and electrolyte salts (e.g., TBAPF6) on solution diffusivity, conductivity, etc. The results demonstrate the platform's capability to enhance understanding of redox flow battery chemistry. While our system was conceived for redox flow battery research, its modular design and versatility enable application across a wide range of electrochemical studies.*

8:15 AM *EN06.02.02
Effect of Spin-State and Molecular Clustering on Electrochemical Stability of Fe complexes in Aqueous Redox Flow Batteries *Hye Ryung Byon and Donghwi Ko; Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

The development of low-cost and long-life energy storage systems (ESSs) is essential to address the increasing demands for energy and environmental concerns. Redox flow batteries (RFBs) are promising grid-scale ESSs due to their safety, cost-effectiveness, and decoupled energy and power density. While vanadium-based redox flow batteries are currently the most prevalent, offering high cell voltage, large capacity, and stability, the limited abundance of vanadium in the Earth's crust (0.012%) raises concerns about future supply shortages. In contrast, Fe-based transition metals are abundant in the Earth's crust and are significantly cheaper (5000 times) than vanadium metals, making them a potential solution to supply and cost issues.

Fe-based compounds in aqueous RFBs typically exhibit high redox potentials and are mainly used as posolytes. To develop an all-Fe RFB, negolyte materials with lower redox potentials are necessary. Phenolate moieties have been employed to reduce the redox potential of Fe complexes due to their π-donor and strong Lewis base properties. However, these ligands primarily form Fe complexes in the high-spin state with weaker binding affinity, leading to low electrochemical stability.

Here, we introduced a secondary amine group capable of forming strong σ bonding with the Fe metal center under aqueous conditions. Additionally, sulfonate groups on phenolate rings were utilized to facilitate intermolecular H-bonding with neighboring secondary amine groups, enhancing the σ bonding between amines and irons and promoting molecular clustering. We also investigated a Fe complex including hydroxyl groups on phenolate rings as a control group, which cannot form intermolecular H-bonding and molecular clustering, as confirmed by small angle X-ray scattering measurement. Evans method and Raman analysis confirmed higher effective magnetic moment values and weaker metal-ligand binding affinity for the hydroxylated Fe complex. Cyclic voltammetry and aqueous RFB measurements demonstrated superior electrochemical stability for the sulfonated Fe complex compared to the hydroxylated one, which decomposed rapidly. Furthermore, the sulfonated Fe complex exhibited high solubility in water at 0.7 M and demonstrated stable cycling of the RFBs for 300 cycles in a neutral aqueous electrolyte at a concentration of 0.5 M.

8:45 AM ^EN06.02.03
Developing Sodium Superionic Conductors as Membranes in High-Voltage Aqueous Redox-Flow Batteries
David Kwabi; University of Michigan, United States

Ceramic sodium superionic conductors (NaSICONs) have garnered considerable attention as ion-exchange membranes in aqueous redox-flow batteries (RFBs) because they can eliminate crossover-induced capacity fade. Two obstacles to their practical use are long-term microstructural instability in most RFB electrolytes and low mechanical strength, the latter of which requires that the conductor material is deployed in flow cells as thick and highly resistive pellets. This talk will introduce our efforts toward overcoming both challenges. We show that

NaSICON pellets with nominal composition $Na_{3.4}Zr_2Si_2PO_{12}$ synthesized via a solution-assisted solid-state reaction (SA-SSR) exhibit greater morphological and electrochemical stability against a wide range of neutral-pH to strongly alkaline electrolytes than analogues synthesized using more conventional methods. The origin of this enhanced stability is a virtually negligible amount of an amorphous Na- and P-rich phase that is strongly etched by aqueous solutions. We demonstrate that NaSICON membranes fabricated using the SA-SSR process can enable a number of hybrid and non-hybrid aqueous flow cell configurations with voltages exceeding 1.5 V and crossover-free cycling for > 100 hours.

Flow Battery for Large Scale Energy Storage *Xianfeng Li; Chinese Academy of Sciences, China*

To accelerate the wider utilization of renewable energies is an extremely important strategy to achieve carbon neutralization. Nowadays, the electrochemical energy storage technologies, which can overcome the intermittence and instability of renewable energies, are receiving more and more attention. Among various electrochemical energy storage technologies, flow batteries exhibit outstanding features such as independently tunable power and energy, high safety, high efficiency, long lifespan and great environmental benignity, very suited for large-scale and user-side energy storage applications. Currently, flow battery energy storage technology has been at the initial commercialization stage. However, the energy density and cost of flow batteries have not yet fully met the market demands, limiting the realization of their commercialization and industrialization goals. To this end, it is crucial to design and optimize the structure of key materials for flow batteries and develop new flow battery systems with high energy density and low cost. Therefore, this report will introduce the research and development of flow battery energy storage technology in detail and provide an outlook for its future development.

Print-and-Plate Porous Electrodes for Flow Batteries *Dylan M. Barber[1], Sofia Edgar[1], Michael S. Emanuel[1], Michael D. Nelwood[1], Bok Y. Ahn[1], Thomas Cochard[1], Justin Platero[2,1], Benito Roman-Manso[1], Thiagarajan Soundappan[2], Kiana Amini[3,1], Chris H. Rycroft[4,1], Shmuel Rubinstein[1,5], Michael J. Aziz[1] and Jennifer A. Lewis[1]; [1]Harvard University, United States; [2]Navajo Technical University, United States; [3]The University of British Columbia, Canada; [4]University of Wisconsin–Madison, United States; [5]The Hebrew University of Jerusalem, Israel*

Flow batteries contain redox-active species that are stored in the liquid state and pumped through porous electrodes. High-performance electrodes should be designed to limit losses from charge transfer, resistance to electrical conduction, and hydraulic pressure drop. A complex interplay between electrode composition and architecture as well as electrolyte flow dynamics controls their performance. Most flow batteries use porous electrodes composed of randomly oriented (e.g., electrospun) carbon fibers, whose intrinsically disordered structure makes these important structure-property-performance relationships difficult to elucidate. Here, we report a "print-and-plate" fabrication method to generate conductive electrodes with programmable lattice architectures. Our three-step fabrication process involves: (i) direct ink writing of micro-architected lattices, (ii) *electroless nickel plating to enhance conductivity, and (iii) gold electroplating to impart electrochemical stability. The resulting electrode lattices consist of microscale features that exhibit mΩ sq^{-1} sheet resistance and sufficient porosity for low pressure drop in flow battery applications. We directly visualize their function in an anthraquinone disulfonate (AQDS) half-cell with chronopotentiometry and in situ fluorescence microscopy. Based on these observations, we then employ inverse design to strategically encode lattice defects (e.g., missing fiber segments) to investigate their effect on performance. Using confocal fluorescence microscopy, we quantitatively mapped the state of charge with sub pore-scale resolution in these print-and-plate electrodes in an operando AQDS half-cell. Our integrated approach for electrode design, fabrication, and testing provides a powerful platform for understanding and improving the performance of porous electrodes in electrochemical flow cells.*

Probing the Dynamics Between the Components of the Electrolyte System for Designing Improved Redox Flow Batteries *Mamta Dagar and Ellen M. Matson; University of Rochester, United States*

Emergent, flowable electrochemical energy storage technologies suitable for grid-scale applications are often limited by sluggish electron transfer kinetics that impede overall energy conversion efficiencies. Moreover, technoeconomic models project equivalent weight target of 150 g/mol per electron for redox active molecule–supporting electrolyte pairs. To address these current challenges in the development of non-aqueous redox flow batteries, we focus on titanium-doped polyoxovanadate-alkoxide clusters and tune their physicochemical properties by modifying surface capping ligands, altering the composition of the supporting electrolyte, and studying the effect of solvent system on the battery performance metrics. Our results illustrate that the one electron reduction and oxidation processes exhibit characteristically different rates, suggesting that different mechanisms of electron transfer are operative. We report that mixtures of propylene carbonate and acetonitrile can lead to a three-fold increase in the rate of electron transfer for one electron oxidation, and a two-fold increase in the one electron reduction process as compared to pure acetonitrile for the multimetallic assembly, $[Ti_2V_4O_5(OMe)_{14}]$*. Furthermore, organic functionalization of the cluster core leads to enhanced solubility, and changing the supporting electrolyte and electrode material can yield improved capacity retention. The results provide insight into the utility of probing the dynamics of the electrolyte system using electroanalytical techniques to systematically tune the design of next generation flow batteries.*

11:00 AM *EN06.02.07

Development and Evaluation of Anion Exchange Membranes for Enhanced Non-Aqueous Redox Flow Battery Efficiency *Shelley Minteer; Missouri University of Science and Technology, United States*

The synthesis and characterization of poly(norbornene) (PNB) anion-exchange membranes (AEMs) were studied to improve redox flow batteries. PNB is of copolymer of butyl norbornene (BuNB) and bromobutyl norbornene (BrBuNB) with varying amounts of tetramethyl hexadiamine crosslinker. The performance of the AEMs was investigated in model non-aqueous redox flow batteries. Performance evaluation included several key factors, including stability in a non-aqueous solvent, charge-carrying ions permeability, electric cell resistance, cross-over of redox-active molecules, and mechanical properties. The BuNB-based AEMs outperformed the commercial FAPQ-375 membrane in cycle battery tests showcasing their superior performance characteristics. Long-term stability tests showed that the top performing PNB membrane exhibited an impressive 83% total capacity retention over 1000 charge/discharge cycles. The low loss was primarily due to its minimal crossover. In contrast, the FAPQ-375 commercial membrane experienced significantly lower capacity retention, measuring only 28%, due to high crossover.

11:30 AM EN06.02.08

Synthesis, Characterization and Chemical Stability Analysis of Tetrasubstituted Hydroquinones for Positive Electrolytes of Aqueous Organic Redox Flow Batteries *Daniel A. Pollack[1,1], Thomas Y. George[1], Yan Jing[1,2], Tatsuhiro Tsukamoto[1,3], Jordan D. Sosa[1], Roy G. Gordon[1,1] and Michael J. Aziz[1]; [1]Harvard University, United States; [2]National University of Singapore, Singapore; [3]Tokyo Institute of Technology, Japan*

Broader adoption of renewable energy technologies will benefit from cost-effective and scalable energy storage methods to address the intermittency of renewable sources. The development of aqueous organic redox flow batteries (AORFBs), utilizing organic molecules composed of earth-abundant elements, represents one promising approach. Organic molecules may be readily functionalized to modulate chemical properties, including solubility and redox potential, and aqueous systems offer several advantages with respect to cost, conductivity, toxicity, and flammability. Organic species are, however, prone to decomposition, which may dramatically limit system lifetimes and practical implementation.

Chemical degradation represents a particularly significant challenge for positive electrolyte (posolyte) active species, as higher reduction potentials are typically associated with increased susceptibility to nucleophilic reactions with water. To address this problem, we designed tetrasubstituted hydroquinone posolyte active species candidates hypothesized to possess high stability, solubility, and redox potential. The synthesis of three such candidates, hydroquinonetetrasulfonic acid (HQTS), 2,5-dibromohydroquinone-3,6-disulfonic acid (HQDBDMS), and hydroquinonetetramethylsulfonic acid (HQTMS), will be reported. Although chemical stability studies revealed surprisingly rapid decomposition of the HQTS redox couple, the other two candidates demonstrated significantly greater stability. HQDBDMS, in particular, exhibited reversible redox kinetics and no observable decomposition after 15 days of cell cycling. Solubility, permeability, diffusivity, kinetic rate constants, and cell polarization performance will also be reported.

This presentation will highlight promising new hydroquinone AORFB posolyte active species candidates and will demonstrate how the synthesis of novel targets guided by chemical stability analysis can promote continued improvements in battery lifetime and performance.

11:45 AM EN06.02.09

Influence of Crossover on Capacity Fade of Symmetric Redox Flow Cells *Thomas Y. George, Eric M. Fell, Kyumin Lee, Michael S. Emanuel and Michael J. Aziz; Harvard University, United States*

Organic redox reactants offer tunable structures through chemical synthesis, thereby unlocking a vast space of physical and chemical properties for the design of high-performance flow-based electrochemical systems. Evaluating the stability of these redox reactants under conditions of electrochemical cycling between oxidized and reduced states is of paramount importance for choosing materials with which to build durable electrochemical devices, including long-lifetime redox flow batteries. Organic redox reactants in flow batteries are subject to myriad state-of-charge (SOC) dependent chemical reactions that can result in structural changes and the loss of redox activity under cycling conditions, and these reactions may be superimposed on top of crossover though the membrane, complicating the matter of understanding the cause of capacity fade.

The volumetrically unbalanced compositionally symmetric cell (hereafter referred to as symmetric cell) method was devised to isolate the contribution of chemical decomposition to capacity fade.[1] In principle the symmetric cell minimizes concentration gradients across the membrane, which would otherwise drive crossover. However, under conditions when the time-averaged SOC of capacity limiting side (CLS) and non-capacity limiting side

(NCLS) deviate from 50%, net crossover may occur and influence the measured capacity.[2]

We tested symmetric cells of anthraquinone disulfonic acid (AQDS) with Nafion membranes of varied thickness and manufacture (NR211, NR212, N115, and N117, ranging 25–183 μm). Membranes were tested both as-received and pretreated with a common procedure of soaking in water at elevated temperature and then dilute hydrogen peroxide.[3] *We found no significant difference in capacity fade rates of symmetric cells with any of the membranes as-received, indicating a negligible influence of crossover. However, we observed increased capacity fade with increased crossover flux through pre-treated membranes. Supported by zero-dimensional modeling and operando UV-vis spectrophotometry, we propose a mechanism for net crossover in AQDS symmetric cells based on a higher time-averaged concentration of quinhydrone dimers in the NCLS than in the CLS, driving net crossover of AQDS reactants out of the CLS. Further, we illustrate other hypothetical scenarios of net crossover using the zero-dimensional model. Overall, many membrane-electrolyte systems used in symmetric cell studies have sufficiently low crossover flux as to avoid the influence of crossover on capacity fade, but under conditions of higher crossover flux, complex interactions of crossover and chemical reactions may result in diverse capacity fade trajectories, the mechanisms of which may be untangled with appropriate measurements and modeling.*

Evaluating Vanadium Redox Flow Batterie Electrodes—A Holistic Approach *Roswitha Zeis[1,2]; [1]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [2]Karlsruhe Institute of Technology, Germany*

One key component of VRFBs is the electrode, which influences the cell efficiency, the VRFB lifetime, and the amount of side reactions during operation. Typical VRFB electrodes are based on carbon in the form of carbon felts, carbon cloths, or carbon paper. These electrodes combine good electronic conductivity, high open porosity, and a three-dimensional structure, which allows the electrolyte to flow through. Since the pristine commercial materials show poor wettability, affinity to side reactions, and low electrochemical activity, several types of electrode materials, modifications, and treatments have been proposed [1].
Our study presents a comprehensive multimodal characterization of different electrode materials, focusing on various types of carbon electrodes. Our research team has integrated electrochemical characterization based on cyclic voltammetry and electrochemical impedance spectroscopy [2] with dynamic vapor sorption, synchrotron x-

ray imaging [3], scanning electron microscopy, and atomic force microscopy [4]. This extensive multimodal characterization approach helps us understand the chemical and physical properties, such as the electrolyte permeability and catalytic activity and provides detailed insights into the electrode structure.

High-Voltage Membrane-Free Redox Flow Batteries *Jianbing J. Jiang; University of Cincinnati, United States*

While membrane-free batteries have been successfully demonstrated in static batteries, membrane-free batteries in authentic flow modes with high energy capacity and high cyclability are rarely reported. Here, we present a newly developed high-voltage liquid/liquid membrane-free battery employing a Mg metal anode in both static and flow configurations. This system leverages the advantages of the high voltage and fast kinetics of the Mg metal anode within a biphasic membrane-free flow setup to enable the independent optimization of energy and power. The biphasic system utilizes a CH2Cl2 catholyte and an aqueous anolyte to address the passivation issue of Mg metal in traditional electrolyte systems. In addition, a Mg2+-conductive interface was implemented to modify the Mg metal electrode, preventing direct contact between the Mg metal and water molecules to further mitigate the passivation issue. Notably, the batteries operating under ambient atmospheric conditions exhibit remarkable oxygen tolerance. The Mg||TEMPO and Mg||C3-PTZ batteries were tested under static, stirred, and flow conditions. The initial analysis focused on the charge/discharge performance at different catholyte material concentrations. Notably, the Mg||TEMPO (0.5 M) and Mg||C3-PTZ (0.5 M) batteries exhibited exceptional performance over 500 cycles, with capacity retention rates of 97.84% and 98.87%, respectively, (under static conditions) and 93.58% and 92.16% (under flow conditions). In addition, both Mg||TEMPO (0.5 M) and Mg||C3-PTZ (0.5 M) under flow conditions outperformed the power performance in the static configuration, with power densities of 195 and 191 mW/cm2, respectively. Overall, the newly developed cost-effective Mg battery exhibited remarkable battery performance, paving the way for innovative applications of Mg chemistry in flow batteries.

Enhanced Solubility and Stability of Polysulfide/Ferrocyanide Redox Flow Batteries *Mahla Sarfaraz Khabbaz[1], Xiaoliang Wei[1], Sepideh Biabani[1], Diqing Yue[1] and J. David Bazak[2]; [1]Purdue University, United States; [2]Pacific Northwest National Laboratory, United States*

Redox flow batteries are a promising solution for large-scale stationary renewable energy storage, capable of consistently delivering power to the grid. However, achieving high energy density, long-term stability, and low cost remains a challenge. Vanadium redox flow batteries as a present candidate are limited by their high cost and low energy density, which causes the search for alternative options for redox systems. Sulfide-based systems can raise interest for anolytes due to their abundance, high capacity, and low cost. Despite this high potential, the polysulfide species present in the anolyte solution are suffered from sluggish redox reactions and irreversible crossover through the cation exchange membrane, resulting in significant capacity fading and reduced cycle life.

In this study, we revisit the polysulfide redox couple and demonstrate enhanced cycling performance including boosted energy density and cycle life. A promising electrolyte engineering strategy has been evaluated to increase the solubility of polysulfide species, and new permselective membranes with an improved polysulfide blocking ability were used to slow down the crossover of polysulfides. The mechanisms underlying the enhancement were investigated using multimodal methods to elucidate the structures of electrolyte solutions and membrane materials.

Durability and Mechanisms of Kinetic Enhancement of Vanadium Redox Flow Battery Electrodes *Kaycee Gass, Alan Pezeshki, Doug Aaron and Matthew Mench; The University of Tennessee, Knoxville, United States*

The kinetic behavior of porous carbon electrodes in vanadium redox flow batteries is controlled by both the surface area and the inherent activity of the surface. Improvements in the kinetics has been demonstrated through adding catalysts or thermal pre-treatment of electrodes. Catalytic additives may be undesirable due to added cost and complexity. Instead, we desire to enhance the kinetic performance of porous carbon electrodes using low-cost and scalable treatments that have robust, sustained performance enhancement. Developing an understanding of the physicochemical mechanisms responsible for performance enhancements will guide future research direction to optimize treatment protocols for maximum performance and durability resulting from the treatment.

In this talk, efforts to optimize the practical enhancement in performance as well as the underlying fundamental mechanisms (i.e. which of surface area and inherent surface activity plays a bigger role) of the performance gain for thermally treated porous carbon electrodes will be given. Electrodes are analyzed following thermal, hydrothermal, or soaking treatments in a variety of environments. Additionally, we investigated the beginning-of-life durability resulting from various treatments under various electrochemical protocols. Electrochemical surface area (ECSA), electrochemical impedance spectroscopy (EIS) and polarization behavior were utilized to understand the impact of treatments in situ. The physical properties of as-received and treated electrodes, both un-used and post-mortem were characterized using a variety of techniques including electrochemical impedance spectroscopy (EIS), scanning electron microscopy (SEM), x-ray diffraction (XRD), energy-dispersive x-ray spectroscopy (EDS), Fourier transform infrared spectroscopy (FTIR), and Raman spectroscopy.

Interestingly, we find evidence for both short and longer-term enhancements that can result from electrode treatment based on either surface functionalization or physical morphology modification of the base electrode material. It is commonly assumed that performance gains are achieved through higher inherent surface activity via addition of nitrogen or oxygen-containing surface functionalities added by thermal treatments. In this talk, we present evidence that permanent morphological changes (i.e. surface area increases) drive the enhance kinetic performance observed as a result of treatments.

The results of this work show the impacts of electrode treatment on performance, beginning-of-life durability of the performance enhancement, and lend evidence to a method of kinetic enhancement via surface morphological changes that provide a more long-term positive impact on kinetic performance of the electrode. Specifically, heat treatment in an ammonia atmosphere is shown to provide a stable performance gain under cycling conditions where other treatments showed a steep drop-off in kinetic performance with cycling. Therefore, treatments which enhance electrode surface area as a result of treatment are good candidates for durable performance enhancements in VRB electrodes. Practical aspects of the ammonia treatment (time, temperature, etc) will be presented, as well.

Metallic Porous Electrodes for Flow Cells *Qing Chen; The Hong Kong University of Science and Technology, Hong Kong*

Leveraging our group's expertise in fabrications based on selective dissolution, we attempt to bridge the gap between commercial metallic foam, highly permeable but low in the specific area, and nanoporous metals, which are not widely applied as electrodes in flow cells for the perceived low permeability. By controlling the porosity, the pore orientation, the pore size, and the hierarchy, we reveal the impacts of these structural characteristics on common electrode properties such as the surface area, the effective diffusivity, and the hydraulic permeability. We further demonstrate the use of oriented and hierarchical nanoporous metals as efficient and catalytic electrodes in redox flow batteries and electrolyzers.

Effects of Current Density and Flow Velocity on Morphological Change of Zinc During Deposition and Dissolution by Operando Observation in Zinc Flow Battery *Masatsugu Morimitsu and Yusuke Tachida; Doshisha University, Japan*

A rechargeable zinc flow battery, especially zinc/air battery, is one of the most promising candidates for a large-scale of stationary energy storage system linked to solar or wind power generation, because there are some merits such as a high theoretical energy density, low cost of zinc, an air-breathing cathode, and a high safety of non-flammable aqueous electrolyte. The flow system of the electrolyte that is KOH solutions is believed to be effective to suppress the generation of zinc dendrite and non-uniform distribution of zinc and zinc oxide, while there has been still little information on the effects of the charge-discharge conditions and the dimensions, design, and flow parameters of the cell on the morphology during zinc deposition and dissolution. This paper reports the results on the operando visualization of the zinc anode during charge and discharge at different operating conditions of current density and flow rate.
The results indicated that the critical limits of current density and flow rate at which the zinc deposit becomes laminar and smooth during charge, while the current density and the flow rate also control which the deposited zinc is easily dissolved or changed to zinc oxide. It was further revealed that the kinetic parameter defined as current density per flow rate (i/v) is the significant factor to the zinc deposit morphology and the discharge mode which is zinc dissolution or zinc oxide generation. This means that the discharge mode is affected by the deposit's morphology obtained during charge, while the morphology after discharge strongly influences on the zinc deposit morphology in the next cycle. Finally, it was suggested that the parameter, i/v, is valuable in design of zinc flow battery to suppress the non-uniform distribution of zinc and zinc oxide and the internal short circuit by zinc dendrite.

Unlocking Capacity and Stability in Halide Flow Batteries with Zwitterionic Trappers *Gyohun Choi and Dawei Feng; University of Wisconsin-Madison, United States*

Aqueous redox flow batteries are promising grid energy storage technology due to their safety and ability to decouple power and capacity. Particularly, halide-based catholytes have been used due to their high solubility and redox potential. However, the performance of halide catholytes has been hindered by their intrinsic properties such as crossover, free dihalogen release, and low capacity utilization due to the formation of polyhalides. To overcome those issues, polyhalide complexing cations (PCCs), which consist of an organic cationic motif such as quaternary ammonium, imidazolium, and pyridinium, have been used as additives to trap charged polyahlide species. Although these PCCs effectively reduced the crossover and free dihalogen release, the hydrophobic PCC-polyhalide complex requires complex flow engineering and hindered discharge kinetics. Here, we designed organic soft-hard zwitterionic trappers (SH-ZITs) as novel polyhalide complexing agents composed of soft cationic and water-soluble hard anionic motifs. The addition of SH-ZITs not only prevented polyhalide crossover and dihalogen release but also maintained a homogeneous solution at a high state-of-charge, unlocking the capacity and stability of the halide catholyte. This results in stable operation with an average coulombic efficiency of over 99.9% and no significant decay after more than 1000 cycles over two months.

SESSION EN06.04: Mediated Flow Batteries
Session Chairs: Patrick Cappillino and Qing Wang

Hynes, Level 3, Room 307

8:30 AM *EN06.04.01
Redox-Mediated Processes for Flow Batteries—From Capacity Boosting to Combined Renewable Hydrogen Generation *Daniel Rourke[1], Shabdiki Chaurasia[1], Eylul Ergun[1], Tulsi Poudel[2], Daphne Poirier[2], Patrick J. Cappillino[2] and Ertan Agar[1]; [1]University of Massachusetts Lowell, United States; [2]University of Massachusetts Dartmouth, United States*

Redox flow batteries (RFBs) have recently attracted significant attention as a grid-scale energy storage technology due to their ability to decouple energy and power ratings, unprecedented scalability, and cost-effectiveness in long-duration storage [1]. However, the low energy density of RFBs, primarily due to the limited concentration of redox-active species in electrolytes, remains a critical challenge [2-3]. One promising approach to address this limitation is the utilization of solid charge storage materials in the tanks. Similar to a typical flow battery operation, the mediator (i.e., redox-active species), which is oxidized in the flow cell, is pumped to the external tanks. Upon interaction between the mediator and the solid charge storage materials in the tank (i.e., the redox-mediated process), the oxidized mediator is reduced, and the charge is transferred to the solid charge storage material [4]. In this way, the redox-mediated process enables the shuttling of charges between the flow cell and the solid charge storage material, greatly increasing the theoretical capacity of the system [4-5].

In this presentation, an overview of the presenter's most recent research utilizing redox-mediated processes for addressing the key issues in RFBs will be provided. In the first part, a high energy density redox-mediated flow battery system using highly stable redox active species and Prussian Blue analogue solid storage materials will be introduced. The efforts to understand the interplay between two kinetic processes, the electrochemical reaction in the flow cell and the indirect redox-mediation reaction in the tank, will be discussed. Furthermore, an in-line ultramicroelectrode voltammetry setup is employed to gain fundamental insights into the interactions between solid charge storage materials and mediators, as well as how intercalation cations influence the kinetics of the *indirect redox targeting reaction. In the second part of the talk, our research groups' recent progress on dual-circuit RFBs [6], a different concept utilizing the redox-mediated processes, combining energy storage with indirect water electrolysis for renewable hydrogen generation, will be summarized.*

***Redox-Mediated Metal-Air Fuel Cells** Qing Wang; National University of Singapore, Singapore*

Electrochemical energy conversion and storage technologies have been pivotal in propelling global sustainable development. However, traditional electrochemical processes which are centered on intricate "electrode-electrolyte interface" confront substantial challenges when applied to emerging large-scale applications with open systems and distributed resources, for which the system generally involves evolving interfaces with the formation of new phases or requires the supply of feedstock and removal of products. This is especially the case for metal-air battery systems. Metal-air batteries present an alternative approach to achieving high power generation. Besides considerably higher volumetric energy density, the storage and transportation of solid fuels in metal-air systems are more practical compared to that of hydrogen fuel cells. However, metal-air systems face formidable challenges from both the metal and air electrodes, regardless of electrolyte conditions. The redox-mediated approach offers an elegant solution by directing the oxygen reaction from the cell compartment to a separate reactor tank. This approach has been exemplified in Li/Zn/Fe-air battery chemistries, showing the feasibility of loading solid fuels in external tank, which greatly facilitates the refueling process. While the concept has been successfully demonstrated, the development of viable devices necessitates systematic studies on the materials aspects (redox mediators, membranes, and catalysts) and engineering optimizations.

***Advanced Microelectrochemical Methods for Capturing Dynamics and Reactive Trends in Redox Flow Battery Electrolyte Systems** Joaquin Rodriguez-Lopez; University of Illinois at Urbana-Champaign, United States*

Redox flow batteries (RFBs) are emerging devices for energy storage in which charge capacity and power are decoupled. This allows for versatility in the exploration of electrolyte design principles that maximize desirable properties – or combinations of them – such as the concentration and redox potential of the redox active, the conductivity of the electrolyte, or electrode/electrolyte interactions. In this context, we are interested in examining the electrochemical properties of redox active molecules on emerging types of electrolytes which might display exciting new attributes. To understand these properties at a mesoscopic level of interaction between the electrolyte and the electrode, and at concentrations that are relevant for redox-flow battery or on individual

particles/ electrode sites relevant to flow batteries, we used techniques based on small electrodes such as scanning electrochemical microscopy (SECM),[1] scanning electrochemical cell microscopy (SECCM), and interdigitated electrode arrays. These techniques allow a broad range of experiments at microscales, including generation-collection and kinetic measurements with minimal convection effects. In this presentation, we will discuss how these capabilities can be used for its application in the evaluation of two emerging electrolyte systems: bicontinuous microemulsions (uEs)[2], and redox-matched flow batteries[3].
As examples, we will describe how confining microemulsion electrolytes between a tip and a substrate leads to stochastic responses that we believe exhibit the impact of charge transfer (i.e., electron and ion transfer processes) across phases. This transport may lead to mechanical deformation and convective effects which are dependent on the nature of the SECM mode used, and other electrolyte properties. The nature and concentration of the electrolyte matter when describing the behavior of the stochastic responses, which are also correlated to macroscopic characteristics (e.g., Coulombic efficiency) of the samples. Another example where electrolyte concentration matters significantly is in the use of polymeric materials for redox-matched flow batteries, in which immobilized redox components are accessed by redox mediators. In these cases, determinining the impacts of ionic strenght and accessibility of the mediator is crucial. To this point, techniques cuh as SECCM help isolate individual components such as particles while microelectrochemical arrays enable the versatile inspection of various reaction conditions using automation [4]. In summary, microelectrode techniques such as SECM, SECCM, and interdigitated arrays hold promise for the elucidation of charge transfer dynamics that are typically lost in bulk electrochemical measurements.

Redox Targeting as a Strategy to Thin the Crowd, Toward High Energy Density Flow Battery Electrolytes

Patrick J. Cappillino[1], Tulsi Poudel[1], Daphne Poirier[1], Daniel Rourke[2], Eylul Ergun[2] and Ertan Agar[2]; [1]University of Massachusetts Dartmouth, United States; [2]University of Massachusetts Lowell, United States

Redox flow batteries (RFBs), in which charge-carrying, liquid electrolytes are pumped through electrochemical cells, are a promising, developing energy storage technology. In these systems, the energy capacity scales with the volume of electrolyte stored in tanks, and the power scales with the size of the cell. This decoupling gives RFBs potential advantages for long- and medium duration grid energy-storage applications and a favorable safety profile compared with integrated systems like lithium-ion batteries. A significant remaining challenge in the advancement of RFBs is that the concentrations necessary for high energy-density often lead to high viscosity. So-called, "crowded electrolytes" often result in poor performance due to pumping losses and slow kinetics.

This presentation reports progress on a promising nonaqueous RFB, comprising a bio-inspired catholyte called vanadium hydroxyiminodiacetate (VBH) and an organic anolyte. This system operates at moderate concentration, to high states of charge, with excellent cyclability. Furthermore, we report progress on a redox-targeting flow battery (RTFB) system, designed to overcome the viscosity challenges associated with high-concentration electrolytes by incorporating solid boosters into the system. The RTFB studies comprise investigation of the interaction between VBH, as a solution-phase mediator, and solid, cobalt hexacyanoferrate (CoHCF) booster. By independently monitoring the redox state of VBH, using electronic spectroscopy, and CoHCF, using infrared spectroscopy, we demonstrate tightly coupled electrochemistry that can be controlled by modifying the intercalation cation.

Redox Mediated Electrochemical Systems—From Conventional to Flow Batteries *Jagjit Nanda[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States*

Low cost, scalable and long-life energy storage systems are critical for accelerating decarbonization of the electric grid. Department of Energy's (DOE) Long Duration Storage Shot aims to reduce the cost of grid-scale energy storage by 90% in the next decade for systems with durations of 10+ hours. Redox targeted concept applied to broad class electrochemical processes are relevant to energy storage and conversion in both aqueous and nonaqueous media.[1-2] Target solvated-ion interaction coupled with facile electron transfer at the phase boundary between redox tuned mediators and high-capacity electrode materials when optimized are drivers for high energy density and rate performance. For example, mediated redox flow batteries (RFBs) could potentially overcome the current bottleneck in both energy density and cost by utilizing low-cost organic mediators work in tandem with earth abundant high-capacity electro-active materials (Na, S, Mn and Fe) thereby, increasing energy density by 10X with a significant reduction in material cost. The talk will focus on role of redox mediated processes to enable performance in RFBs, solid-state and Li and Na compounds.[3-4]

Elucidating Design Principles for Redox-Mediated Flow Batteries Through Physics-Based Modeling *Nicholas J. Matteucci, Chris T. Mallia and Fikile Brushett; Massachusetts Institute of Technology, United States*

Redox-mediation, or redox-targeting, is an emerging concept within the flow battery community that offers a pathway to dramatic increases in energy density while retaining independent scaling of power and energy. In these systems, soluble redox-active mediators act as charge shuttles between the electrodes within the electrochemical cell and the "off-electrode" materials in the external tanks.[1,2] Literature reports indicate that by incorporating solid active materials, redox-mediated flow batteries (RMFBs) can extend the charge-storage capacity of the flow battery,[2-3] accommodate previously inaccessible sets of active materials,[4] and unlock new modes of operation.[5-6] However, the presence of reactive solid active materials in the tanks significantly alters the performance characteristics of the flow battery which may frustrate assessments of technical and economic potential. Accordingly, we have developed a qualitatively-validated mathematical model to aid in predicting the behavior of RMFBs.[7] The framework employs physics-based constitutive equations to represent the transient mass and charge dynamics in the flow cell and tank, for both the dissolved mediators and solid active species. Notably, we use mixed potential theory as a thermodynamically-consistent method of describing the driving force and rates between the mediator and solid.

In this presentation, we will discuss how this model can offer useful insights into the RMFB design-space. We employ dimensional analysis, relationships for pressure drop in porous media, and principles of cycling stability to explore how material properties, operating protocol, and system architecture connect to trade-offs in capacity utilization, power output, and parasitic pumping losses. By outlining general performance trends and incorporating constrained optimization, we demonstrate how this model framework can serve as a tool for guiding the operation *of present-day RMFBs and establishing material property targets for next-generation RMFBs. Ultimately, this work aims to provide actionable design strategies that accelerate the development of redox-mediated systems.*

Redox-Mediated Phenomena in Thin-Film Model Systems Chris T. Mallia, Carl Thompson and Fikile Brushett; *Massachusetts Institute of Technology, United States*

The energy density of conventional redox flow battery (RFB) systems is limited by solubility of the charge-storing species in the mobile liquid electrolyte. To enable dramatic increases in energy density, a redox-mediated approach, where redox species transport charge between an "inert" electrode and a spatially-separated, high-capacity material (substrate), can been considered.[1–3] *A fundamental aspect of this design is a heterogeneous chemical reaction between a soluble redox-active species with a material of a different phase (solid) that is submerged in the liquid electrolyte.*[4] *Such reactions are analogous to, and of interest in, electrochemical deposition, wet-etching, and material processing. Despite potential energetic benefits for the RFB, the introduction of spatially and temporally distinct chemical reactions complicates system design and operation, requiring careful consideration of solid-solution reactant combinations, conditions, and reaction kinetics.*[4] *With the intention of more broadly understanding redox-mediated reactions, we here focus on characterizing the reaction dynamics of model systems. Specifically, elemental metallic thin-films and both powder and single-crystal lithium-ion intercalation compounds are chosen as learning platforms from which important findings about reaction mechanisms can be gleaned, and comparisons made.*

In this presentation, we will describe several redox-mediated reactions of interest for energy dense RFB systems, and electrochemical processing of materials. Specifically, we focus on lithium-ion intercalation materials (e.g. LFP), and metals (e.g. zinc, copper) in combination with different soluble redox couples, in both aqueous and non-aqueous environments. Metal substrates evolve as reaction proceeds, causing surface passivation phenomena and growth of a corroded interface, while LFP is instead controlled by solid-state phase transformation. For all considered systems, surface and bulk composition, reaction products and rate, and morphology are expected to heavily depend upon choice of mediator and electrolyte conditions. Reactions will be characterized using operando optical microscopy and in-situ voltammetry, supported by analytical measurements (e.g., SEM, FTIR, XRD) performed before and after testing. The surface morphology and chemical evolution of both substrates and mediators will be discussed. We will also present theoretical considerations for the choice of reactants and solid-state materials for energy storage.

Bromine Catholyte Management in Redox-Flow Batteries—Safety and Durability *David Zitoun[1], Kobby Saadi[1], Samuel Hardisty[1], Raphael Flack[1], Peter Fischer[2], Michael Kuttinger[2] and Peter Pintauro[3]; [1]Bar-Ilan University, Israel; [2]Fraunhofer Institute for Chemical Technology, Germany; [3]Vanderbilt University, United States*

Bromine catholyte in redox-flow batteries (RFBs) technology is considered a promising electrochemical storage solution as a sustainable electricity storage solution due to its fast kinetics, highly reversible reactions and low chemical costs. The main bottlenecks of bromine RFBs, either coupled with hydrogen, zinc, vanadium or polysulfide, are the safety concerns of concentrated bromine, the corrosion from bromine species resulting in a high cost of system and the rapid fading of the anolyte electrode performance in the highly corrosive environment. On the catholyte side, bromine displays a high energy density when coupled with complexing agents that decrease the vapor pressure and increase the safety, either by complexing with ethyl, hexyl-pyridinium bromide or with resins.[1,2] The membrane chemistry can also be modified to reach a higher permselectivity and decrease the bromine crossover.

On the anolyte side, in hydrogen-bromine RFB, the hydrogen catalyst precious group metal (PGM) is poisoned by the catholyte crossover,[3] resulting in high PGM loading (~1-2 g/kW) and short lifetime (~10^2 hours). PGM loading can be decreased ten-fold by encapsulating the catalyst with a coating designed with a high permselectivity towards the hydrogen anolyte.[4] The coating has been developed through conformal polymerization,[5] carbon nanotube encapsulation,[6] atomic layer deposition[7] and core-shell electrospinning.[8]

Herein, we shall present the electrochemistry of catholytes, the electrocatalysis of surface-modified catalysts and cycling RFBs. In an attempt to solve the safety, durability and cost issues of bromine RFBs, we have developed a general platform, including electrodes, electrolytes and membranes, with the potential to solve general poisoning and corrosion in aqueous electrolytes.

11:45 AM EN06.04.09
Unveiling Composition-Dependent Transport Properties in Imidazole—Levulinic Acid Systems for Redox Flow Batteries *Giselle de Araujo Lima e Souza[1], Benworth Bryce Hansen[2], Kaylie Glynn[2], Miguel Muñoz[3], Emilia Pelegano-Titmuss[1], Burcu Gurkan[3], Steven Greenbaum[1], Mark Tuckerman[4] and Joshua Sangoro[2]; [1]Hunter College, United States; [2]The Ohio State University, United States; [3]Case Western Reserve University, United States; [4]New York University, United States*

Redox flow batteries (RFBs) require highly efficient electrolytes for optimal energy storage and release. One challenge in developing such electrolytes is the inverse relationship between viscosity and ionic conductivity, particularly in systems governed by vehicular diffusion mechanisms. This relationship can hinder the performance of RFBs, as increasing charge carrier concentrations often increases viscosity due to stronger intermolecular interactions, thus decreasing overall conductivity. However, enhancing proton-coupled electron transport (PCET) through the Grotthuss mechanism (proton hopping) can significantly boost the performance of electrolytes with low inherent conductivities, paving the way for better RFB systems.
In this work, we explore concentrated hydrogen bond electrolytes (CoHBEs) systems composed of imidazole [Im] and levulinic acid [LA], which shows great potential as an RFB electrolyte. We provide a comprehensive analysis including thermal properties, densities, viscosities, and ionic conductivities, supplemented by molecular insights from dielectric spectroscopy and ^{1}H and ^{15}N NMR and diffusion NMR.
Our study reveals that the PCET mechanisms in the [Im][LA] system are highly dependent on composition. By leveraging eutectic melting point depression and hydrogen bonding networks, conditions favorable for the Grotthuss mechanism are created, enhancing proton transport. Through a detailed investigation of macroscopic transport properties and molecular dynamics, it has been demonstrated that the [Im][LA] system forms [LA]- and [Im]-rich Grotthuss chains at room temperature, resulting in superior PCET performance in a non-aqueous liquid electrolyte.

Redox-Mediated Modular Electrochemical Synthesis to Exploit Dynamic Electricity Markets and Electrochemically Recover Ammonia *Song Jin; University of Wisconsin-Madison, United States*

Homogenous redox couples and heterogenous redox-active materials can be utilized to decouple electrochemical reactions. Decarbonizing the power grid requires the widespread adoption of renewable (wind/solar) power sources but the unpredictable and intermittent nature of renewable power motivates the development of flexible electrochemical manufacturing technologies that can shift power demand/supply across space-time and scales. I will discuss new redox-mediated modular electrochemical synthesis (ModES) strategies capable of providing demand flexibility at different timescales by participating in multiple electricity markets (day-ahead, real-time, and frequency regulation). Using a fast proton-conducting redox material, copper hexacyanoferrate, highly rate-mismatched modular electrochemical synthesis was achieved by decoupling half-reactions with different intrinsic kinetics to produce chemicals under drastically different reaction rates and timescales: the fast hydrogen evolution reaction and slow persulfate production reaction. Such a strategy enables flexible participation in different electricity markets and can reduce electricity cost of chemical production by 30-40%. I will also discuss how the electrochemical manufacturing of chemicals can be integrated with the electrochemical recovery of ammonium (and other nutrient) ions by using redox reservoir materials with ion selectivity. These results introduce innovative strategies for flexibly integrating modular electrochemical manufacturing processes various chemicals into the fluctuating power grid to achieve more economical and sustainable operations.

Nanostructured Thin-Film Composite Membranes for Redox Flow Electrochemical Separations *Wangsuk Oh, Nayeong Kim, Hyewon Kim, Roderick I. Mackie and Xiao Su; University of Illinois at Urbana-Champaign, United States*

Fermentative organic acid production has been recognized as a sustainable approach for waste valorization. However, the complex organic acid distribution and dilution of fermentation products pose challenges for selective acid recovery, requiring energy-intensitve downstream separation processes. Redox couple-incorporated electrodialysis systems have recently shown promise for energy-efficient organic acid separation, although the lack of suitable membrane designs for effectively separating similar organic ions remains a hurdle. Herein, thin-film composite membranes with a nanostructured polyelectrolyte top layer for selective organic acid separation are demonstrated. Catalyst-free polymer modification methods are developed to molecularly tailor the hydrophobicity of the polyelectrolytes and their phase behaviors. On-surface phase separation of the polymers, synergistically tuned by the polymer modification, enables the formation of a nanoscale and uniform active layer on the membrane support. The nanostructured layer enhances the permeability of organic acids with higher molecular selectivity, overcoming a conventional flux-selectivity trade-off. Furthermore, redox-mediated electrochemical separation is demonstrated for the recovery of organic acids from real fermentation effluents. Selective organic enrichment with low energy consumption is achieved by taking advantage of the nanostructured membranes and reversible redox reactions. This study shows the potential of nanostructured polyelectrolyte composite membranes integrated with a redox flow electrochemical system for realizing valuable organic ion recovery with high selectivity and energy-efficiency.

High Efficiency Acid-Base Generator for Carbon Management *Dawei Xi, Zheng Yang, Michael S. Emanuel and Michael J. Aziz; Harvard University, United States*

Carbon dioxide capture is a critical technology for achieving carbon neutrality and mitigating the impacts of global warming. One promising approach involves electrochemical generation of concentrated acid and base. This effectively decouples the carbon capture-release process from the electrochemical cell, avoiding the kinetic limitations associated with reactions involving CO_2.
Designing an electrochemical acid-base generator with high current efficiency and low energy cost is challenging. Following investigations of the crossover rates of protons and hydroxide ions through ion-exchange membranes, we designed a multichambered electrochemical cell for generating weak acid and strong base. By optimizing the center chamber with a well-designed flow field, we achieved acid-base production at high concentrations (> 1M) and high Coulombic efficiency (> 94%) while maintaining relatively low energy costs (100 – 289 kJ mol^{-1}*, at 20 – 200 mA* cm^{-2}*). With this device, we have demonstrated practical carbon management in simulated flue gas capture, direct air capture, and green production of slaked lime, as one step toward green cement production.*
The key components of our prototype can be adapted for use in other electrochemical cell designs, ensuring high efficiency in concentrated acid-base utilization in other application scenarios. For example, management of the pH-difference and the acid-base crossover inside electrochemical systems is also crucial in pH-decoupling aqueous redox flow batteries, enabling the cell to achieve higher cell voltages and correspondingly higher energy densities, as well as supporting a broader range of redox pair combinations.

3:30 PM EN06.05.04
Bipolar Membrane-Assisted Carbon Capture and Utilization *Amit N. Shocron, Arpita Iddya, Yanghua Duan and Menachem Elimelech; Yale University, United States*

Global efforts target carbon neutrality by 2050, highlighting the critical role of CO_2 *accumulation in driving climate change. Moreover, limiting global warming below 2 °C requires net negative carbon emission, namely, active removal of* CO_2 *from the atmosphere, also termed carbon capture. Carbon can be captured from various sources, including air, seawater, and point sources, using various methods, including thermal, chemical, and electrochemical. Notably, electrochemical-driven pH swings present a promising strategy for energy-efficient and high-flux carbon capture from point sources.*

Sustainable decarbonization also requires closing the carbon cycle, necessitating sustainable alternatives to fossil fuels as raw materials. A promising avenue is the reduction of captured CO_2 *to other valuable resources, including sustainable fuels like methane and methanol, as well as CO, which can be used for synthesizing hydrocarbons. Efficient* CO_2 *reduction requires expensive catalysts, such as Au, or a precisely controlled acidic environment. Therefore, bipolar membranes (BPMs) are occasionally used to promote water splitting and maintain an acidic environment near the cathode.*

Combining the capture of CO_2 *from point sources with its utilization in a single process has the potential to be a key component in closing the carbon cycle. While a simultaneous process can be done with dual function materials (DFMs) that include capturing and catalytic sites, their high cost makes them less attractive. Additionally, effective carbon capture necessitates an alkaline environment, while its utilization is more efficient in an acidic environment. Therefore, alternative approaches that separate these two steps within a single process should be explored.*

Here, we present a simultaneous carbon capture and utilization approach that eliminates the need for DFMs. We designed a closed-loop system consisting of two electrodes, a BPM, and an electrolyte with a redox couple that does not involve H^+ or OH^-. This combination is leveraged to induce a pH swing, increasing pH in the anode channel, and decreasing pH in the cathode channel. The elevated pH facilitates efficient carbon capture, while the lower pH enables efficient carbon reduction in the cathode. We developed a continuum model of the entire system and used it to investigate the impact of various parameters on pH swing, asses the available redox couples, and establish key design rules.

3:45 PM EN06.05.05
Electrochemical CO2 Capture with pH-Independent Redox Chemistry *Sang Cheol Kim and Steven Chu; Stanford University, United States*

Capturing anthropogenic carbon dioxide is essential to meet the climate targets. Despite the progress in decarbonizing the grid and transportation, some sectors remain difficult to decarbonize, and carbon capture is necessary to reach carbon neutrality. The incumbent technology for carbon capture utilizes amine sorbents to scrub CO_2 using thermal stimuli; however, the thermodynamic penalty for CO_2 capture and release is high and the heating of non-active water solvent with high heat capacity contribute to the high energy cost. As a result, current energy input needed is an order-of-magnitude larger than the theoretical minimum free energy associated with the entropy change. Alternatively, electrochemical carbon capture using redox-active sorbents has recently been gaining attention. Electrochemical activation specifically targets active materials, circumventing energy loss to substrate heating. Among various electrochemical CO_2 capture methods, electrochemical modulation of pH is a promising strategy that leverages the dependence of inorganic carbon solubility on pH.
In this work, we present a pH-independent redox chemistry for energy efficient CO_2 capture. Our method is based on modulating the pH by changing the activity coefficient of H^+. By circumventing direct modulation of H^+ concentration, we can swing the pH without associated entropic penalties in the redox reaction. This minimizes the thermodynamic energy input for pH swing and CO_2 capture and release, which we demonstrate in a flow cell. Through molecular dynamics and density functional theory simulations, we find that H^+ activity is modulated by polarizing water molecules. We demonstrate with in-situ infrared spectroscopy that bicarbonates and formed and released through redox reactions and electrochemical modulation of the pH.

4:00 PM EN06.05.06
Redox-Mediated Flow Cell System for Direct Recovery of Spent Lithium Iron Phosphate *Zhiyu Wang, Songpeng Huang and Qing Wang; National University of Singapore, Singapore*

The widespread application of lithium-ion batteries (LIBs), particularly those based on lithium iron phosphate (LFP) cathode material, has led to significant environmental challenges due to their disposal. Traditional recycling techniques, such as pyrometallurgical and hydrometallurgical processes, are energy-intensive, costly, and environmentally unfriendly. LIB capacity deterioration primarily occurs through damage to the active material (e.g., irreversible phase transitions, particle cracking) and loss of carrier ions, with the latter being more common in temperature-controlled systems used in large-scale applications.
This study introduces a novel redox-mediated electrochemical approach for the direct recovery of spent LFP materials by restoring the lost lithium. With a regenerative flow cell system, spent LFP materials are compositionally recovered with the addition of lithium sources (i.e., LiOH) mediated by redox-active species. The system could operate at a large scale and low cost. Characterization of the recovered LFP confirms that its electrochemical properties and structural integrity are comparable to the pristine LFP, with fully restored capacity, good capacity retention, and rate performance.
This redox-mediated electrochemical recovery method offers significant advantages over conventional direct

recycling approaches in terms of reaction rate and operation flexibility. We anticipate it provides a viable solution for the valorization of end-of-life LIBs, contributing to a circular economy and reducing the environmental impact of battery waste.

4:15 PM EN06.05.07

CO_2 Capture and Consecutive Conversion into Cyclic Carbonates in a Redox Flow *Jeong Hyun Kim, Junho Jang, Youngin Cho and Ki Tae Nam; Seoul National University, Korea (the Republic of)*

Electrochemical methods are promising for CO_2 mitigation due to their potential for high energy efficiency, adaptability to decentralized operations, and alignment with renewable energy sources. Among the two main approaches for electrochemical CO_2 mitigation—electrochemical CO_2 capture and electrochemical CO_2 reduction—the extended concept of redox-flow batteries often adopts the CO_2 capture approach. In these systems, cathode reactions generate alkaline species capable of capturing CO_2. Diluted CO_2 streams are treated by contact with an electrolyte containing these species, followed by oxidation reactions that facilitate CO_2 release, ultimately separating CO_2 from the feed gas. To achieve an energy-efficient capture process, research focuses on developing cell components, primarily redox-active species with high reversibility and facile reaction kinetics, such as quinones, bipyridines, and transition metal complexes.

While the use of separated CO_2 gas is addressed in other fields, integrating CO_2 capture and utilization processes can significantly reduce overall energy requirements. Thus, electrochemical systems that simultaneously generate bases and reduce CO_2 are under development. In these systems, electrons are introduced to chemisorbed CO_2 species such as carbamates and carbonates, yielding CO_2 reduction products and bases.

In this study, we propose a redox-flow system that captures CO_2 and subsequently converts it into cyclic carbonates. Our system integrates CO_2 capture and conversion through a series of domino reactions triggered by the electrochemical generation of organic bases. Unlike other redox flow systems that use redox-active species targeting highly reversible redox reactions for CO_2 capture, our system utilizes vicinal halohydrin molecules as precursors of alkaline species, which spontaneously undergo intramolecular cyclization reactions after capturing CO_2 and yield cyclic carbonates. Our method achieves a Faradaic efficiency of up to 100% for ethylene carbonate production, demonstrating highly selective sequential capture and conversion reactions. Additionally, it is expandable to the synthesis of various cyclic carbonates directly from diluted CO_2 sources.

4:30 PM EN06.05.08

Engineering the Electrolyte System for Improved Non-Aqueous Redox Flow Batteries *Mamta Dagar[1], James R. McKone[2], Ellen M. Matson[1] and Timothy Cook[3]; [1]University of Rochester, United States; [2]University of Pittsburgh, United States; [3]University at Buffalo, The State University of New York, United States*

The ever-growing global energy demands require efficient and robust storage schemes to be successfully fulfilled by intermittent renewable resources (e.g. solar, wind). Redox flow batteries (RFBs) are emergent, flowable electrochemical energy storage technologies suitable for grid-scale applications. However, the advancement of RFB chemistries is impeded by several key limitations including solubility of charge carrier, stability of electrolyte, and sluggish charge transfer kinetics at the electrode-electrolyte interface. To address these current challenges in the development of non-aqueous RFBs, we leverage mutual interactions between the different components of battery electrolyte (charge carrier, solvent, supporting electrolyte, and electrode) to derive general relationships between the electrolyte composition and performance metrics.

Specifically, we demonstrate the utility of titanium doped polyoxovanadate-alkoxide (TiPOV-alkoxide charge carriers) clusters as charge carriers in non-aqueous media. While installation of two Ti centers in the hexavanadate core results in improved cell voltage (1.73 V vs 1.1 V), however, the solubility and stability of the resulting cluster in *acetonitrile remains poor. To overcome this limitation, we propose the synthesis of TiPOV-alkoxide derivatives bearing surface ligands with alkoxyether moieties. The resulting clusters* $[Ti_2V_4O_5(OCH_3)_{11}(TRIOL^R)]$ *(R =* OCH_3*,* $OC_2H_5OCH_3$*) retain the electrochemical properties but demonstrate fourteen-fold greater solubility over that of their homoleptic congeners in acetonitrile. Furthermore, employing alkali metal cations (instead of non-coordinating tetrabutylammonium ion) in the supporting electrolyte yield enhanced stability through cation pairing effects, which results in improved battery performance. Apart from elucidating the effect of charge carrier modification on the solubility and supporting salt's contribution in imparting stability to the battery electrolyte, we also focus on the role of solvent in boosting the charge transfer kinetics of TiPOVs. Our results indicate that the acceptor number of the solvent dictates the rate of electron transfer of the reduced species. Moreover, mixed solvent systems (with propylene carbonate) can yield even faster kinetics as compared to pure acetonitrile. Fitting experimental results to mathematical models reveal that this behavior is due to solvent–solvent interactions, which result in disruption of the solvent shell around the active material, making it amenable to facile charge transfer.*

In addition to using molecular engineering tools to improve the performance of RFBs, we also evaluate the interfacial interactions of TiPOVs with the electrode material. Through Raman and X-ray photoelectron spectroscopy, we show the plausible decomposition pathway(s) on carbon electrodes. The results garnered from these measurements enable us to propose alternate ways to circumvent degradation of TiPOV-based charge carriers – employing Ni foam as the electrode material in the negative compartment leads to improved capacity retention.

Overall, these results provide insights into the utility of probing the dynamics of the electrolyte system using electroanalytical and spectroscopic techniques to systematically tune the design of next generation flow batteries.

4:45 PM EN06.05.09
Predicting Viscosity of Electrolytes for Redox Flow Batteries *Maricris Mayes, Ahmed Abdulai, Benjoe Rey Visayas, Edwin Benson, Gwendalyn Myers, Tulsi Poudel and Patrick J. Cappillino; University of Massachusetts Dartmouth, United States*

Redox flow batteries represent an evolving technology with significant potential for large-scale energy storage solutions. Despite their advantages, achieving higher energy densities through increased active-material concentrations has led to increased electrolyte viscosities, impeding their practical applications. We conducted combined experimental and comprehensive atomistic molecular dynamics simulations to understand the viscosity changes at a molecular level. Our study focused on both the oxidized and reduced states of the highly stable vanadium bis-hydroxyiminodiacetate complex, involving a variety of alkylammonium cations at different temperatures. The simulations closely match experimental viscosities for concentrations up to 0.5 M, revealing critical insights into solvation dynamics, ion-pairing, and fundamental chemical interactions. These insights would enable the tailored development of electrolyte blends with improved transport properties.

Gas Diffusion in Catalyst Layer of Flow Cell for CO_2 Electroreduction to C_{2+} Products *Nageh K. Allam; The American University in Cairo, Egypt*

The use of gas diffusion electrode (GDE) based flow cell can realize industrial-scale CO_2 reduction reactions (CO_2RRs). Controlling local CO_2 and CO intermediate diffusion plays a key role in CO_2RR toward multi-carbon (C_{2+}) products. In this work, local CO_2 and CO intermediate diffusion through the catalyst layer (CL) was investigated for improving CO_2RR toward C_{2+} products. The gas permeability tests and finite element simulation results indicated CL can balance the CO_2 gas diffusion and residence time of the CO intermediate, leading to a sufficient CO concentration with a suitable CO_2/H_2O supply for high C_{2+} products. As a result, an excellent selectivity of C_{2+} products ~ 79% at a high current density of 400 $mAcm^{-2}$ could be obtained on the optimal 500 nm Cu CL (Cu500). This work provides a new insight into the optimization of CO_2/H_2O supply and local CO concentration by controlling CL for C_{2+} products in CO_2RR flow cell.

EN06.06.02

Redox Properties of Solid Booster and Solution Phase Mediator in a Non-Aqueous Redox Targeting Flow Battery System *Tulsi M. Poudel[1], Daphne Poirier[1], Daniel Rourke[2], Eylul Ergun[2], Patrick J. Cappillino[1] and Ertan Agar[2]; [1]University of Massachusetts Dartmouth, United States; [2]University of Massachusetts Lowell, United States*

Application of Non-aqueous redox flow battery systems are hindered by low energy density. To mitigate the issue, the concept of using solid phase 'Booster' in the electrolyte tank containing solution phase active material 'Mediator' is used in a Redox Targeting Flow Battery (RTFB) System. The solid phase booster, with tuned reduction potential, increases the energy density of the solution phase mediator and obviates the need for high concentration which leads to increased viscosity and decreased performance. Here, we investigate the redox reaction between the RTFB mediator tetrabutylammonium vanadium(iv)(bis)-hydroxyiminodiacetate (TBA_2VBH), which is soluble in a non-aqueous solvent, with Cobalt (II) Hexacyanoferrate (III) (CoHCF), a solid booster. An ex-situ analysis has been carried out to measure the concentration of the mediator in both oxidation states via UV-vis spectroscopy, while independently monitoring the oxidation state of the booster using FTIR spectroscopy. We provide evidence of the importance of the nature of the cations present in the electrolyte, which (de)intercalate within the lattice of the booster during redox cycling. Further, we demonstrate that this property can be used to tune the redox reaction between the RTFB booster and mediator, which must precisely match to have a reversible RTFB system. Cyclic voltammetry analysis further confirms the redox behavior of CoHCF in the present of various cations in the electrolyte system.

EN06.06.03

Dendritic Growth Suppression in Hybrid Redox Flow Batteries *Vivekanand Kumar and Manoj Neergat; Indian Institute of Technology Bombay, India*

Hybrid redox flow batteries, including zinc-bromine, zinc-cerium, soluble lead, and all-copper systems, undergo metal deposition and dissolution processes during their charge-discharge cycles. The progressive growth of dendrites over multiple charge-discharge cycles is an inevitable phenomenon in such devices. Starting with an initial performance loss, dendritic growth can lead to short-circuiting failure. This work is concerned with studying the influence of electrolyte composition, electrode morphology, and operational parameters on dendritic growth during electrodeposition of the materials relevant to redox flow batteries: zinc, lead, and copper. The results show that the formation of dendrites is dependent on the reduction potential of the metal ions, with zinc exhibiting the *most pronounced dendritic growth as a result of its high reduction potential. Various suppression strategies are examined, including the use of additives, surface coatings, and advanced electrode materials. Electrochemical techniques like cyclic voltammetry, chronoamperometry, and impedance spectroscopy are used to analyze the efficacy of these strategies. Understanding dendritic growth mechanisms offers valuable insights into the improvement of battery performance, longevity, and safety.*

EN06.06.04

Near-Infrared-Induced Photoredox Catalysis Using Bridged Fluorescein Derivatives *Dogyeong Lee and Jungkyu Lee; Kyungpook National University, Korea (the Republic of)*

Near-infrared (NIR) fluorescent probes are highly valuable in various fields such as fundamental research and medical applications due to their unique properties, such as reduced photodamage to biological entities, deep tissue penetration, and low background autofluorescence. In recent, NIR-induced photoredox catalysis has emerged as a promising field to driving photochemical reactions. In particular, organic NIR photoredox catalysts offer low cell toxicity, making them valuable for biological applications. To develop effective NIR organic photoredox catalysts, we have investigated the synthesis and characterization of efficient photoredox catalysts. Specifically, we observed that bridged fluorescein derivatives (e.g., coerulein B, bridged eosin Y, and bridged dibromofluorescein) are promising candidates for NIR photoredox catalysts. In this presentation, we detail the synthesis of these fluorescein derivatives and their performance in photopolymerization under NIR light. Furthermore, we propose the mechanism of photoredox catalysis using these derivatives through spectroscopic analyses, including fluorometry, cyclic voltammetry, electron paramagnetic resonance. Additionally, we demonstrate a stimulus-responsive NIR photoredox catalysis. We envision that our investigation will not only elucidate the mechanism of NIR photoredox catalysis, but also broaden the application of NIR fluorescent probes.

EN06.06.05

Influence of Linker Group on Bipolar Redox-Active Molecule (BRM) Performance in Non-Aqueous Redox Flow Batteries *Samantha Macchi and Travis M. Anderson; Sandia National Laboratories, United States*

Non-aqueous redox flow batteries (NARFBs) have garnered broad interest as a stationary energy storage device due to their high voltage operation compared to traditional aqueous flow batteries. Bipolar redox-active molecules (BRMs) have been recently employed in NARFBs to alleviate issues related to crossover which can hinder the performance of RFBs. In this work, BRMs comprised of ferrocene (Fc) and phthalimide (PI) active moieties were covalently linked with tethering groups of varying structure and length. The stability and overall performance of Fc-n-PI BRM-based NARFBs was greatly influenced by the length and steric shielding ability of the linker group. Primary sources of capacity loss are found to be BRM degradation for straight chain spacers <6 carbons and membrane (Nafion) fouling. Fc-hexyl-PI exhibited the most stable battery cycling and coulombic efficiencies of >98% over 100 cycles (~13 days). A NARFB using Fc-hexyl-PI as an active material exhibited high working voltage (1.93 V) and maximum capacity (1.28 Ah L^{-1}).

EN06.06.07

Redox Mediator to Accelerate the Electrosynthesis of Dimethyl Carbonate *Sam E. Lofland[1] and Naohiro Fujinuma[2]; [1]Rowan University, United States; [2]Sekisui Chemical Ltd, Japan*

We have developed an Pd-Au catalyst for the electrosynthesis of dimethyl carbonate (E-DMC) from methanol and CO. While the catalyst displays high (>90%) faradaic efficiency for dimethyl carbonate, the resulting current density is too low to be of commercial use. To accelerate the production, we have expanded the catalytic environment by incorporating redox halide mediators. Both LiCl and LiBr enhanced the current density by more *than fivefold. We have identified 5 steps in the reaction for E-DMC that take place on the surface of the Pd-Au catalyst without the redox mediator. With the redox mediator, indications are that carbonyl halide is synthesized at the surface of the metal alloy and then in the electrolyte, the halogens are replaced by methanols to produce DMC. This pathway requires only one reaction step at the surface of the alloy, freeing up catalytic sites, leading to faster production. It is worth noting that this route produces and consumes organic halides in the same reaction and may lead to less toxicity.*

EN06.06.08

Investigation of Choline Bromide-Based Electrolyte For High Performance Supercapacitors *Zhanibek Ayaganov[1], Annie Ng[2] and Vladimir Vladimir[1]; [1]Institute of Combustion Problems, Kazakhstan; [2]Nazarbayev University, Kazakhstan*

Choline bromide (ChBr) has been less explored as an electrolyte material. This work demonstrates the promising potential of ChBr as a novel eco-friendly aqueous electrolyte for hybrid supercapacitors. At its optimized concentration of 3.5 M, the ChBr solution exhibits a maximum conductivity of 79.56 mS cm^{-1} at the room temperature, along with a viscosity of 3.15 mPas and a density of 1.14 g cm^{-3}. A reduction in water activity of the optimized ChBr electrolyte concentration extends the electrochemical stability window (ESW), enabling operation up to 1.9 V for two-electrode cells. When the current densities increase from 0.5 to 5 A g^{-1}, the hybrid supercapacitor based on ChBr electrolyte with the optimized mass ratio of electrodes composed of commercial microporous carbon (Maxsorb) demonstrates impressive specific energy and capacitance retention from 41 to 36 Wh kg^{-1} and from 330 to 300 F g^{-1} (per mass of one electrode), respectively. These performance parameters are highly competitive with hybrid devices based on organic electrolytes. The experimental results obtained from this work demonstrate possibilities for further development and applications of ChBr-based hybrid systems in energy storage devices.

Maximizing Efficiency—A Numerical Modeling of 2-Terminal Perovskite/Silicon Tandem Devices as to Different Bottom Cell Structures *Hoyoung Song[1], Sang-Won Lee[2], Youngho Choe[1], Yoonmook Kang[1], Donghwan Kim[1] and Hae-Seok Lee[1]; [1]Korea University, Korea (the Republic of); [2]Stanford University, United States*

2-terminal perovskite/silicon (Si) tandem solar cells have made significant progress in terms of efficiency and are considered suitable candidates for the next generation of photovoltaic devices. To date, most studies on 2-terminal perovskite/Si tandems have primarily focused on the development of the top cell, including tuning the perovskite bandgap, passivating interface defects, and improving film deposition methods on textured Si surfaces. Additionally, significant efforts have been dedicated to optimizing the interlayer types and properties. Existing optimizations of the silicon bottom cell have often been limited to specific structures previously reported to exhibit high efficiency or have explored new configurations such as "Inverted TOPCon" and "PERC+TOPCon" combination structure [1-2].
However, to achieve broader and higher efficiency possibilities, it is crucial to optimize each bottom Si solar cell structure independently. In tandem design, the spectrum transferred to the bottom cell significantly varies depending on the bandgap and structure of the top perovskite cell. It has been confirmed that the generation profile of the bottom cell differs based on the transmitted spectrum, particularly showing a more uniform generation profile when receiving filtered light compared to the standard AM1.5G spectrum. This variation influences the selection of the optimal structure for the bottom cell. Therefore, the electrical and optical requirements for bottom cells vary and must be reconsidered to meet these specific needs.
In this study, optical and electrical optimization modeling was conducted using SunSolve and Quokka2 programs to verify the characteristics and maximum efficiency of the 2-terminal perovskite/Si tandem cell considering the Si bottom cell structure. Optical optimization and current matching were performed by adjusting the thickness of each layer using the n-i-p and p-i-n tandem structures, reported to exhibit high efficiency. We considered two types of bottom cell structure: homojunction (PERC, TOPCon) and heterojunction (HIT). Additionally, the bottom cell structure was fixed as an opening local front-contact structure within the passivation layer for the homojunction to maintain a commercially dominant single-cell structure and good electrical connectivity to the transparent conductive oxide (TCO) interlayer. Moreover, to optimize the electrical characteristics, the bulk characteristics, substrate type, and junction location were changed to perform modeling, and the maximum efficiency possible for each structure was determined. Consequently, we proposed an improvement method and structure capable of achieving maximum possible efficiency of more than 30% as a tandem device for each bottom cell structure.

10:45 AM EN07.01.03

Minimizing Recombination Losses of Wide-Bandgap Perovskite for Highly Efficient Perovskite-Based Tandems *Fengjiu Yang[1,2], Philipp Tockhorn[2], Artem Musiienko[2], Felix Lang[3], Dorothee Menzel[2], Jiselle Ye[2], James Brown[1], Kaitlyn Vansant[1], Henry Snaith[4], Dieter Neher[3], Lars Korte[2], Steve Albrecht[2], Emily Warren[1], Joseph J. Berry[1] and Kai Zhu[1]; [1]National Renewable Energy Laboratory, United States; [2]Helmholtz-Zentrum Berlin für Materialien*

und Energie, Germany; [3]University of Potsdam, Germany; [4]University of Oxford, United Kingdom

Metal halide perovskite-based tandem solar cells are promising green energy candidates to further improve thin film solar cells' efficiency for lower carbon dioxide emission of the energy conversion system. The wide-bandgap perovskite works as a top cell light harvester and typically consists of a mixed halide composition, which is currently limiting the overall tandem performance due to halide-segregation, bromide-involved defects states, and non-ideal contact materials leading to significant recombination losses [1,2]. As a result, the open circuit voltage (V_{OC}) deficit is larger for perovskites with bandgaps >1.7eV than it is for medium bandgap ones [3,4]. In addition, upscaling the active area is a prerequisite for industrial application.
Here, we develop new triple halide perovskite compositions with bandgaps of ~1.8 eV for all-perovskite tandem and 1.68 eV for perovskite-Si tandem, by combining additives and surface treatments. With the function of the additive and surface treatment, the recombination losses of ~1.8 eV perovskite bulk and interfaces have been reduced, resulting in a long carrier lifetime is up to 3 μs compared to 0.9 μs of the control sample. As a result, the V_{OC} of a single-junction ~1.8 eV device reached 1.36 V with antisolvent quenching and >1.34 V with nitrogen quenching. By combining with a mixed tin-lead narrow bandgap perovskite as a bottom cell, a certified efficiency of 27.5% for an all-perovskite tandem solar cell is achieved. In addition, the energetic alignment offset between 1.68 eV perovskite and carrier transport materials has been decreased with the help of additive and surface treatment. The carrier lifetime and recombination losses of perovskite film itself and interfaces are also decreased. Finally, the 1.68 eV bandgap perovskite solar cell realized a V_{OC} of 1.29 V with 23% efficiency for a 0.09 cm^2 device and 18.0% efficiency on a small module of 4 cm^2 with 4 subcells. This progress allows us to fabricate highly efficient perovskite-based tandems and accelerate commercialization.

An Outlook on Thin-Film Tandems *Vera Steinmann; First Solar, United States*

Is multijunction PV needed to help us meet the worldwide increasing energy demand?
Crystalline silicon single junction solar modules are to-date the most successful (cost + efficiency) and most broadly deployed PV technology in the world. Yet, even higher efficiencies have been demonstrated in silicon-perovskite tandems, surpassing the Shockley-Queisser limit of single junctions. Many factors point towards the future of PV being tandems. What will be the role of thin-film tandems, i.e., tandems comprising of a thin-film top and thin-film bottom cell?
We will discuss the opportunities and challenges of thin-film tandems, and the research & development work required to bring thin-film tandems to market.

SESSION EN07.02: Advances in Perovskite Material Development

Kinetics vs. Thermodynamics—Pathways to Improving the Stability of Halide Perovskites *Nakita K. Noel; University of Oxford, United Kingdom*

Since the first demonstration of efficient halide perovskite solar cells, there has been sustained and growing research interest in this class of materials. With facile deposition processes and excellent optoelectronic properties, these materials have found applications not only in photovoltaics, but in a myriad of optoelectronic devices. While research into halide perovskites for light emission and X-ray detection is just beginning to surge, perovskites are most well known for their remarkable PV performance, achieving certified power conversion efficiencies over 26% in single junction devices. Despite their truly impressive device performance, these materials have not yet reached their true potential. One potential hurdle to this is an incomplete understanding of the crystallisation dynamics and interfaces in halide perovskite thin-films, which can result in marked changes to the long-term stability and performance of these devices. In this talk, I will discuss kinetic approaches to fabricating improved stability halide perovskite thin-films and devices of a variety of bandgaps. Importantly, I will discuss how utilising various kinetic pathways enable us to stabilise conventionally thermodyamically unstable phases, opening new pathways to perovskite-based tandem devices.

2:00 PM *EN07.02.04

Surface Engineering and Growth Control for High-Performance Perovskite-Based Tandem Solar Cells *Kai Zhu; National Renewable Energy Laboratory, United States*

Organic-inorganic hybrid halide perovskites have attracted significant R&D attention in the photovoltaic (PV) community as a competitive technology for future PV applications. The certified efficiency of single-junction perovskite solar cell (PSC) has reached over 26%. In addition to single-junction PV applications, perovskites are also attractive for developing efficient dual-junction tandem solar cells. By tuning perovskite compositions, the optical bandgaps of perovskites can be adjusted over a wide range (e.g., 1.2 eV to 1.8 eV) with demonstrated high efficiency levels (e.g., >20%), making perovskites suitable for a variety of tandem configurations. In this talk, I will discuss our recent progress on suppressing defects in perovskites with a wide range of perovskite compositions. I will present a few strategies on surface engineering and growth control to improve device stability under operational conditions. These strategies are effective for suppressing defect formation, improving bulk and surface morphology, and minimizing ion migration in mixed halide perovskites. The physical and optoelectronic properties of perovskites can be affected by controlling the precursor chemistry and growth conditions. In addition, I will discuss our recent progress toward understanding the link between indoor and outdoor PSC degradation behaviours. To push perovskite PV toward commercialization, it is critical to understand device reliability under real-world outdoor conditions where multiple stress factors (e.g., light, heat, humidity) coexist. Understanding the link between indoor and outdoor behaviors is necessary to help identify accelerated indoor testing protocols to quickly guide perovskite PV development.

Continued Progress Toward the Development of High-Performance III-V/Si Tandem Solar Cells

Tyler J. Grassman[1], Lauren M. Kaliszewski[1], Tal Kasher[1], Marzieh Baan[1], Jacob T. Boyer[1,2] and Steven A. Ringel[1]; [1]The Ohio State University, United States; [2]Hughes Research Lab, United States

The monolithic, epitaxial integration of III-V compound semiconductor materials and devices with Si substrates and devices has been a 'holy grail' of (opto)electronics materials research for decades, especially in the area III-V/Si multijunction ("tandem") solar cells. Such an architecture holds the potential to deliver high conversion efficiencies on par with pure III-V multijunction structures, with application to reliable power generation in both terrestrial and certain (aero)space use cases, but at a fraction of the cost. One of the most promising approaches to this end is via direct heteroepitaxial GaP/Si integration, enabling the use of active Si subcells and bandgap/lattice constant engineering for target III-V devices via compositional (metamorphic) grading over $GaAs_yP_{1-y}$ *(or, potentially,* $Ga_{1-x}In_xP$*). Despite decades of effort, the current certified AM1.5G records for such cells remain relatively low: 23.4% for a* $GaAs_{0.75}P_{0.25}$*/Si dual-junction (or 25% for uncertified, small-area) and 25.9% for a GaInP/GaAs/Si triple-junction. However, work from the author's group and others around the world focused toward refining the metamorphic III-V/Si platform material quality — specifically with respect to the development of heteroepitaxial processes and growth structures enabling threading dislocation densities as low as* 2×10^6 cm^{-2}*, as well as device design approaches for optimal performance at these achievable defect densities, and characterization methods that have proven essential for both — have brought the 30% AM1.5G "threshold" within sight. To this end, we will discuss recent and ongoing work from our group that has produced 20%* $GaAs_{0.75}P_{0.25}$ *top cells and associated high-performance tunnel junctions that, when combined with state-of-the-art Si bottom cells, will substantially shrink this important performance gap.*

4:00 PM EN07.03.02

Development of High-Efficiency Si Tandem Solar Cell Modules for Solar-Powered Vehicle Applications

Masafumi Yamaguchi[1], Tatsuya Takamoto[2], Hiroyuki Juso[2], Kyotaro Nakamura[1], Ryo Ozaki[1], Taizo Masuda[3], Takashi Mabuchi[3], Kenichi Okumura[3], Nobuaki Kojima[1] and Yoshio Ohshita[1]; [1]Toyota Technological Institute, Japan; [2]Sharp Corporation, Japan; [3]Toyota Motor Corporation, Japan

Solar-powered vehicles are very attractive for reducing CO_2 *emission and creation of new market [1]. Development of high-efficiency (> 30%) and low-cost solar cell modules is very important. Previously, the authors have reported driving test data for Toyota Prius and Nissan eNV 200 demonstration cars installed with Sharp's high-efficiency III-V 3-junction solar cell modules with a module efficiency of more than 30% and have demonstrated longer driving range of 26 km/day average (at solar irradiation of* $4kWh/m^2/day$*) compared to 16 km/day average for Sono Motors Sion installed with Si back contact solar cell modules with a module efficiency of 21%. However, cost reduction of multi-junction (MJ) solar cells is necessary for solar-powered vehicle applications. Development of Si tandem solar cells [2] such as III-V/Si and perovskite/Si tandem solar cells is very promising for cost reduction in addition to high-efficiency.*

This paper presents chronological efficiency improvements of the Si tandem solar cells and modules including our new world record efficiency (33.7%) InGaP/GaAs/Si 3-junction tandem solar cell module with an area of $775cm^2$ *[3]. The Si 3-junction tandem solar cell modules with an efficiency of more than 35% are shown to have driving distance potential of more than 30 km/day average and more than 50 km/day on a clear day [1]. Toward 35% module efficiency Si tandem solar cell modules, efficiency potential of various Si tandem solar cells was analyzed by using measure of external radiative efficiency (ERE) [4]. The authors have defined bandgap energy Eg dependence of* $\triangle V_{oc,rad}$ *(* $= E_g/q - V_{oc,rad}$*) for radiative open-circuit voltage* $V_{oc,rad}$ *relative to* E_g/q *as* $\triangle V_{oc,rad}$

[V] = 0.1836 + 0.0671 Eg [eV] for Si and III-V compounds and △Voc,rad [V] = 0.1708 + 0.0671 Eg [eV] for perovskite [5].
Practically feasible efficiencies of Si tandem solar cells estimated by assuming ERE of 20%, optical loss of 5% and resistance loss of 2% are 37.6% and 43.4% for 2-junction and 3-junction Si tandem solar cells, respectively. Because 3-junction tandem solar cells have higher potential efficiency by about 6% compared to 2-junction tandem solar cells, development of high-efficiency perovskite based 3-junction solar cells is suggested to be very attractive. Because optimum bandgap energy combination [6] of Si tandem solar cells is 1.73 eV/Si and 2.01 eV/1.50 eV/Si, optimization of bandgap energy for perovskite/Si tandem solar cells is necessary. Differences of non-radiative recombination loss in III-V compounds and perovskite materials are also discussed in this paper. Potential of driving distance of solar-powered vehicles installed with current various solar cell modules including our world record efficiency III-V/Si 3-junction solar cell module was estimated based on test driving data [1]. The III-V/Si 3-junction tandem solar cell modules show great potential of solar-powered vehicle applications.

Impact of Annealing of $BaSnO_3$ in Forming Gas on Its Optoelectronic Properties *Prahlad Prajapat, Sushobhita Chawla and Balasubramaniam Kavaipatti; Indian Institute of Technology Bombay, India*

Annealing of $BaSnO_3$ single crystals and films in inert and reducing atmospheres, such as Ar, N_2, and H_2S, has been proven to enhance their optoelectronic properties due to altering the thermodynamic feasibility of oxygen vacancy

formation and incorporation of foreign elements. However, the impact of annealing on the thermodynamic feasibility of oxygen vacancy defects and extrinsic defects (due to the presence of foreign elements) in polycrystalline $BaSnO_3$ *has yet to be explored.*
This work $BaSnO_3$ *pellets synthesized by solid-state reaction, annealed in the temperature range 600 °C to 1000 °C, for varying durations from 10 minutes to 12 hours, under air, vacuum, Ar, and forming gas. In all the samples, the O1s spectra, as investigated by XPS analysis, show peaks corresponding to the oxygen lattice site (*O_L*) and oxygen vacancy (*O_V*). All pellets exhibit conductivity regardless of the annealing environment. However, a significant difference is seen in the pellets annealed in forming gas: they show enhanced conductivity and turn black. This colour change is not due to free charge carrier absorption, as confirmed by UV-DRS analysis of samples from all annealing environments. We investigate the reason behind this phenomenon. While the formation of Sn along with the* $BaSnO_3$ *phase is already reported during annealing in forming gas above 900 °C, it is suggested that the presence of hydrogen, evidenced by CHNS elemental analysis, might play a role before 900 °C. Hydrogen is most probably incorporated in the interstitial sites of the* $BaSnO_3$ *lattice. The H-interstitial is compensated by conduction band electrons.*
The study investigates the interplay of defects and their effects on optoelectronic properties through comprehensive optical characterization using UV-DRS and electrical characterization via variable temperature Hall measurements.

EN07.04.03

Influence of PSS on Carrier Lifetime in Crystalline Silicon *Kengo Yamanaka[1], Yasuyoshi Kurokawa[2], Masashi Kato[1], Tetsuo Soga[1] and Shinya Kato[1]; [1]Nagoya Institute of Technology, Japan; [2]Graduate School of Engineering, Nagoya Univercity, Japan*

The fabrication process of crystalline silicon solar cells often involves high-vacuum and high-temperature processes for the formation of p-n junctions and anti-reflection coatings, which increases the process costs. Considering this, our study focuses on using PEDOT with a low refractive index to form the p-n junction and anti-reflection coatings under non-vacuum and low-temperature conditions. Although conventional PEDOT:PSS (PH1000) possesses high conductivity, silicon heterojunction (SHJ) solar cells using PEDOT have been reported to perform poorly compared to conventional SHJ solar cells using hydrogenated amorphous silicon. Previous studies have shown that PSS thin films exhibit excellent passivation effects on the silicon interface. Based on this prior research, we investigated the impact of the PSS content in PEDOT:PSS on the carrier lifetime. Two types of PEDOT:PSS (PH1000 and G1) with varying ratios of PEDOT to PSS, and a PSS solution were mixed with 10% ethylene glycol and a small amount of Triton. This mixture was stirred at room temperature, 500 rpm, for approximately 24 hours using a magnetic stirrer. Following this, a silicon substrate (n-type, 260-300 μm, 1-5 Ω ·cm) with the oxide layer removed by hydrofluoric acid was coated with the PEDOT film and PSS thin film using the spin-coating method. The carrier lifetime was measured using the μ-PCD (Microwave Photo Conductivity Decay) method. The ratio of PEDOT to PSS is 1:2.5 for PH1000 and 1:3 for G1. The results showed that the sample using G1 with a higher PSS ratio exhibited higher carrier lifetime compared to that using conventional PH1000, indicating the G1 with higher PSS ratio has a higher passivation effect. This improvement is attributed to the structural changes in PEDOT due to the increased PSS content, which enhances its adsorption onto the silicon interface. Acknowledgments: PEDOT:PSS (G1) was provided by Shin-Etsu Polymer Co., Ltd. References [1] J. Chen et al. Appl. Phys. Lett. 110 (2017) 083904.

EN07.04.04

Diminished Angular Dependency of Crystalline Silicon Microwire Solar Cells Through Broadband Antireflection Using Transparent Spheres *Youri Lee[1], Kangmin Lee[2] and Kwanyong Seo[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States*

Efficiently capturing incident light while minimizing surface reflection is the first step to ensuring high power conversion efficiency (PCE) in solar cells. However, since the position of the sun changes depending on the season and time of day, the light absorption of the solar cell is not constant. The amount of light absorbed by a solar cell decreases as the angle of incidence of light increases. Therefore, it is necessary to minimize the light absorption loss induced by the increase in the angle of light incidence to maximize solar power generation. In this study, we employed microwire structures not only to maximize light absorption but also to minimize light absorption loss according to the angle of light incidence. Additionally, we added transparent light-scattering silica beads between the microwires to further minimize light absorption loss according to the angle of incidence of light. As a result, we confirmed that the PCE of the solar cell without the structure decreased by over 55% when the incident angle of light changed from 0 to 60°, whereas the PCE of the solar cells with microwires and silica beads in between decreased by less than 35%. This work provides a novel strategy to reduce the angular dependence of PCE degradation of the solar cells.

EN07.04.05

Molecular Engineering of Self-Assembled Monolayers for Inverted Wide-Bandgap Perovskite Solar Cells and Perovskite-Silicon Tandem Solar Cells *Gwisu Kim and Sang Il Seok; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Minimizing interfacial defect states is crucial in perovskite photovoltaics, especially considering the layered structure of perovskite solar cells. Self-assembled monolayers (SAMs) exhibit impressive optoelectrical properties by passivating defect states at the substrate or the perovskite bottom surface. However, non-uniform SAM formation results in unpredictable interfacial properties between the SAM and the perovskite layer. Here, we improve the quality of the buried interface between the SAM and perovskite through molecular engineering of the SAM solution. The introduction of the Lewis base molecule, 1-acetylguanidine (AG), in the SAM film facilitates the formation of highly ordered SAM molecules on the substrate via mixed interactions of ionic and hydrogen bonding. In addition, the SAM film with AG shows a strong interaction with undercoordinated lead ions at the perovskite bottom surface, effectively suppressing interfacial recombination losses and improving energy-level alignment due to change in work function. With the ordered SAM molecules and minimized buried interface defects, we achieve impressive power conversion efficiencies of 22.54% and 21.19% for active areas of 0.096 cm^2 and 1.00 cm^2, respectively, with an open-circuit voltage (V_{oc}) of 1.27 V in wide-bandgap perovskite solar cells. Furthermore, when combining the molecularly engineered SAM with silicon bottom solar cells, we achieve a PCE of 29.90% (1.00 cm^2), while retaining over 80% of the initial PCE after over 500 hours of operation.

EN07.04.06

Modification of Sub-Micron Pyramid Texturing on Crystalline Silicon for Tandem Solar Cells *Sol-I Bae and Kwanyong Seo; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Crystalline silicon (c-Si) solar cells, due to their suitable bandgap of 1.1 eV, high open circuit voltage of up to 750 mV, and mature technology, are considered the leading candidate for the bottom cell in tandem configurations. However, c-Si bottom cells often exhibit lower current density than high band-gap top cells, such as perovskite and organic solar cells, which significantly reduces overall efficiency due to current mismatch.

To overcome this intrinsic drawback, surface texturing technology, particularly pyramid texturing, can be employed. Pyramid texturing is a commonly used method to improve the current density of c-Si solar cells. This technique typically utilizes pyramids with sizes of 3 to 5 µm. However, this structure is difficult to stack due to the thickness of emerging thin-film solar cells produced by solution fabrication processes, which is much lower than *the 3-5 μm pyramid structure.*

Since most thin-film based top solar cells for tandems are fabricated through solution processes, stacking these top cells requires c-Si surface structures with moderate heights of less than 1 μm. In this study, we investigated the optimal structure size through simulation, aiming for low reflectance on the front surface of c-Si solar cells while accommodating the integration of top cells. By adjusting key factors of the surface texturing process—such as etchant concentration, etching time, etching temperature, and additives—we modified the size and uniformity of the pyramid structures on the silicon surface.

The resulting pyramid structures exhibited a uniform height of 1.0-1.3 μm, lower than the conventional 3-5 μm height, and achieved a reflectance of 12.5%, which was significantly lower than the 44.9% reflectance of planar silicon surfaces. This outcome demonstrates the feasibility of producing structures that can be covered by the thickness of solution-processed top cells, highlighting the potential for efficiency enhancement in c-Si-based tandem solar cells.

EN07.04.07

Influence of Light Incidence Angle and Polarization on the Performance of Perovskite Solar Cells with Nanostructured Protective Glass Layer

Muhammad N. Al Farisi, Alip Kurniawan and Poetro Sambegoro; Bandung Institute of Technology, Indonesia

Perovskite solar cells (PSCs) are considered viable alternatives to traditional silicon solar cells because they are cost-effective while potentially offering high performance. However, their stability and toxicity remain issues. A conductive glass layer is commonly used to safeguard the PSCs from moisture and other elements while also serving as a transparent electrode. The glass protecting layer can also improve the cell's efficiency via light-trapping if nanostructures are implemented on top of the layer. Our research evaluated the possibility of using different nanostructure designs—planar, nanocone, nanopyramid, nanotube, and nanorod—on the glass protecting layer of a methylammonium lead iodide ($MAPbI_3$) solar cell under various lighting conditions induced by the Sun's movement and its randomly polarized nature. The absorptivity of each design was simulated in a three-dimensional domain. For all nanostructures, we varied the zenith angle from 0° to 89°, and for the nanopyramid structure, we also varied the azimuth angle from 0° to 45° to simulate different lighting conditions due to the Sun's movement. Additionally, the light was polarized in the s- and p- directions for each incidence angle. The study reveals that all studied nanostructured PSC models have a lower dependency on zenith angles compared to the planar model, with the nanocone, nanotube, and nanorod designs absorbing on average 5.42%, 4.22%, and 3.81% more light, respectively than the planar model. The nanopyramid structure also shows low zenith angle dependency but is highly dependent on the azimuth angle, absorbing approximately 56% less light than the planar design at 89° zenith and 30° azimuth angles. We also calculated the daily absorbed irradiation for each PSC model based on the Sun's position at the equator on the vernal equinox by integrating the hourly absorbed irradiation. The results indicate that the nanocone design achieves the highest increase in daily absorbed irradiation, about 3.80% more than the planar model.

EN07.04.08

Towards Commercialisation with Lightweight, Flexible Perovskite Solar Cells for Residential Photovoltaics

Philippe J. Holzhey[1,2], Michael Prettl[3], Silvia Collavini[4], Nathan Chang[5] and Michael Saliba[6,7]; [1]Adolph Merkel Institute, Switzerland; [2]Helmholtz-Zentrum Berlin, Germany; [3]Vrije Universiteit, Netherlands; [4]San Sebastian, Spain; [5]University of New South Wales, Australia; [6]Universität Stuttgart, Germany; [7]Forschungszentrum Juelich GmbH, Germany

Metal-halide perovskites have emerged as a promising class of next-generation solar cells. Here, we assess what lifetimes and efficiencies perovskite solar cells (PSCs) have to reach to lower the price of commercial residential photovoltaic (PV) further. We find that using light and flexible substrates, as opposed to heavy and rigid ones, reduces the total installed system cost of PSCs. The flexibility and lighter weight culminate in a lower balance of systems (BOS) cost, as it is possible to use different mounting methods. Concretely, we analyse the scenario when the modules are directly stuck onto a roof without requiring a racking. That reduces both labour and material costs. This effectively lowers the necessary efficiency or lifetime of PSCs (T80 value) required to achieve the same electricity cost as commercialised silicon. We find that a rigid perovskite module with 17% efficiency would need at least 24 years to be competitive with residential-installed silicon. In comparison, a light, flexible module with the same efficiency would only need to last 19 years. We find that flexible PSCs present a most promising commercialisation route because they can enable low manufacturing and BOS deployment costs, which opens up commercial viability at lower efficiencies or lifetimes. Finally, we extend our analysis toward tandem structures with perovskite-silicon or all-perovskite tandem architectures. (1)

P. Holzhey et al., Toward commercialization with lightweight, flexible perovskite solar cells for residential photovoltaics, Joule (2023), https://doi.org/10.1016/j.joule.2022.12.01

EN07.04.09

The Working Principle of Integrated Perovskite-Organic Solar Cells *Kai O. Brinkmann[1,2], Pang Wang[1,2], Sven Opitz[1,2], Nikhil Fulabhai[3], Seren D. Oez[4], Felix Lang[5], Selina Olthof[4], Martin Stolterfoht[3] and Thomas Riedl[1,2]; [1]Bergische Universitat Wuppertal, Germany; [2]Wuppertal Center for Smart Materials and Systems, Germany; [3]The Chinese University of Hong Kong, Hong Kong; [4]University of Cologne, Germany; [5]University of Potsdam, Germany*

In recent years multi-junction devices comprising perovskite and organic solar cells gained increasing interest, as a potentially more stable alternative to all-perovskite devices.[1,2] In parallel with the rise of perovskite-organic tandem solar cells, so called “integrated” perovskite-organic solar cells have garnered interest in the community with reported efficiencies exceeding 24%.[3] In this type of devices, the organic bulk-heterojunction (BHJ) is directly processed on top of the perovskite wide-gap cell without any charge transport or interconnecting layers in between. While the principle of operation for tandem solar cells is well-known and widely accepted, there is still a lack of sound fundamental understanding of how these integrated perovskite-organic devices work. Although the J-V characteristics often exhibit a strong s-shape, numerous studies have reported an extension of the external quantum efficiency into the near infrared by adding a BHJ on top of the perovskite absorber. Indeed, these integrated devices seem to operate inversely to a serially connected tandem solar cell, as instead of the voltage, the current is added, which somewhat contradicts the intuitive understanding of how a tandem solar cell with sub-cells connected in series would behave and seemingly violates some very basic rules of thermodynamics. For a direct comparison we fabricated perovskite-organic tandems as well as integrated cells with the similar choice of perovskite and BHJ and similarly reproduced the fundamentally different behaviours of both concepts.

In this work, we provide for the first time a conclusive description of the working mechanism of integrated perovskite-organic solar cells. In stark contrast to real tandem solar cells, where the sub-cells are connected in series, we reveal that integrated devices comprise two solar cells connected in parallel. We introduce a simple equivalent circuit model that includes the parallel connection and an extraction barrier at the interface between the narrow-gap absorber and the wide-gap perovskite, to account for the offset between the narrow- and wide-gap absorber energy gap. Our model is able to not only reproduce the characteristics of devices built in our lab almost ideally but it can also explain multiple reports from the literature. After validation through subcell-selective characterization, photoelectron spectroscopy, and complementary drift-diffusion simulations, we use our model to evaluate the general prospects of integrated devices.

We demonstrate that the extraction barrier present in the organic subcell is crucial for the functionality of the device. Reducing this barrier, aside from being thermodynamically questionable, would deteriorate the performance of the integrated device. Finally, we conclude that integrated devices most likely do not share the prospects of tandem devices to overcome the detailed-balance limit. Instead, integrated devices should be considered single-junction devices that may benefit from enhanced passivation, charge extraction, and transport through the bulk-heterojunction processed on top.

Controlling Passivation Quality of Tunnel Oxide Layers via Thermal Oxidation with Gas Flow Control for High-Efficiency TOPCon Solar Cells

Yire Han and Kwanyong Seo; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Tunnel Oxide Passivated Contact (TOPCon) solar cells have gained much attention due to their high open-circuit voltage (V_{oc}) resulting from the superior passivation performance of the tunnel oxide layer compared to conventional crystalline silicon solar cells such as PERC or PERT. The passivation quality of the tunnel oxide layer is determined by its thickness and uniformity, which significantly affect the Voc value due to the trade-off between photo-induced charge collection and surface passivation. Chemical oxidation using nitric acid (HNO_3) introduces unintended nitrogen atoms into the tunnel oxide layer, deteriorating its passivation quality. In this study, we formed high-quality tunnel oxide layers using thermal oxidation by systematically adjusting the oxygen and nitrogen gas flow. By adjusting the gas flow ratio, the thickness uniformity of the tunnel oxide layer was improved from ±0.7 nm to ±0.2 nm on a 4-inch wafer scale, as analyzed by ellipsometry mapping. At an optimized thickness of 1.3 nm, the tunnel oxide layer exhibited a resistance of 10 mohm cm, an implied Voc of 734 mV, and a lifetime of 2 ms. This study verifies that the method of forming tunnel oxide layers using gas flow control can produce high-quality, large-area ultrathin silicon oxide (SiO_x) layers in TOPCon solar cells.

All Oxide Lead-Free Bismuth Ferrite Perovskite Absorber Based FTO/ZnO/$BiFeO_3$/Au Solar Cell with Efficiency ~ 12%:—First Principle Material and Macroscopic Device Simulation Studies with Experimental Realization

Priyambada Sahoo; Indian Institute of Technology Jodhpur, India

The current study depicts the photovoltaic performance of interesting low band gap multiferroic Bismuth Ferrite (BiFeO3) absorber material in all oxide solar cells configured as FTO/ZnO/BiFeO3/Au. The optoelectronic and macroscopic device simulations have been carried out using density functional theory (DFT) and solar cell capacitance simulator (SCAPS-1D) software. The DFT study on $BiFeO_3$ is calculated while considering the Hubbard parameter. The Hubbard parameters are implemented for Fe-3d and O-2p orbitals, and the obtained bandgap (~ 2.5 eV) matches the experimentally obtained value. Hence, the parameters obtained from the electronic and optical calculations are implemented in macroscopic simulation to study FTO/ZnO/$BiFeO_3$/Au solar cell performance. The impact of variation of various parameters associated with the thickness, donor-acceptor carrier concentration, interface defect, electron affinity, series-shunt resistance and metal work function of the absorber layer, electron transport layer and metal contacts on the solar cell's performance are investigated under realistic conditions. An optimized efficiency of 11.92 % is obtained with a maximum 1.033 V open circuit voltage, 15.27 mA/cm^2 short circuit current density and 75.59 % fill factor obtained after full optimization. This study on Bismuth

ferrite-based absorber materials will open an alternative road to the toxic lead-based solar cell absorber material. Hence, the obtained theoretical simulation is verified through experimental realization with the fabrication of FTO/ZnO/BiFeO3/metal contact solar cell, while structural, optical, and electrical characterization are carried out in the BiFeO3 thin film geometry to correlate the theoretical and experimental output.

Interfacial Passivation Using 2D Perovskite for an Efficient and Stable Wide-Bandgap Perovskite Solar Cells

Deeksha Gupta, Laxmi Choudhary, Johns Aji and Dinesh Kabra; Indian Institute of Technology Bombay, India

The three-dimensional/two-dimensional (3D/2D) heterostructure recently emerged as a fascinating approach for making efficient, scalable, and stable perovskite solar cells (PSCs). The 2D capping layer is crucial in perovskite/electron transport layer (ETL) interfacial passivation and in inhibiting environmental stress [1,2,3].
In this work, we demonstrate a novel solution process to tailor the dimensionality (n) of the 2D perovskite at the 3D perovskite/ETL interface of p-i-n device architecture by tuning the molar concentration of 2D perovskite precursor. We optimized the molarity of 2D precursor by varying its concentration and found that 10 mM is the optimum concentration on top of wide bandgap (WBG) 3D perovskite layer ($FA_{0.83}Cs_{0.17}Pb(I_{0.8}Br_{0.2})_3$, 1.67 eV). However, further increase in concentrations (> 10 mM) led to the formation of mixed phases (n=2, 3, 4) of 2D perovskite as confirmed by X-ray diffraction (XRD) and steady-state photoluminescence (SSPL) measurements. Furthermore, transient photovoltage/photocurrent and fluorescence decay experiments reveal that an optimized 3D/2D heterostructure enables efficient passivation of perovskite surface defects, prolongs carrier lifetime, retard non-radiative interfacial recombination, and forms better energy level matching with ETL.
The optimized 2D modified wide-bandgap PSCs demonstrate an average power conversion efficiency (PCE) of ~20.75% (0.175 cm^2) and ~18.43 % (0.805 cm^2) and an open-circuit voltage (V_{oc}) of ~1.21 V in a p-i-n architecture. Furthermore, the unencapsulated devices exhibit excellent air (RH ~ 55-60%) and heat (85°C) stability by retaining 98% and 82% of their initial efficiency after 800 hours respectively.

Enhancing Light Absorption in Photoactive Layer of Organic Solar Cells Using Plasmonic Copper Nanorods

Thapelo E. Seimela, Nolwazi Nombona and Mmantsae M. Diale; University of Pretoria, South Africa

Bulk-heterojunction organic solar cells have gained much interest due to low cost and large-scale fabrication. However, their power conversion efficiency (PCE) suffers from charge recombination, limiting commercialization. In this study, the plasmonic resonance of colloidal copper nanorods (CuNRs) have been employed to enhance light absorption inside phenyl-C_{60}-butyric acid methyl ester: poly(3-hexylthiophene) (P3HT:PCBM). The CuNRs with diameter of 20.60 ± 0.54 nm and length of 57.81 ± 1.5 nm induced transverse and longitudinal absorption peaks at 450 and 680 nm respectively inside P3HT:PCBM. The peaks intensify with increase in concentration of CuNRs. The incorporation of CuNRs improved the PCE of a ITO/PEDOT:PSS/P3HT:PCBM:CuNRs/Ag device by 3,78%. CuNRs in P3HT:PCBM has the potential to improve power conversion efficiency of organic solar cells by inducing plasmonic *resonance.*

ALD-Deposited SiO_2 Layers on Germanium Substrates—Material Characterization and Surface Passivation Properties

Gerard Rivera Vila[1], Mansur Gamel[1], Gema Lopez[1], Moisés Garín[2] and Isidro Martín[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Universitat de Vic, Universitat Central de Cataluny, Spain

Thermally grown silicon dioxide (SiO_2) is one of the key surface passivating materials utilized for research scale silicon photovoltaic devices [1]. However, there is a need for alternative deposition methods when using other substrates rather than silicon. Atomic-Layer Deposition (ALD) is a versatile thin film deposition technique which enables the deposition of highly uniform and compact films at relatively low temperatures (100-200C). Herein, we report the material characterization of ALD-deposited SiO_2 films applied to the surface passivation of crystalline germanium (c-Ge) substrates. This material has been used as bottom cell in multijunction devices [2] and, recently, it has also been identified as a cost-effective candidate for thermophotovoltaic devices where IR photons from a thermal emitter are transformed into electrical energy [3-4].

The ALD deposition is based on the sequential pulsing of 3-aminopropyltriethoxysilane (APTES), water and ozone [5]. We characterized the layer by depositing 40 nm on 1.2 Ω.cm p-type c-Ge substrates at three different deposition temperatures (150, 175, and 200C).

Firstly, the chemical composition of the deposited films was examined using x-ray photoelectron spectroscopy (XPS) leading to almost stoichiometric films for all three deposition temperatures. Additionally, the optical properties of the film were characterized in the IR region by infrared spectroscopic ellipsometry. The measurements provided the refractive index and extinction coefficient along the 5 – 25 µm wavelength range. Although all the results are very close together, the SiO_2 layer deposited at 200C is the closest one to the optical properties of thermal oxide.

The electrical properties of the films were characterized through a metal-semiconductor-oxide structure. Current-voltage (I-V) characteristics show a decrease in leakage current when deposition temperature increases, indicating that more compact layers are obtained at 200C. Additionally, we measured capacitance-voltage (C-V) curves, revealing the presence of a slightly positive fixed charge density in the layers.

From the different characterization techniques, we can confirm that high-quality SiO_2 films were obtained via ALD, with an optimum deposition temperature of 200C. Currently, we are testing the passivating properties of these films on c-Ge(p) by two different approaches: 40 nm SiO_2 films and a ~1nm SiO_2 film capped with 50 nm ALD-deposited Al_2O_3 films, where the SiO_2 layer works as an interface layer between the c-Ge(p) and the Al_2O_3. Special attention is paid to the exploration of a post-deposition anneal to activate the fixed charge density present in the layers, which has a crucial impact on field-effect passivation. Preliminary results show surface recombination velocities as low as 38 cm/s, improving the values obtained by single Al_2O_3 films and comparable to the ones reported in the literature [6]. A detailed description of the results will be reported at the conference.

Ligand-Assisted Bulk and Interfacial Modification of Inverted Perovskite Solar Cell for Improved Stability

Prashant Kumar[1,2], Wenzhan Xu[1], Wenhao Shao[1], Yuanhao Tang[1] and Letian Dou[1,1]; [1]Purdue University, United States; [2]Central University of Jharkhand, India

Perovskite-based photovoltaic technology is the most prominent and sustainable solution to cater to accelerated energy demand. For commercialization, the benchmark golden triangle criteria of cost-effectiveness, stability, and power conversion efficiency must suffice. Until now, the material has fulfilled the criteria of cost-effectiveness and efficiency but is hindered by the limitations posed due to device instability when compared to its rival counterpart, silicon solar cell technology. Herein, in this work, we have incorporated T-FA-HI ligands in bulk to improve inverted perovskite solar cell performance, mainly stability. With 1 mol % of T-FA-HI in the perovskite solution, the device's stability increased significantly compared to control devices. The device retained an efficiency of up to 85% upon light illumination for 1000 hours. The T-FA-HI ligand showed 90 % retention of the photoconversion efficiency when kept at 85 degrees C for 500 hours. The impressive performance achieved on devices with T-FA-HI ligand is attributed to the shorter chain with thiophene in the molecular structure as it accelerates the charge transportation process. In addition, it suppresses non-radiative recombination and passivates defects in the perovskites.

EN07.04.16

Improving Thickness Independence Through Counter-Anion Size Engineering in Polyfluorene-Based Cathode Interlayers

Jeongsu Kim, Yurim Bae and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)

In organic photovoltaics and tandem devices, poly [(9,9-bis(3'-(N,N-dimethylamino) propyl)-2,7-fluorene)-alt-2,7-(9,9-ioctylfluorene)] (PFN) is commonly used as a cathode interlayer material (CIM) due to its alcohol solubility. However, the representative PFN-based CIM, PFN-Br, exhibits limitations in scalability due to significant variations in efficiency with changes in cathode interlayer thickness. To improve the thickness tolerance of the cathode interlayer, we propose a simple substitution of the anion from Br^- to $TFSI^-$. PFN-TFSI, containing the bulkier counter anion (7.9 Å), disrupts interchain interactions, resulting in an amorphous property. Devices employing PFN-TFSI maintain 90% of their initial efficiency when the cathode interlayer thickness is increased from 5 to 15 nm, with consistent efficiency across the device area. Moreover, PFN-TFSI facilitates uniform film formation, even on large surfaces up to 25 cm2. This study demonstrates the potential of PFN-TFSI for scalable device applications.

EN07.04.17

A Two-Step Processed Dion-Jacobson Perovskite for Enhancement of Solar Cell Efficiency and Stability

Mi Hee Jung; Sejong University, Korea (the Republic of)

In this work, we demonstrate that the HTI (HTI = histammonium iodide) dication was incorpoarated into the PbI_2 precursor solution to induce the preferred vertical orientation of the 2D Dion-Jacobson (DJ) perovskite film using a two-step deposition. 2D DJ (HTI) $(FA)_x(MA)_{1-x}Pb_nI_{3n+1}$ (FA = formamidinium, MA = methylammonium) films show a significantly improved film quality with enlarged grain sizes and vertical oriented to the substrate. Moreover, peovskite films parepared from the HTI embeded PbI_2 layer also exhibit greatly reduced film decomposition from oxygen and humidity in ambient air condition. As a result, the champion device shows a high power conversion

efficiency (PCE) of 13.06%, in contrast to 7.98 % for 3D $(FA)_x(MA)_{1-x}PbI_3$ perovskite device without HTI dication. The 2D DJ (HTI) $(FA)_x(MA)_{1-x}Pb_nI_{3n+1}$ devices show enhanced stability, maintaining 72% of its initial power conversion efficiency (PCE) after 2000 h in ambient air condition (relative humidity 35 ~ 50%). However, the 3D $(FA)_x(MA)_{1-x}PbI_3$ perovskite device dropped to 24% of its PCE within 2000 h. Our results suggest that the precursor engineering containing 2D perovskite organic spacer in two-step process is a potential approach toward to further improve the PCE and stability of 2D DJ perovskite solar cell.

EN07.04.18

Stable and Efficient Photo-Rechargeable Batteries Using Ruddlesden-Popper Perovskite-MoS_2 Hybrid Heterojunction

Rashid Malik Ansari and Shahab Ahmad; Indian Institute of Technology Jodhpur, India

To minimize energy poverty at remote locations and run autonomous devices like IoT and smart city products, sustainable off-grid power solutions are required. Photo rechargeable batteries (PRBs) combine energy harvesting and energy storage technologies into a single device that offer a compact energy solution.[1,2] We have shown a hybrid heterojunction based on $(BA)_2(MA)_3Pb_4I_{13}$ and MoS_2 nanoflakes for efficient Li-PRB application. Where BA and MA stand for $CH_3(CH_2)_3NH_3^+$ and $CH_3NH_3^+$ respectively. The presence of MoS_2 in RP perovskite precursor solution triggered heterogeneous nucleation which results in the formation of heterojunction of type II. Such nucleation cause to improve structural, morphological, optical, optoelectronic, and ultimately photoelectrochemical properties of RP perovskite. The hybrid photodetector has shown 9.7 μAcm^{-2} transient photocurrent density at 0.0 V bias under Xe-lamp illumination (1 Sun) which are ~16 times higher as compared to its pristine material-based photodetector due to efficient extraction of electrons from perovskite to MoS_2.[3] Such enhanced transient photocurrent density is beneficial to improve the photo conversion and storage efficiency (PC-SE) of hybrid Li-PRBs. Hybrid Li-PRB have demonstrated an average discharge specific capacities for three cycles from 128.66 $mAhg^{-1}$ to 180.67 $mAhg^{-1}$ (photo-enhanced: 40.42 %) at 64 mAg^{-1}, from 103.76 $mAhg^{-1}$ to 138.27 $mAhg^{-1}$ (photo-enhanced: 33.27 %) at 70 mAg^{-1} under white LED illumination. The demonstrated Li-PRB is photo-charged to 1.3 V under 1 Sun illumination within ~ 1.63 hours and has shown PC-SE of ~0.52 % which outperforms other metal halide perovskite based PRBs.[4] Finally, the scalability of these low-temperature solution processed hybrid photocathodes is demonstrated by fabricating a photo-battery module, comprising of three Li-PRB cells, which is operated between 5.00 V to 0.02 V at 68 mAg^{-1} and shown photo-enhanced discharge time of ~ 74 %. The MoS_2 nanoflakes and RP perovskites based heterostructures based photoelectrodes can offer new avenues for the development of efficient and scalable photo-batteries.

EN07.04.19

Transparent Metal-Oxide Photovoltaics for Energy Harvesting and Storage for Sustainable Platforms

Joondong Kim; Incheon National University, Korea (the Republic of)

A transparent photovoltaic (TPV) energy harvesting method would provide more degrees of freedom for deployment on windows, buildings, vehicles, and surfaces with less soil dependency. This study designs a TPVintegrated energy storage system (capacitor charger) as a sustainable energy platform. The TPV device comprises a metal-oxide junction with a thin Si layer to enhance light utilization across a broad spectrum. Wide-bandgap metal-oxide-based materials absorb high-energy ultraviolet (UV) photons, while the Si layer captures longer wavelength lights due to the lower bandgap. The TPV structure (FTO/NiO/p+-Si/a-Si/n+-Si/AZO/ITO) exhibits an average visible transparency of 37 % and a power conversion efficiency of 4.97 % under 405 nm UV light illumination. The excellent electrical characteristics with a short-circuit current density of 10.1 mA/cm2 and open-circuit voltage value of 0.79 V allow TPVs to serve as a power source for rapidly charging capacitor banks in the energy storage unit. This PV-linked capacitor energy system can illuminate LED lamps, suggesting an on-site sustainable energy platform. The proposed Si-embedded TPV demonstrates electric power generation across broad wavelengths, enabling the bi-directional PV utilization of sunlight and indoor light sources for energy harvesting both day and night.

EN07.04.20

Halide Vapor Phase Epitaxy of Ge from an Elemental Source *Edgard Winter da Costa[1], Megan Goh[2], Kevin Schulte[1], Matthew Young[1], John Simon[1] and Aaron Ptak[1]; [1]National Renewable Energy Laboratory, United States; [2]Amherst College, United States*

Halide vapor phase epitaxy (HVPE) shows promise for low cost III-V device manufacturing because of its high growth rates compared to other growth methods and the use of lower cost elemental precursors [1]. In HVPE, the elemental sources react in situ with anhydrous HCl to form volatile metal chloride growth species. Germanium (Ge) is one useful semiconductor material that is typically grown using $GeCl_4$ or GeH_4 but has never been grown using an elemental Ge source by flowing anhydrous HCl over Ge metal to form a volatile chloride, as is done for Ga and In in HVPE. This would be a useful advancement for HVPE growth toward the development of, for example, an epitaxial bottom junction of an inverted triple junction solar cell, which helps enable substrate reuse, or as a sacrificial layer for epitaxial lift off or controlled spalling. Also, recycled Ge substrates can be used as source material, conserving this critical material. Therefore, our goal is to develop and understand the growth of Ge from an elemental Ge source by HVPE. Thermodynamic calculations suggest the driving force for $GeCl_2$ generation from HCl and Ge is high in an inert N_2ambient, but the driving force for growth is low. In contrast, little $GeCl_2$ forms in situ from HCl and solid Ge in an H_2 carrier, although the driving force for growth from an externally injected $GeCl_x$ source is high, presenting a challenge to control the ambient in the source and deposition regions. Here, we show that it is possible to deposit Ge by generating $GeCl_2$ from solid Ge and HCl in a N_2 ambient and then supplying a source of active hydrogen locally at the substrate to drive growth.
We grew Ge at 350 Torr and 800 °C, using elemental Ge also held at 800 °C, in a N_2 ambient. The source region where the $GeCl_2$ forms is contained within a quartz boat that is physically separated from the deposition region. To achieve Ge growth, we inject hydride gases, AsH_3 and PH_3, as sources of active hydrogen, to the growth surface. We do not observe Ge growth unless a supply of active hydrogen is added to the system, consistent with thermodynamic calculations. For a given HCl(Ge) flow rate, the Ge growth rate initially increases with increasing hydride flow, but then begins to decrease. The maximum growth rate reached increases with increasing HCl(Ge), and the peak growth rate also shifts to higher hydride flow rates with higher HCl(Ge), which likely indicates a competition between growth and etching processes because AsH_3 is known to etch Ge surfaces [2]. Ge growth from a chloride likely features a kinetic barrier analogous to that observed for GaAs growth, namely the saturation of the surface with Cl atoms. We speculate that the addition of active hydrogen to the surface, in this case in the form of pyrolyzed hydrides, reduces the Cl from the surface and allows for continued Ge growth. One drawback of using group V hydrides to drive the Ge reaction is that the group Vs are dopants in Ge. We observed As or P concentrations in the Ge films, using secondary ion mass spectrometry, in the range of $4x10^{17}$ – $1x10^{18}$ atoms/cm^3,

concentrations that can drastically influence device characteristics. However, we note that there are numerous other "helper molecule" options that can provide active hydrogen without doping or etching the material. This work provides a path forward for the deposition of high-quality Ge for optoelectronic devices from an elemental source.

8:30 AM *EN07.05.01

Pathways to Efficient and Stable Perovskite/Silicon Tandem Photovoltaics *Stefaan De Wolf; King Abdullah University of Science and Technology, Saudi Arabia*

In this presentation I will discuss the multiple ways how monolithic perovskite/silicon can be fabricated, built from textured silicon heterojunction solar cells, with an emphasis on solution of the perovskite top cell. Bulk and contact passivation of the perovskite are instrumental to obtain a high performance, which can be obtained through molecular additive engineering. Combined, this led to a certified power conversion efficiency of 33.7% for a monolithic perovskite/silicon tandem solar cell. This will be followed by a discussion about the outdoor performance of such tandems and the need for robust and perovskite-compatible encapsulation to do so. I will then move on to discuss reliability aspects of such tandems under accelerated degradation tests such as damp-heat testing and reverse-bias degradation. I will conclude my talk with arguing how bifacial perovskite/silicon tandems aid in improved performance as well as stability, thanks to their reliance on narrow-bandgap perovskites for optimal performance.

9:00 AM EN07.05.02

Performance Modeling and Analysis of One-Year Outdoor Data of a 4-Terminal GaAs/Si Tandem Module

Robert Witteck, Martin Springer, William E. McMahon, John Geisz and Emily Warren; National Renewable Energy Laboratory, United States

In this study, we analyze the long-term outdoor performance of a 4-terminal mechanically stacked GaAs/Si tandem mini module deployed for over one year in Golden, Colorado, USA. Current–voltage measurements of each sub-cell were taken every five minutes, with the other sub-cell operating at its maximum power point.

We employed a set of filter criteria to select measurement points proximate to standard test conditions (STC), facilitating the extraction of corresponding diode parameters for the sub-cells. Additionally, we determined the temperature coefficients of the sub-cells from outdoor data and applied a correction factor based on precipitable water vapor to account for temperature-correlated spectral changes impacting the GaAs top cell. Utilizing these correction coefficients, we can convert unfiltered data points to STC power ratings and extract raw power *production data.*

The translated performance data revealed a dimensionless performance ratio and degradation rates for each sub-cell, determined through linear regression analysis. The analysis showed degradation rates of 4.10% per year for the GaAs top cell and 2.48% per year for the Si bottom cell. The largest degradation was observed in the short-circuit current density (J_{sc}). We investigated our module packaging after outdoor deployment and found a delamination between the front glass and encapsulant, which is likely the cause for the performance degradation.

To confirm that package degradation is the main contributor to performance decline, we simulated the outdoor performance of the module and the individual sub-cells using PVcircuit, a circuit solver for tandem cells. PVcircuit was used with all parameters held constant except for the J_{sc}, ensuring that any changes in performance could be attributed to variations in J_{sc}. The simulation results showed excellent agreement with the measured module power, suggesting that the reduction in J_{sc} could explain the observed performance degradation. This finding is consistent with the identified delamination failure mode in the module packaging, known to primarily reduce the short-circuit current. Thus, the modeling results confirm that packaging degradation is a main contributor to the observed performance decline.

Our findings indicate that III-V-on-Si technologies are suitable for extended outdoor deployment, provided that appropriate module packaging is used. This type of analysis can be extended to emerging tandem technologies, such as perovskites-on-Si. At the conference we will show detailed results on our degradation analysis and the applied modeling approach for tandems.

9:15 AM EN07.05.03
Reducing the Doping and Defect Density in Mixed Sn-Pb Halide Perovskite by SnF_2 *Jasmeen Nespoli, Maartje J. van der Meer and Tom J. Savenije; Delft University of Technology, Netherlands*

Last years mixed Sn-Pb perovskites have been applied in single- and multi-junction solar cells as absorbers with a low bandgap energy down to 1.2-1.3 eV, reaching power conversion efficiencies of 23%. However, the performance is still limited by tin oxidation resulting in p-type self-doping. To counteract doping, a plethora of additives has been explored, including SnF_2. To shed light on the functionality of this additive, we prepared mixed Sn-Pb perovskite thin films ($Cs_{0.25}FA_{0.75}Sn_{0.5}Pb_{0.5}I_3$) with varying amounts of SnF_2 ranging from 0 to 20 mol% in the spin-coating solution. The dark conductivity of corresponding thin films was analyzed via steady state microwave conductance techniques. A large decrease of more than one order of magnitude in conductivity from ~85 to <~2 S/m was observed on going from 0 to 1-2 mol% SnF_2, while no further measurable reduction occurs for higher SnF_2 concentrations. Moreover, we demonstrate that the minimum SnF_2 addition required to achieve this reduction in conductivity is not absolute but is highly dependent on the initial quality of the SnI_2 precursor. In addition, we also investigated the dynamics of laser-induced excess carriers as function of the SnF_2 concentrations using time-resolved microwave conductivity. Although the charge carrier mobility is not affected, the charge carrier lifetime progressively increases with higher SnF_2 concentrations up to 10 mol% from ~102 to ~442 ns. By fitting the laser intensity-dependent photoconductivity signals with a model, the main kinetic parameters affecting the photocarrier dynamics can be extracted. From the results we conclude that both the doping but also the defect density concomitantly decreases with increasing SnF_2, with the most prominent changes between 0 and 2 mol%. Via additional measurements of optical and opto-electronic properties we also noticed a slight reduction in the Urbach energy and optically active, shallow trap states upon SnF_2 addition. In contrast, no significant structural and/or morphological changes of the perovskite films on SnF_2 addition could be discerned. Therefore, it is inferred that only a minuscule fraction of the mixed Sn-Pb perovskite is modified by SnF_2, in contrast with the tremendous improvement in the charge carrier properties. We attribute this improvement to the fact that SnF_2 scavenges the *oxidized Sn^{4+} from the spin-coating solution, leading to reduced self-doping. To suppress doping and reduce the crystal defect density, our work underlines the importance of the quality of the SnI_2 precursor in combination with the optimal SnF_2 concentration on the perovskite opto-electronic properties.*

9:30 AM *EN07.05.04
A Perspective on Durability of Perovskite Tandem Modules *Erin M. Sanehira; CubicPV Inc., United States*

Perovskite-based tandem solar technologies hold immense promise as commercial products but must first meet stringent market requirements: durable at high efficiency. In this talk, I will discuss CubicPV's approach to developing a 4T perovskite/Si tandem product. I will also discuss our focus on durability as perovskite/Si tandem modules must withstand diverse environmental stresses such as light (including UV), heat, bias, water, and oxygen to achieve long-term reliability. While challenges related to water and oxygen can be mitigated through improved packaging designs, ensuring durability against light, heat, and bias necessitates careful material and device stack design. This presentation will delve into the critical durability challenges facing perovskite tandem technologies and propose potential pathways to overcome these obstacles effectively.

Atomic Layer Deposited (ALD) Layers and Interfaces in Perovskite-Based Photovoltaics *Mariadriana Creatore; Eindhoven University of Technology, Netherlands*

Innovation in thin film and interface engineering has played an essential role in pushing the conversion efficiency of the most widespread photovoltaic (PV) technology, i.e. crystalline silicon-based (c-Si), towards its thermodynamic limit. In this respect, ultra-thin, conformal, high-purity Al_2O_3 thin films synthesized by ALD are key in c-Si PV manufacturing industry as they passivate the c-Si surface, thereby suppressing a major channel of electron-hole pair recombination.
In the past years we have explored the ALD synthesis of thin films and interfaces in metal halide perovskite- based photovoltaics. The latter has rapidly reached a conversion efficiency of 26% and, when coupled with c-Si PV in a tandem device, leads to efficiencies already beyond 34%.
In this contribution I will discuss the merits which ALD offers to perovskite-based PV by focusing on NiO-based hole transport layers and SnO_2 buffer layers. Specifically, we have synthesized by ALD thin (< 10 nm) NiO layers which enable homogeneous anchoring of self-assembled monolayers (SAMs) for "lossless" (i.e. in terms of suppression of charge recombination) SAM/perovskite interfaces and narrow spread in conversion efficiency of perovskite [1] and tandem perovskite/c-Si devices [2]. Presently, our studies include the appropriate selection of the ALD Ni-precursor for accurate control over film stoichiometry, Ni oxidation state and layer resistivity, leading to careful engineering of NiO/(SAM)/perovskite interfaces in both wide- and narrow-band gap perovskites for all-perovskite tandem devices.
ALD SnO_2 is highly appealing because of its present implementation in perovskite PV R&D and industry as buffer

layer, i.e., imparting thermal and environmental stability to the device, while protecting the perovskite absorber and fullerene electron transport layer from the sputtering of the transparent top contact. More recently, ALD SnO_2 is explored as solvent barrier layer in the tunnel recombination junction of perovskite/perovskite tandem PV, to prevent the damage of the wide-gap perovskite absorber when processing the narrow- band gap perovskite cell. Although we can conclude that several ALD merits are already extensively acknowledged by the PV community, studies addressing ALD film growth on challenging substrates such as fullerenes and metal halide perovskites are rarely reported in literature. We are convinced that these studies provide the needed rationale to implement more efficiently these layers at device level and promote process upscaling. Therefore, this contribution will also highlight the adoption of in situ diagnostics, namely spectroscopic ellipsometry and IR spectroscopy, to characterize the ALD SnO_2 growth on two commonly adopted fullerenes, C60 and [6,6]-phenyl-C61-butyric acid methyl ester (PCBM). Our studies show that a substrate-inhibited growth occurs in the case of PCBM and, to a minor extent, in the case of C60, with respect to c-Si [3]. Moreover, IR spectroscopy highlights the loss of vibrational features of the ester group in PCBM upon SnO_2 growth, whereas C60 is chemically unaffected. We conclude that the delayed film growth and chemical modifications detected on PCBM are responsible for the consistently lower device performance when ALD SnO_2 is grown on PCBM instead of C60.

Titanium Silicide—A Promising Candidate as the Recombination Layer for Perovskite/TOPCon Tandem Solar Cells *Dowon Pyun[1], Dongjin Choi[1], Soohyun Bae[2], Sang-Won Lee[3], Hoyoung Song[1], Seok-Hyun Jeong[1], Solhee Lee[1], Jae-Keun Hwang[1], Sujin Cho[1], Myungji Woo[1], Yerin Lee[1], Kyunghwan Kim[1], Youngmin Kim[1], Youngho Choe[1], Yoonmook Kang[1], Hae-Seok Lee[1] and Donghwan Kim[1]; [1]Korea University, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of); [3]Stanford University, United States*

*To overcome the theoretical efficiency limits of single-junction solar cells, concept of multi-junction or tandem solar cells has been proposed. In tandem solar cells, two subcells with different energy bandgaps are stacked and connected in series. During the operation, two different types of carriers are transported from each subcell and recombined at the interlayer. The interlayer, which bridges two different solar cell technologies, determines the performance of tandem devices. Since the ideal open circuit voltage (V_{OC}) is equal to the sum of the V_{OC} of each subcell, recombination of carriers at the interlayer without any potential loss is required for a high-efficiency tandem device. Barrier-free interlayers can be realized using recombination layers. Especially, transparent conductive oxide (TCO) materials have been widely employed as recombination layers, attributed to their high transmittance and conductivity. However, application of TCO has following limitations: (1) sputtering damage on bottom cell and (2) scarcity of indium. Therefore, the development of TCO-free recombination layers is necessary. In this work, titanium silicide ($TiSi_2$) was proposed as recombination layer for perovskite/tunnel oxide passivated contact (TOPCon) 2-T tandem solar cells as an alternative to conventional TCO-based recombination layers for the first time. $TiSi_2$ was fabricated in two steps: (1) Ti deposition and (2) oxidation. Thin Ti layer was directly deposited on the p^+–Si and subsequently oxidized at 600 °C for 30 min in an O_2 atmosphere. Ti film was oxidized to TiO_2 (denoted as ox-TiO_2), and $TiSi_2$ was simultaneously formed at the Ti-Si interface. Diffusion was a key mechanism in the formation of $TiSi_2$ in this work. Therefore, the reaction formation mechanism was interpreted based on the diffusion theory and experimental results. The optical and electrical properties of the ox-TiO_2 and $TiSi_2$ layer were optimized, respectively, by controlling the initial Ti thickness (5~100 nm). With the initial Ti 50 nm, the lowest optical reflectance and highly ohmic contact between the TiO_2 and p^+–Si layers with a contact resistivity of 161.48 mΩ*cm^2 were obtained. In contrast, the TCO interlayer shows Schottky behavior with much higher contact*

resistivities. It is demonstrating the remarkable potential of $TiSi_2$ as recombination layer. Furthermore, as the recombination layer of $TiSi_2$ and the electron transport layer (ETL) of TiO_2 are formed simultaneously, the process steps for tandem fabrication became simpler. Finally, the $MAPbI_3$/TOPCon tandem device yielded an efficiency of 16.23%, marking the first reported efficiency for a device including silicide-based interlayer.
As a proof-of-concept stage, this work focused on analyzing the properties of $TiSi_2$ and demonstrating the $TiSi_2$-applied tandem device. Formation mechanism of $TiSi_2$ and its properties as a recombination layer were explored. Therefore, the basic structures of subcells ($MAPbI_3$ top cell without any treatment & TOPCon bottom cell without passivation layer) were combined into tandem architecture. In other words, additional optimizations of subcells are essential for improving the device efficiency further. Despite that, the efficiency exhibited in this work certainly implies that silicide-based materials are promising candidates for recombination layers in perovskite/TOPCon tandem solar cells.

11:15 AM EN07.06.03
Tailored Semiconducting Heterojunction Interlayer for Efficient Perovskite Solar Cells *Jongbeom Kim, Jaewang Park and Sang Il Seok; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

In perovskite solar cells (PSCs) with heterogeneous multi-layers, minimizing defects between layers, and aligning energy levels precisely is critical for achieving higher open-circuit voltages and fill factors. A key strategy in achieving these goals involves the introduction of a semiconducting interlayer positioned between the charge-selective layer and the perovskite light absorber, forming a heterojunction with the perovskite layer. This tailored interlayer serves to minimize energy level misalignment and defects. This study explores the notable enhancement in the power conversion efficiency (PCE) of PSCs through a customized heterojunction semiconducting interlayer that can be chemically and physically integrated with the perovskite layer. The interlayer, engineered to ensure fewer defects and harmonized energy levels, was crafted by combining methoxy-phenethylammonium iodide and cyclohexylammonium bromide onto the light-absorbing perovskite thin film. Establishing a heterojunction between the perovskite and the Fermi-level controlled semiconducting interlayer facilitated rapid charge transport and reduced defect density on the perovskite surface. Consequently, an exceptionally high PCE of 26.28% (certified 25.82 per cent) was achieved under standard AM 1.5 global illumination. Furthermore, the encapsulated device exhibits sustained initial efficiency (25.91%) of over 88% following continuous light exposure for 440 h. Impressively, it maintains 100% of its initial efficiency in ambient conditions for over one year (9,000 h). These results underscore the effectiveness of our tailored interlayer design in advancing the domain of high-performance PSCs.

SESSION EN07.07: Real World Considerations for Multijunction Devices

2:00 PM *EN07.07.02
Fundamentals and Design Considerations for Tandem Solar Cells with 2-, 3- and 4-Terminals *William E. McMahon; National Renewable Energy Laboratory, United States*

Tandem solar cells with two or more subcells can outperform single-junction solar cells, but their additional complexity brings with it additional design considerations. One high-level decision which must be made is the *number of external electrical connections to be used. Here we will discuss design decisions associated with two-junction tandem solar cells with two, three, or four terminals. The discussion will be framed in terms of 2-junction tandem solar cells (comprised of a top subcell and a bottom subcell), but the concepts are extensible to tandem solar cells with more junctions.*

In a 4-terminal tandem solar cell, each subcell (top and bottom) has two contacts such that power from each is collected independently. In a 2-terminal tandem, the subcells are series-connected such that the same current passes through both subcells (I_top = I_bottom). In a 3-terminal tandem, the third terminal collects any excess current from between the subcells, thereby eliminating any current-matching constraints. Instead, a 3-terminal tandem is typically constrained by module circuitry to operate in a voltage-matched configuration with V_top/V_bottom = m/n, where m and n are integers.

In principle, a 4-terminal tandem should maximize the energy collected as the operating conditions and incident solar spectra vary. In practice, these advantages must be balanced against the parasitic losses associated with the additional current-collection layers required for a 4-terminal device. At the other extreme, a 2-terminal tandem will be most sensitive to changes in incident spectra, but its simpler architecture typically has fewer inherent losses, which can give it a higher baseline efficiency under any given fixed spectrum. A 3-terminal tandem is a compromise between these two extremes, with less spectral sensitivity than a 2-terminal tandem, but fewer parasitic losses than a 4-terminal tandem (because it has one less current-extracting layer). However, 3-terminal tandems will typically be connected in an interlaced voltage-matched configuration, which creates some additional complexity.

The fundamentals and design/material considerations for each of these configurations (2-, 3- and 4-terminal) will be discussed and compared.

Vapor Phase Deposited Perovskite-Si Tandem Solar Cells *Henk J. Bolink; Universitat de València, Spain*

We will report on the progress on vapor phase deposited perovskites, including novel low vacuum based deposition methods such as close space sublimation. Advances on widebandgap perovskite compositions in particular related to their photoluminescence quantum yield will be presented. The integration into perovskite-silicon tandem and the difficulties encountered will be described.

4:00 PM EN07.08.02
Two-Step $MAPbI_3$ Integration by Low-Vacuum Proximity-Space-Effusion in Inverted Semitransparent Perovskite Solar Cells for Tandem Applications *Emanuele Smecca[1,2], Vitantonio Valenzano[2], Salvatore Valastro[1], Ioannis Deretzis[1], Giovanni Mannino[1], Graziella Malandrino[3], Gianluca Accorsi[1], Silvia Colella[1], Aurora*

Rizzo[1], Gaetano Calogero[1], Andrea Listorti[4], Antonino La Magna[1] and Alessandra Alberti[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università del Salento, Italy; [3]Università degli Studi di Catania, Italy; [4]Università degli Studi di Bari Aldo Moro, Italy

Hybrid Organic-Inorganic Perovskites are worldwide one of the most investigated materials today, due to their unique properties impacting various fields as Photovoltaics, (PV), Light Emission Devices(LEDs) and Photodetectors. In PV, thanks to the wide absorption range and excellent charge carrier lifetime and diffusion of the material, Perovskite Solar Cells (PSCs) were able to reach the exceptional goals of 26.1%. All their exceptional properties, are strictly related to the possibility of preparing high quality films in terms of crystallinity, thickness and low defect density, are strictly related. In this perspective, although vacuum deposition methods are more suitable in terms of industrial throughput, they were less investigated, despite some seminal work demonstrating how hybrid organic inorganic perovskite films prepared by co-evaporation possess higher stability and performances with respect films prepared by spin coating techniques. Herein, we developed an innovative vacuum deposition method to prepare $CH_3NH_3PbI_3$ ($MAPbI_3$) thin film for semitransparent perovskite solar cells. The method applies a two steps Low-Vacuum Proximity-Space-Effusion (LV-PSE) under about 10^{-2} mbar conditions to produce high-quality thin layers of phase-pure $MAPbI_3$. The parameter optimization was supported by process simulation. We show that, during the process of CH_3NH_3I (MAI) deposition (second step) on PbI_2 (first step) at a given substrate temperature, the conversion of the PbI_2 film to $MAPbI_3$ occurs from the top-surface inward via an adsorption-incorporation-migration mechanism guided by the gradient of MAI concentration. The quality of the final layer arises from this progressive conversion that exploits the lattice order of the mother PbI_2 layer. Finally, p-i-n solar cells were prepared using ITO/PTAA/$MAPbI_3$/PCBM-BCP/Al architectures with photo-active layer thickness of 150nm. This layer, characterized by an Average Visible Transmittance (AVT) as high as 20%, produced an average efficiency of 14.4% that is a remarkable result considering the transparency vs. efficiency countertrend that indeed demands a proper balance from the quality of the material.

Very importantly, we demonstrated that further down scalability of the $MAPbI_3$ layer is feasible as proved by reducing the thickness down to 80 nm. In this specific case, the devices showed an average efficiency of 12.9% withstanding an AVT of 32.8%. This notable efficiency recorded on those extremely thin layers benefits from the exclusive quality of the $MAPbI_3$ grown with the developed method.

Lastly, integration of LV-PSE $MAPbI_3$ layers into monolithic Si-Perovskite tandem solar cells have been simulated with the Seftos software by Fluxim, using as input the optical constants of the material measured by Spectroscopic Ellipsometry. Current matching is achieved for a $MAPbI_3$ thickness of 300 nm, demonstrating that the integration is feasible even with this medium-bandgap perovskite, provided semi-transparency preserves performances and low lattice defects as in the LV-PSE material.

4:15 PM EN07.08.03

Pulsed Laser Deposition of Wide Band Gap Perovskites for Monolithic Perovskite/Silicon Tandem Devices

Suzana Kralj, Marly Nales, Tatiana Soto Montero and Monica Morales-Masis; University of Twente, Netherlands

Perovskite-silicon tandem solar cells hold great promise due to high efficiencies (> 33%) and low-cost materials [1,2]. However, the integration of the perovskite top cell, conformally and with uniform thickness onto the textured silicon wafers, still presents a challenge. Physical vapor deposition (PVD) methods facilitate conformal deposition and thickness control, but their full potential in fabricating the perovskite top cell has yet to be explored [3-7].

In this work, we investigate the use of pulsed laser deposition (PLD) as a single-source physical vapor deposition technique to develop $Cs_xFA_{1-x}Pb(Br_yI_{1-y})_3$ films for p-i-n single-junction and monolithic tandem devices. Structural analysis via X-ray diffraction (XRD) confirms the formation of crystalline α-phase perovskite films with a preferential (100) orientation which showed to be crucial for a good device performance. Morphological characterization by scanning electron microscopy (SEM) and atomic force microscopy (AFM) reveals the formation of dense and *smooth films on both planar and textured silicon substrates at various deposition rates. Furthermore, by precisely controlling bromide ion incorporation in the PLD target, we demonstrate the tunability of the perovskite bandgap energy, ranging from 1.58 to 1.68 eV, as determined by photoluminescence measurements. This bandgap tunability enables optimal alignment with the underlying silicon absorber, and combined with thickness control, facilitates current matching conditions in monolithic device integration.*

Taking advantage of the conformal and rapid deposition with PLD and/or sputtering deposition, we also studied the formation of the inorganic scaffold in the hybrid sequential method, a widely used technique for fabricating perovskite top cells . A layer of PbI_2*:CsBr (in 10:1 ratio) is deposited at a rate of ~ 55 nm/min and the formation of the perovskite layer is finalised with a spin coating of organic cation solution containing formamidinium iodide (FAI) and bromide (FABr) in ethanol. We compare the hybrid and single-step PLD method for the growth of* $Cs_xFA_{1-x}Pb(Br_yI_{1-y})_3$ *absorbers, in terms of optoelectronic performance with respect to grain size, film orientation, surface passivation and final device performance.*

In conclusion, we underscore the potential of PLD in advancing the fabrication methodologies of perovskite-based monolithic tandem solar cells. With the added benefits of bandgap tuning, precise thickness control, and conformal coverage, this method shows promise for achieving efficient current matching conditions in monolithic perovskite/silicon tandem solar cells. Therefore, our aim is to contribute to ongoing efforts to optimize physical vapor deposition techniques for the scalable production of high-performance perovskite/silicon tandem solar cells.

Enhancing Perovskite Tandem Solar Cells—Comparative Analysis of Alternative Hole Transport Layers for Improved Efficiency and Stability

Gaurav Kapil[1,2], Qing Shen[1], Hiroshi Segawa[2] and Shuzi Hayase[1]; [1]The University of Electro-Communications, Japan; [2]The University of Tokyo, Japan

All perovskite tandem solar cells (APTSC) are garnering substantial attention within the solar cell community due to their remarkable improvement in power conversion efficiency (PCE). Since their initial demonstration, the PCE of APTSCs has surged from less than 5% to over 28% [1,2]. This rapid progress underscores the potential of APTSCs to revolutionize solar energy technology. At present, the highest-performing APTSCs predominantly employ PEDOT: PSS as a hole transport layer. Despite its widespread use, PEDOT: PSS has inherent drawbacks due to its acidic and hygroscopic nature, making it less than ideal for long-term solar cell applications. Its tendency to absorb moisture and degrade over time compromises the stability and efficiency of solar cells [3]. In response to these limitations, our research focused on identifying and testing alternative hole transport layers that could potentially enhance the performance and durability of APTSCs. We explored a variety of materials, including hole-selecting monolayers based on carbazole moieties, those without carbazole moieties, and inorganic hole transport layers such as nickel oxide (NiOx). By examining these alternatives, we aimed to determine their impact on the efficiency, light stability, and thermal stability of APTSCs. Our comparative analysis revealed that some of these alternative hole transport layers exhibit promising improvements in the stability and efficiency of APTSCs. For instance, solar cells utilizing monolayers without carbazole moieties demonstrated significant enhancements *in both PCE and light stability. These findings suggest that the selection of appropriate hole transport materials is critical for optimizing the performance of perovskite tandem solar cells. Additionally, we conducted comparative studies on tin-lead (Sn-Pb) solar cells incorporating various hole-selective monolayers. It was observed that conventional PEDOT and 2PACz exhibited substantial declines in performance under prolonged light exposure. Conversely, the monolayers without carbazole moieties, referred to as A and B in our study, significantly improved the PCE and light stability of the solar cells. These improvements highlight the potential of these alternative materials to facilitate more robust and efficient APTSC fabrication processes. This research provides valuable insights into the development of more efficient and stable perovskite tandem solar cells, paving the way for their broader adoption in the renewable energy sector. By advancing the understanding of alternative hole transport layers, we contribute to the ongoing efforts to enhance the viability and longevity of APTSCs. The positive outcomes of our study could accelerate the integration of APTSCs into commercial solar energy solutions, ultimately supporting the global transition to sustainable energy sources.*

Impact of Energy Level Mismatch on the Photostability of Wide Bandgap Perovskite Solar Cells *Luis Victor Torres Merino; King Abdullah University of Science and Technology, Saudi Arabia*

Halide segregation in wide bandgap (WBG) halide perovskites is an important bottleneck towards long operational lifetimes of perovskite-based multi-junction solar cells. To minimize this phenomenon, aside from other well-known strategies such as perovskite defect passivation, enhancing the charge carrier collection needs to be effectively addressed. Here, we will discuss the need to enhance hole and electron collection to minimize halide segregation in WBG perovskites. For this, we will elucidate systematically the impact of the valence band and the conduction band offsets and barriers formed at the hole transport layer (HTL) and electron transport layer (ETL) interfaces with the perovskite layer, its influence on halide segregation, and ultimately on WBG perovskite solar cell (PSC) photostability. In fact, we find that optimized interface energetic alignment significantly enhances the long-term photostability of the WBG PSCs under continuous AM1.5G illumination. By studying different perovskite compositions, we highlight the universality of our method. Furtherly, our results show that photostable devices can be predicted when comparing transport layer/perovskite interfaces using photoluminescence's evolution and transient surface photovoltage spectroscopies, in correlation with halide segregation. We believe the methodology employed in this work can be used to accelerate the development of photostable WBG PSCs.

SESSION EN07.09: Scalable Manufacturing of Perovskite-Based Tandems

Scalable Fabrication Processes for Perovskite-Based Tandem Photovoltaics *Ulrich W. Paetzold; Karlsruhe Institute of Technology, Germany*

Up-to-date as of November 14, 2024

Perovskite-based multijunction solar cells have made remarkable advances in power conversion efficiency over the past decade. The technology is on the doorstep of commercialization. Despite these advances, it remains an open question which fabrication technology – solution-based, vapor-based, or a combination – is best suited to deposit the perovskite absorber layer. Solution-based processes dominate at the laboratory scale, benefiting from fast optimization feedback and straightforward integration in modern research laboratories. Slot-die coating and inkjet printing are established scalable solution-based fabrication techniques that are heavily investigated concerning large-area and high throughput deposition. On the other hand, vapour phase deposition processes dominate today's established thin-film manufacturing. This contribution will present a recently published balanced viewpoint from industry and academics on the advantages and disadvantages of solution-based and vapor-based large-area deposition processes for perovskite absorber layers.

The latest developments at the Karlsruhe Institute of Technology on vapor phase and solution-processed deposited of perovskite absorber layers in perovskite/Si tandem solar cells will be presented. We will report on advances in monitoring and controlling of the thin film formation for vapor phase and solution-based deposition, including sequential and hybrid deposition routes. Using photoluminescence imaging, we analyse the formation of the thin film morphology during the annealing, gas quenching or vacuum quenching step. For the hybrid route, the inorganic precursor materials are deposited by vacuum processes, while the organic materials are deposited from the solution in a second step by inkjet printing or slot die coating. Insights on the thin film formation on textured and planar silicon bottom solar cells will be shared along with the latest developments in controlling the homogeneous formation of perovskite thin films processed by the hybrid route on larger areas.

Intermediate-Phase Engineering via Dimethylammonium Cation Additive for Stable Mixed Halide Perovskite Solar Cells *David McMeekin[1], Philippe J. Holzhey[1,2], Sebastian Fürer[3], Steven Harvey[4], Laura T. Schelhas[4,5], James Ball[1], Suhas Mahesh[1], Seongrok Seo[1], Nicholas Hawkins[1], Jianfeng Lu[3], Michael Johnston[1], Joseph J. Berry[4], Udo Bach[3] and Henry Snaith[1]; [1]University of Oxford, United Kingdom; [2]Helmholtz-Zentrum Berlin, Germany; [3]Monash University, Australia; [4]National Renewable Energy Laboratory, United States; [5]SLAC National Accelerator Laboratory, United States*

Achieving the long-term stability of perovskite solar cells is arguably the most important challenge required to enable widespread commercialization. Understanding the perovskite crystallization process and its direct impact on device stability is critical to overcoming this hurdle. Surprisingly, we find that intermediate phases that occur during the crystallization process are critical for long-term stability. The commonly employed dimethylformamide/dimethyl sulfoxide (DMF/DMSO) solvent system for $FA_yCs_{1-y}Pb(I_xBr_{1-x})_3$ perovskite (FACs) results in poor crystal quality, microstructure and the retention of DMSO. That ultimately leads to inferior material stability compared to the DMF/dimethylammonium (DMF/DMA) processing method presented here. We replace DMSO with DMACl to control the perovskite intermediate precursor phases accurately. By precisely controlling the 2H to 3C perovskite phase crystallization sequence, we tune the grain size, texturing, orientation (corner-up vs face-up) and crystallinity of the FACs perovskite system.

A population of encapsulated devices showed a T80 lifetime (for the steady-state PCE) of 1190 h as the median value under simulated sunlight at 65 °C in air, under open-circuit conditions. In contrast to a median value of T80 = 780 hours for conventional DMF/DMSO devices. Our work introduces an innovative processing route that allows *higher overall perovskite device stability with fewer defects by controlling the intermediate phase domains during the perovskite formation. This work highlights the importance of material quality in achieving long-term operational stability and shows that it is necessary to find alternative processing routes without DMSO. An important step towards stable multijunction devices. (1)*

Development and Scaling of Slot-Die-Coated Perovskite/Silicon Tandem Two-Terminal Photovoltaic Cells

Zachary Holman[1,2]; [1]Arizona State University, United States; [2]Beyond Silicon, United States

Two-terminal perovskite/silicon tandem solar cells have repeatedly been demonstrated with efficiencies exceeding 30%, but significant challenges remain to scaling to 5,000 wafer per hour throughput with high yield and ensuring reliability over a module's lifetime. This talk will share Beyond Silicon and ASU's progress in slot-die coating perovskite top cells on full-area M2 silicon heterojunction bottom cells. Both the microscopic and milliscopic texture of the silicon wafer—which result from the combination of the wafer sawing, saw-damage removal etching, and texturing—determine the morphology of the perovskite layer. We categorize the most common perovskite slot-die coating defects, many of which stem from the underlying silicon texture, and introduce techniques to eliminate them or mitigate their effects. With proper defect control, the tandem device performance across a wafer becomes spatially uniform and exceeds 26%.

***The Multiple Roles of $(Ag,Cu)(In,Ga)(S,Se)_2$ in Tandem Solar Cells** Marika Edoff; Uppsala University, Sweden*

The chalcopyrite material $(Ag,Cu)(In,Ga)(S,Se)_2$ is investigated as both bottom cell and top cell in tandem devices, due to its bandgap range, which ranges from 1.0 for $Ag_xCu_{1-x})InSe_2$ with x=0 to 0.25, to 1.8 eV for $AgGaSe_2$ or 2.4 eV for $CuGaS_2$. The present world record of 23.65 % efficiency made in collaboration with First Solar ETC and Uppsala University has an effective bandgap of 1.12 eV and consists of $(Ag,Cu)(In,Ga)Se_2$ with an Ag/(Ag+Cu) ratio of 0.1. In-depth grading of the Ga/(Ga+In) ratio is used as a means to form a charge selective back contact, which reduces the charge density at the back contact, while keeping a good ohmic contact. It is also possible to use a sulfur-based surface treatment resulting in S substituting for part of the Se at the surface as in the former 23.35 % record device by Solar Frontier.
While both the present and former world record cells use back contacts based on molybdenum, new designs are needed to optimize the cells for use in tandem devices. For the bottom cell to be competitive to crystalline silicon with its 1.1 eV bandgap, very low effective bandgaps are targeted down to 1.0 eV, which means that the surface consists of $(Ag,Cu)InSe_2$ or $CuInSe_2$. Furthermore, given the present Si development, bi-faciality will also be an important asset, which requires a transparent back contact. For the top cell in a tandem, it will be necessary to

significantly increase the bandgap to values above 1.5 eV and also to deposit the cells on a transparent back contact. A high bandgap means that either a high sulfur and/or high gallium concentration is needed.
A low bandgap (A)CIGSe bottom cell can be combined either with a perovskite top cell, with CdTe or with a high bandgap (A)CIG(S)Se top cell. For the CIGS-perovskite tandem, both 2-terminal and 4-terminal solutions are possible and a record monolithic two-terminal device made at the Helmholz Zentrum Berlin reaches 24.2 % using a CIGS bottom cell with 1.1 eV bandgap. This device differs from many of the devices presented recently in the literature, since it is a fully functional tandem. In several publications, higher numbers are presented as four terminal results, using a perovskite cell as a filter and measuring the devices separately. For the all-CIGS tandem in the on-going project SITA, funded by the EU, we are investigating a back illumination configuration for the top cell, but with a concept using either current or voltage matching for the full module.
Both for bottom cell and top cell scale-up, the properties of the transparent contacts are important. For a four-terminal solution, avoiding parasitic absorption caused by free carriers is even more crucial than for two terminal devices. Additionally, for the transparent contacts deposited on the substrate before the CIGS deposition, the demands on chemical integrity are high. The contacts need to be able to sustain high temperatures in a corrosive environment without losing either transparency nor conductivity.
In this contribution, the challenges in adapting the CIGS device to obtain a suitable tandem partner, both as bottom and as a top cell are discussed and new developments aiming to increase the efficiency and the energy yield are discussed.

11:00 AM EN07.10.02
Improved Passivation Performance of Al_2O_3 Interlayer/SnO_x Thin Films Continuously Grown Through Atomic Layer Deposition *Bireswar Mandol and Balasubramaniam Kavaipatti; Indian Institute of Technology Bombay, India*

Atomic layer deposition of aluminium oxide thin films is introduced as a passivating tunnelling interlayer between electron-selective Tin oxide contacts and silicon absorbers. The surface recombination velocity and specific contact resistance were investigated as a function of both Al_2O_3 (1-5 nm) and SnO_x (10-50 nm) thickness. The thin SiO_x passivation layer grown naturally without HF pre-treatment on substrate enhance the carrier lifetime of the stacks by 10 µs. The thermal history of the Al_2O_3 layers prior to SnO_x deposition, and the thermal history of the completed Al_2O_3/SnO_x stacks were also investigated. When an SiO_x/Al_2O_3 passivating stack was introduced, the carrier lifetime and the implied open circuit voltage increased from 22 µs to 875 µs and from 568 to 637 mV, respectively. The introduction of ultrathin ALD-Al_2O_3 significantly reduced the number of oxidation states that acted as defects. The ALD-SnO_x/ultrathin Al_2O_3 stack is an extremely transparent, highly promising, electron selective contact layer that can be used in the design of future Si heterojunctions, without the need for a-Si passivation layers.

11:15 AM EN07.10.03
Earth-Abundant Sb-Based Absorbers for Next-Generation Photovoltaics *Ruiqi Wu and Alex M. Ganose; Imperial College London, United Kingdom*

New cost-effective photovoltaics are urgently needed to reach the UK's renewable energy targets. Recently, lead halide perovskites have emerged as a remarkably efficient class of absorbers but are limited by their poor stability and inclusion of toxic lead. Antimony-based materials show promise as photovoltaics due to their dispersive lone-pair states that confer many similar properties to their lead counterparts including strong optical absorption and small effective masses. Compared with conventional lead-containing photovoltaics, antimony is a non-toxic and earth-abundant element that could reduce potential regulatory and environmental barriers to commercialisation. In this work, using relativistic density functional theory (DFT), we study the optoelectronic properties of antimony-based materials for use in single and multi-junction solar cell applications. Full Heusler K_2CsSb and tilted *antiperovskites A_3SbP are highlighted for their favourable optoelectronic properties including direct bandgaps, low effective masses and strong optical absorption, as well as high device performance with maximum theoretical efficiencies of 24–31% for 200 nm films. First principles defects calculations reveal the materials do not possess any deep trap states and are not expected to experience large voltage losses from non-radiative recombination.*

11:30 AM EN07.10.04

First-Principles Design of Tandem Solar Cell Absorbers in the AM2Pn2 Family via Alloying *Andrew Pike[1], Zhenkun Yuan[1], Muhammad R. Hasan[2], Kirill Kovnir[2] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]Iowa State University of Science and Technology, United States*

Some compositions of the formula AM_2Pn_2 have recently been observed as promising solar absorbers through high-throughput computing such $BaCd_2P_2$ [1]. In this talk, I will discuss generating new candidate materials from a parent structure by isovalent substitutions (A= Ba, Sr, Ca, Yb, Eu, Mg, M=Mn, Mg, Cd, Zn, Pn= Bi, Sb, As, P). We explore the thermodynamic and electronic properties of these compounds to screen for those which may be suitable for the top junction of tandem solar photovoltaics. We find that in this family many of the materials are thermodynamically stable in the same crystal structure and have a wide range of computed bandgaps. To design materials for tandem solar cells, we explore alloying these materials and screen for optimal properties. I will discuss computational tools to screen for stable and desirable alloys in a high throughput fashion and suggest promising material candidates for tandem solar cells.

11:45 AM EN07.10.05

Zintl Phosphide $CaZn_2P_2$Thin Films as Candidate Semiconductors for Tandem Top Absorbers *Shaham Quadir and Sage Bauers; National Renewable Energy Laboratory, United States*

The development of tandem photovoltaics and photoelectrochemical solar cells both calls for exploring new absorber materials with band gaps in the range of ~1.5–2.3 eV, for use in the top cell in conjunction with a suitable narrower-gap bottom cell. An outstanding challenge is to identify materials with suitable baseline optoelectronic and defect properties, good stability in operational environments, and the ability to be synthesized under conditions which will not cause damage to any underlying layers or withstand the synthesis of subsequent layers. Here, we demonstrate that the Zintl-phosphide compound $CaZn_2P_2$ represents a compelling candidate semiconductor for tandem solar cell applications as a top absorber. We prepare phase pure, ~500 nm-thick $CaZn_2P_2$ thin films using a scalable reactive sputter deposition process from Ca and Zn metallic targets in PH_3 gas. It is found that crystalline $CaZn_2P_2$ forms at growth temperatures as low as 100 °C, which is useful for monolithic device integration, but has remained elusive for many existing inorganic absorber materials. UV-vis spectroscopy shows that $CaZn_2P_2$ thin films exhibit a high optical absorption of ~10^4 cm^{-1} at the ~1.95 eV direct transition. Room temperature photoluminescence (PL) measurements show near band edge optical emission at 1.95 eV and time resolved microwave conductivity (TRMC) measurements indicate a long photoexcited carrier lifetime of up to 30 ns at a fluence of 2 10^{13} cm^{-2}, further confirming $CaZn_2P_2$ as an attractive top cell absorber. While carbonates are found to form on the surface of $CaZn_2P_2$ films exposed to the atmosphere, as expected from a Ca-containing material, the bulk is highly stable in both ambient conditions and moisture, as evidenced by the persistent PL and TRMC measurements. The observed optoelectronic properties of $CaZn_2P_2$ are supported by first-principles calculations, which show favorable defect properties, especially the absence of low-formation-energy, deep intrinsic defects. Furthermore, $CaZn_2P_2$ is but one of several AM_2P_2 materials, hinting at a new and exciting family of *emerging Zintl phosphide semiconductors. Overall, our study should motivate future work integrating $CaZn_2P_2$, and similar potential top cell absorber materials into tandem solar cells.*

SESSION EN07.11: Tandem Applications of Organic and Perovskite Photovoltaics

Enhancing Ambient Stability of Perovskite-Organic Tandem Solar Cells for IoT Applications *Yan Wang and Zonglong Zhu; City University of Hong Kong, Hong Kong*

As the "Made in China 2025" strategy and Industry 4.0 advance, the prominence of cutting-edge information technology and eco-friendly manufacturing becomes increasingly pivotal. Central to this is the Internet of Things (IoT), which calls for technological refinement, particularly in the realm of energy supply. IoT devices, often subjected to variable conditions, demand high efficiency, stable operation voltage, and particularly robust environmental stability from perovskite solar cells as the energy supply candidate. However, while effective, the traditional encapsulation techniques are intricate and costly. In response, we propose the perovskite-organic tandem solar cell (POTSC), which has achieved over 25% photovoltaic conversion efficiency (PCE) and an output voltage of 2.1V, attracting significant research attention. Despite superior MPP tracking and thermal stability, the long-term environmental stability of these tandem cells has been less explored, posing a barrier to their IoT integration.
Considering the p-i-n device architecture, the ambient stability of the POTSC is predominantly dictated by the back organic subcell, thereby imposing heightened demands on the organic active layer materials. Our study leverages an all-polymer bulk heterojunction (BHJ) to enhance both efficiency and stability. We introduce a novel polymer acceptor, PYSe2F-T, designed to absorb near-infrared light, broadening the absorption spectrum and boosting current density. Additionally, we optimize polymer packing with PffBQx-T by altering the polymerization sites, achieving a fill factor (FF) on par with the best polymer-small molecule BHJs. Notably, the all-polymer system exhibits superior performance in air processing, indicating its potential for the future fabrication of tandem solar cells and modules in ambient conditions. These innovations yield a PCE of 24.6% of the corresponding POTSC, resonating with leading research. The all-polymer device demonstrated exceptional ambient stability, maintaining 80% of its initial efficiency after 1000 hours in a ~50% humidity environment, unencumbered by encapsulation—a stark contrast to polymer-small molecule devices, which retained less than 50% of their initial performance. Cross-sectional SEM, photoluminescence (PL) mapping, and contact angle measurements illuminated the dense interpenetration framework of the proposed all-polymer blend, effectively shielding the perovskite subcell from atmospheric elements and enhancing overall stability.
Our findings underscore the potential of all-polymer POTSCs as a sustainable energy solution for IoT. The demonstrated processing advantages and stability under ambient conditions suggest a promising future for the scalable fabrication of high-performance solar cells, propelling the IoT toward a new era of energy-efficient and environmentally benign technologies.

1:45 PM EN07.11.02

Universal Photostability of Non-Fullerene Organic Solar Cells in Tandem Cells *Kai O. Brinkmann[1,2], Pang Wang[1,2], Maximilian Schiffer[1,2], Manuel Runkel[1,2], Timo Maschwitz[1,2], Christian Tückmantel[1,2], Guorui He[3], Felix*

Lang[3] and Thomas Riedl[1,2]; [1]Bergische Universitat Wuppertal, Germany; [2]Wuppertal Center for Smart Materials and Systems, Germany; [3]University of Potsdam, Germany

Perovskite-based multi-junction solar cells demonstrate promising potential and offer a solution to overcome theoretical limits of single-junction cells by reducing thermalization losses. Although notable efficiencies are already achieved by emerging perovskite/silicon and all-perovskite tandem devices, significant challenges persist, including the substantial carbon emissions due to energy-intensive silicon wafer production or fundamental stability concerns due to the oxidation of Sn^{2+} *to* Sn^{4+} *in narrow-gap perovskites. Solution-processed narrow-gap non-fullerene acceptor (NFA) organic solar cells (OSCs) circumvent these issues and present a compelling choice as rear cells in perovskite-based tandem devices. In our previous work, the benchmark PM6:Y6:*$PC_{61}BM$ *ternary OSCs maintained approximately 95% of its efficiency after 5000 hours of continuous operation under irradiation with low-energy photons (l = 850 nm), but it degraded rapidly when illuminated with a white light-emitting diode (LED), indicating that the visible spectral region is responsible for device degradation.[1] In a perovskite-organic tandem solar cell, the wide bandgap perovskite sub-cell serves as a low-pass filter that protects the organic sub-cell against high-energy photons.[2] While the photostability of the perovskite-organic tandem devices is still limited by the photostability of the wide gap perovskite, NFA based organic solar cells might be a better choice as the narrow gap sub-cell compared to Pb-Sn perovskite solar cells.*

In this work, we demonstrate that the favorable photostability is generally found for a wide range of narrow-gap Y-type acceptors (Y18 ($E_g = 1.31$ *eV), CH1007 (*$E_g = 1.30$ *eV), mBzS-4F (*$E_g = 1.25$ *eV)), that we identified to show great promise in tandem operation by showcasing efficiencies > 23%, among the highest values reported for perovskite-organic tandem solar cells with each of the respective NFAs. On the path to further explore the photostability of NFA based ternary OSCs in more detail, we utilize monochromatic LED sources covering the spectral range from 375-850 nm. Our results reveal that under continuous operation in the maximum-power point with low-energy photons (*$\lambda > 590$ *nm), the devices show excellent long-term stability (> 1000 hours), while higher-energy photons (*$\lambda < 530$ *nm) infer degradation. Combining these wavelength-selective degradation studies with in-situ photoluminescence, Raman spectroscopy and photoluminescence quantum yield investigations, we systematically investigate the distinct contributions of the donor polymer and the Y-type NFA along with possible degradation pathways in both cases. Hereby we also identify the degradation threshold energies of each constituent – an information that is not only crucial for the design of tandem solar cells, but also might provide the lever to design photo-stable single junction organic NFA-based solar cells.*

Nitrogen Functionalized Perylene Materials as Cathode Interlayers in Organic Photovoltaics *Kathryn M. Wolfe and Gregory Welch; University of Calgary, Canada*

The application of organic materials as cathode interlayers (CILs) in organic photovoltaics (OPVs) is an emerging strategy to increase their performance. Polar groups on CILs serve to tune the work function of the cathode as well to block holes from the donor materials in the bulk heterojunction, allowing for efficient charge cascade and thus increased performance. CILs such as PFN-Br and PDINN are known high performance CILs used in conventional OPVs, both of which are processable from green solvents which do not affect the underlying bulk heterojunction upon printing/casting, which is critical to the performance of the devices.[1,2] In terms of PDINN and CILs of the like, these compounds utilize amines appended at the imide positions that are capable of doping the perylene π-

conjugated core via intramolecular electron transfer independent of conjugation. In this work, nitrogen functionalization on the core of perylene materials, such as perylene diimides and perylene tetraesters, is explored. These materials were applied as CILs to provide high performance & green solvent processable OPVs, and serve to fill the gap in the knowledge in terms of nitrogen doped perylene CILs via core functionalization.

Kinetics of Photogenerated Carbon Dangling Bonds in Organic Photovoltaic Thin Films—An EPR Study

Raghunandan B Iyer[1,2], Maurissa K. Higgins[1,2], Katelyn E. Noack[1,2], Joshua Wolanyk[1,2], Matthew Dygert[1], Sarah D. Cady[2], Erik M. Dykstra[1,2], Rana Biswas[1,2,2], Ruth Shinar[2] and Joseph Shinar[1,2,2]; [1]Ames Laboratory, United States; [2]Iowa State University of Science and Technology, United States

Recent developments in bulk heterojunction (BHJ) organic solar cells based on non-fullerene acceptors (NFA) have rekindled interest in single junction BHJ organic photovoltaic (OPV) solar cells with >19% efficiency reported by multiple groups. The low cost, lightweight, and flexible OPVs are promising as a renewable energy source, and as photodetectors in chemical and biological sensors. However, long-term stability issues continue to be a significant obstacle for OPV commercialization.

Oxygen, moisture, and photon irradiation are known to be the major sources of degradation in BHJ OPVs. Proper encapsulation can prevent extrinsic degradation caused by ambient oxygen and water, but intrinsic degradation resulting from thermal processes and radiation still occurs. Multiple studies have investigated photogenerated defect formation in OPVs. The presence of carbon dangling bond (CBD) defects in photodegraded OPVs was suggested theoretically and identified using electron paramagnetic resonance (EPR) spectroscopy and optoelectronic measurements, but the mechanisms underlying the intrinsic photodegradation, particularly the early kinetics, still need to be completely understood.

We report the investigation of early kinetics of spin-active photogenerated CDB defect formation and annealing in oxygen- and moisture-free environments using X-band EPR spectroscopy. Specifically, BHJ blends of poly[[4,8-bis[5-(2-ethylhexyl)-2-thienyl]benzo[1,2-b:4,5-b']dithiophene-2,6- diyl]-2,5-thiophenediyl[5,7-bis(2-ethylhexyl)-4,8-dioxo-4H,8H-benzo[1,2-c:4,5-c']dithiophene-1,3-diyl]] (PBDB-T):PCBM and PBDB-T:ITIC are examined under irradiation at 300 nm to monitor the time evolution of CDBs for over 200 hours. The presence of CDBs in the samples generated in an oxygen- and water-free environment is confirmed by the obtained g-values. For the PBDB-T:PCBM blend, the spin count increases steadily until ~40 hours of irradiation, whereas for the PBDB-T:ITIC blend, it increases until ~60 hours. Subsequently, there is a notable decrease in the rate of defect formation. Further, the CDB defect count follows a power-law t^{β} with irradiation time t, where β ~0.55-0.58. Theoretical analysis reveals a monomolecular defect creation model consistent with the expected theoretical value β= 1/2.

Our findings deepen the understanding of early degradation kinetics in BHJ OPV films. This research is pivotal in developing enhanced materials that mitigate defect formation, thus advancing the stability of OPV systems essential for applications in large-scale energy production and biochemical optical sensing.

2:30 PM EN07.11.05
Stabilizing the Interfaces of Efficient Perovskite Solar Cells *Bin Chen; Northwestern University, United States*

Perovskite photovoltaics have achieved remarkable progress over the past decade, with the best lab-scale cells now reaching over 26% power conversion efficiency. This rapid advancement is largely due to a better understanding and control of the interfaces within perovskite solar cells. As we transition from single-junction to multi-junction solar cells, interface quality becomes even more critical, given the increasing number of heterojunctions. Each additional sub-cell introduces two new interfaces, which must be carefully managed. In this talk, I will discuss the instability of these interfaces, especially under combined stress of light and heat, and the pathways toward their stabilization. One example of instability is the interdiffusion of cations between the bulk 3D perovskite and popular passivating 2D perovskite layers in 2D/3D heterostructures. Another is halide migration through the interface into the carrier transport layer and even the electrode. I will also present strategies to stabilize the 2D/3D interface using non-2D passivation layers and methods to block halide migration under accelerated conditions by employing compact, uniform metal oxide barrier layers.

2:45 PM EN07.11.06
Diamine Surface Passivation and Post-Annealing Enhance Performance of Silicon-Perovskite Tandem Solar Cells *Margherita Taddei[1,2]; [1]University of Washington, United States; [2]National Renewable Energy Laboratory, United States*

We show that the use of 1,3-diaminopropane (DAP) as a chemical modifier at the perovskite/electron-transport layer (ETL) interface enhances the power conversion efficiency (PCE) of 1.7 eV bandgap FACs mixed-halide perovskite single-junction cells, primarily by boosting the open-circuit voltage (V_{OC}) from 1.06 V to 1.15 V. Adding a post-processing annealing step after C_{60} evaporation, further improves the fill factor (FF) by 20% from the control to the DAP + post-annealing devices. Using hyperspectral photoluminescence microscopy, we demonstrate that the annealing step helps improve compositional homogeneity at the top and bottom interfaces of the solar cell, which prevents detrimental bandgap pinning in the devices and improves C_{60} adhesion. Using time-of-flight secondary ion mass spectrometry, we show that DAP reacts with formamidinium present near the surface of the perovskite lattice to form a larger molecular cation, 1,4,5,6-tetrahydropyrimidinium (THP) that remains at the interface. Combining the use of DAP and the annealing of C_{60} interface, we fabricate Si-perovskite tandems with PCE of 25.29%, compared to 23.26% for control devices. Our study underscores the critical role of chemical reactivity and thermal post-processing of the C_{60}/Lewis-base passivator interface in minimizing device losses and advancing solar-cell performance of wide-bandgap mixed-cation mixed-halide perovskite for tandem application.

Argyrodite- and Halide-Containing All-Solid-State Lithium Batteries *Virginie Viallet[1,2], Dhanush Shanbhag[1,3], Julien Porcq[1,3], Claude Guéry[1,2], Christian Masquelier[1,2], Jérémie Auvergniot[3], Florencia Marchini[3] and Laura Albero Blanquer[3]; [1]Université de Picardie Jules Verne, France; [2]FR CNRS 3459, France; [3]Umicore, Belgium*

Inorganic All-solid-state batteries (ASSBs) are attracting great interest as next-generation energy storage systems due to their potentially better safety and higher energy density compared to the current lithium-ion batteries with organic liquid electrolytes[1-4]. The development of these batteries is based, on the one hand, on exploration of electrolyte conductors with fast ionic conductivity (10^{-3} S.cm^{-1}) and high voltage stability "windows" and, on the other, on the optimization of the interfaces between electrolyte and active materials at the positive and negative electrodes. Major research efforts have been undertaken to optimize inorganic solid electrolytes (SEs) including sulfides, oxides, polymers and halides. Among them, sulfides, and halides are more promising owing to their high ionic conductivities, their plasticity enabling good contact with electrode materials and suitable integration conditions in All-Solid-State batteries systems conditions, in particular compared to oxide electrolytes.

*For sulfides, the **Argyrodite-type Li_6PS_5X (X = Cl, Br, and I) family** has been extensively investigated [5-6] and a very high ionic conductivity of over 10 mS.cm^{-1} at room temperature was recently found in the compound $Li_{5.3}PS_{4.3}Cl_{1.7}$[7]. Due to the lower cost of chloride-based Argyrodite-type SEs than that of Argyrodite-type SEs with other halide ions, industrial and fundamental battery applications mainly concentrate on this compound. We undertook a detailed investigation on how the anion disordering in the structure influences the global Li^+ ion transport and we found a new compositional space that allows to build promising All-Solid-State Batteries [8]. However, some problems still need to be solved, such as their reactivity with H_2O in air and the production of poisonous H_2S, which requires inert gas atmosphere during synthesis and handling.*

*That's why the inorganic **metal-halide SEs family**, including **Li_3MCl_6 (M = In, Er, Sc, Yb, etc.)** and **Li_2ZrCl_6**, has gained increasingly attention in recent years as several of its members exhibit excellent compatibility with high-voltage cathode materials and are suitable as catholytes in SSB. We undertook an exploratory work on halide solid electrolytes, carried out through the prism of two selected samples, Li_3InCl_6 and Li_2ZrCl_6. While much investigation remains to be done to understand all the mechanisms involved in those compounds, this work has shown different* *ways to synthesize them and successful methods to improve the ionic conductivity.*

After a brief description of an ASSB and its requirements, in terms of solid electrolyte and processing, we will present the optimization of two electrolytes, a sulfide and an halide, and their integration in full all-solid state cells.

Keyword: *All-Solid-State Batteries, inorganic solid electrolyte, ionic conductor, Argyrodite-type electrolytes, halide-type electrolytes*

AI-Driven Characterization of Composite Electrode Microstructures in Solid-State Batteries *Anja Bielefeld, Alexander Weiss, Johannes Schubert, René Rekers and Moritz Pawlowsky; Justus-Liebig-Universität Giessen, Germany*

Solid-state batteries (SSBs) represent a promising frontier in next-generation energy storage systems. This research focuses on the microstructural effects in composite electrodes for SSBs, utilizing electrochemical simulations based on Focused Ion Beam-Scanning Electron Microscopy (FIB-SEM) imaging.
Key to this research is the examination of how processing conditions, particle morphology, particle size distribution, and composition influence the microstructure of composite electrodes. These factors critically determine the residual porosity and homogeneity of the microstructure, which in turn directly impact the effectiveness of current pathways[1-4] *and the active interface area*[3,5,6] *within the composite electrodes. Ultimately, these microstructural aspects affect battery performance, making their understanding and control essential for designing more efficient and durable SSBs.*
We will discuss U-Net neural networks for efficient image segmentation and processing of (FIB-)SEM images, focusing on cathode composites that feature sulfide solid electrolytes, such as Li_6PS_5Cl*, and NCM cathode materials, such as* $Li_xNi_{0.8}Co_{0.1}Mn_{0.1}O_2$*. Synthetic datasets are used for training, and the segmentation model is validated against experimental data. This AI-driven approach is intended to facilitate a detailed and accurate characterization of microstructural features, where simulations of electrochemical behaviors and performance predictions can be based on.*
While the primary focus is on lithium-based SSBs, the findings are likely applicable to other systems, such as potassium- and sodium-based SSBs, due to the similar challenges and mechanisms involved in their microstructural optimization. Consequently, the insights gained from this research extend beyond lithium, offering valuable implications for the development of various next-generation energy storage systems.
This study enhances the fundamental understanding of how microstructural characteristics influence the performance of SSBs. The interplay between microstructure and material design is critical, and this work exemplifies how advanced characterization and AI/ML applications can drive the discovery and optimization of next-generation energy storage materials and cell designs.

Facilitating Kinetics by Multifunctional Solid-State Electrolyte in Lean-Electrolyte Lithium-Sulfur Batteries

Hyunji Park, Jooyoung Lee and Choongho Yu; Texas A&M University, United States

Lithium-sulfur batteries are considered one of the promising next-generation rechargeable batteries due to their high theoretical specific capacity of 1675 mAh g^{-1} and the use of low-cost sulfur. Considering practical aspects including cost and energy density, the electrolyte/sulfur (E/S) ratio should be decreased to less than 3 μL mg^{-1}. Under lean-electrolyte conditions, sulfur cathodes suffer from low ionic conductivity due to the high viscosity of the electrolyte, sluggish sulfur reaction kinetics, and poor infiltration of highly concentrated catholyte. This also induces poor cycle life because the irreversible insulating Li_2S can passivate the host materials and deteriorate the reactivity of active materials during cycling. Here, we propose a multifunctional sulfide-based solid electrolyte as an effective polysulfide catalyst for lean lithium-sulfur batteries. The superionic solid electrolyte $Li_{10}GeP_2S_{12}$ (LGPS) provides a lithium-transporting pathway in cathodes due to its higher ionic conductivity compared to that of highly concentrated liquid catholyte. Additionally, density functional theory (DFT) calculations show that LGPS has the ability to absorb polysulfide intermediates, providing an immobilizing effect. The solid electrolyte as a catalyst facilitates the process of solid-liquid-solid conversion including the nucleation and growth of Li_2S, thereby decreasing charge transfer resistance. The kinetically improved composite electrode shows a high areal capacity of 6.13 mAh cm^{-2} with high sulfur loading of 8.1 mg cm^{-2} and a low E/S ratio of 2.9 μL mg^{-1}. This work demonstrates that a superionic solid electrolyte used as a catalyst can enhance the kinetics of lean lithium-sulfur batteries through its catalytic effect and high ionic conductivity.

Can Ion Implantation Enable Solid-State Batteries? An Atomistic Investigation of Radiation Induced Damage in Garnet Solid Electrolytes

Scott Q. Monismith, Josey Mcbrayer, Noah B. Schorr and Remi Dingreville; Sandia National Laboratories, United States

Li-metal based batteries with a solid electrolyte are often considered the holy grail of energy storage solutions in that they are higher energy density and safer than their liquid electrolyte counterparts. However, one persistent

problem that plagues these batteries is the growth of lithium filaments through the solid electrolytes, which leads to short-circuits and failure early in life. Microstructural characteristics (i.e. cracks and grain-boundaries) drive this failure mode by either orchestrating brittle fracture of the electrolyte or by increasing the local electronic conductivity such that lithium preferentially precipitates at local "hot spots."

Ion implantation of solid electrolytes may curb both failure mechanisms by inducing compressive stresses which inhibit crack growth and deflect dendrites. It may also increase the wettability of the grain boundaries with respect to lithium, leading to an increased thermodynamic barrier to plating at grain-boundaries. However, the process of ion implantation necessarily leads to radiation induced damage in the material, and the precise nature of the damage as well as its effects on the material properties is ill understood at this early stage in ion-implanted electrolyte development. As ion implantation can be a time-consuming and expensive process, using nano- and mesoscale modeling tools can be a more efficient way to answer key research questions regarding the effects that the implantation process has on solid electrolytes.

To that end, we employ a suite of molecular dynamics (MD) techniques, using $Li_7La_3Zr_2O_{12}$ *(LLZO) as a pedagogical example, to understand (i) the nature of the amorphous damage introduced by ion implantation (ii) the effect of anneal temperature on the crystal structure and resulting Li ion conductivity (iii) the effect of defects on grain-boundary and bulk fracture behavior. We demonstrate that during the irradiation process, oxygen and lithium comprise the majority of interstitial defects while oxygen vacancies are comparatively common. Furthermore, anneal temperature and defect concentration must be simultaneously optimized to maximize Li ion conductivity. Lastly, we derive cohesive zone laws derived for both grain-boundaries and the bulk crystal at different Frenkel pair concentrations, showing that the fracture energy of LLZO is significantly altered in both the bulk and at the grain-boundaries. While, on its face, an increase in fracture energy constitutes a benefit to the long-term reliability of solid electrolytes, an unfortunate byproduct is that the applied compressive stress required to deflect dendrites increases commensurately. In total, our results show that ion implantation may help enable solid electrolytes for Li metal batteries, but that care and attention must be paid in optimizing the balance between the various alterations to material properties.*

Development of Sulfide Solid Electrolytes with Sodium-Ion Conductivity *Akitoshi Hayashi, Kota Motohashi and Atsushi Sakuda; Osaka Metropolitan University, Japan*

All-solid-state lithium rechargeable batteries have attracted attention because of their long cycle life, high safety even at high temperature, and high power/energy density. Sulfide electrolytes with high lithium-ion conductivity and good deformability are the most promising materials for application in solid-state rechargeable batteries used in electric vehicles, which are targeted for commercialization by 2030. All-solid-state sodium batteries are also important as the next-generation battery after all-solid-state lithium batteries, and their realization requires the continuous material design and development of sodium-ion conductors. Sodium-ion conducting sulfides are expected to have the advantages of high conductivity and favorable deformability due to the weaker Lewis acidity of sodium ions. Sulfide electrolytes with sodium-ion conductivity have been developed during the last decade [1]. To achieve high ionic conductivity, it is effective to prepare glass electrolytes with high sodium content by the *rapid-quenching or mechanochemical methods. Crystallization of glass electrolytes can improve their conductivity by stabilizing metastable crystalline phases in the glass matrix, a typical example being Na_3PS_4 glass-ceramics with a conductivity of 10^{-4} S cm^{-1} [2]. The doping of sodium-ion vacancies in Na_3SbS_4 by partial substitution of W for Sb was effective in enhancing conductivity to the level of 10^{-1} S cm^{-1} [3,4]. Focusing on the high-temperature stability of sodium polysulfide melts, we have developed a synthesis procedure of glassy and crystalline sulfide electrolytes at ambient pressure [4-7]. The $Na_{2.88}Sb_{0.88}W_{0.12}S_4$ electrolyte was synthesized directly from a stoichiometric mixture of Na_2S, S, Sb and W by heating at ambient pressure followed by cooling [4]. In addition, several glassy sulfide electrolytes with sodium-ion conductivity and compatibility with Na metal negative electrode are discussed [5-7].*

Machine Learning and Big-Data Aided Materials Discovery and Interface Design in All-Solid-State Batteries

Ling Chen; Toyota Research Institute of North America, United States

All-solid-state batteries (ASSBs) hold significant promise for enhanced safety, energy density and power density compared to conventional lithium-ion batteries. A critical step to unlock the full potential of ASSBs is the discovery of materials mitigating the significant challenges such as low bulk conductivity and poor interface stability. Traditional trial-and-error based materials research are often slow and labor-intensive, presenting significant bottlenecks. In this talk, we explore the transformative potential of artificial intelligence (AI) in expediting the discovery and optimization of materials for ASSBs. We start with the patterns of fast ionic conduction unveiled through AI analysis of crystalline structures. Furthermore, we discuss the application of machine learning potential in understanding the collective conduction dynamics. Finally, we employ the big-data analysis to another domain of ASSB research, the design of electrolyte-electrode interfaces.

Central Metal Halide Bond Dependent Chemical Compatibility of Halide Solid Electrolytes with Li_6PS_5Cl for All Solid State Cell

Susmita Bera, Lily Mandal, Ripan Biswas and Abhik Banerjee; TCG Centres for Research and Education in Science and Technology, India

Halide solid electrolytes have gained a lot of research attention in the past decade due to their wide electrochemical stability window, especially their high oxidative stability enables their use with high voltage cathodes. None the less their limited reduction stability against Li metal enforces a bilayer separator configuration with sulfide solid electrolytes in all solid-state batteries. However, there are indication/ concern of electrochemical incompatibility between the halide and sulfide solid electrolyte. Here, we study the chemical *reactivity between sulfide SE Li_6PS_5Cl with halide SE by varying the central metal ion and their impact on cell performance in bilayer configuration. We performed operando electrochemical impedance spectroscopy, operando temperature dependent synchrotron X-ray diffraction, ex-situ X-ray photoelectron spectroscopy and differential scanning calorimetry to quantify the reactivity between the sulfide and halide SE. We infer, that the reaction kinetics is indeed determined by the central metal atom of the halide solid electrolyte with Li_3InCl_6 and Li_2ZrCl_6 being highly reactive with Li_6PS_5Cl whereas Li_3YCl_6, Li_3ScCl_6 and Li_3ErCl_6 being stable. Our work provides a guideline for selecting HSE and SSE pair for bilayer all solid-state batteries.*

A First-Principles Based Study of Fundamental Thermodynamic, Kinetic and Mechanical Properties of Lithium and Its Alloys *Sesha S. Behara, Jeremiah Thomas and Anton Van der Ven; University of California, Santa Barbara, United States*

All-solid-state batteries are increasingly being recognized as a viable high-energy density alternative to commercial lithium-ion batteries. Lithium alloys play a crucial role in enabling uniform plating and stripping of lithium metal in all-solid-state batteries. The specific role metal additions play in morphological evolution at the anode remains poorly understood, however, their ability to form alloys with lithium appears to be crucial. Despite their increased importance, many fundamental properties of lithium-metal alloys remain poorly characterized and understood. In this contribution, we report on a systematic first-principles study of fundamental thermodynamic, kinetic and mechanical properties of lithium and several important Li-M alloys (M = Mg, Ag, Zn, Al, Ga, In, Sn, Sb and Bi). Most lithium-metal alloys prefer perfect stoichiometric intermetallic compounds, with the exception of Li-Mg, which forms a solid solution. We show that pure lithium and its alloys have an unusually flat energy landscape along paths that connect the BCC crystal structure to close-packed structures such as FCC and HCP. Only when the concentration of the alloying element increases does the energy landscape become progressively stiffer. We predict exceptionally low migration barriers for lithium diffusion in pure Li and many Li-intermetallics comparable to superion conductors. The concentration of vacancies crucial for mediating substitutional diffusion, however, is predicted to be very low in metallic Li and most Li-M intermetallics, resulting in low diffusion coefficients despite the unusually low migration barriers. We identify several intermetallic compounds, such as B32 LiAl and LiGa, $D0_3$ Li_3Sb and Li_3Bi, which favor structural vacancies at the higher ends of their voltage stability windows that, coupled with very low migration barriers, show exceptionally high Li mobilities. We believe our results are relevant to experimental researchers and the large community of battery modelers of morphological evolution and are invaluable in directing the rational design of all-solid-state batteries.

Enhanced Cycling Stability of All-Solid-State Lithium-Sulfur Battery Through Nonconductive Polar Hosts
Yuan Yang; Columbia University, United States

All-solid-state lithium−sulfur batteries (ASSLSBs) are promising next-generation battery technologies with a high energy density and excellent safety. Because of the insulating nature of sulfur/Li2S, conventional cathode designs focus on developing porous hosts with high electronic conductivities such as porous carbon. However, carbon hosts boost the decomposition of sulfide electrolytes and suffer from sulfur detachment due to their weak bonding with sulfur/Li2S, resulting in capacity decays. Herein, we propose a counterintuitive design concept of host materials in which nonconductive polar mesoporous hosts can enhance the cycling life of ASSLSBs through mitigating the decomposition of adjacent electrolytes and bonding sulfur/Li2S steadily to avoid detachment. By using a mesoporous SiO2 host filled with 70 wt % sulfur as the cathode, we demonstrate steady cycling in

ASSLSBs with a capacity reversibility of 95.1% in the initial cycle and a discharge capacity of 1446 mAh/g after 500 cycles at C/5 based on the mass of sulfur.

Lithium Imide—A Novel Solid Electrolyte for Li-Ion Batteries *Oskar Soulas, Alex G. Squires, Jeremy Lowen, Josh W. Makepeace and David O. Scanlon; University of Birmingham, United Kingdom*

Antifluorite lithium imide (Li_2NH) has been extensively studied for use in hydrogen storage, but its high Li-ion conductivity has allowed it to be re-examined as a potential solid electrolyte.[1,2] *This is particularly interesting as the constituent elements are earth abundant and lightweight. Synthesis and processing are also cheap and require low energy input compared to other leading lithium solid electrolytes such as the lithium garnets.*[1,2] *Previous studies have identified a wide electrochemical stability window further suggesting that Li_2NH could be suitable for use as a solid electrolyte.*[2] *Working with experimental collaborators, we are looking to understand the diffusion processes and validate as-yet-unpublished promising experimental results.*

In this study, we investigate the nature of the ion-conducting properties found in members of the lithium-amide lithium-imide lithium-nitride solid solution. This starts with the end members, Li_2NH and $LiNH_2$. We observe atom dynamics on a femtosecond scale using high-quality bulk Ab Initio Molecular Dynamics (AIMD), allowing us to compare the bulk conductivities of the stoichiometric, lithium stuffed, and lithium deficient structures. Benchmarking MLIPs against DFT allows us to run these simulations over a long period of time at a reduced cost whilst ensuring that accuracy is maintained. Our analysis provides unprecedented insight into the coupled nature of ion movement in these systems.

4:00 PM EN08.02.08

Implications of the Mechanical, Electronic and Ionic Properties of Bulk and Surface Li_6PS_5Cl Argyrodite Structures on Lithium Filament Resistance *Gregory Pustorino[1], Harsh D. Jagad[1], Wenzao Li[1], Min Feng[1], Matteo Poma[1], Jeonghyun Ko[2], Priya Johari[3] and Yue Qi[1]; [1]Brown University, United States; [2]SK Battery R&D Center, Korea (the Democratic People's Republic of); [3]Shiv Nadar (Institute of Eminence Deemed to be University), India*

Li-filament growth has been experimentally observed in numerous promising solid electrolytes (SEs), such as garnet $Li_7La_3Zr_2O_{12}$ (LLZO), NaSICON-type $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (LAPT), Li_2PO_2N (LiPON), and argyrodite Li_6PS_5Cl (LPSC), therefore preventing the use of Li-metal anodes in all-solid-state-batteries (ASSBs). Herein, we probed the mechanical, electronic, and ionic properties of LPSC, with density functional theory (DFT) calculations, and compared with other SEs to determine the relevant factors for predicting Li-filament resistance in SEs.

LPSC has a complicated structure which can incorporate anion inversion between S^{2-}/Cl^-; and has Li^+ distributed among two Wyckoff sites (24g and 48h). In order to probe the bulk and surface properties of LPSC, we first determined a representative bulk structure that incorporates S^{2-}/Cl^- inversion, and Li^+ distributed among 24g and 48h sites, via random structure sampling. The lowest energy bulk structures contained no S^{2-}/Cl^- inversion and had ~80% of Li^+ in 48h sites after relaxation, which agrees with previous experimental studies.

The shear modulus and fracture energy of the bulk LPSC were also calculated to *understand the mechanical resistance to filament growth. Surfaces were cleaved in the (100), (110), and (111) directions, with the (100) direction having the lowest fracture energy. For the (100) direction of LPSC, four additional surfaces were cleaved with the following stoichiometries: Li_2S-rich, Li_2S-deficient, LiCl-rich, and LiCl-deficient. Of these surfaces, the Li_2S-deficient slab had the lowest fracture energy (0.20 J/m^2), which is far lower than the fracture energy of LLZO (1.76 J/m^2). Due its low fracture energy, and small shear modulus (10 GPa), especially when compared to LLZO (56 GPa), LPSC is likely to experience mechanical cracking.*

Surface bandgaps were found and compared to the bulk for all four (100) surfaces. It has been proposed that a reduced surface bandgap and excess electrons trapped inside internal defects, such as pore surfaces or crack surfaces, can directly reduce Li^+ to Li^0, leading to filament growth ahead of the crack tip in SEs. Bandgap and electron distribution calculations indicated no significant excess electron trapping in the LPSC surfaces. Additionally, due to the low fracture energy of all the surfaces tested, we predict that LPSC will form Li-filaments through dry-cracks, with a mechanical crack opening up first, then Li^+ flowing in to fill the crack. This is consistent with experimental observations and opposite to the wet-cracks found in LLZO.

4:15 PM EN08.02.09

Ion-Exchange in LLZTO to Induce Compressive Stress and Improve Electrochemical Performance *Sydney Morris[1], Harsh D. Jagad[1], Stephen J. Harris[2], Changmin Shi[1], Yue Qi[1] and Brian Sheldon[1]; [1]Brown University, United States; [2]Lawrence Berkeley National Laboratory, United States*

This experimental study builds on a computational model that analyzed the feasibility of ion-exchange (IX) in the solid electrolyte (SE) lithium lanthanum zirconium tantalum oxide (LLZTO) [1]. IX is commonly used to increase the fracture resistance of glasses. Employing IX to induce compressive stress in a solid electrolyte like LLZTO also has the potential to improve electrochemical performance by delaying lithium (Li) filament penetration through the SE. To explore this, various salt chemistries and heat treatments were employed. A multi-beam optical stress sensor (MOSS) was used to measure curvature due to the IX induced stress. Scanning electron microscope (SEM) and electron-dispersive X-ray spectroscopy (EDS) were used to further characterize samples. Electrochemical tests with symmetric Li/Li cells, including long-term cycling tests and critical current density (CCD) measurements were used to benchmark improvements in electrochemical performance compared to baseline values. Results demonstrate that carefully controlled IX with LLZTO can introduce stress in the near surface layer, increase CCDs, and improve long-term cycling performance in a symmetric Li/Li cell.

Combinatorial Printing of Functionally Graded Solid-State Electrolyte for High-Voltage Lithium Metal Batteries *Qiang Jiang, Stephanie Atampugre, Yipu Du, Lingyu Yang, Jennifer L. Schaefer and Yanliang Zhang; University of Notre Dame, United States*

Heterogeneous multilayered solid-state electrolytes (HMSSEs) have been widely explored for their broadened working voltage range and compatibility with electrodes. However, due to the limitations of traditional manufacturing methods such as casting, the interface between electrolyte layers in HMSSE can decrease the ionic conductivity severely. Here, a novel combinatorial aerosol jet printing (CAJP) is introduced to fabricate a functionally graded solid-state electrolyte (FGSSE) without sharp interface. Owing to the CAJP's unique ability (in *situ mixing and instantaneous tuning of the mixing ratio), FGSSE with smooth microscale compositional gradation is achieved. Electrochemical tests show that FGSSE has excellent oxidative stability exceeding 5.5 V and improved conductivity (>7 times of an analogous HMSSE). By decoupling the total resistance, we show that the resistance from the electrolyte/electrolyte interface of HMSSE is 5.7 times the total resistance of FGSSE. The Li/FGSSE/NCM622 cell can be stably run for more than 200 cycles along with improved rate performance.*

Microscopic Insights into Enhancing Mechanical Properties and Ionic Conductivity in Sodium Solid Electrolytes *Miaofang Chi[1,2] and Zhenwu Fang[2]; [1]Duke University, United States; [2]Oak Ridge National Laboratory, United States*

Solid-state sodium batteries offer a safer and more stable alternative to traditional liquid electrolyte batteries, significantly reducing risks such as leaks and fires. Additionally, sodium's abundance and cost-effectiveness relative to lithium make these batteries a promising option for scalable, sustainable energy storage. Sodium-ion solid electrolytes, particularly sodium zirconium phosphate (NaSICON), are distinguished by their low manufacturing costs, superior ionic conductivity, broad electrochemical windows, and robust chemical and thermal stability, making them outstanding candidates for all-solid-state sodium batteries. However, challenges such as limited mechanical properties and high interfacial resistivity limit their practical application. In this presentation, I will share our recent studies that elucidate the microscopic origins of these limitations and explore potential microstructural enhancements. A comparison of different ceramic solid electrolytes will also be provided.

9:00 AM *EN08.03.02

Atomic Resolution Imaging of Structure Evolution in Li-Rich and Disordered Rock-Salt Cathode Materials
Weixin Song[1], Emma Hedley[2], Miguel A. Pérez-Osorio[1], Jun Chen[1], Liquan Pi[1], Zhiyuan Ding[1], John-Joseph Marie[1], Robert House[1], Peter Bruce[1] and Peter D. Nellist[1]; [1]University of Oxford, United Kingdom; [2]Monash University, Australia

Atomic resolution transmission electron microscope (TEM) can allow direct imaging of defects in battery materials, but for imaging of cathode materials there are significant challenges. These challenges include the beam sensitivity of the materials, especially in their charged state, and the low image contrast of low atomic number elements such as Li and O. We have shown that the simultaneous application of annular dark-field (ADF) imaging and ptychography in the scanning TEM (STEM) can overcome these challenges. The ADF image allows for identification of the TM sublattice. Ptychography, being a phase-sensitive imaging mode, allows observation of Li and O. It also makes efficient use of the scattered electrons, allowing lower doses and therefore reduced beam damage, and also the correction of residual aberrations improving contrast and precision in images of cathode materials. By dismantling cells at various points in the charge-discharge cycle and using anaerobic transfer to the microscope, the evolution of the degree of crystallinity and the nature of defects has been studies using the simultaneous ADF and ptychography approach.

As an example of this approach to studying cathode nanostructure, in previous work we have previously shown that an O sublattice distortion occurs in $Li_{1.2}Ni_{0.13}Mn_{0.54}Co_{0.13}O_2$ (LRNMC) on charge that persists on discharge which can be associated with the voltage hysteresis seen in these materials [1].

We have gone on to show that honeycomb ordering within TM layers consists of domains of different rotations. The projection through the inclined boundaries between such domains can be erroneously interpreted as being a rhombohedral disordered phase. We find the domains shrink on charge, but that they can partially regrow in size on discharge.

At the end of the TM-oxidation region and before the high voltage O oxidation plateau, we observe Li occupying alkali-layer tetrahedral sites on opposite sides of the TM layers, forming Li-Li dumbbell configurations. We also observe the in- and out-of-plane TM migration as well as a partial phase transition from O3 to O1 stacking. In the O1 stacking phase, tetrahedral Li is absent, consistent with our DFT calculations indicating the O1 phase is not thermodynamically stable to accommodate tetrahedral Li.

Finally, we show how direct real-space imaging can reveal details of the structural correlations associated with short-range order in a range of disordered rock-salt cathode materials.

Understanding Solid-State Synthesis of Layered Oxide Cathodes by Operando Synchrotron Characterization

Wenhua Zuo, Guiliang Xu and Khalil Amine; Argonne National Laboratory, United States

The chemical and structural transformations during solid-state synthesis are crucial for developing cost-effective, durable, and high-energy inorganic battery cathodes. However, the thermodynamic and mechanic origins and their effects on synthetic reactions are yet to be fully elucidated. In this work, using a manganese (Mn)-rich precursor specifically targeted for cost-effective cathodes, we decoupled the distinct contributions of thermodynamic parameters in the solid-state synthesis of P2-type Mn-rich layered oxide cathodes for sodium-ion batteries. By utilizing operando synchrotron X-ray diffraction, full field 3D transmission X-ray tomography, high-resolution transmission electron microscopy, and density functional theory calculations, we identified the key reaction pathways that governing the transformation during solid-state synthesis. These pathways ultimately affect the crystallite size, morphology, and electrochemical properties of the resultant layered oxide materials.

Metastable Lithium-Rich Niobium and Tantalum Oxides *Sarah Ko and Kent J. Griffith; University of California, San Diego, United States*

Lithium-rich early transition metal oxides are the source of excess removeable lithium that affords high energy density to lithium-rich battery cathodes. They are also candidates for solid electrolytes in all-solid-state batteries. These highly ionic compounds are sparse on phase diagrams of thermodynamically stable oxides but soft chemical routes offer an alternative to explore new alkali-rich crystal chemistries. In this work, a new layered polymorph of Li_3NbO_4 *with coplanar* $[Nb_4O_{16}]^{12-}$ *clusters is discovered through ion exchange chemistry. A more detailed study of the ion exchange reaction reveals that it takes place almost instantaneously, changing crystal volume by more than 22% within seconds. The transformation of coplanar* $[Nb_4O_{16}]^{12-}$ *in L-*Li_3NbO_4 *into the supertetrahedral* $[Nb_4O_{16}]^{12-}$ *clusters found in the stable cubic c-*Li_3NbO_4 *is also explored. Furthermore, this synthetic pathway is extended to access a new layered polymorph of* Li_3TaO_4*. NMR crystallography with* $^{6,7}Li$*,* ^{23}Na*, and* ^{93}Nb *NMR, X-ray diffraction, neutron diffraction, and first-principles calculations is applied to* A_3MO_4 *(A = Li, Na; M = Nb, Ta) to identify local and long-range atomic structure, to monitor the unusually rapid reaction progression, and to track the phase transitions from the metastable layered phases to the known compounds found by high-temperature synthesis. This study has implications the expansion of lithium-rich transition metal oxides and associated battery materials and for ion exchange chemistry in non-framework structures. The role of techniques that can detect light elements, local structure, and subtle structural changes in soft-chemical synthesis is emphasized.*

Operando Neutron Imaging-Guided Gradient Design of Li-Ion Solid Conductor for Extremely High Mass-Loading Cathodes *Hongli Zhu and Tongtai Ji; Northeastern University, United States*

High mass-loading cathodes are crucial for achieving high energy density in all-solid-state batteries from lab scale to industry. However, as mass-loading increases, electrochemical performance is significantly compromised due to sluggish kinetics. Operando neutron imaging of a high mass-loading NMC 811 cathode of 33 mg/cm^2 *(5.0 mAh/cm*^{2}*, 180 µm thick) reveals the lithiation prioritization of the cathode active material (CAM) from the solid electrolyte layer to the current collector side. In addition to the tortuosity, another key limitation to ion transfer in the cathode arises from the mismatch between the uniform distribution of the solid electrolyte (catholyte) in the conventional composite cathode and the non-uniform* Li^+ *flux generated by the Faraday reaction of CAMs. Therefore, a novel design with a gradient in the catholyte concentration is engineered to match the* Li^+ *flux distribution, aiming to eliminate the ion transfer obstacle. This innovative approach demonstrates enhanced rate performance, even with ultra-high mass-loading cathodes. A* $LiCoO_2$ *composite cathode with 100 mg/cm*^{2} *ultra-high mass-loading exhibited an areal capacity of 10.4 mAh/cm*^{2} *at a current density of 2.25 mA/cm*^{2}*. This work demonstrated an effective gradient design to optimize ion transport in high mass-loading cathodes to overcome the kinetic barrier and achieve high battery performance.*

Lighting the Path—Design Principles for Halide-Ion Solid Electrolytes Through Spectroscopy and Simulation *Jingxiang Cheng, Victor Gomez and Sarbajit Banerjee; Texas A&M University, United States*

Lithium-ion energy storage technology has become ubiquitous due to its unmatched energy density and diverse form factors. However, the large-scale production of lithium-ion batteries raises concerns about material *criticality. Halide-ion batteries have emerged as a promising alternative, offering higher theoretical energy densities with substantially less criticality concerns as compared to lithium and post-lithium-ion technologies. This growing interest in halide-ion batteries has spurred research into anion migration mechanisms in periodic solids. Rare-earth oxyhalides, capable of crystallizing in diverse structures with well-separated halide-ion slabs, represent potential solid electrolytes for these batteries. By controlling synthesis methods and processing conditions, we prepare compositionally complex oxyhalides stabilized in different polymorphic forms. We will discuss LaOCl and ErOCl crystallized in PbFCl and and YOF/SmSI structures as model systems to explore composition—structure—function correlations. We will specifically discuss the role of site-selective modification in altering halide-ion migration pathways, diffusion energy barriers, and transition states. Using a combination of first-principles simulations, X-ray spectroscopy techniques, X-ray scattering and electrochemical impedance spectroscopy we examine vacancy formation and its implications for halide-ion mobility. Notably, X-ray Excited Optical Luminescence spectroscopy represents a novel probe for characterizing halide ion defects and mobility. First-principles simulations, including nudged elastic band calculations and ab initio molecular dynamics enable mapping of halide ion migration pathways. We will discuss the role of co-intercalation and anion replacement in introducing localized distortions within the halide layers, which provides access to low-energy anion-hopping mechanism. By examining the modulation of ionic conductivity with site-selective modification on the cation and anion sublattice and developing systematic—structure function correlations, we aim to advance understanding of ion transport phenomena within solid-state electrolyte systems and to design components vital to next-generation halide batteries.*

11:00 AM EN08.03.07

Unraveling Nano-Engineered Microstructure in Large Particle DRX Cathode Particles *Tara P. Mishra[1], Han-Ming Hau[2,1], Tucker M. Holstun[2,1], Colin Ophus[1], Karen Bustillo[1] and Gerbrand Ceder[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States*

Lithium-ion (Li-ion) batteries are pivotal to technological progress, thanks to their impressive energy density and longevity. However, conventional cathode materials, which predominantly rely on layered and spinel structures, depend on limited and controversial resources such as nickel (Ni) and cobalt (Co). Disordered rocksalt (DRX) materials have emerged as a new class of high-capacity earth-abundant cathodes. The remarkable performance of high Mn-content large particle (~1 μm) DRX materials appears to be enabled by a transformation of the material to a spinel-like (δ-phase). This phase shows partial disorder at multiple length scales making classical characterization techniques challenging. In this work, we use scanning electron nano diffraction (SEND) with the help of a pixelated detector to understand the phase transformation of the DRX cathodes to the δ-phase upon chemical delithiation. We find the δ-phase to be a partially disordered spinel with the transition metals (Mn and Ti) showing 16c/16d order over a short coherence length. Furthermore, using high-resolution HAADF-STEM imaging, we observe the existence of the antiphase boundaries that separate nanoscale (~3 nm) spinel domains. The atomic insights help to explain the superior performance of the large particle chemically delithiated DRX cathodes. Through this study, we will showcase how correlative microscopy can solve exciting material problems across different length scales.

11:15 AM EN08.03.08

Cation Disorder and Anionic Transport in New Complex Oxides from Experimental and Computational NMR Spectroscopy *Frederic Blanc; University of Liverpool, United Kingdom*

Melilite $La_{1.54}Sr_{0.46}Ga_3O_{7.27}$ *(Nat. Mat.* ***2008****, 498) and langasite* $La_3Ga_{5-x}Ge_{1+x}O_{14+0.5x}$ *(*$x < 1.5$*) oxides (Chem. Mater.* ***2019****, 5742) have attracted significant research interests as next generation solid electrolytes owing to their high oxide ion conductivity in the 600°C and 800°C temperature range. Multinuclear, multidimensional NMR data aimed*

*at elucidating cation disorder and oxygen dynamics in melilite (JACS **2023**, 21817; ChemPhysChem **2024**, e202300934) and langasite (JACS **2024**, 14022) have established the oxygen transport mechanism of these highly conductive phases.*
Structural information is provided by multinuclear magic angle spinning (MAS) NMR experiments up to 1.5 GHz, 35.2 T at the NHMFL and is aided by first principles computation using an ensemble-based approach to comprehensively model the complex sites disordered. Powerful insights into the local dynamics are also gained from a range of ^{17}O and ^{71}Ga high temperature (HT) MAS NMR approaches and obtained with exciting probe capabilities enabling experiments up to 700°C under MAS at 850 MHz, 20 T to be recorded.
Strongly deshielded signals in the ^{17}O MAS NMR spectra are observed in the doped phases, which are not observed for the pristine materials, and are assigned to defective oxygen interstitials associated with La^{3+} or Ge^{4+} doping in melilite and langasite, respectively. Five-coordinate Ga sites accommodating the interstitial defects are also clearly identified from ^{71}Ga NMR spectra at 35.2 T. Coalescence of all the signals in the ^{17}O HT MAS NMR spectra of melilite and langasite above 300 °C and 400 °C, respectively, indicates chemical exchange between all signals implying the unexpected participation of all oxide ions in the diffusion mechanism. This work addresses profound debates in the literature and suggests design rules for next generation fast oxide ion conductors.

Repelling Polysulfide Shuttling in All-Solid-State Lithium-Sulfur Batteries Using Dynamic Anionic Polymers

Hao Lyu, Xin Gao, Xueli Zheng, Yi Cui and Zhenan Bao; Stanford University, United States

Lithium-sulfur (Li-S) batteries are positioned as a promising alternative to current lithium-ion batteries as next-generation energy storage technologies. However, polysulfide shuttling poses a pressing barrier to realizing this target. Li-S batteries are characterized by their unique capabilities including high energy density and cost-effectiveness, however, the migration of polysulfide species within the battery electrolyte severely compromises their performance, leading to rapid capacity decay and reduced cycle life. Addressing this issue is crucial for unlocking the potential of Li-S batteries in applications ranging from portable electronics to electric vehicles.
In response to this challenge, our research introduces an approach designed to inhibit the shuttling of polysulfide species in an all-solid-state Li-S battery using dynamic, anionic polymer networks. By developing a polymer electrolyte network that integrates charge centers with solvation-tuning side chains, we strategically modify the solvation environment to make it unfavorable for lithium polysulfides to diffuse into the bulk electrolyte, but instead to stay in place to participate the redox processes in the sulfur cathode. This dual-action mechanism effectively prevents polysulfide migration, thereby enhancing the battery's cycling stability and performance. We performed a comprehensive analysis combining experimental observations with density functional theory (DFT)-based calculations to elucidate the underlying interactions at play. We further used in situ optical monitoring, Raman spectroscopy, and X-ray absorption spectroscopy to obtain direct evidence of the polymer electrolyte's ability to repel lithium polysulfides during battery operation. The integration of these techniques provides a robust framework for understanding the complex dynamics influencing Li-S battery performance, offering insights that extend beyond conventional analytical methods.
The implications of our findings offer a viable pathway to significantly improve the performance and extend the lifetime of Li-S batteries. By demonstrating a tangible solution to the polysulfide shuttling problem, our work contributes to the broader adoption of Li-S technology in a wide array of energy storage applications. As we continue to refine and optimize our polymer electrolyte design, we anticipate further breakthroughs that will solidify the position of Li-S batteries as a cornerstone of sustainable energy systems.

11:45 AM

Materials for Renewable and Low-Carbon Energy Technologies—Advancements, Challenges and Prospects

Muhammad Asif; King Fahd University of Petroleum and Minerals, Saudi Arabia

In response to energy and environmental challenges like growing demand for energy, depleting fossil fuel reserves, soaring energy prices, risks with security of supplies, and above all climate change, the world is seeking a sustainable energy transition. With decarbonization being at its heart the energy transition is being primarily propelled by renewable energy. The global energy sector is already being led by solar energy and wind power with over 85% of the world's total installed power generation capacity in 2023 coming from solar photovoltaic (PV) and wind turbines. In recent years solar PV and wind power have made huge advancements on technological fronts. This study examines the role advanced materials have played in the success of these technologies in terms of improving their durability, efficiency, cost reduction, and environmental sustainability. It also explores the materials-related challenges the renewable sector needs to address. The performance enhancement goals in the renewable sector – as reflected by the development of more efficient solar cells, and bigger and more powerful wind turbines, can only be achieved through more sophisticated and high-performance materials.

SESSION EN08.04 Solid State Battery-Sodium
Session Chairs: Miaofang Chi and Peter Nellist
Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Ballroom C

1:30 PM *EN08.04.01
Enabling Ambient Sodium-Sulfur Batteries *Rachel Carter[1], Cynthia Pyles[1], Louis Morris[2], Alison McCarthy[1], Michael W. Swift[1], Matthew J. Lefler[3], Zachary Neale[1], Vinh Nguyen[1], Darryl Boyd[1], Jeffrey Long[1], Adam Dunkelberger[1], Debra R. Rolison[1], Iryna Zenyuk[4], Adrien Stejer[4], Jasbinder Sanghera[1], Woohong Kim[1] and Megan B. Sassin[1]; [1]U.S. Naval Research Laboratory, United States; [2]ASEE Postdoctoral Appointment, United States; [3]Excet, INC, United States; [4]University of California, Irvine, United States*

Ambient sodium-sulfur batteries exploit the high energy electrochemical reaction of the globally abundant elements. However, these batteries are not yet realized due to their complex conversion reactions. Five groups of distinct expertise at US Naval Research Laboratory are combining to address fundamental knowledge gaps and a demonstrate a commercially viable system. We utilize unique in-situ spectroscopy and optical microscopy to better understand the fundamentals of the reaction. These findings inform electrolyte component selection and electrode design. Glassy-blends of chalcogens, previously explored for infrared optics, demonstrate distinct discharge mechanism that limits undesirable polysulfide formation. Finally, electrode design of the sulfur cathode is supported by a novel carbon nanofoam paper (CNFP) developed at NRL, which had tunable porosity, surface area, thickness, and sulfur loading. This platform demonstrates high areal capacity (>4 mAh/cm2) and impressive capacity retention. Combining these findings, we demonstrate the scalability of this cathode in a lab-scale pouch prototype, accompanied by a metallic sodium anode, and sandwiched with spectroscopy-informed electrolyte.

Halide-Based Solid Electrolyte with High Ionic Conductivity for All-Solid-State Sodium Batteries *Laisuo Su; The University of Texas at Dallas, United States*

All-solid-state batteries (ASSBs) are becoming a promising energy storage technology as they bring the safety of state-of-the-art batteries to the next level by replacing flammable organic liquid electrolytes (OLEs) with nonflammable solid electrolytes (SEs). The good mechanical properties of SEs further allow the usage of metal anodes to achieve very high energy density. Thus, developing SEs with desired properties is crucial to the commercialization of ASSBs. Despite the tremendous progress that has been made in the past decades, the progress and application are still in the infancy, experiencing numerous challenges for sodium solid-state batteries due to inherently low room-temperature ionic conductivity, interface complications, and fabrication. Inorganic halide-based SEs have emerged as a game changer because of their fast-conducting characteristics, adequate thermodynamic stability, great deformability, and good oxidative stability. Moreover, halide-based SEs are generally stable against moisture owing to their positive hydrolysis reaction energy. However, most of the studied halide-based SEs are based on the Li-ion system, with only a few based on the Na-ion system. Moreover, despite halide-based Na SEs theoretically having high ionic conductivity, experimentally obtained samples have much lower ionic conductivities compared to their Li counterparts (usually < 0.1 mS cm^{-1}). Therefore, developing halide-based SEs with high Na$^+$ ionic conductivity is crucial for Na ASSBs. We recently identified a new Na halide-based SE with a room temperature Na$^+$ ionic conductivity over 1 mS cm^{-1}. The activation energy is also as low as 0.23 eV. Interestingly, the material shows a mixed amorphous and crystalline phase, and its ionic conductivity decreases with the increase of the crystalline phase. The ionic conductivity of > 1 mS cm^{-1} is already comparable to some organic liquid electrolytes and thus is sufficient for many practical applications. The developed strategy has the potential to be applied to other halide-based SEs to improve their ionic conductivity, promoting the development of SIBs.

2:15 PM EN08.04.03
Computational Design of Fluorophosphate Cathode Materials for Na-Based Batteries *Hafssa Arraghraghi and Matteo Bianchini; Universität Bayreuth, Germany*

Significant scientific and economic challenges are presented by developing battery systems with increased energy storage capacity. Geopolitical issues might pose supply chain risks for lithium (Li)−ion batteries, which are frequently used in portable electronics. As an alternative, sodium−ion batteries (NIBs) have emerged as a promising candidate due to their potential for economic viability and reduced supply chain vulnerabilities.
One of the most examined cathode materials is the fluorophosphate family $Na_3V_2(PO_4)_2F_{3-2y}O_{2y}$ *(0 < y < 1), which has demonstrated superior performance to most layered oxides and is being developed as a competitive sodium−ion cathode material in academia and in the start-up environment [1]. Current research is directed towards improving the performance of* $Na_3V_2(PO_4)_2F_3$*, that experimentally has shown impressive stable capacity and commendable rate capability over 4000 cycles [2]. Recently, we reported new computational and experimental findings regarding the solid-state synthesis of* $NVPF_{3-2y}O_{2y}$ *compounds, notably* $Na_3V_2(PO_4)_2F_2O$ *and* $Na_3V_2(PO_4)_2FO_2$*, where we have identified favorable thermodynamics for an innovative synthesis route, particularly when utilizing* $(VO)_2P_2O_7$ *as starting material [3].*
Nonetheless, V is not an abundant element (roughly with the same content as Ni in the Earth crust) and more importantly does not have a developed supply chain at large scale. Therefore, the use of alternative elements to replace V in the NVPF structural framework would be highly welcome. Our work is directed towards enhancing the sustainability and performance of $Na_3V_2(PO_4)_2F_3$ *by substituting Vanadium with other transition metal elements. While some of these have been recently investigated [4], we propose an ample selection of substitutional elements and investigate them via Density Functional Theory (DFT) with VASP, using the more accurate r2SCAN functional with D4 dispersion corrections [5], as well as the nudged elastic band (NEB) method to compute activation barriers for Na migration. Finally, we are exploring the feasibility of various synthesis routes of* $Na_3V_2(PO_4)_2F_3$ *with these alternative transition metals.*

2:30 PM BREAK

3:00 PM EN08.04.04
Design Principles for Sodium Superionic Conductors *Shuo Wang[1,2], Jiamin Fu[3], Xueliang A. Sun[3,2] and Yifei Mo[1]; [1]University of Maryland, United States; [2]Eastern Institute of Technology, Ningbo, China; [3]University of Western Ontario, Canada*

Motivated by the high-performance solid-state lithium batteries empowered by lithium superionic conductors as solid electrolytes, sodium superionic conductor materials share great promises for enabling novel sodium batteries with high energy, low cost, and sustainability. Designing sodium superionic conductors with high ionic conductivities is a great challenge, hindered by the lack of appropriate design principles. Here, by studying the structures and diffusion mechanisms of Li-ion versus Na-ion in solids, we reveal that fast Na^+ Na-ion conductors exhibit the unique structural features of face-sharing high-coordination sites. By employing the new design principle based on this feature, we discover over a dozen of new families of fast Na-ion conductors in oxides, sulfides, and halides. Remarkably, a new chloride family of Na-ion conductors $Na_xM_yCl_6$ (M = Lanthanide) with UCl_3-type structure is discovered and experimentally confirmed with high Na ionic conductivities > 1 mS/cm at room temperature. Our results not only guide the future development of fast Na-ion conductors for new sodium batteries, but also consolidate and generalize different design principles for fast ion conductors, which can be further extendable and applicable to develop other types of ion-conducting materials for many different energy applications.

3:15 PM EN08.04.05
Realization of Long-Life Sodium-Ion Batteries Using Structure Engineered Cathodes and Heterostructured Anodes *Hyojun Lim[1,2], Ju Li[2] and Sang-Ok Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States*

Sodium-ion batteries (SIBs), as an alternative to conventional lithium-ion batteries, are gaining attention due to the earth-abundant and cost-effective nature of sodium resources. However, the realization of SIBs has been hindered by the lack of suitable cathode and anode materials for SIBs.
In terms of cathode materials, the Na-layered oxides provide high capacities but struggle with stability issues. The polyanionic materials are chemically/electrochemically stable but have lower reversible capacities and poor rate

performance. The Prussian blue analogues (PBA) offer moderate capacity, easy synthesis as well as excellent chemical stability, but to achieve good performance, control of microstructure and interstitial water is necessary. We developed long-life cathode materials (polyanionic and PBA) through elemental doping and surface modification strategies.

For the anode materials, hard carbon has been identified as a promising candidate for its reversible sodium-ion reactivity, but it has limited specific capacity, failing to meet high energy density requirements. Conversion- and alloy-based anodes offer high theoretical capacity but face challenges like volume changes, slow kinetics, and instability. To address these, we developed high-performance heterostructured anodes composed of conversion- or alloy-based materials (high capacity) and carbonaceous or ceramic materials (sodium-ion reactivity and chemical/electrochemical stability).

The physical and electrochemical properties of the designed cathodes and anodes were investigated through in-depth physicochemical analyses and battery tests. Various post-mortem analyses were also conducted to reveal electrode degradation phenomena and the effect of well-designed structures. Furthermore, we assembled and tested a full-cell, thereby evaluating the practical realization of SIBs.

3:30 PM EN08.04.06

Nb-Doped TiO$_2$ as a Promising Anode Material for Sodium-Ion Batteries *Alexander Eitner[1], Ahmed K. Al-Kamal[1], Md Yusuf Ali[1], Mohammed-Ali Sheikh[1], Hartmut Wiggers[1,2] and Christof Schulz[1,2]; [1]Universität Duisburg-Essen, Germany; [2]University of Duisburg-Essen, Germany*

Due to their low costs and high sustainability, sodium-ion batteries (SIBs) represent an alternative to lithium-ion batteries (LIBs) especially in the area of stationary battery storage and for small BEVs. Besides hard carbon, nanoscale TiO$_2$ is an attractive anode material in SIBs and doping with niobium is known to improve its electronic conductivity as well as the kinetics of the de-/intercalation of Na$^+$ ions. These effects are related to the formation of defects and lattice widening, leading to improved electrochemical properties in comparison to undoped TiO$_2$, i.e., capacity and rate capability.

We report a single-step synthesis of niobium-doped TiO$_2$ nanoparticles by scalable spray-flame synthesis based on a solution of titanium (IV) isopropoxide (TTIP) dissolved in mixtures of ethanol and ethyl hexanoic acid [1]. Niobium(V) ethoxide was identified as a preferred Nb precursor and added as dopant to the solution and materials with varying dopant concentrations were synthesized. The as-synthesized powders were analyzed with SEM/EDX confirming Nb concentrations matching the precursor mixture. XRD with Rietveld refinement revealed that the synthesized materials mainly consist of anatase with a minor contribution of rutile and Nb$_2$O$_5$ at higher doping concentration. Doping with Nb was also confirmed due to an increase of lattice parameters with higher Nb concentration. XPS analysis reveals the formation of Nb–O–Ti bonds, and the detected main oxidation state of +5 of Nb indicates successful incorporation of Nb^{5+} into the TiO$_2$ lattice.

Electrochemical analyses show an improved electronic conductivity and a higher Na$^+$ diffusion kinetics for the Nb-doped TiO$_2$ in comparison to undoped TiO$_2$. The highest reversible capacity of 194 mAh/g at 0.1 C and 83.7 ± 1.5 % capacity retention at 0.5 C after 100 cycles was observed for a material with 2 at.% Nb. This single-step synthesis route of these high-performing doped TiO$_2$ nanomaterials provides promising anode material for sodium-ion batteries.

Achieving High Energy Density, Nickel-Free Sodium-Ion Full Cells with Direct-Contact Presodiation *Rhys A.*

Otten[1], Jessica R. Gallawa[1], Hala E. Soliman[1], Cyrus K. Kirwa[2], Autumn N. Peters[1] and Amy L. Prieto[1]; [1]Colorado State University, United States; [2]New Mexico State University, United States

Much like lithium-ion batteries, sodium-ion batteries are plagued by loss of cyclable ion inventory at both the cathode and the anode which limits the realized capacity of a cell. Loss of sodium ions due to the formation of the solid electrolyte interphase at the anode occurs primarily during the initial cycles of a battery, but in high volume expansion materials, such as antimony (Sb), this can be a continuous loss mechanism. Presodiation treatments aim to compensate for future losses by introducing an excess of sodium (Na) ions into the anode prior to cycling. Among the most industrially relevant of these techniques is direct-contact presodiation. In this work, we demonstrate the ability to controllably and reproducibly presodiate Sb, a high-energy density alloying anode through control of both pressure and time of treatment to enable a sodium-ion full-cell with improved initial coulombic efficiency (ICE) and without any critical materials at the anode or the cathode. In addition, we compare the effectiveness of our treatment method against a standard electrochemical presodiation protocol and analyze the surface chemistry of the anode in both cases with X-ray photoelectron spectroscopy (XPS).

4:00 PM EN08.04.08

Quantifying Continuous Configurational Entropies in Solid Electrolytes from Molecular Dynamics Simulations *Samuel W. Coles[1] and Benjamin J. Morgan[2]; [1]University of Cambridge, United Kingdom; [2]University of Bath, United Kingdom*

Within structurally related families of solid electrolytes, increasing disorder of some form is often associated with increased ionic conductivity. One such form of disorder that is often invoked to explain trends in ionic conductivity is the spatial or "configurational" disorder of the mobile ions. As a general rule, materials in which the mobile ions occupy identical regularly arranged sites are poor solid electrolytes, while materials with mobile ions that are disordered over crystallographically inequivalent sites often have much higher ionic conductivities. Providing the mobile ions occupy well-defined crystallographic sites, the degree of site disorder can be quantified from molecular dynamics simulation data using Shannon-like discrete configurational entropies, which are calculated as a function of the probabilities of each site being occupied [1].

While this approach yields semi-quantitative "configurational entropies" for the mobile ion species, the resulting values depend on the choice of discrete sites within each structure and on the approach used to assign mobile ions to individual sites. In addition, it necessarily gives a "coarse-grained" description of the mobile-ion configurational entropy and may discard useful information.

In this talk, we will present an alternative approach, wherein we calculate a continuous configurational entropy using methods drawn from the field of solution chemistry [2], using as input the time-average density of the mobile ion species calculated from molecular dynamics simulation. Obtaining well-converged results for the continuous single-particle entropy requires well-converged low-variance mobile ion densities, which we calculate using advanced statistical mechanical sampling techniques [3, 4].

While full thermodynamic calculations require accounting for many-body contributions to the configurational entropy, the single-particle configurational entropy is a useful descriptor for quantifying the degree of disorder for the mobile ion species in solid electrolytes. As an illustrative example, we apply our method to the lithium-ion solid electrolyte $Li_7La_3Zr_2O_{12}$ *(LLZO) and compare results for the low-temperature poorly-conducting tetragonal phase versus high-temperature highly-conducting cubic phase. Our results predict that the change in configurational entropy for the transition from tetragonal to cubic LLZO includes a non-trivial contribution from the host-framework configurational entropy, which would be considered to be zero using a discrete-site-projection scheme. This result* *provides a quantitative link between host-framework flexibility, mobile-ion disorder, and ionic conductivity in this archetypical lithium-ion solid electrolyte.*

All-Solid-State Lithium Battery with $LiNiO_2$ Cathode

Longlong Wang[1], Malachi Noked[2], Doron Aurbach[2] and Peter Bruce[1]; [1]University of Oxford, United Kingdom; [2]Bar-Ilan University, Israel

We report an all-solid-state lithium battery (ASSLB) based on a sulfide solid electrolyte and a $LiNiO_2$ *cathode. The latter is prepared with an outside-in structure.[1-3] The cathode is enabled by a high-pressure* O_2 *synthesis and subsequent atomic layer deposition of an ultrathin* $Li_xAl_yZn_zO_\delta$ *(LAZO) protective layer comprising a LAZO surface coating and an Al and Zn near-surface doping region. This interphase enhances the structural stability and interfacial dynamics of the cathode as it mitigates continuous side reactions at the cathode/solid electrolyte interface. Our ASSLBs exhibit a high areal capacity of 4.65 mAh/cm*^{2}*, a high specific cathode capacity of 203 mAh/g, cycling stability corresponding to 92% capacity retention after 200 cycles and a rate capability of 93 mAh/g.*

Towards a Universal Design Principle for Low-Hysteresis High-Valent Redox in Battery Cathodes—Synergizing Cationic Ordered Vacancies with Tunable Metal-Ligand Hybridization

Hugh B. Smith[1], Gihyeok Lee[2], Sravan Kumar Bachu[1], Aubrey Penn[1], Victor Venturi[1], Yifan Gao[1], Ryan Davis[3], Kevin H. Stone[3], Adrian Hunt[4], Iradwikanari Waluyo[4], Eli Stavitski[4], Wanli Yang[2] and Iwnetim I. Abate[1]; [1]Massachusetts Institute of Technology, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]SLAC National Accelerator Laboratory, United States; [4]Brookhaven National Laboratory, United States

Sodium-ion batteries have the potential to meet growing demand for energy storage due to their low costs stemming from natural resource abundances, but their cathode energy densities must be improved to be comparable to those of lithium-ion batteries. One strategy is accessing high voltage capacity through high-valent redox reactions. Such reactions usually cause instability in cathode materials, but $Na_2Mn_3O_7$ *has demonstrated excellent performance and reversibility in the high-valent regime due to its unique lattice structure with ordered Mn vacancies. This work expands the universality of the ordered vacancy as a design principle and increases the material candidates with such exceptional electrochemical behavior. Our approach involves synergizing cationic ordered vacancies with tunable metal-ligand hybridization through partial metal substitution. The impact of substitution in the low- and high-valent regimes is investigated through advanced microscopy and in-situ synchrotron X-ray characterization techniques. Substitution leads to larger specific capacities, enhanced cycle stability, and superior rate performance. This study lays the foundation for developing new cathode materials with*

stable high-valent redox through substitution of redox-active transition metals by employing cationic ordered vacancies and partial transition metal substitution as design principles in tandem.

Investigating Olivine Cathodes for Enhanced Energy Density in Lithium-Ion Batteries—Utilizing Advanced Characterization Techniques Spanning from Atomic to Electrode Level *Wonchan Hwang, Jaehwan Kim and Jungjin Park; Korea Institute of Science and Technology, Korea (the Republic of)*

The pursuit of high energy density has spurred significant interest in layered cathodes such as lithium nickel cobalt manganese oxide (NCM) and lithium nickel cobalt aluminum oxide (NCA), renowned for their excellent energy storage capabilities. However, Ni- and Co-based layered cathodes face significant thermal instability, resulting in a thermal runaway in short circuits, high-temperature exposure, and similar scenarios. Recently, lithium iron phosphate (LFP) has emerged as an alternative due to its enhanced structural and thermal stability, despite the absence of expensive metals such as Co and Ni. However, LFP encounters significant challenges, notably its inherently low redox potential and capacity (energy density), which undermines its competitiveness in electric device applications such as electric vehicles (EVs) and energy storage systems (ESSs).
Boosting energy density can now be accomplished by engineering active materials and electrode configurations. New strategies, such as increasing the working voltage through fine-tuning of active materials and/or using thick electrodes to augment the ratio of active materials per unit area, can achieve a breakthrough in elevating energy density within the existing battery volume dimension. However, transitioning to thick electrodes poses challenges related to electron and ionic conductivity, as well as the structural stability of the electrode.
Herein, I will present integrated strategies for enhancing the high-energy density of olivine cathodes. This includes not only atomic modifications such as substitutional doping with manganese to achieve a high redox voltage, but also particle/electrode engineering techniques like optimizing tap and press density, all characterized by advanced analyses. A comprehensive understanding will provide insights into conducting research on olivine-based cathodes and contribute to the impact of secondary batteries in both academia and industry

EN08.05.03

Gallium Ferrite as an Anode Material for Lithium-Ion Batteries *Mohan K. Bhattarai[1], Shweta Shweta[1], Shivaraju Guddehalli Chandrappa[1], Birendra Ale Magar[2], Ubaldo Córdova Figueroa[2], Ram Katiyar[1], Brad R. Weiner[3] and Gerardo Morell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]University of Puerto Rico at Mayagüez, United States; [3]University of Puerto Rico at Rio Piedras, United States*

Graphite, the commercially successful anode for lithium-ion batteries (LIBs), faces challenges such as an unsustainable supply chain and slow rate capabilities, highlighting the need for alternative anode materials. This study introduces $GaFeO_3$ (GFO), a novel alloy-conversion-based material, as a promising anode for LIBs. Bulk GFO materials were synthesized using a solid-state method. Electrochemical performance evaluations revealed that GFO anodes delivered an initial high discharge capacity of approximately 890 mA h g^{-1} at a current density of 100 *mA g^{-1}. Cyclic voltammetry (CV) studies confirmed an alloy-conversion-based reaction mechanism in the GFO anode, which was corroborated by density functional theory (DFT) calculations. The overall electrochemical performance of GFO suggests its potential as a viable alternative anode for LIBs.*

EN08.05.04

Cement-Based Electrolytes for Energy Storage Application *Birhan A. Abdulahi[1,2]; [1]Chalmers University of Technology, Sweden; [2]Wollo University, Ethiopia*

The global demand for energy is rapidly increasing. Currently, fossil fuels are the primary energy source, but they are both environmentally harmful and non-renewable. Renewable energy sources, such as solar cells, are gaining attention as potential replacements for fossil fuels. However, solar energy is mainly harnessed during daylight, necessitating the storage of excess energy for use at night. Energy storage devices are thus essential for this purpose. Buildings consume about one-third of the current energy production. One strategy to create self-powering buildings involves using concrete-based batteries.

In this study, cement-based electrolytes were developed for energy storage devices, leveraging the large surface area of buildings to store substantial amounts of energy. By incorporating various polymer additives, the properties of the cement-based electrolytes were optimized. Key properties such as pore size distribution, compressive strength, and ionic conductivity were crucial for these applications. The most effective composite electrolyte, balancing moderate strength and conductivity, was chosen to fabricate the energy storage devices. The electrochemical properties of these devices were then characterized using cyclic voltammetry and galvanostatic charge-discharge methods. This paper presents the test results, along with detailed analyses and discussions.

EN08.05.05

Development and Characterization of Molecular Organic Solid-State Electrolytes (MOSSEs) for Enhanced Safety and Performance in Lithium-Ion and Metal Batteries *Hilal AlSalih and Yaser Abu-Lebdeh; National Research Council, Canada*

There is a need to replace volatile and flammable liquid electrolytes with solid-state electrolytes to improve safety in lithium-ion batteries (LIB) and to enable the use of metallic lithium in next-generation solid-state batteries. Current research is focused on polymer electrolytes (salt-in-solvating polymer), polymer gels (electrolyte solution-in-polymer), and inorganic materials (e.g., oxide ceramics, sulfides, or halides). Each class of solid-state electrolyte has its own advantages and disadvantages. Active research is also being conducted on composites that combine the benefits of each to achieve optimal properties such as good ionic conductivities (σ), high lithium-ion transference numbers, and good thermal and electrochemical stability. However, challenges remain, including lithium dendrite growth during recharge and poor interfacial contact between the electrolyte and the two electrodes. A promising new class of solid electrolytes is Molecular Organic Solid-State Electrolytes (MOSSEs), which involve dissolving salts in molecular solvents that form solids at room temperature, particularly at the solvate-forming stoichiometry. These materials are known for their excellent mechanical properties—being very soft and malleable—and for their high ionic conductivities due to the presence of ion-conducting channels within the structure. In this work, we formulated different MOSSEs by mixing lithium salts in organic solvents at the solvate molar composition as indicated by the respective salt/solvent phase diagrams. These crystalline electrolytes were rationally designed to form stable cathode and anode interfacial layers (CEI and SEI). The ionic conductivity of these solid electrolytes was quantitatively analyzed using Electrochemical Impedance Spectroscopy (EIS) and they were also characterized using Differential Scanning Calorimetry (DSC), Thermogravimetric Analysis (TGA), and Fourier-Transform Infrared Spectroscopy (FTIR), and were cycled in half cells with NMC 811 and lithium metal electrodes

EN08.05.06

Colloidal Syntheses-Driven Discovery of Inorganic Solid Electrolytes Containing Unconventional Crystal Lattices and Composition to Optimize Ionic Conductivity and Mechanical Stability Parameters

Progna Banerjee; Loyola University Chicago, United States

Lithium-ion (Li$^+$), and beyond-Li$^+$ batteries power most portable electronic devices[1] and electric vehicles. Although current commercial Li$^+$ batteries primarily use liquid electrolytes, all-solid-state batteries[2] have been increasingly explored due to their improved safety[3] and energy density (500 Wh-kg, LGPS-type[4]). Solid electrolytes[5] allow to avoid the use of volatile, flammable organic electrolytes and increase Li$^+$ conductivity[6], chemical stability, electrochemical stability, and cycle life[7] of ion batteries. The biggest problem with solid electrolytes is the high temperatures[8] required (>353 K) for Li$^+$ to move around in the electrolyte materials. Sustainable battery development will additionally require solid electrolytes manufactured from earth abundant materials. Moreover, the correlation between crystal structural aspects[9] (such as the phase, cationic Schottky defects) and ionic mobilities remain inconclusive and material-dependent.

We utilize variations of colloidal hot-injection methods to synthesize nanostructured inorganic I-VI, IV-VI, V-VI nanocrystals with excellent size dispersity. Using post-synthetic cation exchange mechanisms in both colloidal and solid states, we achieve two key objectives: (a) engineer defects and determining how local structural perturbations induced by small amounts of Li$^+$, Na$^+$ intercalations can facilitate the intercalation of other cations (Zn^{2+}, Al^{3+}) to stabilize beyond-Li$^+$ solid electrolyte materials with fast ionic conductivities. (b) fully exchanging one or more cationic species at ambient conditions from these nanocrystals with alkali or other suitable elements, enabling the design of potentially unlimited compound combinations within a fast timescale of seconds or minutes.

We were able to test the ionic conductivity performance of these compounds at ambient conditions reaching 1 Ω^{-1} cm^{-1}, significantly higher than that of commercially used solid electrolytes. Further, using Argonne's Advanced Photon Source, we demonstrated the structural stability in these nanocrystals up to several Gigapascals (GPa), making these solid electrolytes promising candidates for battery fabrication processes that range only between 100-100 MPa. Moving forward, in my independent laboratory in Chicagoland starting in Fall of 2024, my new academic research group will focus on connecting our discoveries and understanding from fundamental inorganic chemistry, condensed matter physics, electrochemistry, and nanoscale colloidal synthetic techniques to solid battery electrolyte materials innovation.

Design Criteria for Zero-Strain Behavior in Colquiriite-Type and Tungsten-Bronze-Type Inorganic 3d-Transition-Metal-Fluoride Compounds for Alkali-Metal-Ion Batteries—A First-Principles Study

Christian Elsaesser[1,2], Aljoscha F. Baumann[2,1], Daniel Mutter[1] and Daniel F. Urban[1,2]; [1]Fraunhofer Institute for Mechanics of Materials, Germany; [2]Universität Freiburg, Germany

Mechanical stresses and strains in the microstructure of cathode materials evolving during electrical *charge/discharge cycles can reduce the long-term performance and stability of intercalation-type alkali-metal-ion batteries. In this context, crystalline compounds exhibiting zero-strain (ZS) behavior are of particular interest for cathode materials of all-solid-state ion batteries. Experimental observations of an approximate ZS behavior have been reported for instance for quarternary colquiriite-type metal fluorides or for transition-metal fluorides with tetragonal tungsten-bronze (TTB) structures. Using a computational first-principles method based on density functional theory (DFT), we have investigated the potential of both colquiriite-type [1] and tungsten-bronze-type [2] inorganic metal-fluoride compounds as ZS cathode materials. The focus of this presentation will be on iron-based fluorides with tungsten-bronze structures.*

DFT simulations were conducted to study the intercalation of the alkali-metal ions Li^+*,* Na^+*, and* K^+ *into the TTB and two related tungsten-bronze structures of the (cubic) perovskite (PTB) and hexagonal (HTB) types. We describe compensating local volume effects that can explain the experimentally measured low global volume change of* Na_xFeF_3*. We discuss the structural and chemical prerequisites of the host structure that enable a ZS insertion mechanism for alkali-metal ions in tungsten-bronze-type structures, and we present a qualitative descriptor to predict the local volume change for faster screening and discovery of novel ZS battery materials.*

Discovering Low-Viscosity Molecules Using an Integrated Physics-Based Modeling, High-Throughput Screening, and Active Learning Approach (2)— Screening from PubChem Database *Nobuyuki N. Matsuzawa[1], Hiroyuki Maeshima[1], Tatsuhito Ando[1], Atif Afzal[2], Benjamin Coscia[2], Andrea Browning[2], Mathew D. Halls[2], Karl Leswing[2] and Tsuguo Morisato[2]; [1]Panasonic Industry Co., Ltd., Japan; [2]Schrödinger, Inc., United States*

Molecules exhibiting lower viscosities than conventional organic solvents are in high demand for applications in electrochemical devices such as lithium-ion batteries and various capacitors. These molecules improve the electric resistance and efficiency of the devices, particularly at low temperatures. To identify low viscous molecules, we have performed screening of 290,000 molecules from the GDB database by applying machine learning (ML) techniques combined with an active learning approach. We identified more than 100 molecules with viscosities less than 0.35 cP. The details of this result will be presented at the part (1) of our talks. As the molecules in the GDB database are limited to those containing C, N, O, S and halogen atoms, we extended our research to the screening of low viscous molecules from the PubChem database [1], which includes molecules that may have atoms other than C, N, O, S and halogens. We built an ML model for viscosity using molecular dynamics (MD) calculated viscosities of 20,465 molecules as a training data set. The resulting ML model was then applied to screen 962,695 molecules from the PubChem database. An active learning approach was applied to the screening where MD calculations were performed on ML-model suggested candidate molecules to iteratively improve the ML model. The screening process resulted in the identification of over 400 molecules with MD-calculated viscosities less than 0.15 cP.

A 3D Cu_xSi_y ***Nanofoam—An Advanced Substrate for High-Density Si Nanowire Growth and Enhanced Lithium-Ion Battery Performance*** *Ibrahim Saana Aminu, Kevin M. Ryan and Sumair Imtiaz; University of Limerick, Ireland*

Binder-free silicon nanowire (Si NW) anodes are promising candidates for replacing graphite anodes in next-

generation high-performance lithium-ion batteries (LIBs), offering a significant boost in energy density. However, fabricating binder-free Si NW anodes with adequate active mass loading and long–term stable cycling capacity is challenging due to the limited surface area of planar current collectors (CCs). Standard pure Cu-foil CCs are particularly problematic because of the ubiquitous formation of Li+ inactive Cu-silicide phases. In this work, a mechanically robust binary–phase 3D Cu_xSi_ynanofoam CC is developed as a universal binder-free substrate for efficient growth of high-density Si NWs. While in most systems the intermediate formation of copper silicide particles is undesirable, we have successfully controlled the silicide formation in situ by constraining it to occur in a 2D network structure that is mechanically robust and strongly embedded onto the planar Cu-foil surface. The nanofoam network architecture not only limits the formation of silicide monoliths but also facilitates homogeneous distribution of well-segregated, nano-sized catalyst seeds, resulting in a high-density/single-phase Si NW growth with areal-loading in excess of 1.0 mg/cm^2. The electrodes exhibit an average Coulombic efficiency of >99.6%, a stable electrochemical performance for >900 cycles, and 88.7% capacity (~2.0 mAh/cm^2) retention in half-cells. A full-cell configuration of Si NWs@3D Cu_xSi_y versus lithium manganese oxide (LMO) cathode delivers a capacity of ~1177.1 mA h/g at 1C with a stable rate capability performance. The 3D Cu_xSi_y nanofoam CC also supports a wide-range of metal-catalyzed (Sn, In, Bi, Al, Cu, Ni, Mn, Sb, and Zn) Si NW growth, demonstrating the general applicability of this anode architecture. These results represent significant advances in the development of binder-free Si NW electrodes for advanced LIBs.

Enhancing Lithium-Ion Battery Anodes—Silicon-Carbon Based Monolayers *Nidhi Duhan and T J D. Kumar; Indian Institute of Technology Ropar, India*

Energy storage methods are crucial for addressing the intermittency of renewable energy sources. Among the various technologies available, lithium-ion batteries (LIBs) dominate the market due to their superior attributes like energy density, no memory effect, etc. However, a critical issue lies with the anode material, typically graphite, used in commercial LIBs, which has a limited capacity of 372 mAh/g.

In this context, the unique electronic, thermal, chemical, and surface properties of two-dimensional (2D) materials make them promising candidates for energy storage applications. Specifically, carbon and silicon have emerged as complementary choices for anode materials. Silicon anodes, despite their high theoretical capacity, suffer from extensive volume changes during lithiation and delithiation, which can lead to mechanical degradation. Conversely, carbon-based anodes exhibit stable structural integrity but possess lower lithium affinity and capacity. By combining these materials, the weaknesses of one can be mitigated by the strengths of the other. The stable carbon matrix can compensate for the volumetric changes of silicon, while silicon's large capacity can enhance the overall performance of the carbon matrix.

In light of this, our research focuses on investigating the potential of carbon–silicon-based anodes, specifically Si-doped γ-graphyne (SiG) and C-doped silicyne (C-silicyne) nanolayers, for their applicability as LIB electrodes using density functional theory (DFT). Both monolayers were found to be thermally and dynamically stable, with binding energies for lithium ranging from -1.33 eV to -1.35 eV, indicating favorable interactions between the monolayers *and lithium atoms.*

To further understand the lithium migration over these monolayers, we employed the climbing image-nudged elastic band (CI-NEB) method to evaluate the minimum energy pathways. Our results show that the energy barriers for lithium migration are 0.67 eV and 0.21 eV for SiG and C-silicyne, respectively, suggesting efficient charge/discharge processes. The maximum storage capacities obtained for SiG and C-silicyne are 1005 mAh/g and 836 mAh/g, respectively, which are significantly higher than those of commercially used graphite anodes and many reported materials.

Moreover, both SiG and C-silicyne exhibit a low working potential range of 0.4-0.6 V, implying their efficiency as silicon-carbon-based anodes. These promising results indicate that both monolayers hold significant potential as anodes for next-generation LIBs. Our study provides a valuable reference for experimentalists and highlights the potential of SiG and C-silicyne nanolayers in enhancing the performance of lithium-ion batteries through improved storage capacities and efficient charge/discharge processes. The synergistic combination of silicon and carbon in these nanolayers paves the way for advanced energy storage solutions that could better accommodate the growing demand for renewable energy integration.

EN08.05.14

Crystallographic Dimensionality Determines the Electrochemical Reaction Mechanism in Alkali Transition Metal Chlorides *Michael Spencer, Tae Gyu Yun, Marguerite Flynn and Alexis Grimaud; Boston College, United States*

Intense research efforts on transition metal chalcogenides (oxides and sulfides), pnictides (nitrides and phosphides) and fluorides have demonstrated the complex, intertwined effects of structural and chemical changes on their electrochemical response leading to intercalation, conversion or displacement reactions when reacting with lithium. Prior efforts largely left halides (e.g. chlorides, bromides, and iodides) unexplored due to their heightened solubility in classical liquid electrolytes. A significant knowledge gap for the electrochemical reactivity of transition metal halides remains, as well as a limited chemical library by which the iono-covalent bonding character in energy storage materials can be tuned. Recently, our group provided the first demonstration of electrochemical lithium ion insertion in TM halides (VX_3; X = Cl, Br, I) using superconcentrated electrolytes that suppress the solubility of halides, opening new chemistries for intercalation compounds. In this work, we employ superconcentrated electrolytes to demonstrate the composition- and structure-dependent electrochemical reactivity of a new family of halide compounds with A_2MCl_4 stoichiometry (A = Li or Na and M = Cr, Mn, Fe and Co) that were previously never studied in liquid electrolytes. Comparing four lithiated compounds with different transition metals, we demonstrate that they all undergo a conversion reaction when reacting with 2 Li^+ per formula unit, the reaction being associated with large polarization and limited cycling ability. However, electrochemical studies reveal a unique low polarization and reversible reaction in Li_2CoCl_4. Combining in situ XRD with post-mortem XPS and TEM/EDS analysis, we demonstrate that Li_2CoCl_4 first reacts with one Li^+ following a displacement reaction. This reaction is enabled by the formation of a Li_6CoCl_8 intermediate, which shares a similar anionic framework as pristine Li_2CoCl_4, ensuring the topotactic insertion of Li^+ balanced by the Co^{2+}/Co^0 redox couple and the formation of metallic Co nanoparticles. Comparing these compounds, we propose that two criteria are necessary to trigger the displacement reaction in A_2MCl_4 compounds: the presence of 1D chains of edge-sharing octahedra and availability of a metal-deficient intermediate. Screening a multitude of A_2MCl_4 compounds, we demonstrate the universality of these design principles which extend to Na-ion materials by demonstrating a low-polarization, reversible displacement reaction for Na_2MnCl_4 when cycled in Na-based superconcentrated electrolyte. Overall, our work provides a broad understanding of structure-property relationships controlling the reactivity of ternary transition metal halides with alkali cations.

EN08.05.15

Carbon-Based Materials for Energy-Storage Devices, from Current Collectors to Electrodes *Jongha Hwang and Woo-Jin Song; Chungnam National University, Korea (the Republic of)*

The rational design of carbon-based materials is attractive for the development of energy-storage devices. Especially well-organized carbon materials with high electrical conductivity, large surface areas, synergetic active sites, and controllable pore sizes have advantages for highly efficient electrochemical reactions. Herein, we report 3D hybrid nano- and micro-structured carbon-based materials for energy storage devices, such as supercapacitors, Li-based batteries, and aqueous electrolyte-based batteries.
Firstly, we developed a three-dimensional carbon-based current collector with high electrical conductivity and a large surface area. The large surface area and high electrical conductivity are crucial factors for high-performance current collectors. However, the carbon-based current collector has a relatively lower electrical conductivity than the metal-based current collector. We solved this issue by utilizing the metal particles embedded in the graphene-based structure. The Ni-OH-loaded current collectors as a pseudo-capacitor showed 197.5 Wh/kg of high energy density and 815.5 W/kg of power density in a two-electrode system.
Second, we utilized the carbon-coating technique with a cost-efficient phenolic resin for the silicon-based anode in Li-ion batteries. Silicon, as an abundant resource, has a high theoretical capacity (3579 mAh/g), but its large volume change during the repetitive charge-discharge process is a critical problem for high-performance Li-ion batteries. We solved it by using a carbon-coated silicon anode. This anode achieved 3092 mAh/g of high specific capacity and almost 100% capacity retention at 0.05C after 50 cycles.
Finally, we introduced the carbon-based protection layer on the zinc anode in aqueous Zn-ion batteries (AZIB). AZIB has numerous advantages, such as non-flammable electrolytes, abundant resources, and reversibility. However, the irregular dendrite formation on the Zn surface is a critical issue in aqueous Zn batteries. The introduction of an optimized carbon-coated Zn anode accomplished an outstanding cycling performance of more than 1000 hours at 4mA/cm^2 in a symmetrical cell test.
In summary, we designed carbon-based materials with a large surface area, high electrical conductivity, and high mechanical strength from the current collector to the electrode for an efficient electrochemical reaction. Our strategies could solve many issues in various energy-storage devices, such as high charge transfer resistance, huge volume expansion of active materials, and irregular dendrite formation. These results indicate that the rational design of carbon-based materials can provide a positive perspective for the study of next-generation batteries.

EN08.05.16

Novel Polymer Electrolyte for Greener and Safer Solid State Batteries *Luca Bargnesi[1], Tomaz Ivancic[2], Itziar Aldalur[3], Nicola Boaretto[3], Devaraj Shanmukaraj[3], Maria Martinez[3], Catia Arbizzani[1] and Michel Armand[3]; [1]Università di Bologna, Italy; [2]University of Ljubljana, Slovenia; [3]CIC energiGUNE, Spain*

Lithium-ion batteries became the most widely used energy storage systems due to their high energy density, power, robustness, and reversibility and are playing a key role for the energy transition towards renewable sources. However, the current commercial batteries contain electrolyte solutions with flammable organic solvents, raising not only safety and reliability concerns but also environmental issues [1]. Novel Li-ion technology involves developing solid-state batteries that enhance energy density and safety, making them ideal for the next generation of high-performance batteries [2].
Polymer electrolytes (PEs) provide several benefits compared to liquid and inorganic solid electrolytes, including better resistance to electrode volume changes during charging and discharging, enhanced safety features, excellent flexibility, and ease of processing. Additionally, under certain conditions, solvent-free polymer electrolytes can minimize or even prevent dendrite growth [3].
Alternative polymer matrices and single ion conducting salts are highly sought after to reduce the crystallinity of

the conventional PEO electrolytes and bring about homogenous Li deposition respectively. Based on our previous research , a flowable jeffamine based polymer electrolyte was reported to have appreciable ionic conductivity. However, these polymers lacked mechanical stability and single ion conducting property thereby limiting its role as buffer layers on Li metal. Herein we report the stable operation of a flowable polymer electrolyte (FPE), by incorporating novel functionalised ethyl cellulose as filler that renders mechanical stability resulting in a self-standing polymer electrolyte. The addition of functionalized fillers in addition to mechanical stability renders appreciable ionic conductivity and single-ion conducting properties without the addition of a lithium salt.

In Situ Electrochemical Techniques for Investigating Lithium Ordering and Electronic Transitions in Wadsley-Roth Phases

Everett J. Zuras and Alexis Grimaud; Boston College, United States

Lithium-ion batteries (LIBs) with fast-charging capabilities have the potential to drive wider adoption of electric vehicles and eliminate a substantial CO2 emission source. LIBs typically utilize graphite negative electrodes due to their low cost, widespread availability, and high energy density. However, operation of these batteries at high current densities leads to lithium plating reactions, reducing the lifespan of the cell. This has motivated the search for alternative negative electrode materials, of which niobium-based Wadsley-Roth oxides (WRs) are one promising candidate. WRs crystallize into units of repeating "blocks", which exhibit edge sharing between metal polyhedra at the block boundaries and corner sharing between polyhedra within the block. The resulting structure has wide tunnels for fast lithium diffusion and exhibits high capacities due to the multielectron redox capabilities of Nb^{5+} *and the number of available lithiation sites in the structure. While numerous materials with varied block sizes, polyhedral coordination, and metal cation substitutions have been proposed, the impact of these factors on intercalation behavior remains uncertain. This presentation explores how block size, coordination type, and cation substitution influences electrochemical behavior and structural evolution during lithiation. The electrochemical cycling behavior of these phases is shown to be very similar, outside of the initial redox potential related to the substituted cation, while operando synchrotron XRD shows single phase behavior in all of them. However, subtle differences are observed in the lattice contraction/expansion behavior, suggesting that* Li^+ *distribution may be different. In order to probe the ordering behavior, entropic potential measurements were carried out to identify changes in the entropy due to ordering at specific lithium concentrations. This technique reveals fascinating differences in the lithiation behavior of different WR phases. Nevertheless, a common pitfall of entropic potential measurements is that they are impacted by both configurational and electronic entropy evolutions. To address this issue, and to identify insulator-metal transitions during lithiation, in-situ conductivity measurements were employed. These results serve as guiding principles for designing new WRs for fast-charging applications, as well as providing a framework to extend this approach to other intercalation compounds to answer outstanding questions about their mechanisms.*

EN08.05.18

Investigating Polaron Dynamics in Conjugated Polymers Using Molecular Dynamics Simulations

Jyotsana Kala[1,2], Iona Anderson[2], Nicholas Siemons[2] and Jenny Nelson[2]; [1]Indian Institute of Technology Delhi, India; [2]Imperial College London, United Kingdom

Abstract: *Development of safe, sustainable, and cost-effective electrochemical energy storage devices is a priority for the energy transition. Batteries and pseudo capacitors enable the storage and stabilization of intermittent power from renewable energy sources, but new materials are still needed to minimize concerns about materials availability and sustainability. Recently conjugated polymers have received attention for electrode applications. The redox properties and nature of charge transport in such materials determine their suitability as n-type or p-type electrodes. In such structures, redox potentials are primarily controlled by tuning the conjugated backbone, whilst side chains influence the compatibility with different electrolytes and the electrode stability under electrochemical cycling [1, 2]. In practice, the ease of formation and the stability of the charged species, polarons and bipolarons, are influenced by choice of both backbone and side chain [3]. In order to design higher performance polymer electrodes, we need tools to model the nature and dynamics of polarons in conjugated polymer electrodes. Polarons carry non-zero net charges and result in complex interactions between charged species, neutral species and or ions, posing several challenges for molecular dynamics simulation. In the present work we use molecular dynamics to study the structural and ion dynamics of conjugated polymers based on diketopyrrolopyrrole and thiophene backbone. We study how the choice of backbone, side chain, solvent and electrolyte affect polaron formation, polaron stability and redox behavior. These methods can help to design suitable polymer materials for electrode applications in batteries.*

Keywords: *Polymer batteries, Molecular Dynamics, Polarons, Redox Behavior, organic mixed ionic-electronic conductors, electrochemistry,*

Compositionally Tunable Mn–V–Fe Phosphoselenide Nanorods with Minimal Ion-Diffusion Barrier as High Energy Density Battery Electrode Materials

Nageh K. Allam, Sara A. Teama and Ghada Khedr; The American University in Cairo, Egypt

The design and synthesis of novel heterostructured electrode materials are crucial to enable the fabrication of efficient supercapacitor devices. In this regard, transition metal phosphochalcogenides (S, Se) are promising candidates owing to their exotic electronic properties. Herein, a facile two-step hydrothermal protocol was used to synthesize binary and ternary metal phospho-selenide electrodes (Mn–Fe–P-Se, V–Fe–P-Se, Mn–V–P-Se, and Mn–Fe–V–P-Se). The chemical composition, morphology, and structure of the as-fabricated materials were fully investigated. The three-electrode electrochemical evaluation at 1.0 A g^{-1} demonstrated that the ternary metal electrode (MFVP-Se) exhibits a high capacity of 1968.63 C g^{-1}. To assess the practical value of the rationally designed Mn–Fe–V–P-Se electrode material, Mn–Fe–V–P-Se was used as a positive electrode coupled with activated carbon (AC) as a negative electrode to assemble a hybrid supercapacitor device. This Mn–Fe–V–P-Se//AC device delivers a power density of 1999.96 W kg^{-1} with a high energy density of 149.88 Wh kg^{-1} coupled with no capacity loss after 5000 charging/discharging cycles. Additionally, density functional theory calculations revealed that our electrode exhibits suitable adsorption energy for OH^- ions with a minimal diffusion barrier for ions.

EN08.05.20

Environmentally Benign Natural Hydrogel Electrolyte Enables Wide Operating Potential Window for Energy Storage Devices *Heba M. Elsharkawy, Abdelrahman A. Ismail and Nageh K. Allam; The American University in Cairo, Egypt*

The development of energy-efficient storage platforms is of paramount importance. Specifically, wearable, smart, flexible, and portable electronic devices with small size, lightweight, and high safety are of urgent need for several applications. To achieve these criteria, green, sustainable, nonflammable, and biodegradable hydrogel electrolytes are essential. To this end, we developed a LiCl@starch-based hydrogel via readily gelatinization of starch. The ionic conductivity of the synthesized gel was tuned via controlled variation of the LiCl content, as revealed by the electrochemical impedance spectroscopy (EIS) measurements. The developed starch gel network with 2 M LiCl showed ultrahigh ionic conductivity of 0.079 Scm^{-1} *with excellent thermal stability and nonflammability. The rheological characteristics are aligned with enhanced ionic conductivity. Using the commercially available activated carbon (AC), the assembled supercapacitor symmetric device (AC//2-LiCl@starch//AC) withstands a wide operating voltage window of 2.4 V with outstanding specific capacitance (62.3 F/g), energy density, and reliable self-discharge time. These findings imply that this quasi-solid biopolymer gel can be a viable electrolyte for various energy storage devices.*

EN08.05.21

Advancing Strucrutal Supercapacitors with Hydrated Polymer Electrolyte *Parya Teymoory and Caiwei Shen; University of Massachusetts Dartmouth, United States*

Structural supercapacitors, capable of bearing mechanical loads while storing electrical energy, hold great promise for enhancing mobile system efficiencies. However, developing practical structural supercapacitors often involves a challenging balance between mechanical and electrochemical performance, particularly in their electrolytes. Traditional research has focused on bi-continuous phase electrolytes (BPEs), which typically comprise high liquid content that weakens mechanical strength, and inert solid phases that hinder ion conduction and block electrode surfaces. Our previous work introduces a novel approach with a hydrated polymer electrolyte, demonstrating enhanced multifunctionality. This electrolyte, derived from controlled hydration of PET-$LiClO_4$*, forms a trihydrate (*$LiClO_4$*-*$3H_2O$*) structure, where water molecules bond with ions without forming a liquid phase, thereby improving ion mobility while maintaining the base polymer's mechanical properties. This new design also promotes better electrochemical interfaces with electrodes, a significant advancement over traditional BPEs.*
In this study, we further enhance the performance and processability of such hydrated polymer electrolytes by incorporating polylactic acid (PLA) as the base polymer and lithium bis (trifluoromethanesulfonic)imide (LiTFSI) as the salt. The electrolyte, prepared through solution casting and subsequent controlled hydration, consistently remains an amorphous solid solution in both dry and hydrated states, as confirmed by DSC, XRD, and FTIR analyses. Our tests on ionic conductivity and mechanical properties reveal that adding water to the polymer electrolyte substantially increases ionic conductivity while retaining mechanical properties. A specific composition demonstrated a remarkable increase in ionic conductivity coupled with superior toughness surpassing the base polymer. Furthermore, we successfully fabricated and tested structural supercapacitor devices made of composites of carbon fibers and these new electrolytes. The prototypes presented enhanced toughness with significant energy storage performance, demonstrating their vast application potential due to their outstanding multifunctionality.

EN08.05.22

Non-Aqueous K-Ion Battery Performance of MXene-Derived K-Preintercalated Bilayered Vanadium Oxides Electrodes *Timofey Averianov, Xinle Zhang and Ekaterina Pomerantseva; Drexel University, United States*

In this work, we demonstrate the performance of MXene-derived K-preintercalated bilayered vanadium oxide (MD-KVO) in non-aqueous K-ion energy storage system, focusing on the relationships between the MXene-to-oxide transformation process, structure and composition of the material as well as its electrochemical properties. By tuning synthetic parameters, we demonstrated control of the confined species in the interlayer region of BVO. Specifically, we obtained MD-KVO by first preparing V_2CT_x MXene using a dilute mixed acid etchant, followed by dissolution in a reaction with hydrogen peroxide, and recrystallization via hydrothermal treatment. The MD-KVO exhibited nanoflower morphologies, in agreement with the previously reported V_2CT_x-derived oxides [1], with wide nanosheet "petals" 0.5 – 2.0 µm in lateral size and 4.0 – 5.0 nm in thickness. Energy-dispersive X-ray spectroscopy (EDS) and thermogravimetric analysis (TGA) measurements were used to estimate the composition of the MD-KVO as $K_{0.400}V_2O_5$●$0.086H_2O$. This compositional data was used to modify a $Na_{0.56}V_2O_5$ model for pair distribution function (PDF) refinement. By replacing interlayer Na atoms with the experimentally determined K and H_2O content, we observed an evolution of the c lattice parameter from 8.90 Å in $Na_{0.56}V_2O_5$ to 9.57 Å in $K_{0.400}V_2O_5$●$0.086H_2O$ after refinement, consistent with the (001) d-spacing of 9.59 Å calculated from synchrotron X-ray diffraction. By including spherical diameter as a refinement constraint, an optimal fit was obtained at a diameter of 55.5Å, indicating the local average crystallographic order. Beyond this distance, structural disorder reduces refinement capability with this model. Initial cycling of this material in non-aqueous K-ion cells in a narrow potential window of 2.0 – 3.7 V showed the best stability. Extending the window below 2.0 V or above 3.7 V showed significant degradation of the material's charge storage properties within the first 5 cycles. Vacuum drying the MD-KVO at 200°C improved cycling stability when the window is extended, indicating that interlayer water participates in parasitic reactions that hamper stability in K-ion systems. We showed improved capacities of 72.75 mAh/g in a 1.5 – 3.8 V window as compared to 50.81 mAh/g in a 2.0 – 3.7 V window. In this extended window, the MD-KVO electrode exhibited good rate capability, with an average capacity of 41.21 mAh/g at 200 mA/g. These results demonstrate how the structure and composition of the MXene-derived K-preintercalated bilayered vanadium oxide influence its electrochemical performance in non-aqueous K-ion batteries.

Dual Metal-Ion Preintercalation of Bilayered Vanadium Oxide Cathode Enables Synergistically Enhanced Intercalation Battery Performance

Xinle Zhang and Ekaterina Pomerantseva; Drexel University, United States

In this work, we demonstrate a synthesis strategy for enhancing the performance of intercalation battery electrodes via chemical preintercalation of two types of metal ions. We will illustrate the developed strategy by presenting bilayered vanadium oxide (BVO) simultaneously preintercalated with Li^+ and Mg^{2+} ions and showcase the synergistically enhanced capacity and cycling stability using the lithium-ion battery system as an example. We found that the Li^+ and Mg^{2+} ions can be preintercalated into an interlayer region of BVO structure separately through a two-step approach. The first step introduces Mg^{2+} ions using a wet-chemical precipitation step. In the second step, Li^+ ions were preintercalated by hydrothermal treatment of the precipitate in LiCl solution. We determined and compared the number of preintercalated Mg^{2+} ions before and after hydrothermal treatment using atomic absorption spectroscopy (AAS) and concluded that the Li^+ ions were preintercalated by partial exchange with Mg^{2+} ions in the second step. The Li^+ ion storage properties of the Li^+ & Mg^{2+} simultaneously preintercalated phase (LMVO) were investigated with the reference of Li-preintercalated BVO (LVO) and Mg-preintercalated BVO (MVO). LMVO electrode exhibited 2nd cycle specific capacity of 245 mAh g^{-1}, which is comparable to 280 mAh g^{-1} delivered by LVO and is significantly higher than 175 mAh g^{-1} delivered by MVO. After 50 cycles, the LMVO retained 58% of its 2nd cycle capacity, which is comparable to the 67% capacity retention of MVO and significantly higher than the

22% capacity retention of LVO. Therefore, our study for the first time experimentally confirms the hypothesis [1, 2] that chemical preintercalation of electrochemically active ions facilitates solid-state ion diffusion, thus leading to increased specific capacity; and chemical preintercalation of electrochemically inactive ions stabilizes the structure of electrode materials, thus improving the cycling stability. Additionally, the role of structural water in the LMVO phase on its electrochemical cycling performance was investigated. By employing low temperature annealing [3] for both active material and electrodes, the cycling stability of LMVO after 50 cycles can be further improved by 21% due to reduced amount of structural water. The low temperature annealed LMVO retained 174 mAh g^{-1} after 50 cycles at a current density of 20 mA g^{-1}, and able to deliver 153 mAh g^{-1} at a current density of 200 mA g^{-1}. Our findings shed light on the role of structural water and diverse chemically preintercalated ions in the interlayer regions of layered electrode materials, providing insights into developing novel electrode materials with enhanced electrochemical properties for next-generation energy storage systems beyond lithium-ion batteries.

Functionalized WS_2-MWCNT Hybrid Nanostructures for Li-Ion Battery Anodes— Towards Binder-Free Approach

Bikram Mondal and Shahab Ahmad; Indian Institute of Technology Jodhpur, India

Tungsten disulfide (WS_2), among various transition metal dichalcogenides (TMDs), has garnered significant attention as a potential intercalation host material for lithium-ion batteries (LIBs). This interest is attributed to its unique graphite-like layered structure, high theoretical specific capacity of 433 mAh g^{-1}, relatively low cost, and excellent charge transport and mechanical properties [1]. However, WS_2 based anodes face several challenges, including pulverization, low electronic and ionic conductivities, an unstable solid-electrolyte interphase (SEI) layer, and thermal runaway issues, which limit their application in practical devices [1]. To address the technical challenges of WS_2-based anodes in LIBs, recent research has focused on hybrid nanostructure-based anodes [2–4]. We demonstrate the effective functionalization of WS_2 nanoflakes and MWCNT (multiwalled carbon nanotube) bundles using the n-type semiconducting polymer PCBM (Phenyl-C61-butyric acid methyl ester). This functionalization facilitates the formation of hybrid nanostructures, resulting in significantly enhanced performance of WS_2 anodes in LIB applications. PCBM functioned as a conductive bridge between the WS_2 hexagonal nanoflakes and the MWCNT bundles, thereby significantly reducing junction resistance. Additionally, PCBM functionalization mitigated the agglomeration and pulverization of the WS_2 nanoflakes. The functionalization of WS_2 and MWCNTs with PCBM is confirmed by the FTIR and Raman spectroscopies. The demonstrated WS_2-PCBM/MWCNT hybrid nanostructures based anodes were cycled for 500 cycles at current density of 1.0 A g^{-1}, where has shown a stable average discharge specific capacity of ~485.73 mAh g^{-1} with coulombic efficiency (CE) of close to 100% [5]. In addition, the PVDF binder-free WS_2-PCBM/MWCNT hybrid nanostructure-based anode has displayed an average discharge specific capacities of ~1224 mAh g^{-1} for up to 25 cycles at current density of 0.1 A g^{-1} with coulombic efficiency of ~99.99%. Thus, our work offers new avenues to explore the utility of PCBM as a carbon conductive to boost the performance of the WS_2 based anodes for Li-ions and other metal-ion batteries. Additionally, our findings offer a groundbreaking and scalable methodology for the development of traditional binder-free electrodes.

Elucidating Anisotropic Ionic Diffusion Mechanism in Li_3YCl_6 Using Molecular Dynamics Simulations

Yizhou Zhu; Westlake University, China

Halide-based solid electrolyte has emerged as promising materials for the development of solid-state batteries, due to their high ionic conductivity and excellent chemical properties. Li_3YCl_6 is a prototype halide-based superionic material that features anisotropic ionic diffusion. Elucidating the ionic transport and optimizing the conductivity in such anisotropic materials is crucial for enhancing the performance of solid-state batteries. In this work, by using molecular dynamics simulations with a machine learning force field, we systematically study the anisotropic ion diffusion behavior, including directional conductivity contribution, concerted migration, disorder-order transition in Li_3YCl_6. Our results prove that the fast c-direction is the major contributor to total diffusivity, especially under room temperature. The hcp anion arrangement leads to anisotropic diffusion mechanism. Lithium diffusion along the c-direction exhibit a highly concerted feature, which is absent in the ab-plane diffusion. A disorder-order transition of lithium sublattice can occur below a critical temperature. Our results show that the ordering occurs with a regular pattern of lithium ions. The lithium sublattice ordering is strongly influenced by yttrium cation arrangement and can be suppressed if a small amount of Li/Y anti-site defects are present. These understanding can help to provide guidance for the future development of anisotropic superionic materials.

High-Performance All-Solid-State Lithium Metal Batteries Enabled by Ionic Covalent Organic Framework Composites

Jun Huang and Yoonseob Kim; The Hong Kong University of Science and Technology, China

Ionic covalent organic frameworks (iCOFs) are crystalline materials with stable porous structures. They hold great potential for ion transport, particularly as solid-state electrolytes (SSEs) for all-solid-state Lithium metal batteries (ASSLMBs). However, achieving an ionic conductivity of over 10^{-3} S cm^{-1} at room temperature using pure-iCOF-based SSEs, even adding additives such as lithium salts, is challenging as the voids work as strong resistances. Thus, highly conductive iCOFs typically require quasi-solid-state configurations with organic solvents or plasticizers. In this study, we prepared composites comprising iCOFs and poly(ionic liquid) (PIL) to make all-solid-state iCOFs electrolytes with an exceptional ionic conductivity up to 1.50×10^{-3} S cm^{-1} and a high Li^+ transference number of > 0.80 at room temperature. Combined experimental and computational studies showed that the co-coordination and competitive coordination mechanism established between the PIL, lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) and iCOFs enabled rapid Li^+ transport while restricting $TFSI^-$ movement. ASSLMB cells, made of composite SSEs and $LiFePO_4$ composite cathode, demonstrated an initial discharge capacity of 141.5 mAh g^{-1} at 1 C and r.t., with an impressive capacity retention of 87% up to 800 cycles. Overall, this work presents a breakthrough approach for developing advanced SSEs for next-generation high-energy-density ASSLMBs.

EN08.05.27

Electrochemical Performance of Spinel $CuFe_2O_4$ Obtained from End-of-Life Lithium-Ion Batteries for Lithium-Ion Batteries Anode Ayat Elshazly; *Central Metallurgical Research and Development Institute, Egypt*

$CuFe_2O_4$ with a tetragonally distorted spinel structure has been prepared from End-of-Life lithium-ion batteries (LIBs). In this study, copper (Cu) was recycled from spent lithium-ion batteries (LIBs) and used to synthesize copper ferrite ($CuFe_2O_4$-LIBs), which was applied as an anode for Li-ion batteries. The solvothermal method was used to synthesize $CuFe_2O_4$-LIBs with spinel structures used as raw materials of the LIB anodes and commercial reagents. Cu in spent LIBs can be leached efficiently using inorganic and organic acids as a leaching agent and separated effectively from the leaching solution. All leaching conditions were optimized and results from the characterizations of the prepared $CoFe_2O_4$ ($CoFe_2O_4$-LIBs) show that it possesses high purity of $CuFe_2O_4$. The formed copper ferrite was then attached to a graphene nanosheet ($CuFe_2O_4$-G) via the one-step solvothermal method. X-ray diffraction (XRD) identified the formation of spinel-type $CuFe_2O_4$, which formed nanoparticles that could be seen under scanning electron microscopy (SEM) analysis, and the $CuFe_2O_4$ and $CuFe_2O_4$-G were evaluated by cyclic voltammetry and galvanostatic charge-discharge measurements. Using $CuFe_2O_4$ and $CuFe_2O_4$-G as an anode, it has an excellent specific capacity versus Li metal. The composite showed high electrochemical capacitance (>500 F/g at 1 A/g), good rate performance, and cycling stability. These findings demonstrated that the composite, as a kind of electrode material, had a high specific capacitance and good retention. The work has scientific interest particularly because of the correlation between the structure of the recycled material and its electrochemical properties.

EN08.05.28

Additive Manufacturing and Characterization of Micro-Architected $LiFePO_4$/C Composite Electrodes for Li Ion Batteries Yingjin Wang, Yuchun Sun and Julia R. Greer; *California Institute of Technology, United States*

Electrodes with 3D architected structures hold the potential to disrupt the trade-off between high energy density and power density in commercial 2D slurry batteries. 3D electrodes offer the advance of a large interphase area between the electrode and the electrolyte and allow for a greater active material mass loading without increasing the ion diffusion distance in electrode compared with slurry electrodes.

We design, synthesize, and characterize a 3D $LiFePO_4$ (LFP)/C composite electrode with tilted cubic architecture and 150μm beam diameter. In this additive manufacturing (AM) process, a polymer scaffold is first printed via vat photopolymerization (VP)-based additive manufacturing technique, which provides a high resolution of 50μm and flexibility in structural design. Then ion precursors are infused into the hydrogel scaffolds and calcined at 800°C under inert atmosphere to produce LFP/C composite micro-lattices with a porous surface and 500nm LPF particles formed in the micro-lattices. The chemical composition is tuned by the ion precursor concentrations and optimized for electrochemical performance. The concomitant formation of carbon within the lattice provides a pathway for electron transport and reduces the internal resistance of the electrode. X-ray powder diffraction and thermogravimetric analysis were applied to determine the chemical composition of the LFP/C micro-lattice. The uniform distribution of C, O, P, and Fe elements is revealed through energy dispersive X-ray (EDX) mapping. To characterize its electrochemical properties, the LFP/C electrode was assembled into a coin cell against Li foil. The formation of electrochemical active LFP was confirmed by the cyclic voltammetry (CV) curve. This method is amenable to printing a wide range of electrode materials and offers the advantages of 3D architecture on the overall cell electrochemical performance.

EN08.05.29

Growing Faceted Lithium Crystals to Enable Stable Solid-State Li Metal Batteries Ke Zhou and Ping Liu; *University of California, San Diego, United States*

Observing and controlling the nucleation and growth of lithium metal in solid-state lithium (Li) metal batteries are crucial for optimizing their performance. However, this has been challenging largely due to the instability of the Li/solid-state electrolyte (SSE) interface and the large stack pressure commonly employed which prevent assessment of the morphology of Li deposition. We report here our observation of faceted Li crystal growth in a solid-state battery. The interfacial instability of the sulfide electrolyte Li_6PS_5Cl with Li is overcome by modifying the interface with a bifunctional molecule, sodium 3-mercapto-1-propanesulfonate (3M1P). Surprisingly, the deposited Li is found to crystalize into a hexagonal close-packed structure that has only been previously known to be stable at low temperatures and high pressure. Moreover, the crystals are oriented with their (0001) facet parallel to the substrate, thus facilitating intimate contact and a homogeneous Li^+ flux between Li/SSE. As a result, the pellet and laboratory pouch cells of Li/LPSC@3M1P/NCM811 successfully completed 500 and 100 cycles respectively under a modest stack pressure of 2 MPa. Our findings demonstrate the effectiveness of controlling Li crystal growth in enabling stable solid-state batteries.

EN08.05.30

Exploring Cationic Substitutions in $NaAlCl_4$ and Na_2ZnCl_4 with Density Functional Theory and Machine Learning *Michael F. Häfner[1,2] and Matteo Bianchini[1,2]; [1]Universität Bayreuth, Germany; [2]Bayerisches Zentrum für Batterietechnik, Germany*

$NaAlCl_4$ is an established solid electrolyte in high-temperature Na-based battery systems,[1] but its ionic conductivity is not sufficient for room-temperature applications.[2] To address this shortcoming, we explored the substitution of various elements into the structure of $NaAlCl_4$ with density functional theory and machine learning methods to identify and evaluate stable substitution options.
The computationally demanding vibrational contributions to the most promising substitutions were obtained with the assistance of on-the-fly machine-learned potentials, which expedite the phonon calculations by at least one order of magnitude at a minor error of 0.7±1 meV/atom at room temperature.
Isovalent substitutions were found to be most favorable, with potassium and silver being promising choices as substitutes for sodium and gallium for aluminum, yielding a stability below 4 meV/atom compared to their respective ternary chlorides. Evaluations of the configurational space of these substitutions indicate large disorder, with the exchange of Al with Ga resulting in a full solid solution.
Substitutions with ions of differing charges usually did not result in stable structures, with one notable exception for the ion pair Al^{3+} and Zn^{2+}. Based on the lattice of Na_2ZnCl_4, a stable structure type with separate layers for the differently-charged cations and a significant amount of Na vacancies was found.
The ionic conductivity of the substituted structure was evaluated using MD simulations assisted by the general-purpose machine learning model MACE-MP-0,[3] and the substitution of Al^{3+} and vacancies into Na_2ZnCl_4 was found to significantly enhance the mobility of the Na^+ ions in the structure.
In conclusion, our investigation may assist the fast, reliable discovery and evaluation of novel fast Na conductors and other materials by inclusion of thermodynamic properties and machine learning.

Solution-Based Br Doping of Li3PS4 Solid Electrolyte via Ball-Milling for Improved Conductivity and Cyclability in All-Solid-State Batteries *SolHui Park, Yeyeong Hwang, Inho Park, HoBum Park and Yun Jung Lee; Hanyang University, Korea (the Republic of)*

In electrolyte research, improving conductivity and stability is still a crucial and ultimate goal. To this purpose, elemental doping is often suggested for sulfide solid-state electrolytes (SSEs). Because most solvents are reactive with sulfide SSEs, doping sulfide SSEs has historically involved an inconsistent and labor-intensive solid-state reaction. Here, we present an effective solution-based method for ball-milling lithium thiophosphate (Li_3PS_4 or LPS) to facilitate Br-doping, employing dibromomethane (DBM) as the solvent and Br-source. By pulverizing LPS particles and introducing Br-doping at the same time, this "mechano-chemical" technique significantly increases Li^+ ion conductivity to 1.3 mS cm^{-1}, 8 times higher than that of undoped LPS at just 1.14 atomic percent Br doping. At such a low doping concentration, this conductivity level is among the highest reported for LPS SSEs. The effectiveness of these chemical and physical modifications depends on the LPS to DBM ratio. In all-solid-state lithium-metal batteries, the modified LPS showed outstanding cycling stability with decreased overpotential. The Li-Li symmetric cell demonstrated highly stable Li deposition and stripping for over 1350 hours, and the full cell with a Li metal anode and $Li[Ni_{0.8}Co_{0.1}Mn_{0.1}]O_2$ cathode retained 83% of its initial capacity after 100 cycles. This approach, with potential applications in the slurry fabrication of LPS SSEs, offers a novel and effective method for producing high-performance sulfide SSEs for large-scale applications.

EN08.05.32

An All Carbon Fiber-Based Structural Battery *Leif E. Asp; Chalmers University of Technology, Sweden*

Here a structural battery composite made from thin carbon fiber reinforced polymer composite electrodes is discussed. The negative electrode consists of this layer of carbon fibers in a spread tow. The positive electrode, the cathode, consists of lithium iron phosphate (LFP) coated onto carbon fibers, again in a spread tow. The electrodes are typically 30 micrometer thick [1]. The electrodes are set apart by an electrically insulating, ionically conductive, separator. Here we use, e.g., glass fiber and cellulose based separators. The stacked layers are impregnated by a bicontinuous structural battery electrolyte, where a glassy polymer provides mechanical load transfer between fibers, and electrodes, and a liquid electrolyte facilitates Li-ion migration between the electrodes. The multifunctional performance of the structural battery composites exceeds a specific energy density of 30 Wh/kg at a tensile modulus of 60 GPa for the strucutral battery composite cell.

This paper presents recent progress in carbon fiber based structural battery composites. In particular, the coupled electro-chemo-mechanical processes and their effect on the strucutral battery composite material and its constituents will be discussed. During electrochemical cycling, the elastic properties of the electrode materials, i.e., carbon fiber and lithium iron phosphate, swells/shrinks and undergoes changes in elastic moduli [2]. These changes to the composite's constituents give rise to high internal stresses that may cause damage to the structural battery electrolyte or the fibers and thereby affect the multifunctional performance of the structural battery composite [3]. To conclude the presentation, routes towards imporoved multifunctional performance as well as damage tolerant structural battery composites is discussed.

Advanced Electrolyte Design for High-Energy Batteries with Li Metal and Micro-sized Silicon Anodes

Aimin Li and Chunsheng Wang; University of Maryland, United States

To tackle the increasing environmental deterioration, the electrification of modern society needs to be fulfilled with low-cost, safe, and high-energy batteries. Lithium (Li) metal and silicon (Si) represent the ideal materials to upgrade the conventional carbonaceous anodes due to their high theoretical specific capacities (3860 mAh g^{-1} of Li and 3579 mAh g^{-1} of Si vs. 372 mAh g^{-1} of graphite) and low electrochemical potentials (-3.04 V of Li and -2.74V of Si vs. SHE). However, extreme challenges have been put forward for effective electrolyte design to maximize the energy efficiency of these high-energy materials. The solid-electrolyte interphase (SEI) formed in the conventional carbonate electrolytes is organic-rich and unstable when facing the volume change during the charge/discharge of Li metal and Si anodes. Therefore, new electrolyte design strategies and advancements are in urgent demand to promote robust, inorganic interphases for high energy efficiency on these promising materials.

We present here cutting-edge electrolyte design principles considering all aspects of chemical, electrochemical, and material science, which govern the interphase formation process on both high-energy Li metal and micro-sized Si anodes and facilitate LiF SEI for long-term cell cycle performance. [1-3] We first propose an electrolyte strategy through solvent design from a synthetic chemistry perspective, promoting anion reduction, and suppressing solvent degradation, which enables high reversibility on both Li metal [1] and micro-sized Si anodes. [2] Our study further indicates that when solvent reduction is inevitable, the reductive products of the solvent should be controlled for high-modulus inorganic components, for example, Li_2O formation from sulfolane reduction, and the formation of polymerized organic ingredients need to be minimized. [3] The aggregated solvation originating from synthetic solvent design will also play a big role in the interphase formation process, therefore, both solvent stability (vs. anion stability) and solvation between Li^+ cation and solvent/anion in the electrolytes are important driving forces for effective LiF SEI formation. By leveraging the reductive priority between the solvents and anions, we demonstrate an effective inorganic interphase (LiF or Li_2O) formation over a wide voltage range in different electrolytes. New records of cycle performance were achieved in both anode-free Cu||NCA lithium metal cells [1] and Si||NMC811 full cells using micro-sized Si anodes. [2-3]

In summary, we showed the potential of synthetic strategies for advanced electrolyte development, which represents a powerful tool for next-generation high-energy batteries. The successful utilization of micro-sized Si anodes with simple electrolyte innovation demonstrates great promise for cost-effective, high-energy batteries with improved safety.

Enabling Improved Battery Performance Through High Volume R2R Manufacturing in Vacuum *Subramanya Herle; Applied Materials, Inc., United States*

While significant improvements in energy density have been achieved in Li-ion industry since the commercial introduction by Sony in 1991, the current battery architecture and materials are reaching their limits. New materials and battery architectures (such as Lithium metal anodes, pre-lithiated Si/structured anode, metallized current collectors and solid electrolytes) hold the promise of significantly increased energy density especially at the pack level (150 Wh/kg, 250 Wh/l to 250 Wh/kg, 750 Wh/l). (Ref. 1). Multiple announcements by governments and automobile manufacturers have led analysts to project a lithium battery market of >4,300 GWh by 2030 (Ref. 2). These projections, however, are predicated on the assumption of availability of increased energy density, lower cost of materials at scale and improved safety. Current Li-ion industry is using non-vacuum processes for roll to roll manufacturing of electrodes. Next generation materials have special handing needs and engineered interface requirements which can ideally be addressed though vacuum deposition techniques. In this talk, we discuss the benefits of vacuum deposition processing for next generation ultra pure lithium deposition for Si/SiOx-Gr prelithiation and Li metal anodes. References:

Probing the Structural Phase Transformation of Octahedral Sulfur and Its Implications on the Electrochemistry of Metal-Sulfur Batteries *Neeraj Pal and Aninda J. Bhattacharyya; Indian Institute of Science, India*

Due to its high specific theoretical capacity (1675 mAh/g), sulfur is a potential cathode in next-generation rechargeable batteries. Moreover, the low cost of S sulfur provides an economic advantage and makes it appealing for large-scale energy storage. Recently, an interesting fundamental finding reveals a crystalline to amorphous phase transformation of sulfur when mixed with high surface area carbon. This binary mixture configuration effectively resembles a sulfur-cathode in metal-sulfur batteries. Systematic time-dependent powder X-ray diffraction and Raman spectroscopy reveal a crystalline to amorphous phase transition, recently called a sulfur spillover.[1] *The structural phase transformation of sulfur in its binary mixture is highly dependent on the specific surface area of carbon, which we have observed only above a specific surface area (> 2000-3000* m^2/g*). As revealed by electron paramagnetic resonance, the non-polar interaction between carbon and sulfur promotes the transformation of crystalline sulfur into highly dispersed amorphous sulfur comprised of small chain sulfur radicals. Sulfur spillover offers an intimate contact between sulfur and carbon, resulting in reduced charge transfer resistance and improvement in the electronic conductivity of the cathode. Following the spillover process, the* *highly dispersed state of sulfur in the composite leads to increased active material utilization and effective polysulfide management, resulting in a superior specific capacity of the sulfur cathode in a lithium-sulfur battery. This phenomenon will be discussed in the context of designing cathode material for the next-generation conversion-based battery system.*

High-Entropy Li-Rich Layered Oxide Cathode for Li-Ion Batteries *Jaemin Kim[1], Songge Yang[1], Yu Zhong[1], Geoffrey Tompsett[1], Seonghun Jeong[2,2], Junyoung Mun[2,2], Neelam Sunariwal[3], Jordi Cabana[3], Zhenzhen Yang[4] and Yan Wang[1]; [1]Worcester Polytechnic Institute, United States; [2]Sungkyunkwan University, Korea (the Republic of); [3]University of Illinois at Chicago, United States; [4]Argonne National Laboratory, United States*

High-entropy oxides (HEOs) have shown significant promise as cathode materials for Li-ion batteries (LIBs) due to their stable solid-state phase and flexible composition. This research explores the structural and electrochemical characteristics of a new non-equimolar high-entropy cathode material, called high-entropy Li-rich layered oxide (HE-LLO, Li1.15Na0.05Ni0.19Mn0.56Fe0.02Mg0.02Al0.02O1.97F0.03), and compares it to a traditional Li-rich layered oxide (PR-LLO, Li1.2Ni0.2Mn0.6O2). By incorporating various cations (Na+, Al3+, Mg2+, Fe3+) and an anion (F-), HE-LLO achieves greater compositional diversity and structural stability through entropy stabilization. Theoretical calculations indicate that HE-LLO has significantly higher configurational entropy than PR-LLO, supporting its high-entropy status. Electrochemical tests reveal that HE-LLO retains 76.8% of its discharge capacity at 0.5C after 200 cycles, while PR-LLO retains only 36.2%. At elevated temperatures (55°C), HE-LLO maintains 76.1% of its discharge capacity after 100 cycles at 5C, while PR-LLO retained only 12.4%. Additionally, HE-LLO demonstrates superior capacity at higher current densities (5C and 10C) compared to PR-LLO. These improvements are attributed to the enhanced phase stability and higher Li+ ion diffusion coefficients in HE-LLO, supported by ex-situ characterizations using both conventional and synchrotron X-ray techniques, and density functional theory (DFT) calculations. This study underscores the potential of non-equimolar HEOs as an innovative design strategy for high-performance LIB cathode materials.

Leveraging Secondary Interactions Through Indigo Redesign for Improved Organic Cathode Materials in Li-Organic Batteries *Hyojin Kye[1], Jong-Jin Park[2], Yejin Ahn[1], Bong-gi Kim[1], Jinsang Kim[3], Seong-Jun Yoon[4] and Ji Eon Kwon[2]; [1]Konkuk University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]University of Michigan, United States; [4]Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Lithium-ion batteries (LIBs) are crucial in today's digital society as the predominant energy storage devices. However, the environmental impact of inorganic materials like lithium, manganese, and cobalt limits their further application. Additionally, their rigid crystal structures and intercalation processes induce extreme volume expansion, which ultimately worsens battery life. Redox-active organic materials (ROMs) are promising alternative cathode materials for next-generation rechargeable batteries. Composed of abundant, lightweight elements such as carbon, oxygen, and sulfur, ROMs offer flexible molecular designs that can be optimized for voltage and

capacity, and facilitate fast ion diffusion and rapid charge/discharge processes.

Small organic molecules have gained attention as cathode materials due to their simple synthesis, well-defined structure, and high specific capacity. Unfortunately, the biggest problem with small-molecule-based cathodes is that they dissolve easily in organic electrolytes, which negatively impacts overall battery cycle stability. To overcome these challenges, we focused on leveraging secondary interactions such as hydrogen bonding (H-bond), dipole-dipole interactions, and π–π interactions, which induce strong intermolecular interactions and thus reduce solubility in the electrolytes. Among many promising molecules, indigo, well-known as a natural dye, has been utilized in organic electronic devices due to its fast charge mobility and possesses both inter- and intramolecular H-bonds. In previous studies, although indigo shows poor solubility in the neutral state, it has been shown that the H-bond is weakened in the reduced state. Therefore, it is important that secondary interactions are maintained throughout the entire redox reaction, necessitating another secondary interaction to replace the H-bond.

Herein, we explored the relationship between the solubility of charged species and secondary interactions by inducing different types of secondary interactions that persist throughout the redox reaction. Inspired by indigo, we developed two indigo derivatives that can intentionally eliminate H-bonds or induce dipolar ionic interactions through S atoms. From single crystal analysis and DFT results, it was confirmed that H-bonds clearly exist in the neutral state and can effectively reduce solubility. However, during the redox process, the inserted Li cation disrupted the intermolecular H-bonds, thereby significantly increasing the solubility of the charged state. Notably, the secondary interaction induced by sulfur not only marginally reduced the solubility of the neutral state but also significantly lowered the solubility of the charged state. This is because the Li cation inserted during the redox reaction attracts the partially negative S atom, thereby forming a linkage that connects the dimer. Suppression of solubility by dipole-ion interaction effectively increased battery performance, demonstrating high stability in long-term cycles and retaining over 88% capacity at a very fast charging speed (6 minutes).

Strategies for Stabilizing Organic Electrode Materials for Ultrahigh-Performance Energy Storage Systems

Watchareeya Kaveevivitchai[1,1], Meng-Siou Wu[1,1], Nhu T. H. Luu[1,1], Hsuan-Cheng Kuan[1,1], Cheng-Yueh Wang[1,1], Ilja Popovs[2] and Alexander S. Ivanov[2]; [1]National Cheng Kung University, Taiwan; [2]Oak Ridge National Laboratory, United States

Grid-scale energy storage is emerging as one of the largest potential applications for electrochemical devices and will require abundant, low-cost, ultra-stable electrodes. Organic materials possess many advantages such as sustainability, low toxicity, high redox activity, and chemical/structural tunability toward high energy density. However, to compete with inorganic-based compounds, crucial aspects such as redox potential, capacity, electronic conductivity, and cycling stability need to be improved. To enhance stability and overcome dissolution issues of small-molecule organic materials in various electrolytes commonly used in energy storage devices, we report comprehensive strategies on the material design which promotes favorable supramolecular interactions in the solid state. Highly extended π-conjugation allows facile charge transport and extra-high capacity for ion storage (e.g., Li^+, Na^+, Zn^{2+}, and H^+) with superior rate capability. Covalently assembled organic frameworks are also promising due to exceptionally high structural stability and easily accessible redox-active sites. These strategies will be highlighted together with density functional theory studies, providing proof-of-concept for the development of organic compounds as alternative electrode materials for sustainable energy storage systems, with exceptionally high energy density, rate capability, and cycling stability.

An In-Depth Understanding of Mechanically Disordered Structure for Less Hysteretic Fast Charging *Woosik*

Min, Tae Hwa Hong, Jung Tae Lee and Duho Kim; Kyung Hee University, Korea (the Republic of)

Disordered structures have garnered global attention due to their potential to enhance redox kinetics, increase capacity, and achieve high energy density. Various approaches have been explored, for example, $Li_{1.211}Mo_{0.467}Cr_{0.3}O_2$ (LMCO) transitions into a disordered rock-salt structure after several charge-discharge process, resulting in increased capacity and different operating voltage profiles.[1] *Additionally, cation-disordered Li-excess cathode materials can enable oxygen redox, providing extra capacity with high energy density.*[2] *Contrary to the research on how disordered structure with specific chemistries or chemical treatment can affect battery performance, the study for disordered structure formed by mechanical stress with extrinsic properties is insufficient. Lithium-sulfur batteries, which undergo nearly 80% volumetric change during charge/discharge cycles, are ideal for investigating the effects of mechanical stress-induced distortion. By adjusting the pore size of the host material, mechanical stress can be applied to lithium sulfide (Li_2S), creating disordered structures. This allows for a direct comparison between strained and unstrained Li_2S, providing valuable insights into the impact of mechanical stress on structural stability and battery performance.*

Based on this sulfide model, we hypothesize that mechanical compression can facilitate hysteresis-less fast charging based on three key components: electro-chemo-mechanics, phase transition kinetics, and ionic kinetics. First, a new domain called electro-chemo-mechanics was introduced with the concept of "electrochemical stiffness" ($\rho=\Delta V/\Delta Q$), which relates the voltage to the state of charge (SoC), inspired by the stress–strain relationship in mechanics. Mechanical compression lowers the operating voltage, reducing the initial electrochemical stiffness, and making Li-ion extraction and insertion easier, thus mitigating hysteresis during charging and discharging process. Second, compression destabilizes the unstrained phase, lowering the kinetic barrier and resulting in faster, hysteresis-less phase transitions, as strained Li_2S structures exhibit reduced barriers and lower electrochemical potentials compared to unstrained structures. Third, we examine ionic kinetics, showing that compression breaks the symmetric migration pathways, creating new paths with lower barriers for Li ions, resulting in significantly higher ion mobility and enhanced diffusion rates in strained Li_2S models. These hypotheses were validated through a data-driven approach, combining DFT calculations and experimental analyses. Our findings present a novel method for achieving hysteresis-less fast charging based on various multi-physical perspectives, along with a new domain, electro-chemo-mechanics.

Toward Optimization of Polymer Electrolytes by Electrochemical Characterization— Poly(pentyl malonate) Versus Poly(ethylene oxide)

Jaeyong Lee[1,2], Zach Hoffman[2], Vivaan Patel[2] and Nitash P. Balsara[2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Demand for high-performance rechargeable batteries continues to grow as electric vehicle production increases. The energy density of lithium-ion batteries, used in this application, has not significantly improved in the past decade. Electrodes such as silicon and lithium metal have the potential to increase energy density, but electrolytes that are stable against these electrodes are not yet been identified. Polymer electrolytes have the potential to stabilize these electrodes. Lithium salts dissolved in poly(ethylene oxide) (PEO) were first hypothesized for battery electrolyte applications in 1979 by M. Armand. It is not clear if any of the polymer electrolytes developed in subsequent years is better for battery applications.

For practical applications, electrolytes must support large currents. The limiting current density, i_{lim}, is the maximum current density which can be stably applied across an electrolyte. Salt concentration gradients develop when current passes through an electrolyte, resulting in high concentration near the positive electrode and low concentration near the negative electrode. At the limiting current, either the concentration at the negative electrode approaches zero, or the concentration at the positive electrode approaches the solubility limit. The limiting current is a convenient metric for comparing different electrolytes. To our knowledge, there is no polymer electrolyte present in the published literatures that exhibits a higher limiting current than PEO. Another metric for comparing different electrolytes is the potential drop needed to sustain the limiting current. An ideal electrolyte will exhibit the lowest potential drop and the highest limiting current.

The limiting current and potential drop through an electrolyte can be predicted by Newman's concentrated solution theory. Applying this theory requires knowledge of four concentration-dependent parameters. In these previous studies, it was shown that the limiting current can be predicted using conductivity, κ, salt diffusion coefficient, salt diffusion coefficient, D, current fraction measured in Bruce-Vincent experiment, ρ_+, and the open circuit potential of concentration cells, U. We present values for these four parameters for poly(pentyl malonate) (PPM) mixed with lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) electrolyte. The predicted values of limiting current and potential drop are in good agreement with experimental measurements, which were conducted in symmetric cells using lithium-indium alloy electrodes. The maximum limiting current value of PPM/LiTFSI is about 1.7 times higher than that of PEO/LiTFSI, and the potential drop at the maximum limiting current density through PPM/LiTFSI electrolyte is about 1.6 times smaller than that of PEO/LiTFSI. We present a new plot for comparing the performance of different electrolytes.

11:30 AM EN08.06.10

a-SiN$_x$ as a Next Generation Anode Material for Li-Ion and Solid State Batteries *Moritz Loewenich[1], Melisa Bilgili[1] and Hartmut Wiggers[1,2]; [1]Universität Duisburg-Essen, Germany; [2]University Duisburg-Essen, Germany*

Silicon-based materials offer a wide range of benefits for battery applications. In Comparison to carbon-based anodes, higher energy densities can be reached, and more independent supply chain can be established. Compared to lithium metal, silicon-based materials offer a reduced dendrite formation at similar capacity, which can enable fast-charging, and significantly easier processing suitable for most existing production lines. Looking at solid state batteries, challenges of current silicon technologies are the stability during cycling due to the volume expansion of the silicon causing loss of electrical conductivity and potentially inconsistent cell pressure. Furthermore e.g. for sulphur-based solid electrolytes, a loss of lithium inventory due to reactions on the Si-SE interface is limiting cycle life. Amorphous SiN_x (a-SiN_x) is a promising next-generation anode material which tackles some of those issues from a materials perspective. It is a conversion material which forms a matrix phase in the first cycle, consisting mainly of Li_2SiN_2 and Li_3N. Submicron scale SiN_x can be produced from the gas phase in a hot-wall reactor from monosilane (SiH_4) and ammonia (NH_3). Stoichiometry, size and morphology can be tuned by process conditions. We have demonstrated the scale up from a lab-scale equipment (10 g/h) to a pilot scale equipment (1 kg/h) while still obtaining the desired product and controlling nitrogen distribution in the particles with core-shell type or more homogenous distributions possible. Amorphous SiN_x Powders with a nitrogen content up to 30 wt.%, a specific surface area above 10 m^2/g and Si crystallinity below 5 % can be obtained. a-SiNx is a conversion material, which means that part of the lithium is converted into an intentionally formed matrix phase, affecting the first cycle Coulombic efficiency (FCE). However, it shows greatly enhanced cycle stability for hundreds of full cycles at capacities around 1400 mAh/g. The matrix phase formed in the first cycle dampens electrode swelling, acts as an intrinsic solid electrolyte and prevents excessive SEI growth. The battery performance in respect to nitrogen content and particle size is reported and an optimum in terms of capacity, stability and FCE is proposed.

Correlations Between Functional and Compositional Parameters and Coulombic Efficiency in the Lithium Anode SEI *Betar Gallant; Massachusetts Institute of Technology, United States*

The lithium (Li) metal anode offers significantly higher capacity than graphite and is therefore central to strategies to develop advanced rechargeable battery chemistries that meet range and performance targets for electric vehicles. Although closer than ever, Li anodes still cannot meet the >99.9% Coulombic efficiency (CE) consistently needed for >1,000 cycle life.[1] *This shortfall arises from uncontrolled reactivity at the solid electrolyte interphase (SEI) and resulting SEI properties, leading to inhomogeneous plating and stripping, continuous electrolyte consumption and loss of active Li inventory. Despite progress in electrolyte development, the lack of precise understanding of the SEI still hinders attempts to rationally design an improved interface towards bridging remaining gaps in CE.*

To inform such efforts, our work is advancing quantitative techniques to yield insights into SEI phases and the hidden interplays between their chemistry, properties, and function. We developed a methodology to probe the Li^+ *exchange rate between electrolyte and the Li anode, as modulated by the SEI, in a range of native Li SEI in diverse electrolytes and examined the robustness of the methodology by both electrochemical impedance and Tafel analysis.*[2] *Across numerous electrolytes, we find a strong correlation between* Li^+ *exchange rate and CE, which indicates that phases that promote facile* Li^+ *exchange can serve as a materials chemistry design descriptor for high-performance SEI. Second, we further examined composition-performance relationships in the SEI using a new parallelized titration protocol that enables quantification of lithium oxide (*Li_2O*) in cycled Li electrodes for the first time, alongside numerous other SEI phases.*[3] *We reveal that* Li_2O *is the leading detectable phase underlying high performance of Li metal anodes, beyond that of lithium fluoride (LiF), opening new design trajectories for future electrolytes and potentially reducing the reliance on costly, unsustainable yet pervasive fluorinated electrolytes.*

2:00 PM *EN08.07.02

Unveiling the Degradation Mechanisms of Lithium Batteries Through Lithium Inventory Quantification
Wurigumula Bao; The University of Chicago, United States

There has been growing interest in energy storage technologies, particularly in lithium (Li)-ion/lithium metal batteries, due to the accelerated transition to renewable energy systems worldwide. Accurate diagnosis and understanding of the attenuation mechanisms of batteries are essential for their development. It has been widely proven that, in practical fuel-cell systems, the cross-talk between the cathode and anode impacts cycling *performance. Additionally, electrolyte depletion during cycling also affects battery life. Therefore, it is crucial to develop analytical methodologies to assess changes in the Li inventory within each component. For full-cell studies, key questions include: Where is the active Li after cycling? How much has become inactive Li? In conventional Li-ion batteries, graphite (Gr) and silicon (Si) are used as anode active materials, while transition metal oxides serve as cathode active materials. All active Li originates from the cathode, so the loss of active Li is directly related to capacity loss, making it easier to evaluate cycle life based on coulombic efficiency. After cycling, the active Li remains in the cathode and electrolyte at the discharge state, while the Li on the anode side is primarily inactive. In Li metal batteries, active Li is present in both the anode and cathode before cycling. The additional Li reservoir in the anode compensates for active Li loss during cycling. Thus, assessing the cycle life of Li metal batteries is challenging because coulombic efficiency only partially correlates with active Li loss. To further reveal the full cell system's degradation mechanism, X-ray Diffraction (XRD) was applied to the cathode to quantify the active Li. Titration Gas Chromatography (TGC) was used to quantify the inactive Li in the anode, and Inductively Coupled Plasma Mass Spectrometry (ICP-MS) was applied to evaluate the Li+ concentration in the electrolyte upon cycling. We demonstrate the importance of quantitatively examining Li inventory changes in the full cell system. Furthermore, the results provide unique insights into identifying critical bottlenecks facilitating battery performance development.*

Updates in Lithium-Metal Battery Development *Danielle Gendron; QuantumScape Corporation, United States*

Today’s conventional lithium-ion batteries fall short of meeting the needs of many automotive, consumer electronics, and stationary storage applications. Many believe that the unique cell design of solid-state lithium-metal batteries will help bridge this gap – particularly when it comes to electric vehicles – because the technology is designed to enable longer range, faster charging and enhanced safety compared to conventional lithium-ion batteries. In this talk, Principal Member of Technical Staff, Senior Manager at QuantumScape, Jordi Sastre will highlight recent developments in solid-state lithium-metal technology and review some of the challenges in transitioning from R&D to a commercial product.

3:45 PM EN08.07.04
Discovering Low-Viscosity Molecules Using an Integrated Physics-Based Modeling, High-Throughput Screening and Active Learning Approach (1)— Screening from the GDB Database *Nobuyuki N. Matsuzawa[1], Hiroyuki Maeshima[1], Tatsuhito Ando[1], Atif Afzal[2], Benjamin Coscia[2], Andrea Browning[2], Mathew D. Halls[2], Karl Leswing[2] and Tsuguo Morisato[2]; [1]Panasonic Industry Co., Ltd., Japan; [2]Schrödinger, Inc., United States*

The discovery of low-viscosity molecules is crucial for the development of next-generation batteries and capacitors. Large molecular libraries available in the literature provide a valuable resource for identifying promising candidates. In this study, we utilized the GDB database [1], one of the largest repositories of small molecules, to identify low-viscosity molecules. We employed and benchmarked molecular dynamics methods to accurately compute the dynamic properties without the need for synthesis or empirical testing, validating our calculations against experimental data. Physics-based simulations of viscosity included both Green-Kubo and Einstein-Helfand approaches allowing for robust calculation across the selected molecules. However, the number of molecules of interest from the GDB database is too large (several hundreds of thousands), making it impractical to identify promising candidates using purely physics-based models due to computational costs. Therefore, we implemented advanced machine learning (ML) techniques and smart selection approaches to dramatically reduce the number of physics-based calculations needed. By employing an active learning approach, we optimized the *selection of molecules, enhancing the efficiency of the ML model while targeting low-viscosity candidates. Additionally, we computed the boiling points (BP) of the molecules using ML models trained on experimental BP data. As a result, we identified more than 100 molecules with viscosities less than 0.35 cP and BP above 80°C. We demonstrate that by integrating accurate physics-based models with advanced ML techniques, we can effectively identify top molecular candidates while significantly reducing computational costs.*

4:00 PM EN08.07.05

A Layered Metal-Free Cathode Material for High-Energy, High-Power and Long-Lasting Lithium- and Sodium-Ion Batteries *Tianyang Chen[1] and Mircea Dinca[2]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States*

Eliminating the use of critical metals in cathode materials can accelerate global adoption of rechargeable lithium-ion batteries, especially in large-scale applications such as grid storage. Organic cathode materials, derived entirely from earth-abundant elements, are in principle ideal alternatives but have not yet challenged inorganic cathodes due to poor conductivity, low practical storage capacity despite high theoretical values, or poor cyclability. We describe a layered organic electrode material whose high electrical conductivity, high storage capacity, and complete insolubility enable reversible intercalation of Li^+ ions in between molecular vdw 2D layers, allowing it to compete at the electrode level, in all relevant metrics, with inorganic-based lithium-ion battery cathodes. Our optimized cathode stores 306 $mAh\ g^{-1}$, delivers an energy density of 765 $Wh\ kg^{-1}$, both at the electrode level, which are higher than most cobalt-based cathodes, and can charge–discharge in as little as 6 min. These results demonstrate the operational competitiveness of sustainable organic electrode materials in practical batteries.

4:15 PM EN08.07.06

Locally Concentrated Ionic Liquid Electrolyte with Partially Solvating Diluent for High Performance Lithium Metal Batteries *Yuhe Mu; The University of Texas at Dallas, United States*

Ionic liquids with high concentrations of lithium salts have garnered interest as electrolytes for safe and high-performance lithium metal batteries. However, they are hindered by challenges such as high viscosity and inadequate ionic transport. A locally concentrated ionic liquid with a non-solvating cosolvent has been presented. The designed electrolyte is composed of 1-methyl-1-propyl pyrrolidinium bis(fluorosulfonyl)imide ($Py_{13}FSI$) ionic liquid, Lithium bis(fluorsulfonyl)imide (LiFSI) lithium salts and a non-solvating cosolvent, respectively. The strong electron-withdrawing effect of the fluorinated groups diminishes the solvating ability of co-solvent. As a result of this non-solvating characteristic, the concentrated ionic liquid electrolyte can be diluted while still preserving local Li^+ coordination and enhancing the Li^+ transference number. Additionally, a high proportion of ion pairs and agglomerates in the electrolyte can kinetically accelerate Li-ion transport and promote the formation of a more stable solid electrolyte interphase (SEI) layer. Therefore, the formulated electrolyte demonstrates superior reversible and stable Li stripping/plating behavior with high average Coulombic efficiency.

4:30 PM EN08.07.07

Oxygen Dimerization as a Defect-Driven Process in Bulk $LiNiO_2$ from Novel Structure-Search Methodologies
Alexander Squires[1,2], Lavan Ganeshkumar[3,2], Christopher Savory[1], Seán R. Kavanagh[4] and David O. Scanlon[1,2]; [1]University of Birmingham, United Kingdom; [2]The Faraday Insitution, United Kingdom; [3]University College London, United Kingdom; [4]Harvard University, United States

Recent research points to significant oxygen involvement during the charging of nickel-based lithium-ion cathode materials [1, 2, 3]. Such activity is evidenced by incomplete oxidation from Ni^{3+} to Ni^{4+} in $LiNiO_2$ at the top of charge [1], alongside resonant inelastic X-ray scattering (RIXS) spectra that indicate oxygen-redox activity and oxygen dimer formation [1, 3] . To explore the possibility of oxygen dimerization — particularly the formation of molecular oxygen-like species — in the bulk of $LiNiO_2$ lithium ion cathodes materials at high states of charge, we conduct a redox-product structure search inspired by recent methodological developments for point defect structure prediction [4, 5, 6]. Utilising this novel methodology we find that delithiated $Li_{1-x}NiO_2$ (x = 1) has good kinetic stability towards decomposition into molecular oxygen and reduced transition metal oxides, but that point and extended defects can act as nucleation sites for oxygen dimerization. Certain defects leave local oxygen ions more susceptible to oxidation, these oxidised oxygen species then passivate their excess charge by rebonding and forming oxygen dimers. In this study we draw analogy to behaviours observed in lithium-rich cathode materials and explain how significant differences in observed electrochemistry of the stochiometric and Li-rich materials can be explained despite this highly related bulk reactivity. These results help reconcile conflicting reports on the formation of bulk molecular oxygen in $LiNiO_2$ and other nickel-rich cathode materials, highlighting the role of defect chemistry in driving the bulk degradation of these compounds. We will also discuss the acceleration of this structure search via fine-tuned machine-learned interatomic potentials.

Understanding Voltage Hysteresis and Voltage Fade in Li-Rich Mn-Based Layered Oxide Cathode Materials

Kit McColl[1], Patrick J. Taylor[1], Samuel W. Coles[2,1], Benjamin J. Morgan[1] and Saiful Islam[3]; [1]University of Bath, United Kingdom; [2]University of Cambridge, United Kingdom; [3]University of Oxford, United Kingdom

Lithium-rich manganese-based layered oxide cathodes exhibit high reversible capacity from a combination of transition metal ion redox and oxygen redox. However, these Li-rich materials suffer a loss of energy density during cycling, due to hysteresis and fade in their voltage-capacity curve, which has been associate with their oxygen redox chemistry [1]. Two different forms of voltage hysteresis can be recognised: a large first-cycle hysteresis, resulting in an irreversible voltage loss, and a smaller, persistent hysteresis on later cycles, causing a round-trip cycling inefficiency [2]. A further phenomenon of voltage fade, a gradual drop in average discharge voltage at each cycle, also results in energy density loss over long-term cycling [3]. To improve the practical viability of Li-rich Mn-based cathodes, it is vital that these detrimental electrochemical features are understood and mitigated. Unfortunately, the mechanisms of oxygen redox, including host-framework structural rearrangements, void formation and oxygen loss [4], that are associated with voltage hysteresis and fade, are not well understood at the atomic or nanoscale.

To understand the origin of voltage fade and hysteresis in an exemplary Li-rich Mn-based cathode: $Li_{1.2}Mn_{0.8}O_2$, we employ atomistic modelling, using density functional theory, ab initio molecular dynamics and machine-learning *potentials. By combining these modelling methods, we can map a large structural and chemical space in the material during charge and discharge. In doing so, we resolve distinct atomic- and nanoscale origins for the first-cycle hysteresis, persistent hysteresis, and voltage fade, and identify structural modifications that will mitigate each process. Insights from this work provide clear guidelines for the design of Li-rich cathodes with better short-term and long-term cycling stability.*

The Effect of Metal Doping on the Anode Characteristics of Ge Thin Films in Lithium-Ion Secondary Batteries

Koki Nozawa, Takashi Suemasu and Kaoru Toko; University of Tsukuba, Japan

1. Introduction

Ge has garnered attention as a next-generation anode material due to its high specific capacity and fast lithium diffusion rate[1]*. However, the low capacity retention rate resulting from damage to the film caused by volumetric expansion has posed a significant challenge. In this context, various studies have reported improvements in properties through the addition of metal (M) to suppress volumetric expansion*[2]*. In this study, we investigated the anode properties of Yb_xGe_{1-x}, which had not previously been reported. Remarkably, we discovered a dramatic improvement in these properties. Furthermore, we systematically examined the impact of adding various elements on the anode characteristics, confirming a trend where the larger atomic size of M leads to enhanced anode performance of Ge.*

2. Experimental Procedures

A layer of M_xGe_{1-x} (500 nm thick), where M represents Al, Ag, Cu, Ni, Ta, W, and Yb, was sputter-deposited on a Mo substrate. Subsequently, a two-electrode cell was fabricated by placing metallic Li as the counter electrode and using an electrolyte composed of 1M $LiPF_6$ in EC/DEC (1:1 v/v). Charge-discharge tests were conducted at a current density of 500 mA g^{-1}. The composition of the $Ge_{1-x}M_x$ anode was evaluated using Energy Dispersive X-ray Spectroscopy. To assess the damage to the $Ge_{1-x}M_x$ anode caused by charge-discharge cycling, Scanning Electron Microscope images were acquired post cycling.

3. Results and Discussion

[i] Yb addition effects on Ge

From the charge-discharge characteristics of Ge and $Yb_{0.1}Ge_{0.9}$, it was confirmed that the addition of Yb improves capacity retention. Subsequently, charge-discharge tests on Yb_xGe_{1-x} anodes showed that the initial capacity remained almost constant for $x < 3\%$ but exhibited a decreasing trend for $x > 10\%$. Regarding anode lifespan, Ge *demonstrated a lifespan of only about 60 cycles, whereas the addition of Yb resulted in stable anode performance for approximately 150-240 cycles.*

To evaluate the damage to the Yb_xGe_{1-x} anode caused by charge-discharge cycling, SEM images of the anode post-cycling were acquired. Low-magnification images revealed that the shape of the anode deformed into a rectangular form with an increase in Yb composition. High-magnification images indicated the formation of unique nanoscale structures corresponding to the varying Yb compositions. These shape changes are presumed to result from alterations in the mechanical strength of the Ge thin film due to the addition of Yb.

[ii] Impact of M on Anode Characteristics

Next, we fixed x at approximately 3% and examined the impact of varying the type of M on the anode characteristics of M_xGe_{1-x}. The graph indicates that the anode capacity varies depending on the type of M. We then quantitatively summarized the effect of the atomic size of M on anode performance. While the initial capacity was about 1.3 Ah g^{-1} and almost unchanged regardless of the type of M, it became clear that the larger the atomic size of M, the longer the lifespan of the M_xGe_{1-x} anode.

It was previously unknown that the doped metal element's size affects Ge anodes' lifespan. The findings of this study significantly contribute to the improvement of anode characteristics in secondary batteries.

Perovskite $SrZrO_3$ as a Novel Material for Solar-Assisted Water Splitting *Sanaa Ismail and Nageh K. Allam; The American University in Cairo, Egypt*

Developing novel electrodes for photocatalytic water splitting using computational analysis is a fascinating area of study with important implications for renewable energy generation. Perovskite SrZrO3 has been investigated as a potential catalyst for solar water splitting. Specifically, the synergistic effects of hydrogen doping and oxygen vacancies on the optoelectronic properties of the material have been revealed and discussed. First-principles calculations revealed that interstitial hydrogen defects are energetically favorable compared to substitutional hydrogen in SrZrO3. Moreover, mono- and co-hydrogen occupied oxygen vacancies have also been examined. Hydrogen doping was shown to introduce shallow defect states below the conduction band minimum, which could be beneficial for applications like gate dielectrics. At high oxygen vacancy concentrations, the HOV-OV structural configuration exhibited localized shallow defect states with a 1.3 eV band gap energy, increased dielectric constant, and enhanced optical absorption compared to pristine SrZrO3. This HOV-OV structure was identified as an ideal novel candidate catalyst for photocatalytic water splitting, based on factors such as Gibbs free energy, band gap alignment, low exciton binding energy, and high permittivity. Overall, this computational work provides valuable insights into engineering the optical and electronic properties of SrZrO3 through strategic defect incorporation. The findings could help guide the experimental development of high-performance photocatalysts for renewable hydrogen production.

EN08.08.04

Exploring the Li Intercalation Process in the Functionalized $Mo_2V_2C_3T_2$ (T = O, F, Cl, OH) MXene—Insight from First-Principles Calculations *Raul E. Santoy Flores, Maria G. Moreno Armenta, Jonathan Guerrero Sanchez and Rodrigo Ponce; Centro de Nanociencias y Nanotecnología, Mexico*

MXenes are excellent candidates to be employed as anode in Li-ion batteries due to their electrochemical properties, high electrical conductivity, and low energy barriers for ion diffusion. Recent studies have *demonstrated that bi-metallic MXenes, like $Ti_2Ta_2C_3$, exhibit superior electrochemical performance compared to their monometallic counterparts, offering potential for extended lifespan in energy storage systems. In this work, we investigated the role of the surface functionalization in the Li intercalation process, for this porpouse, we considered the presence of O, F, Cl and OH functional groups onto the surface. Besides, we investigated the activation energy to diffuse the Li ions onto the surface and the theoretical gravimetric capacity. Our findings indicate that the oxidized phase of $Mo_2V_2C_3$ performs exceptionally well as an anode in batteries, providing higher gravimetric capacity with Li-ion integration. These insights highlight the promise of bi-metallic MXenes in advancing cycling stability and energy efficiency in next-generation energy storage devices.*

EN08.08.05

Hydrothermal Synthesis and Enhanced Energy Storage Properties of 2D Ca-Intercalated CoO_2 Nanosheets Derived from Quasi-1D $Ca_2Co_3O_6$ for Electrochemical Applications.

Rajat K. Mohanta, Aswani Yella and Leela S. Panchakarla; Indian Institute of Technology Bombay, India

Transition metal oxides, renowned for their high energy storage capacity and redox activity, holdgreat promise in this regard. Among these oxides, intercalated cobalt oxide (CoO_2) has emerged as a compelling candidate for electrochemical energy storage devices, but its metastable nature poses challenges for long-term stability. To address this, the intercalation of foreign atoms like calcium (Ca) has been investigated to stabilize CoO_2 crystal structure. This study presents a novel approach to synthesizing two-dimensional (2D) Ca-intercalated CoO_2 nanosheets from quasi-1D $Ca_2Co_3O_6$ via a hydrothermal method. The investigation reveals that varying reaction times result in distinct crystal structures, yielding either intercalated CoO_2 nanoscrolls or misfit layered nanosheets of the $CaCoO_2$-CoO_2 phase. These unique structures offer large surface areas, facilitating ion accessibility and efficient charge transport. The Ca intercalation process significantly enhances the stability of CoO_2.To the best of our knowledge, this work represents the first successful stabilization of 2D CoO_2 with Ca intercalation, converting a quasi-1D structure into a misfit layered 2D structure. Characterization techniques including SEM, TEM, high-resolution TEM, selected area electron diffractions, and EDS confirm the crystal structure and phase of the newly synthesised nanosheets.Furthermore, electrochemical evaluations as cathode materials for Zn-ion batteries demonstrate exceptional cycling stability and high specific capacity, establishing these nanosheets as promising candidates for future energy storage applications and beyond.

High-Performance Multifunctional Electrolytes and Additives for Next-Generation Lithium-Ion Batteries

Myeong Ju Lee[1], Jimin Oh[2], Kwang Man Kim[1], Sung You Hong[3] and Young-Sam Park[1]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of); [3]Ulsan National Institute of Science and Technology, Korea (the Republic of)

As the demand for rechargeable batteries surges, concerns about the safety of lithium-ion batteries (LIBs) have intensified. Issues with thermal stability, such as fires and explosions resulting from thermal runaway, are primarily caused by the use of volatile and flammable liquid electrolytes that contain linear or cyclic organocarbonate compounds. Thermal runaway can be triggered by overcharging, external shocks, cell defects and excessive heat, which destabilizes the organic liquid electrolytes. This destabilization leads to overheating, heat accumulation, combustion, and ultimately battery explosions. Despite the development of various flame-retardant additives to prevent combustion and explosions, these often come with a trade-off between reducing flammability and maintaining electrochemical performance. Achieving thermal stability has typically resulted in the reduced electrochemical performance, including lower coulombic efficiency and unstable cycle retention properties. Common flame-retardant additives include organophosphorus-based compounds like trimethyl phosphate, triphenyl phosphate, and tris(2,2,2-trifluoroethyl) phosphite, which work by generating phosphorus-containing

radicals to trap free radicals. Fluorine or sulfur-based flame retardants, known for their moderate-to-good electronegativity, have relatively low HOMO energy levels, providing higher oxidation stability. Compounds such as fluoropropanesultone, trifluoromethyl sulfones, and bis(4-fluorophenyl) sulfone have been shown to improve the interfacial stability of nickel (Ni)-rich cathodes and 5 V-class LIBs. It is believed that achieving simultaneous improvements in thermal and interfacial stabilities could result in better flame retardancy without compromising electrochemical performance. This study introduces a flame retardant with dual fluorosulfate moieties for a Ni-rich $LiNi_{0.9}Co_{0.05}Mn_{0.05}O_2$*/Lithium cell. The study investigates the thermal and interfacial effects of this synthetic functional additive through surface analysis and mechanistic study, demonstrating its unique flame-retardant properties without sacrificing high capacity and cell cyclability. Lastly, a synergistic effect was confirmed by introducing a small amount of a salt-type additive into the developed trade-off-free fluorosulfate-based flame retardant electrolyte.*

Carbon Fiber-Reinforced Redox-Active Polymer Composite as a Multifunctional Cathode for Structural Batteries

JooHwan Eo[1,2], Gonui Hong[1], Min Sang Kwon[2], Min Kook Kim[1] and Ji Eon Kwon[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Electrifying transportation is essential for moving towards a more sustainable future. Currently, lithium-ion batteries (LIBs) are widely adopted for the electrification of transportation, such as electric vehicles (EVs) and electric aircraft, due to their high energy density, cycle stability, and low self-discharge rate compared to other energy storages. However, the gravimetric energy density of conventional LIB packs is still lower than the energy efficiency of internal combustion engines, inevitably increasing the total weight of these vehicles and thereby limiting their driving ranges with the need for frequent recharges.

To address this issue, the concept of structural batteries (SBs) has recently garnered considerable attention for their ability to achieve both mass and volume savings at the system level. SBs are multifunctional components that can simultaneously store electrical energy and carry mechanical load. By integrating an energy storage function into a structural composite, SBs can substantially reduce both the mass and volume of the system. Typically, SBs can be classified into two categories depending on their integration strategies: coupled and decoupled types. The decoupled types correspond to simple combinations of load-bearing structures with energy storage components, where conventional batteries are embedded between structural face sheets. Therefore, the efficiency of mass and volume savings achieved by the decoupled SBs is inconsiderable. In contrast, in the coupled SBs, each material component is designed to simultaneously perform mechanical and energy storage functions. Although the coupled strategy is more ideal for achieving both mass and volume savings, realizing the coupled SBs, which exhibit electrochemical and mechanical performance comparable to commercial LIB packs and structural composites, respectively, is still very challenging.

To prepare coupled SBs, typically, conventional electrode slurries containing transition metal oxide, carbon conducting additives, and PVDF binder, are deposited on the carbon fiber (CF) current collectors, inspired by carbon fiber-reinforced polymer (CFRP) composites. However, such conventional electrode materials lack the ability to bind the CFs, leading to easy delamination even under weak mechanical stresses.

Herein, we present a novel concept of electrode design for coupled SBs: a carbon fiber-reinforced redox-active polymer (CFRRAP), consisting of CFs bound by a polymer matrix exhibiting redox activity. To demonstrate the potential of this concept, we prepared a series of CFRRAP composite cathodes comprised of T300 CFs and a polyimide (PI) resin with different ratios of Super-P carbon additives via a hand lay-up process followed by hot *compression molding. These composite cathodes can carry high mechanical load, which is attributed to the thermoplastic PI resin tightly binding the CFs as a matrix, comparable to conventional CFRP-based structural composites. Simultaneously, the carbonyl groups in the PI matrix can store electrical energy via reversible redox reactions accompanying the insertion/de-insertion of Li-ions. We explored the structure-property relationships between the electrochemical/mechanical properties and Super-P content in the composite cathodes, revealing a trade-off between the electrochemical performance and the electrochemical properties of the composites. At an optimized content, the PI-based CFRRAP cathode exhibits an elastic modulus of 18 GPa and a tensile strength of 213 MPa while delivering a specific capacity of 141 mAh/g with an average discharge voltage of 2.2 V. It is noteworthy that its mechanical and electrochemical properties outperform most coupled/decoupled structural cathodes reported so far. We investigated their charge/discharge mechanism and mechanical failure modes through various analysis methods. It should also be noted that the composite electrodes demonstrate flame retardation properties.*

EN08.08.08

Electrolyte-Free Graphite Electrodes Employing Lithium-Substitution-Modulated Binders for Practical Fabrication of All-Solid-State Batteries *Dong Ok Shin[1,2], Jaecheol Choi[1], Seok Hun Kang[1], Young-Sam Park[1,2], Ju Young Kim[1] and Young-Gi Lee[1]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]University of Science and Technology, Korea (the Republic of)*

The challenges associated with electrically inert binders have been mitigated in conventional lithium-ion batteries (LIBs) by utilizing permeable liquid electrolytes (LEs) for ionic connectivity and carbonaceous additives for electronic connectivity in the electrodes. Unlike electro-conductive binders to exclude the inactive conductive agent, the development of ion-conductive binders has been limited due to the presence of LEs in the electrodes [1].

Meanwhile, all-solid-state batteries (ASSBs) are promising for high-energy storage and safety by using solid electrolytes (SEs) instead of LEs, though poor SE wettability hampers Li^+ transport and sulfide-based SEs may decompose with electrode components [2,3]. To address these issues, our group has proposed a simplified electrolyte-free ASSBs electrode that relies on interfacial conduction between electrode particles, potentially facilitated by ion-conducting binders [2].

In this study, we propose a strategic approach to enhance interfacial Li^+ conduction in ASS, electrolyte-free electrodes, where electrolyte components are entirely excluded, by employing lithium-substitution-modulated (LSM) binders [2]. By precisely adjusting the lithium substitution ratio, we synthesized conductive LSM-carboxymethyl cellulose (CMC) through a controlled direct Na^+/Li^+ exchange reaction, avoiding the use of hazardous acids.

Our findings demonstrate that the electrolyte-free graphite electrode using LSM as the binder, with a maximum degree of lithium substitution (DS_{Li}) of approximately 68%, exhibits significantly higher rate capability and capacity retention compared to those using sodium-CMC (Na-CMC) and LSM with ~35% lithium substitution.

Moreover, we systematically investigated the correlation between phase transition near the bottom region of the graphite electrode and the state of charge (SOC), revealing that the enhancement of interfacial conduction is directly proportional to the DS_{Li} of the CMC binders. We speculate that the creation of continuous interfaces with abundant pathways for mobile ions using the Li^+-conductive binder is the primary mechanism for improved interfacial conduction in the electrolyte-free graphite electrode, thereby reducing significant charge transfer resistance.

EN08.08.09

Towards High-Performance Future of Batteries—The Critical Effects of Metal-Organic-Framework (MOF)-Based Materials on the Electrodes, Electrolytes and Separators

Man Li, Seunghyun Song, Xiong Cheng, Yoonju Oh and Joonho Bae; Gachon University, Korea (the Republic of)

In this work, we present our recent study on the critical effects of metal-organic frameworks (MOF) materials on the most important components of batteries, including electrodes, electrolytes, and separators. Firstly, a novel MOF/Ionic liquid-based solid-state electrolyte (HKUST-1@IL-Li) is designed by immobilizing ionic liquid ([EMIM][TFSI]) in the nanopores of HKUST-1 MOFs. 3D angstrom-level ionic channels of the MOF host can restrict electrolyte anions and act as “highways” for fast Li^+ transport. A high ionic conductivity (6.85×10^{-4} S/cm) and excellent thermal stability of the HKUST-1@IL-Li electrolyte is achieved and as-fabricated $LiFePO_4$/HKUST-1@IL-Li/Li solid-state battery exhibits remarkable performance at high temperature (100 °C). In addition, MOF-derived Co-doped carbon nanosheets are fabricated as cathode hosts for lithium-sulfur batteries (LSBs). Reduced Co nanoparticles evenly distributed on the nanosheets showing the catalytic effect can promote polysulfide conversion. After decorating the carbon nanosheets with DNA molecules, 3D Li_2S nucleation and deposition are realized in a high-sulfur-loaded LSB. A high areal capacity of 8.1 mA h cm^{-2} is achieved for the LSB with a high sulfur load of 10 mg cm^{-2}, which is more than 2 times that of commercial Li-ion batteries. Finally, a MOF/CNT@DNA-Janus interlayer fabricated for LSBs achieves “shuttle effect” suppression and lithium dendrite-free simultaneously. Li^+ transfers through the pathway inside the MOF layer then evenly deposited on the Li anode, which efficiently suppresses the Li dendrites growth. Meanwhile, the experimental evidence combined with theoretical computation of DFT calculations proves that the functional groups on the CNT@DNA layer, such as –P=O and = N–show high adsorption strengths to anchor and block polysulfides. All the research works demonstrate that metal-organic frameworks can be desirable materials for next-generation batteres.

EN08.08.10

Inhibition of Heterogeneous Li Filaments in Inorganic Solid Electrolytes via Work Function Alignments at the Grain Boundary

Jeewon Lee[1], Heebae Kim[1] and Youn Sang Kim[1,2,3]; [1]Seoul National University, Korea (the Republic of); [2]Advanced Institute of Convergence Technology, Korea (the Republic of); [3]Graduate School of Convergence Science and Technology, Korea (the Republic of)

All-solid-state lithium metal batteries (ASSLMBs) with inorganic solid-state electrolytes (ISEs) are promising with high energy density and excellent safety compared to conventional Li-ion batteries using flammable organic liquid electrolytes. However, the ISEs have a severe electrochemical stability issue at ISE boundaries where heterogeneous Li filaments are formed, which causes internal short circuits during cycles by inducing Li penetration through ISEs. From the common fabrication process of ISEs, sintering the solid electrolyte powders,

the microstructure boundaries of ISEs, such as grain boundaries (GBs), are inevitably formed. Therefore, applying an appropriate method at the GBs, the interface between the grain interiors (GIs), based on the intrinsic properties of these microstructures, is important. Fundamentally, the GBs in ISEs have high electronic conductivity, low ion conductivity, and high interfacial resistance, which induce heterogeneous Li filaments at the GBs. Especially among the properties, the high electron conductivity that results from the non-uniform distribution of electronic structures at GBs dominantly contributes to the formation of Li filaments. However, the studies on the electronic structures at the GBs have not proceeded well, even though that is essential to reveal the formation of Li filaments. In this study, we revealed the mechanisms for the origin of Li filaments and introduced the work function alignment interlayer at GBs based on the mechanisms to improve electrochemical stability and ensure superior safety. Among the ISEs, cubic $Li_7La_3Zr_2O_{12}$ *(LLZO) with low electronic conductivity* (10^{-7} ~ 10^{-11} S cm^{-1})*, high bulk ion conductivity* (> 10^{-4} S cm^{-1}) *and high reduction stability (0 V vs* Li/Li^+*) was used for research. From the non-uniform work function between GIs (4.2 eV) and GBs (4.3 eV) of LLZO, electrons transferred from GIs to GBs and accumulated at GBs as the energy levels of the GIs and the GBs were aligned by the Fermi level. Under electric fields, localized current occurred at the electron accumulated points, which caused Li-filament formations at the GBs by encountering Li-ion. Using laser-induced breakdown spectroscopy (LIBS) after the Li plating, we also identified the highly localized Li intensity on the surface and cross-section images of LLZO, which means Li filaments were formed heterogeneously. Based on the mechanisms of Li-filament formation, we introduced the work function alignment interlayer, LiF layer, for LLZO to prevent heterogeneous Li filaments via inhibiting leakage current points at GBs and strongly enhanced the electrochemical stability. With work function alignment interlayer LiF, Li-symmetrical cell (Li/LLZO@LiF/Li) maintains a low overpotential (4 mV) over 4000 cycles and increases the critical current density 5 times compared to the Li-symmetrical cell without the LiF layer (Li/LLZO/Li). This research reveals that microstructure interface engineering based on uniformizing electronic structures at ISE boundaries is necessary for superior safety for ASSLMBs, which can be applied to other ISEs.*

EN08.08.11

Significant Improvement in Stability at High Current Density of $LiFePO_4$-Based Multidimensional Nanocarbon Composite as a Cathode for Lithium-Ion Batteries

Seunghyun Song, Jihyun Kim, Man Li, Xiong Cheng, Yoonju Oh and Joonho Bae; Gachon University, Korea (the Republic of)

Recently, the widespread use of lithium-ion batteries (LIBs) in various applications, ranging from portable electronics to electric vehicles, has spurred significant efforts to improve their technology. These batteries are favored due to their high energy density, long cycle life, and relatively low self-discharge rates, making them essential in the modern energy landscape. Among the various materials used in LIBs, lithium iron phosphate ($LiFePO_4$*, LFP) stands out as a widely used and promising electrode material. This is primarily due to its outstanding characteristics, which include excellent thermal stability, safety, and long cycle life. Especially, LFP is less prone to thermal runaway due to the stable nature of iron phosphate, reducing the risk of thermal runaway and ensuring safer battery operation, making it a safer choice for high-power applications. Nevertheless, the restricted lithium-ion kinetics of LFP, caused by its one-dimensional lithium-ion diffusion pathway, limits its effectiveness in high-performance LIBs. This structural limitation results in slow lithium-ion transport within the electrode, which in turn contributes to poor electrochemical performance, especially under high current conditions. At high currents, the sluggish lithium-ion movement leads to a decrease in capacity and an overall degradation in electrochemical reaction rates. Our study addresses this critical challenge of diminished electrochemical performance at high cycling rates by synthesizing multidimensional LFP-based carbon composites. By engineering the material at the nanoscale, we aim to overcome the intrinsic limitations of LFP. The incorporation of graphene quantum dots (GQDs) and carbon nanotubes (CNTs) with LFP not only improves the one-dimensional lithium-ion diffusion of the material but also significantly enhances its electrical conductivity. The resulting composite material exhibits superior electrochemical characteristics even under high current densities.*

The enhanced lithium-ion diffusivity and increased electrical conductivity ensure that the material can maintain high capacity and stable cycling performance under high current densities. This improvement is crucial for applications requiring rapid charge and discharge cycles, such as electric vehicles and grid storage systems. This study highlights the effective approach of electrode material design in improving the performance of lithium-ion batteries. By focusing on the nano-engineering of LFP and its composites, we demonstrate that it is possible to significantly enhance the material's properties and overcome its inherent limitations. Our findings provide valuable insights into the design strategies for next-generation electrode materials, paving the way for more efficient and reliable lithium-ion batteries.

EN08.08.12

Enhanced Performance of Li-Rich Cathodes by Surface Modification with Iron Oxide for Lithium-Ion Batteries

Yu Hsuan Su, Chi Po-Wei, Wu Phillip M. and Wu Maw-Kuen; Academia Sinica, Taiwan

Lithium-ion batteries (LIBs) are secondary batteries that can be recharged multiple times and are known for their high energy density, high power density, long cycle life, and rapid charging capability. These features make LIBs essential for modern technologies, portable electronic devices, hybrid electric vehicles (HEVs), and large-scale energy storage systems. Their high energy density allows them to store significant energy in a lightweight form, and their long cycle life supports numerous charge-discharge cycles, making them suitable for applications requiring long-term reliability and reduced maintenance, such as electric vehicles and renewable energy storage. The outstanding performance and versatility of lithium-ion batteries have made them a critical component in daily life and in the advancement of renewable energy and sustainable practices. The energy limitation of lithium-ion batteries is closely tied to the cathode materials used, leading researchers to continuously develop various lithium-based compounds. Cathodes with high nickel content, such as nickel cobalt manganese or aluminum (NCM and NCA, respectively), with specific capacities of approximately 200 mAh/g, are prominent candidates to meet the growing energy demands. Additionally, the innovative "lithium-rich Mn-based" materials, represented by the formula $xLi_2MnO_3(1-x)LiMO_2$ *or* $Li(Li_wNi_xCo_yMn_z)O_2$*, have emerged [1-3]. These materials feature excess lithium and utilize redox processes involving transition metal cations and* O^{2-} *anions to achieve higher specific capacities, around 250 mAh/g. However, the oxygen redox reactions at high operating voltages (~4.5V) in these materials may lead to oxygen release and voltage fading during extended cycling, posing challenges for their long-term application. [4-5]*

To mitigate the effects of oxygen redox reactions at high voltages, coating lithium-rich cathode materials with transition metal oxides is a promising approach. Transition metal oxides stabilize and prevent losses by forming strong bonds with oxygen atoms. [6-7] This protective layer also acts as a barrier, inhibiting side reactions between the electrolyte and the cathode surface, which helps maintain capacity and extends battery life. This method enhances the stability and performance of lithium-ion batteries, especially in high-voltage applications. Here, we demonstrate a lithium-rich cathode with $Li_{1.08}Ni_{0.34}Co_{0.08}Mn_{0.5}O_2$ *as the core active material and covered with 1wt% of iron oxide as the shell material. In the experiment section, we use a rotary evaporator to separate the lithium-rich materials in ethanol, and then add a certain concentration of iron nitrate solution as the precursor for the formation of the iron oxide shell. After mixing well and evaporating the solvent, the dried powder was heated at 600 °C for 10 h under atmospheric conditions. From the X-ray diffraction analysis, lithium-rich peaks were observed* *and pointed to the R-3m ($LiMO_2$) and C2/m (Li_2MnO_3) phase space groups. The 1% iron oxide-covered sample did not change the phase, and no impurity phase was formed in the cathode. In the SEM image, the cathode materials maintained a spherical shape with an average particle size of 3–5 μm, and through the EDS mapping of the iron oxide covered sample, the nickel, cobalt, manganese, oxygen, and iron were evenly distributed on the surface. In the electrochemical performance test, in between 2.2V and 4.6V, the iron covered sample shows excellent capacity at around 200 mAh/g in 0.2 C-rate for 100 cycled, better stability compare to the pristine cathode.*

EN08.08.13

Structural and Electrochemical Investigation of TiO_2 Films Deposited onto Lithium-Rich Layered Oxide Cathodes by Atomic Layer Deposition *Wei-Ming Chen[1], Po-Wei Chi[1], Horng-Yi Tang[2], Wu Phillip M.[1] and Wu Maw-Kuen[1]; [1]Academia Sinica, Taiwan; [2]National Chi Nan University, Taiwan*

Lithium metal shows promise as a high-energy-density option for future batteries. However, it faces a common issue of low efficiency during repeated charging and discharging. This problem arises from the forming at the interface an unstable layer the "cathode electrolyte interphase" (CEI).[1] In traditional liquid electrolyte batteries, the CEI layer tends to be uneven and can easily crack when the battery undergoes frequent charge and discharge cycles. This cracking leads to the formation of irregular structures inside the battery and renders some of the lithium ineffective. Conformal coating of ultrathin nm-thick TiO_2 films on electrode material is an effective strategy for improving the longevity of lithium-ion batteries (LIBs).

In this work, the composite material $Li_{1.08}Ni_{0.34}Co_{0.08}Mn_{0.5}O_2$ (AS200) was synthesized using a spray pyrolysis process.[2] Fabrication of TiO_2-coated lithium-rich layered oxide cathodes (LLC) by atomic layer deposition (ALD). TiO_2 was deposited on the aluminium foil with a LLC by ALD. Titanium tetrachloride (TiCl4) and deionized water were used as the precursors. Afterwards, TiO_2 thin films were deposited onto AS200 at 100 °C under a low N_2 pressure of 1.0 mbar with 15 cycles, 45 cycles and 75 cycles, respectively. Besides, the thickness of all films was fixed at 1 nm, 3 nm, and 5 nm. For half-cells, CR2032 coin cells were assembled inside an argon-filled glovebox. AS200 cathode (Ø13 mm), lithium-metal anode (Ø15 mm) and glass fiber separator soaked with electrolyte solution [1.0 M $LiPF_6$ in 1:1 by weight ethylene carbonate (EC)/diethyl carbonate (DEC)] were used.

To analyze systematically the samples, the crystal structure analysis of all prepared samples was conducted using powder X-ray diffraction (XRD) with Cu Kα (λ = 1.5406 Å) radiation in the 2θ range from 10 to 80°. The XRD patterns reveal that all samples exhibit similar diffraction peaks. Furthermore, the microstructure analysis of all of the samples was assessed using a high-resolution transmission electron microscope (TEM).[3,4] Upon examination, it can be observed a well-defined boundary and the absence of lattice fringes on the surfaces of samples. Significantly, the thickness measured at 5 nm.

Herein, we present the results of a low-temperature atomic layer deposition (ALD) process for creating a TiO_2 thin film on composite cathodes made of AS200. The capacity retention and performance of TiO_2-coated cathodes with a 5 nm thickness show significant improvement compared to uncoated reference cathodes, even when subjected to moderate cycling conditions.[5] Therefore, using ALD processes to control the thickness, quality, and conformality of the material (ACEI) is a viable approach to address the stability of the cathode and to improve its C-rate performance.

EN08.08.14

Activation of the Multi-Step Redox Reactions with the Radical-Mediated Pathway by N-Doped Carbon-Embedded $Ti_{0.95}Co_{0.05}N$ Nanowires as a Multifunctional Separator with a High Donor-Number Solvent for Lithium-Sulfur Batteries *Gwan Hyeon Park[1] and Won Bae Kim[1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Graduate Institute of Ferrous & Eco Materials Technology, Korea (the Republic of)*

To commercialize high-energy density Lithium-sulfur batteries, achieving high cell performance in a lean *electrolyte condition with high sulfur loading is imperative. However, continuously produced lithium polysulfides during cycles cannot be readily solvated in the limited amount of electrolyte. The accumulation of soluble lithium polysulfides increases the viscosity of the electrolyte with poor wettability and reduced ionic conductivity, transforming it from a liquid to a semi-solid phase.*

Based on the dissolution-deposition mechanism of lithium-sulfur batteries, electrolyte solvent modification with a high donor-number solvent can enhance the solvation ability of lithium polysulfides and sulfur utilization by modifying a Li^+ *solvated structure according to Pearson's Hard and Soft Acids and Bases theory. The* Li^+ *solvated structure with high donor-number solvents (soft acid) preferentially stabilizes soluble long-chain polysulfides and radicals (*S_3^-*,* S_6^{2-} *and* S_8^{2-}*, soft base), leading to good solvation and high sulfur utilization under the lean electrolyte lithium-sulfur batteries. However, due to the poor compatibility of Li metal with the solvent, optimizing the high donor-number solvent is crucial for achieving high sulfur utilization at the cathode and ensuring Li metal compatibility at the anode, especially under lean electrolyte conditions. Consequently, we aimed to identify a Li metal-compatible high donicity electrolyte by incorporating a 1 vol% of N, N-dimethylacetamide (DMA) into a 1,2-dimethoxyethane (DME)/1,3-dioxolane (DOL) co-solvent (v/v, 1/1) (1 v% DMA, DMA:DME:DOL=1:49.5:49.5 vol%) for the advanced Li-S batteries.*

Some research has reported that the high donor-number solvent can create 'radical-mediated pathways with tri-sulfur radicals'. However, no relationship or elucidation between the radical-mediated pathway and effective electrocatalyst has yet been studied in the lithium-sulfur battery field. Recent research in the oxygen evolution reaction field has declared ferromagnetic catalysts can facilitate an O=O dissociation reaction with the parallel spin alignment of oxygen radicals. Changes in reaction kinetics can also be expected in the case of sulfur, which has similar chemical properties to oxygen. Moreover, the ferromagnetic catalysts have been shown to strengthen the adsorption of lithium polysulfides and weaken the binding energy of the S-S bond in Li_2S_2 *boosting the conversion of* Li_2S *due to the spontaneous spin polarization in the lithium-sulfur battery field.*

In this work, we employed N-doped carbon-embedded cobalt-doped titanium nitride nanowires as a multifunctional separator in 1 v% DMA electrolyte (1 v% DMA@NC-$Ti_{0.95}Co_{0.05}N$ *NWs@PP) for lithium-sulfur batteries. The 1 v% DMA@NC-*$Ti_{0.95}Co_{0.05}N$ *NWs@PP achieved lower polarization of* Li_2S *and* S_8 *formation during cycles, higher* Q_{lower}/Q_{upper} *ratio showing* Li_2S *conversion efficiency, and a discharge capacity of 464.4 mA h* g^{-1} *even after 200 cycles with a decay rate of 0.093% per cycle with a sulfur loading of 3.6 mg* cm^{-2} *and a low electrolyte-to-sulfur (E/S) ratio of 10 μL* mg^{-1}*. Ferromagnetic active domain with d-band shift through cobalt doping into titanium nitride lattice can help adsorb lithium polysulfides including tri-sulfur radicals. Moreover, the cobalt-doped sample activates the radical-mediated disproportionation and chain-breaking reaction (*$S_8^{2-} \rightarrow 2S_6^{2-} + (1/4)S_8$ *and* $S_6^{2-} \leftrightarrow 2S_3^-$*) and facilitates* Li_2S_2 *dissociation with spin-polarized electrons in the ferromagnetic domain.*

EN08.08.15

A Strategy to Stabilize Fe2+/Fe3+ Redox Couple in a New High-voltage Polyanionic Cathode Material for Potassium-ion Batteries *Dipannita Saha and Amartya Mukhopadhyay; Indian Institute of Technology Bombay, India*

Moving forward from Li-ion and Na-ion battery chemistries, K-ion chemistry is deemed to be a sustainable one; with the feasibility of using graphitic carbon as anode material (unlike Na-ion chemistry) being an important added advantage. However, the identification, design, and development of a cost-effective, high-capacity and stable cathode material is a critical step toward the successful development of K-ion batteries [1,2]*. Against this backdrop, the synthesis, air-stability, and performance of a new Fe-based polyanionic cathode-active material for potassium K-ion batteries will be discussed. The cathode material has been synthesized via a facile, low-temperature method, and electrochemical behavior was studied in K 'half' and K-ion 'full' cells. In particular, the as-developed air-stable cathode material exhibits an initial reversible discharge capacity of ~102 mAh* g^{-1} *at a current density equivalent to C/15 in K 'half' cell, supported by reversible Fe-redox and the initial full cell capacity is ~68 mAh* g^{-1} *at* *a current density equivalent to C/15 having cyclic stability equivalent to ~97% after 15 cycles, with good structural-cum-electrochemical stability during continued charge/discharge cycles.*

Stabilizing Green Material Layered Oxide V_2O_5 Cathodes by Cobalt Doping for Rechargeable Lithium-Ion Batteries

Hsin-Yu Hsieh[1], Ting-Ru Kuo[1], Horng-Yi Tang[2] and Wu Maw-Kuen[1]; [1]Academia Sinica, Taiwan; [2]National Chi Nan University, Taiwan

Rechargeable lithium-ion batteries (LIBs) are extensively used in portable devices and electronics. To meet the increasing demands, current studies on LIBs focus on achieving high-energy density, improved safety and highly reliability. As a green material for cathode, layered vanadium pentoxide (V_2O_5) can be easily recycled by heating the material directly at 500 °C. V_2O_5 is an attractive high-capacity cathode material for LIBs. It has a high theoretical capacity of 400 mAh g^{-1}, corresponding to the intercalation and deintercalation of three Li^+ ions per unit formula. However, V_2O_5 faces intrinsic challenges, such as low electronic/ionic conductivity and irreversible phase transformation during the electrochemical process, which limit its application.[1,2] In this work, the organic material melamine was intercalated into the structure to efficiently mitigate structural puckering problems.[3] Additionally, cobalt was doped into the organic/inorganic hybrid material to enhance conductivity.

To prepare the $Co_{0.50}$-m-V_2O_5 precursor solution, V_2O_5 was dissolved in saturated melamine aqueous solution, with a molar ratio of melamine to V_2O_5 of 0.67:1. As the pH changes, V_2O_5 dissolves and then precipitates. Subsequently, cobalt (II) nitrate was dissolved in propylene carbonate (PC) solvent and stirred at 130 °C until the solution, initially the color of firebrick, turned dark green. This dark green gel was then placed under forming gas atmosphere (95% N_2 + 5% H_2) during stirring process for 12 hours. After this, the gel was ground using a planetary ball mill, resulting in the formation of $Co_{0.50}$-m-V_2O_5 powder.

The structural identification and the crystallinity of the Co-doped m-V_2O_5 with varying cobalt ratios were studied using XRD technique. The XRD measurements were collected in the 2θ range of 5–55°. No additional diffraction peaks from impurities were detected. Besides, as the cobalt dopant increased, the two peaks corresponding to (100) and (002) planes shifted toward lower angles, indicating that d-spacing increases with cobalt doping. The FTIR absorption spectrum showed characteristic peaks of V_2O_5 at 680 cm^{-1}, corresponding to the stretching of doubly coordinated oxygen (bridge oxygen) bonds V–O–V.[4] Upon Co doping, the absorption peak at 680 cm^{-1} weakened. This weakening may be due to insertion of metal ions into the structure because of Co doping. Moreover, XPS analysis showed that the introduction of cobalt dopants into V_2O_5 leads to the formation of tetravalent vanadium and confirms the presence of both Co^{2+} and Co^{3+} oxidation states in the samples.[5] Notably, $Co_{0.50}$-m-V_2O_5 exhibited higher electrochemical activity and greater Li^+ ion diffusivity. Consequently, the $Co_{0.50}$-m-V_2O_5 samples demonstrated excellent cycling stability, with a capacity retention ratio of 92.4% after 80 cycles at a rate of 0.2 C.

Neutral Acyl Silanes vs Anion Radical Li Salts as Electrolyte Additives for Lithium-Metal Batteries *Mamta Sham Lal[1], Yogendra Kumar[1], Robin Kumar[1], Devendra Yadav[2], Dmitry Bravo- Zhivotovskii[2], Yitzhak Apeloig[2] and Malachi Noked[1]; [1]Bar-Ilan University, Israel; [2]Technion–Israel Institute of Technology, Israel*

Lithium (Li) metal anode and Ni-rich $LiNi_xCo_yMn_{1-x-y}O_2$ *cathode (NCM) are considered promising candidates for high energy density Li metal batteries. However, lithium dendrite development, HF formation, transition metal dissolution, electrolyte decomposition, and formation of an unstable SEI/CEI layer cause severe electrochemical performance loss. Recently, research has been focused on film-forming organosilicon-derived electrolyte additives for improving the electrochemical activity of Li batteries. In this work, we studied the comparative electrochemical activity of neutral acyl silane with their anion radical Li salt for Li metal anode and nickel-rich, low cobalt, single-crystalline layered oxide cathode (*$LiNi_{0.9}Co_{0.05}Mn_{0.05}O_2$*- NCM90). Three pairs of neutral acyl silane and their anion radical Li salt electrolyte additives were synthesized- 1) di-tert-butyl methyl adamantoyl silane (RR'SiCOAd or **1**, where R is* $(tBu)_2$*, R' is* CH_3 *and Ad is 1-Ad) and* $[RR'SiCOAd]^{\bullet-}Li^+$ *or* $[\mathbf{1}]^{\bullet-}$*); 2) bis(di-tert-butyl methyl silyl ketone) (*$[(RR'Si)_2CO]$ *or **2**) and* $[(RR'Si)_2CO]^{\bullet-}Li^+$ *or* $[\mathbf{2}]^{\bullet-}$ *; and 3) di-methyl amino di-tert-butyl adamantoyl silane (*$Me_2NRSiCOAd$ *or **3**) and* $[Me_2NRSiCOAd]^{\bullet-}Li^+$ *or* $[\mathbf{3}]^{\bullet-}$*. The comparison of the electrochemical performance revealed that the anion radical Li salt additives significantly outperformed their neutral parts.*

EN08.08.18

Binary Composite Solid Polymer Electrolyte with Enhanced Ionic Conductivity and Thermal Stability for Lithium-Sulfur Battery *Praveen Balaji T[1,2], Sebastian Calderon[2], Soumyadip Choudhury[1] and Ernesto E. Marinero[2]; [1]Indian Institute of Technology Kharagpur, India; [2]Purdue University, United States*

In order to meet the energy demands of ongoing scientific and technological applications, it is imperative to advance the development of secondary battery systems that possess higher energy densities. The deployment of lithium-based technologies has been proposed as a means to address the present energy requirements due to the abundance, affordability, non-toxicity, and high energy density of their constituent materials. However, the energy density provided by conventional Li-ion batteries remains inadequate, which may lead to an inability to cope with future energy storage demands. The ideal temperature range for lithium-ion batteries to function is between -20°C and 60°C. Operating the battery outside the optimal temperature range leads to the deterioration of the electrolyte system and compromises the safety. Therefore, there is a need for an electrolyte system that exhibits enhanced ionic conductivity and can function at elevated temperatures. Llthium-sulfur (Li-S) batteries are considered a viable substitute for current Li-ion devices. This is due to their high theoretical specific capacity (1675 $mAh.g^{-1}$*) and energy density (2600* $Wh.kg^{-1}$*), and the cathode (S) is an earth-abundant, environmentally safe material [1]. Ether-based electrolytes are employed in the Li-ion battery system; despite the fact that these liquid electrolytes exhibit superior ionic conductivity, they are hindered by issues such as the polysulfide shuttle effect, inadequate mechanical and thermal stability, and flammability. Thus, safer electrolytes are needed and leading candidates are solid polymer electrolytes[2, 3]. In this work, a polymer electrolyte based on epoxidized natural rubber as host polymer and lithium bis(trifluoromethane) sulfonimide (LiTFSI) as electrolyte salt was developed and characterized. We report on Li-ion transport in composite polymer electrolytes (CPE) comprising High Entropy Oxide (HEO) particles incorporated into PEO/ENR:LiTFSI matrices in varying proportions. The HEO particles were synthesized throuh Sol-gel method. The system with 12% wt. load of HEO nanoparticles exhibited an ionic conductivity of* 8.6×10^{-4} *S/cm at 30°C, which strongly increased at elevated temperatures. The electrolyte system remained stable at high temperatures (100°C) due to the presence of the ENR. This study suggests that the manipulation of polymer morphology through the use of filler particles holds great potential for advancing the development of composite polymer electrolytes[4]. The polymer blends employed enable operation at elevated temperatures on account of the high melting point and amorphous nature of the ENR constituent. The PEO-ENR-based polymer electrolyte systems provide a viable solution to address the drawbacks of traditional polymer* *electrolytes. This advancement opens up opportunities for the effective utilization of high-energy-density Li-S batteries in a wide range of applications, such as electric vehicles and stationary energy storage systems.*

Mixed-Metal Fluoride Pyrochlore Synthesis and Investigation as an Alkali-Ion Battery Cathode *Joshua Willis[1], Patrick P. Ding[1,2], John T. Vaughey[2] and Kenneth Poeppelmeier[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States*

Recent studies have identified iron-fluoride pyrochlores to be a promising cathode for lithium- and sodium-ion batteries as they demonstrate high specific capacities and rapid alkali-ion diffusion using earth-abundant materials. However, there has been limited research into mixed-metal fluoride pyrochlores as intercalation cathodes. Recent work[1] has identified a mechanochemical route to the production of the $NH_4Mn^{2+}Fe^{3+}F_6$ pyrochlore, but required fluorine gas to remove the ammonium ions and oxidize the Mn^{2+} species.
In our work, $NH_4Mn^{2+}Fe^{3+}F_6$ was synthesized by the same mechanochemical method, oxidized to $MnFeF_6$ by several nontoxic alternatives, and electrochemically investigated. These novel oxidation methods allow access to the $Mn^{2+/3+}$ redox, increasing the specific capacity of the material. Removal of ammonium frees the channels, which decreases the barrier to intercalation by alkali ions and increases the rate of ion diffusion. Thus, the mixed-metal pyrochlore can be competitive as a cathode material against other metal-fluoride cathodes. These methods are the first to avoid use of toxic fluorine agents in production of the iron-fluoride pyrochlore type. The obtained pyrochlore was characterized by XRD, XPS, TGA, and IR. The efficacy of this material was then evaluated for use as an alkali battery cathode in an electrochemical cell and is reported for the first time. The high performance of the mixed-metal fluoride pyrochlore in lithium- and sodium-ion batteries demonstrates that an industrially favorable, environmentally friendly pyrochlore synthesis leads to an effective alkali-ion cathode.

Lowering Lattice Strain in High Entropy Co-Free Cathode Enabled by Introduction of Covalency Modulation for Sodium-Ion Batteries *Akanksha Joshi, Mia Ramos and Malachi Noked; Bar-Ilan University, Israel*

Li-ion batteries (LIBs) are already playing a key role in the increased electrification of modern societies [1]. However, the increasing demand for electricity storage systems and the declining lithium resources have pushed the researchers to explore its alternative [2]. Na-ion batteries owing to the high abundancy of sodium resources have recently emerged as a promising alternative to Li-based batteries [3]. The present work aims to achieve a cobalt-free high capacity cathode for Na-ion batteries using high entropy approach. High entropy approach comprises a cocktail effect as it implicates the mixing of more than five elements in a single phase. The challenge

involve with this approach is to create a balance between different elements to get the desired properties. The optimized high entropy cathode delivers a high capacity and appreciable cycle life of 200 cycles at a voltage range of 2-4V. Further, diffraction studies both insitu and exsitu has revealed that the high entropy strategy is effective in suppressing the O3' phase during charging/discharging at 2-4V. However, increasing the voltage window beyond 4V for 200 cycle shows the significant lattice strain on the structure which is further tackled by increasing the covalent character of M-O bond. The presented outcomes strongly motivate to pursue introduction of covalency modulation in high entropy approach in developing efficient cathode for Na-ion batteries.

Keywords: High Configuration entropy, Covalency modulation, Cobalt-free cathode, , O3 layered structure, Na-ion battery

Tailored P/O Type Phase Dependent Ni and Co-Free Cathode for Sodium-Ion Batteries

Mia Ramos, Akanksha Joshi, Ayan Mukherjee, Sankalpita Chakraborty and Malachi Noked; Bar-Ilan University, Israel

The extensive application of Lithium-ion batteries (LIBs) are severely affected by limited lithium reserves and environmental problems associated with lithium mining and processing [1]. This threatening condition has pushed the researchers to look for the alternative of LIBs. Sodium-ion batteries (NIBs) are the best alternative of Li-ion batteries due to its similar chemistry, cost-effectiveness, sustainability and thus it can help in lessening the burden on Li-ion batteries [2]. To achieve high performance in NIBs, cathode material is the limiting factor which makes the advance of stable and efficient cathodes highly crucial. Furthermore, the resources limitations and serious geopolitical concerns around the Cobalt and Nickel have driven the exploration of Fe-Mn based system for the development of cathode [3]. The present work aims to synthesized a tailored mixed phase P/O having Ni and Co-free cathode using the solid-state method. Both P and O type has their own advantages and limitations. P2-type oxides have wider transport channels to facilitate the diffusion of Na+ ions, resulting in a better rate capability. Whereas, higher sodium-ion content in O3-type oxides helps in achieving higher capacities [4]. In our work, we have tried to utilize the assistance of both P and O type phase in improving the rate capability and also the capacity. By changing the concentration of Na-ion, an optimized mixed phase is synthesized. The effect of this coexistence of both phases on the electrochemical performance is investigated and obtained cathode has shown an impressive results with capacity of more than 130 mAh/g. Unlike several other single-phase materials in the Na-Fe–Mn system, biphasic optimized composition displays much-improved cyclability in the 2.4-4.2V range.

Synthesis, Characterization and Optoelectronic Properties of Zinc Oxide Nanoparticles—A Precursor as Electron Transport Layer

Opeyemi S. Akanbi; University of Massachusetts Lowell, United States

The synthesis, characterization, and optoelectronic properties of zinc oxide nanoparticles (ZnO.NP) were studied, utilizing Cordyline fruticosa extract for green synthesis. The nanoparticles were characterized using UV-Vis spectrophotometry, FTIR, X-ray diffraction, SEM, TEM, and EDX analyses. The XRD results revealed a hexagonal wurtzite structure with high crystallinity. SEM and TEM analyses confirmed the formation of ZnO nanoparticles in the nanometer range. Electrical properties were measured using a four-point probe system, demonstrating improved conductivity due to the synthesis method. The study suggests that using plant extracts can tune the properties of ZnO to enhance electron transport and reduce electron recombination, making ZnO.NP is a promising candidate for application in solar cells and organic electronics. Future research should focus on applying these findings to active polymer solar cells to evaluate their viability and efficiency further.

EN08.08.24

Interfacial Stability of Iron (III) Fluoride Intercalation Cathodes

Patrick P. Ding[1,2], John T. Vaughey[2], G. J. Snyder[1] and Kenneth Poeppelmeier[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Iron (III) fluoride and its respective hydrates have recently shown promise as intercalation cathodes for lithium-ion batteries. These fluoride materials represent an alternative method to increasing insertion voltage compared to the commonly studied polyanion inductive effect. In comparison to oxides, only a few studies have been published identifying the changes that occur at the electrolyte-fluoride interface. In this work we investigated the various decomposition phases that form at the active interface on cycling of FeF_3 and pyrochlore FeF_3-$0.5H_2O$ cathodes in various organic electrolytes. Due to the presence of framework fluoride at the interface, we examined the CEI formed both with the standard Gen2 electrolyte (3:7 EC/EMC, 1.2M $LiPF_6$) and the same solvent mix with the more stable salt at 1.0M concentration LiTFSI-based electrolyte. The CEI composition was investigated ex-situ through several techniques including x-ray photoelectron spectroscopy (XPS), glow discharge optical emission spectroscopy (GDOES), and scanning electron microscopy (SEM). Cycling stability of the two cathodes were compared and differences in CEI composition and thickness were investigated during cycling. This work extends our knowledge into interfacial stability of fluoride-based cathodes in common lithium-ion based electrolytes.

EN08.08.25

High-Potential 2V Rechargeable Zinc-Manganese Dioxide Batteries Enabled by Polymer Hydrogels

Ramona Durena, Nikita Griscenko and Anzelms Zukuls; Riga Technical University, Latvia

Over the past decade, research interest in zinc-manganese dioxide batteries has increased substantially due to green policy implementation efforts. These batteries are a potential addition or replacement for Li-ion batteries where their use is too costly or undesirable due to safety concerns. Commercially available alkaline Zn-MnO_2 batteries have a low potential of 1.5 V and are generally non-rechargeable. Many studies have addressed rechargeability problems by modifying the MnO_2 cathode and controlling the depth of discharge. However, the issue of low potential and thus undesirable energy density still needs to be addressed [1,2]. Herein we have addressed these issues and developed high-potential rechargeable aqueous Zn-MnO_2 batteries by employing novel polymer hydrogels.

Our battery design consisted of: (1) Zn anode; (2) alkaline polyacrylamide (PAM) hydrogel; (3) acidic PAM hydrogel; (4) MnO_2 + carbon black Vulcan (13:5) as the cathode. PAM hydrogels were prepared by free radical polymerization. For ionic conductivity, a concentrated sodium perchlorate solution was added before polymerization. In addition, a set of pH-immobilized hydrogels were prepared by adding immobilines to a monomer solution. On the acidic hydrogel side, acrylamide was polymerized with 2-Acrylamido-2-methyl-1-propanesulfonic acid, thus achieving a pH of ~2. On the alkaline hydrogel side, acrylamide was polymerized with (3-Acrylamidopropyl)trimethylammonium hydroxide, reaching a pH of ~12. After polymerization, PAM hydrogels with immobilines were soaked with deionized water, however, hydrogels without immobilines were soaked in sulfuric acid and sodium hydroxide solutions, to achieve the same pH as hydrogels with immobilines. Electrochemical measurements were carried out by utilizing Autolab potentiostat.

By operating the battery in a constant pH electrolyte, the maximum water-electrolyte operation potential window is ~1.23 V. If a dual-electrolyte system is used and the cathode is operated at lower pH values and the anode at higher pH values, the stable electrochemical window of water could be increased above ~2 V [3]. This has been realized by placing the Zn anode in an alkaline electrolyte and the MnO2 cathode in an acidic electrolyte. By creating such a unique battery cell type, it is possible to increase the OCP to 2.45 V.

To prohibit the mixing of acidic and alkaline hydrogel electrolytes, derivatives of polyacrylamide called immobilines were used. The alkaline immobiline contained locked cationic groups and acidic immobiline – anionic groups. Thus, prohibiting positively charged hydrogen ion migration to the alkaline side and negatively charged hydroxyl ion migration to the acidic side.

Using this unique dual-electrolyte increased the open circuit potential of the battery and prevented the formation of an insoluble $ZnMn_2O_4$ compound, allowing the battery to be repeatedly charged and discharged. The constructed pH gradient dual-electrolyte hydrogel Zn-MnO_2 battery provided an open circuit potential of 2.4 V and maintained a discharge voltage above 2 V throughout a week of charged-discharge cycles. The involvement of immobilins in the structure of PAM hydrogels ensured a more stable pH gradient and a discharge potential above 2 V for a week. Moreover, the application of immobilins provided a higher discharge capacity and a better Coulombic efficiency compared to the PAM electrolyte whose pH gradient was provided only by acid and alkali. However, improvements in battery design are needed to ensure better capacity retention and overall Coulombic efficiency.

Novel Self-Regenerative and Non-Flammable High Performance Hydrogel Electrolytes with Anti-Freeze Properties and Intrinsic Redox Activity for Energy Storage Applications

Abdelrahman A. Ismail; The American University in Cairo, Egypt

Hydrogel electrolytes are essential components of a plethora of functional devices due to their flexibility and high electronic and ionic conductivity. However, they suffer from poor water retention (dehydration) during operation. Consequently, the overall performance of the hydrogel-based devices is severely declined as a result of conductivity fading of the hydrogel with poor self-regeneration. To this end, the rational tailoring of hydrogel electrolytes with high conductivity, self-regeneration, non-flammability, anti-freezing ability, stability, and intrinsic redox activity is necessary to enable the fabrication

of highly durable devices. Herein, we demonstrate the design and synthesis of highly ionic conductive LiBr@PVA-based electrolytes. Upon the use of the synthesized hydrogel electrolytes in supercapacitor devices, they revealed intrinsic redox activity with outstanding water retention capability and self-regeneration characteristics.
The mechanism of regeneration and water retention is thoroughly investigated. Also, the devices showed an improved selfdischarge potential (SDP) rate compared to those previously reported using polymeric electrolytes with redox additives. Moreover, the synthesized LiBr@PVA-based electrolytes exhibited high antifreezing properties with stable electrochemical performance before
and after regeneration. Our study provides a universal method to fabricate large-scale hydrogel electrolytes with unique properties and opens the door to fabricate high-performance solid state devices.

EN08.08.27

Advanced Grafted Epoxy Resins—Boosting Dielectric, Mechanical and Thermal Performance for Energy Storage Applications

Yuheng Deng[1], Letitia Kai Yue Teh[1], Yen Wen Wong[1], Qi Wang[1], Weifeng Sun[1], Wen Kwang Chern[1,2], Joo Tien Oh[1] and Zhong Chen[1,1]; [1]Nanyang Technological University, Singapore; [2]Singapore Power Group, Singapore

Epoxy resins have been widely used as encapsulation and dielectric materials in energy storage systems due to their low cost, ease of handling, and good chemical resistance. However, their low dielectric breakdown strength, moderate mechanical reliability, and insufficient thermal stability, reduce the reliability of the material, threatening the operation of energy storage systems. Incorporating micro or nano-sized fillers into the epoxy resin is a common strategy to modify its properties. However, poor interface and agglomeration issues complicate the preparation process and make it hard to gain satisfactory improvement. Besides, large amounts of fillers are needed to achieve significant change, increasing the cost. Conversely, modification at the molecular level can easily solve the dispersion and agglomeration problems. Tiny amounts of additives can lead to significant improvement. Thus, this research explores the potential of introducing grafting agents into the epoxy resin to enhance its reliability. In this study, molecular modification was achieved by introducing small contents (0.5, 1.0, and 1.5 wt.%) of grafting agents into the epoxy/amine resin during the curing process. Allyl chloroacetate (AC) was selected as the grafting agent for its potential to promote crosslinking, thereby enhancing mechanical reliability and thermal stability. Moreover, its polar groups can benefit energy storage, and improve dielectric properties via charge trapping mechanisms. Fourier-transform infrared spectroscopy (FTIR) was used to identify chemical reactions and verify successful grafting. Dielectric breakdown strengths were measured and analysed using Weibull statistics to assess dielectric enhancements. Furthermore, mechanical reliability was evaluated by measuring the tensile strength and Young's modulus. Scanning electron microscopy (SEM) was utilized to reveal failure mechanisms, while energy-dispersive X-ray spectroscopy (EDX) assessed the dispersion of grafting agents. Additionally, dynamic mechanical analysis (DMA) was used to investigate the thermal stability of the modified resin system. The results indicate that the AC-modified epoxy/amine resin system exhibited remarkable improvements in various properties. The dielectric breakdown strength significantly increased to 118% of pure epoxy resin, indicating improved electrical performance. The tensile strength was notably enhanced from 70 to 78 MPa and the Young's modulus also increased from 618 to 787 MPa, providing more reliable mechanical support. Additionally, the glass transition temperature (T_g) of the modified epoxy resin was increased by 10 °C, making it more suitable for harsh operating conditions in energy storage devices. The FTIR results confirmed the successful grafting and provided valuable insights into the mechanisms behind the property improvements. In conclusion, this grafted epoxy resin system exhibited significant improvements in dielectric ability, mechanical reliability, and thermal stability, making it a promising candidate for next-generation energy storage devices. Further optimization of grafting agent selection and incorporation could yield tailored, high-performance epoxy materials for diverse energy storage technologies.

Exploring Pressure and Strain Effects in Argyrodite Solid Electrolytes for Enhanced Solid-State Batteries

Jemma L. Cox and James A. Dawson; Newcastle University, United Kingdom

The global shift towards sustainable energy solutions necessitates advancements in battery technology, prompting a transition from conventional lithium-ion batteries towards more efficient alternatives. Solid-state batteries have emerged as a promising candidate due to their potential for enhance safety, energy density, and lifespan. This research focuses on exploring the viability of argyrodite materials for solid-state battery applications through computational modelling techniques. Utilising tools such as ab initio molecular dynamics (AIMD) and density functional theory (DFT), the research investigates the effects of varying pressure and strain on the structural and electrochemical properties of argyrodite materials. Argyrodites demonstrate remarkable characteristics such as high ionic conductivity, wide electrochemical stability window and compatibility with various electrode materials. By elucidating the intricate relationships between material structure and battery performance, this research aims to highlight the potential of argyrodite materials as a key component in the development of next-generation solid state batteries. The utilisation of argyrodite materials could lead to significant improvements in battery efficiency, cycle life, and safety, thereby accelerating the transition towards sustainable energy solutions.

New Synthesis of Carbonaceous Lithium Hosts for High-Performance Lithium Metal Batteries

Hyungyeon Cha[1] and Namhyeong Kim[2]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Pukyong National Univeristy, Korea (the Republic of)

Lithium metal is a highly promising anode material for next-generation lithium batteries. However, challenges such as non-uniform lithium nucleation, dendritic growth, and significant volume changes lead to rapid cell failure, limiting its practical application. In this study, we present a defective graphene shell grown on a carbon matrix as a stable host for lithium metal, produced via carbide-mediated catalytic hydrogenolysis. This structure features numerous nano-channels with defective graphene shells on its surface, effectively guiding dendrite-free lithium deposition and accommodating a substantial amount of metallic lithium with minimal volume change. As a result, this host demonstrates excellent cycle stability (87.2% capacity retention after 500 cycles) and low dimensional variation (9 µm) in carbonate electrolyte full-cell evaluations. Additionally, when used as a lithium-ion flux-regulating interlayer, our versatile lithium host enhances cycling performance in argyrodite Li_6PS_5Cl-based high energy density all-solid-state battery full-cell configurations.

EN08.08.30

PVDF Coated $Li_7La_3Zr_2O_{12}$ Scaffold for Semi-Solid-State Electrolyte

Youngmin Moon, Dohun Kim and Sangbaek Park; Chungnam National University, Korea (the Republic of)

Semi-solid batteries integrate a synergy of benefits from both liquid and solid electrolytes, which mitigates the risk of flammability and fire hazard from sole reliance on liquid electrolytes. Moreover, they demonstrate lower interfacial resistance compared to solid electrolytes alone. In this study, we utilize the high-ionic-conducting $Li_3La_2Zr_7O_{12}$ (LLZO) (10^{-3} to 10^{-4} S/cm) as the stable oxide solid electrolyte and electrochemically stable PVDF as a polymer matrix absorbing liquid electrolyte to synthesize an ionic-conducting and electrochemically stable scaffold for semi-solid batteries. To address the alkalization of the solvent by Li_2CO_3 on the LLZO surface inducing the gelation of PVDF when mixing LLZO powder and PVDF binder, we fabricate the free-standing LLZO scaffold with LLZO powder and EVA binder first, followed by coating PVDF on the surface of LLZO scaffold. As a result, our PVDF-coated LLZO scaffold shows the high thermal stability, enduring temperatures over 200°C onto the hotplate.

In addition, a Li//NCM811 half-cell assembled using LLZO@PVDF combined with a liquid electrolyte records the reversible capacity of 200mAh g^{-1} at 0.5C without voltage drop during charging-discharging cycles. Notably, our LLZO@PVDF scaffold can be easily fabricated without the process for removing Li_2CO_3 on the surface of LLZO, which will open a new avenue for the development of semi-solid-state batteries.

EN08.08.31

Revisiting Importance of Intergranular Pore Design in Ni-Rich Cathode to Eliminate Residual Lithium Compounds *Hyungyeon Cha and Wooyoung Jin; Korea Institute of Energy Research, Korea (the Republic of)*

With the increasing demand for lighter weight and higher energy for various battery applications, Ni content in cathode material is increasing (60 to 95%) for the lithium-ion battery technology. Therefore, generation of residual lithium compounds such as Li2CO3 and LiOH is inevitable during the synthesis of Ni-rich cathode material, and they are detrimental to cell performance. Residual lithium compounds increase pH of the slurry, which can induce slurry gelation during electrode fabrication process, and gas is evolved when the cell is cycled. Also, residual lithium compound itself can be a resistance layer for the Li-ion, and electron diffusion. Therefore, there have been many researches for the reduction of residual lithium compounds through innovative methods such as Li-reactive coating, washing, annealing or composition change. However, such research mainly focused on eliminating residual lithium species, so they overlook how the residual lithium compounds is formed and existed.

Hence, understanding and selecting appropriate methods dealing with residual lithium compounds is necessary. Here, we intensively investigated the residual lithium compounds in LiNi0.8Co0.1Mn0.1O2. With the conventional titration method, we measured the exact amounts of the residual lithium compounds, and we observed the presence of residual lithium compounds through HR-TEM and EELS. Interestingly, the residual lithium compounds are mostly located in the intergranular pore inside the particle. The HR-TEM results also showed crystalline structure of the residual lithium compounds in the intergranular pore. This result is important because it shows that controlling the residual lithium compounds in the intergranular pore is as important as controlling the particle surface. We also suggest the various approaches including washing, coating, and morphology change to control the residual lithium compounds and provide insights of each process in terms of particle stability and commercial viability

EN08.08.32

Exploration of New Lithium-Ion Conductors Based on Structural Analogy Using Crystallographic Site-Fingerprints *Songjia Kong, Naoki Matsui, Masaaki Hirayama, Ryoji Kanno and Kota Suzuki; Tokyo Institute of Technology, Japan*

In the exploration of solid-state electrolytes (SSEs), researchers have gradually realized the significance of framework structure for lithium ion migration, and have applied refined descriptors based on framework structures, achieving considerable suceesee.[1,2] *Recently, Local structure order parameters (LSOPs) have been reported as reliable procedures for both traditional and machine learning approaches, from the perspective of local environment information, aiming to exploit structure with predicting material properties.*[3] *This new theory could provide the a new perspective of framework structure for next-generation SSEs. Herein, a new semi-supervised learning was attempted, with simplified LSOPs as the material descriptors for exploration of SSEs for the first time. 3835 raw data after preprocessing were converted to simplification-descriptors corresponding to four framework structures, and 171 experimental conductivity data was used as the conductivity to evaluate the clustering quality during the semi-supervised learning. Li-sublattice (LSOP_M) simplification-descriptor was chosen in this work since it performed minimal conductivity variance. In addition, when considering cluster number, cluster number of 11 was used for exploration of common feature within the same cluster; while it was* *cluster number of 228 that was consequently utilized in practical screening. In the cluster depth of 11, famous lithium conductors ($Li_{10}GeP_2S_{12}$, Garnet and Argyrodite-type) were mainly in the cluster #6 and #7, with the characteristic of disordered structures, specifically, compounds in cluster #6 are mainly characterized by a preference of coordination number 2 and 4, while 1 and 2-fold coordination in cluster #7. However, it would be more than 1000 compounds in both clusters, therefore, cluster number of 228 was employed in practical screening, and 147 compounds ultimately were chosen for molecular dynamics (MD) simulation after semi-supervised learning. $Li_3LaP_2S_8$ was selected for experiment validation and obtained the conductivity of 3.21×10^{-7} S cm^{-1} for pristine compound and 1.07×10^{-6} S cm^{-1} for Ge doping ones at room temperature. This study underscores the potential of using local coordination environments within various structural frameworks to discover promising lithium-ion conductors.*

Wet Chemical Treatment-Induced Kinked Cu_2Se-PbSe Nanaowires

Minseong Lee and Yun-Mo Sung; Korea University, Korea (the Republic of)

The utilization of thermoelectric generation (TEG) to convert waste heat into electricity has emerged as an eco-friendly energy production method. Through the advancement of high-performance TE materials, waste heat can be effectively captured and transformed into a robust alternative energy source, offering solutions to emerging energy challenges across diverse applications. The development of selenium (Se) based thermoelectric devices has emerged as a promising alternative to tellurium (Te). Nevertheless, thermoelectric devices based on selenium typically exhibit lower power factor compared to tellurium-based devices. Overcoming this performance gap necessitates a more sophisticated engineering approach.

In this study, we increase the thermoelectric efficiency through nano-structuring and doping strategies. Initially, ZnSe nanowires were grown using the Solution-Solid-Solid (SSS) method with Ag_2Se catalysts. During the growth procedure, NH_4I was added to reduce the reactivity of the zinc precursor, resulting in the formation of numerous stacking faults(SFs). The accumulation of SFs led to the glide of the {111} plane in the zincblende (ZB) phase of ZnSe nanowires, resulting in a zigzag morphology known as a kinked structure. Subsequently, we implemented the Regiospecific Sequential Cation Exchange (RSCE) reaction without altering the morphology. During this process, Pb^{2+} ions exhibited a tendency to selectively undergo cation exchange with the wurtzite (WZ) structure of ZnSe, likely due to the preference of larger Pb^{2+} ions to occupy interstitial sites with relatively larger interplanar distances in WZ rather than ZB. Another cation exchange reaction was conducted using Cu^+ ions instead of Pb^{2+} ions. Due to thermodynamic factors such as the superior stability of the complex formed by Zn ions and oleate and the high bond dissociation energy of PbSe, making it less favorable for cation exchange with Cu^+ ions, the ZB portion of ZnSe selectively undergoes cation exchange with Cu^+ ions, leading to its transformation into Cu_2Se. Furthermore, the structural similarity between the antifluorite phase of Cu_2Se and the ZB phase of ZnSe allows for a more rational kickout mechanism during the cation exchange process, lowering the CE process's activation energy.

To conclude, we successfully synthesized kink-structured Cu_2Se-PbSe superlattice nanowires. The kinked structure and superlattice act as highly effective phonon scattering centers, reducing thermal conductivity. Furthermore, we were able to partially dope PbSe with Cu^+ ions. The dense phase boundary between PbSe and Cu_2Se can alleviate lattice distortion in PbSe during the cation exchange process, facilitating the simultaneous provision of Cu_i and Cu_{Pb}. This enables higher Cu doping concentrations, leading to increased electrical *conductivity and, consequently, a higher power factor. Overall, an enhancement of figure of merit (ZT) was observed in the kinked Cu_2Se-PbSe nanowires*

EN08.08.34

Bimetallic Anionic Organic Frameworks with Solid-State Cation Conduction for Charge Storage Applications

Yan Zhang[1,2], Jiande Wang[3], Petru Apostol[2] and Alexandru Vlad[2]; [1]Anhui University, China; [2]Université Catholique de Louvain, Belgium; [3]Massachusetts Institute of Technology, United States

A new phosphonate-based anionic bimetallic organic framework, with the general formula of A_4-Zn-DOBDP (wherein A is Li^+ or Na^+, and $DOBDP^{6-}$ is the 2,5-dioxido-1,4-benzenediphosphate ligand) is prepared and characterized for energy storage applications. With four alkali cations per formula unit, the A_4-Zn-DOBDP MOFs is found to be the first example of non-solvated cation conducting MOF with measured conductivities of 5.4×10^{-8} S cm^{-1} and 3.4×10^{-8} S cm^{-1} for Li_4- and Na_4- phases, indicating phase and composition effects of Li^+ and Na^+ shuttling through the channels. Three orders of magnitude increase in ionic conductivity is further attained upon cations solvation with propylene carbonate, placing this system among the best MOF ionic conductor at room temperature. As positive electrode material, Li_4-Zn-DOBDP delivers a specific capacity of 140 mAh g^{-1} at a high average discharge potential of 3.2 V (vs. Li^+/Li) with 90% of capacity retention over 100 cycles. The significance of this research extends from the development of a new family of electroactive phosphonate-based MOFs with inherent ionic conductivity and reversible cation storage, to providing elementary insights into the development of highly sought yet still evasive MOFs with mixed-ion and electron conduction for energy storage applications. (Angew. Chem. Int. Ed. 2023, 62, e202310033)

EN08.08.35

Na and K Ion-Conducting Covalent Organic Framework

Wonmi Lee; University of Wisconsin-Madison, United States

Solid-state batteries utilizing sodium or potassium ions (Na- or K-ion) have emerged as promising alternatives to costly lithium-ion (Li-ion) batteries, offering a safer, more cost-effective, and sustainable solution for energy storage. Nonetheless, the practical application of these batteries is hindered by the low ionic conductivity of most solid electrolytes designed for Na- or K-ions. Addressing this challenge, researchers have turned to covalent organic frameworks (COFs), a category of porous polymers characterized by highly ordered network structures. These structures lower the energy barrier for ion migration, thereby providing rapid pathways for ions and making COFs promising candidates as ion conductors.

We synthesized sulfonated cyanurate-linked COFs, specifically designed for sodium or potassium ion conduction (i-COF-1 (Na) and i-COF-1 (K)), through a straightforward, one-step process using affordable starting materials. These COFs demonstrate high ionic conductivity at room temperature without the need for additional salt or solvent. This enhanced performance is attributed to the strategic incorporation of sulfonate groups and the directional channels within the COF structure.

The high Na^+ and K^+ ion conductivities, low cost, and intrinsic framework stability of i-COF-1 make it a promising solid electrolyte candidate for the next generation of non-Lithium-ion secondary batteries.

EN08.08.36

Site-Specific Single Atom Incorporation in Cobalt Spinel Oxide for High-Performance Acidic Oxygen Evolution Reaction

Kangjae Lee[1,2] and Taeghwan Hyeon[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute of Basic Science (IBS), Korea (the Republic of)

The capability to finely control specific surface properties of a catalyst has been recognized as a significant issue in

achieving optimized catalytic processes, owing to the dependence of catalytic performance on these surface properties. Spinel oxides with an AB_2O_4 crystal structure have been of particular interest. Depending on the cation selection at the A and B sites, the physicochemical properties of spinel oxides can be precisely modified.

Very recently, Co_3O_4 has emerged as a representative non-noble metal catalyst for the acidic oxygen evolution reaction (OER), providing a potential substitute for the rare metals Ru and Ir. However, with a few exceptions, the incorporation of metal elements in cobalt spinel oxide has been limited to first-row transition metals (e.g., Fe, Mn, Ni, Cu, and Zn). It is highly desirable to design a cobalt spinel oxide system that can withstand harsh OER conditions while maintaining high reactivity through rational metal cation incorporation. Although intriguing, the physicochemical properties of cobalt spinel oxides that incorporate metal cations other than those mentioned above have not been well elucidated. In particular, the early transition metals in the higher periods of the periodic table, such as Hf, Ta, and W, which readily react with water to form heterogeneous oxides, pose a significant challenge for their atomic distribution in Co_3O_4. Due to the synthetic difficulty, little is known about the unique properties exhibited by these metals in the form of single atoms within cobalt spinel oxide.

Herein, we provide unified understanding on the metal cation incorporation in cobalt spinel oxide crystal structure. First, we developed a general synthetic method that enabled us to directly synthesize the versatile metal doped Co_3O_4 from early transition metals to metalloids. Using highly porous metal organic framework (MOF) structure, we could successfully incorporate Hf, Ta, W, Ti, Ga, Ge, and Pd into Co_3O_4 without formation of any hetero metal oxide species. Second, we clarified each metal species has different stabilization sites in cobalt spinel structure. Ta, W,and Ge have a great tendency to be stabilized on the surface of Co_3O_4, which dramatically increases Co^{2+} species. The dopant-rich shell along with high density of surface Co^{2+} then provides active and protective layers for high-performance acidic OER. Ta doped Co_3O_4 has the low overpotential of 378 mV at 10 mA cm^{-2}, and maintained its activity over 140 hours in acidic electrolytes. According to in-situ XAS and ICP, the protective shell suppresses over-oxidation and dissolution of Co species during the reaction.

In summary, we present a unified picture of the single-atom-doped cobalt spinel oxide crystal structure and a general synthetic principle applicable to a broad range of metal elements beyond the first-row transition metals. Additionally, we elucidate the metal-specific stabilization sites in Co3O4, which exhibit unique surface physicochemical properties. These finely controlled surface properties can enhance catalytic performance and provide durable stability in acidic OER. Our discovery of a general synthesis method for incorporating various metals into cobalt spinel oxide, along with the corresponding control of surface properties, can be applied to various catalytic processes for sustainable energy storage and conversion systems.

EN08.08.37

Phase-Field Modeling of Dendrite Growth and Dead Lithium Formation in Lithium Anode and Mitigation Using a Protective Layer

Bharat R. Pant and Ye Cao; The University of Texas at Arlington, United States

Lithium metal batteries (LMBs) are considered one of the most promising next-generation rechargeable batteries due to their high specific energy capacity (3860 mAh g^{-1}) and low redox potential (-3.04 V vs SHE). However, severe dendrite growth and subsequent formation of dead lithium (Li) during the cycling process impede its practical application. Although several experimental studies have been conducted to investigate the cycling process, there are limited theoretical studies on the dead Li formation. Herein, we developed a phase-field model to simulate the electroplating and stripping process of a Li anode with and without a protective layer. Our simulation clearly shows the growth of dendrites from bare Li anode during charging. These dendrites detach from the bulk anode during discharging and turn into dead lithium. Dendrite growth becomes more severe in subsequent cycles due to enhanced surface roughness on the Li surface, which also increases the amount of dead Li. In addition, it is revealed that the geometry of dendrites plays an important role in the formation of dead Li. Meanwhile, the Li anode covered with the protective layer cycles smoothly without forming dendrites and dead Li. However, a fractured protective layer with a through crack hole may accelerate dead Li. Our results show that Li metal *preferentially grows into the crack hole due to enhanced Li^+ flux and electric field at the tip of the protrusion and forms a large dendrite after penetration. These simulation results thus provide a fundamental understanding of the phenomena of dendrite growth and dead Li formation during the charging/discharging process and shed light on the importance of the protective layer in the prevention of dead Li in LMBs.*

EN08.08.38

Synergistic Effect of Ga-Based Precipitates and Ga-Au Surface Layer on Stabilization of $Li_7La_3Zr_2O_{12}$ Solid Electrolyte *Dohun Kim, Youngmin Moon and Sangbaek Park; Chungnam National University, Korea (the Republic of)*

Garnet-type $Li_7La_3Zr_2O_{12}$ (LLZO) is a promising oxide solid electrolyte with high ionic conductivity and excellent stability toward Li metal. However, the presence of grain boundaries (GBs) cause a decrease in the ionic conductivity and cycling stability of the sintered LLZO. Herein, we promote the Ga precipitation at GBs through excessive doping with Ga/Al/Ta, simultaneously depositing a few nanometers thickness Au layer to form a Ga-Au surface layer. High-temperature sintering of heavily doped LLZO induces Ga precipitation, effectively filling the GB of the pellet. Consequently, the relative density and ionic conductivity are increased. Furthermore, nanoscale Au encounters precipitated Ga and forms a new Ga-Au layer, which reduces the contact resistance. The new layer prevents direct contact between molten Li and Ga-based composites at the GBs, thus enhancing the cycling stability. Therefore, it demonstrates the synergistic effect that the precipitated Ga improves the compactness of the LLZO electrolyte, whereas the Ga-Au layer enhances the cycling stability. It provides a straightforward approach to address the issues originated from GBs and increase the cycling stability of LLZO, thereby contributing to the practical application of all-solid-state batteries.

EN08.08.39

Thermodynamic Descriptors for the Design of Liquid Electrolytes for Sodium Metal Batteries *Jason K. Phong, Christian Plaza Rivera, Jeremiah Johnson and Yang Shao-Horn; Massachusetts Institute of Technology, United States*

Sodium-based batteries are a promising, sustainable alternative to lithium-based batteries due to the high abundance and low cost of sodium resources, providing an attractive pathway to large-scale grid energy storage. While significant advances have been made in the development of high-performance cathode materials, the electrolyte remains the critical limitation for the practical viability of high energy density Na-metal batteries. Conventional sodium liquid electrolytes form poor electrode-electrolyte interfaces due to the high reactivity of Na metal, causing continuous electrolyte decomposition that results in uncontrolled solid electrolyte interphase (SEI) growth, Na dendrite formation, poor Coulombic efficiencies, and irreversible capacity loss. In order to achieve high-performance sodium liquid electrolytes, a fundamental understanding of the correlation between the solvation environment of Na^+ ions in the electrolyte and the reversibility of Na plating and stripping is necessary. In this study, we aim to probe the salt- and solvent-dependent Na^+ solvation energy by measuring the Na electrode redox potential and the electrolyte entropy to correlate with the Coulombic efficiencies and ionic conductivities of diverse electrolyte compositions. We investigate a series of sodium salts such as NaFSI, NaTFSI, and Na FAST-B in various carbonate, ether, and sulfonamide solvents at different concentrations. Our preliminary analysis reveals that changing the electrolyte solvent can alter the redox potential by > 1 V and that weakly solvating solvents with low donor numbers demonstrate an upshift in their redox potentials, implying that the reducing ability of Na metal is weakened. We also observe that the anion identity does not vary the redox potential as significantly as the solvent identity does. We further correlate the electrolyte-dependent redox potential with the ion solvation structure via Raman spectroscopy. This work reveals how the electrode potential and the electrolyte entropy can serve as descriptors for Na metal reversibility, which will guide the design of high-performing liquid electrolytes for *practical Na-metal batteries.*

EN08.08.40

Designing Dynamic Li-Based Anode Interphase Evolution for All-Solid-State Batteries Using Halide Solid Electrolyte *Se Young Kim[1], SeongMin Bak[2], Eugene Jeong[1,3] and Gyu-Min Noh[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Hanyang University, Korea (the Republic of)*

Recent progress in lithium all-solid-state-batteries (ASSBs) has been mainly focused on improving ionic conductivity and electrochemical oxidative stability of solid electrolytes (SEs) to achieve high energy density ASSBs. Although various types of SEs including oxides, sulfide, and halides have demonstrated their feasibility as a Li-ion conductors featured by high ion conductivity (≥ ~ 1 mS/cm), their chemical instability at high and low voltage in direct contact to 4V-class cathode materials and Li-based metal anodes, respectively, still hinder the commercialization of ASSBs. In this regard, the halide SEs have been spotlighted due to their wide electrochemical stability window that enables to use 4V-class cathode materials without surface coating. However, poor chemical stability to Li metal still remained as a challenge to achieve the high energy density ASSBs. For this reason, the electrochemical properties of halide SEs and their application to ASSBs generally tested by adopting Li-In alloy anode, but absence of understanding formation mechanism and chemistry of the interphase between Li-In alloy anode and halide SEs. In this work, the interphase formation mechanism between Li_3YCl_6 *halide SE and various Li-based alloys including Li-In is explored and cation/anion doping strategy to stabilize the interphase between halide SEs and Li-based alloy anodes will be suggested. By combination of postmortem analysis, such as scanning electron microscopy, X-ray diffraction, X-ray spectroscopy, and electrochemical analysis, we revealed stabilization mechanism of the anode interphase layer and design rules for stable Li based alloy anodes. We believe that our findings on anode interphase layer evolution and the strategy to improve the chemical stability of halide SEs to Li metal will suggest new design rules of halide SEs to achieve a high energy density ASSBs.*

EN08.08.41

A Kinetically Controlled Biphasic Cu-Zn Alloy Passivated Anode via Green Laser Activatable Alloying of Monolayered Cu Nanoparticles for Zinc-Ion Batteries *Yeongje Lee, Sanghyeok Bae, Beomjung Baek, Dongyoung Kim and Sunho Jeong; Kyung Hee University, Korea (the Republic of)*

Zinc-ion batteries (ZIBs) have emerged as a promising alternative to lithium-ion batteries due to their inherent safety, cost-effectiveness, and environmental friendliness. However, the performance and longevity of ZIBs are often hampered by issues such as a dendrite growth and undesirable side reactions at the zinc (Zn) metal anode. A development of effective passivation layers is prerequisite to address these challenges. In this study, we introduce a novel laser irradiation alloying method to form a thin Cu-Zn alloy passivation layer on the surface of Zn metal anodes. This innovative method overcomes the limitations of conventional thermal processes, which typically produce thick layers that impede ion transfer and increase internal resistance. By employing ultrafast laser irradiation technique, we achieve a precise control on composition and crystalline structure, resulting in a heterogeneous surface layer composed of Cu-rich and Zn-rich biphasic alloys.

Our laser irradiation method offers several advantages. It significantly regulates a photothermally driven diffusion reaction, minimizing the oxidation reaction of monolayered copper nanoparticles, which facilitates the formation of a thin bipahsic Cu-Zn alloy passivation layer with a suitable surface topology. This improved surface characteristic enhances the wettability and hydrophilicity of the Zn anode, which in turn boosts Zn ion affinity at the electrolyte interface, effectively suppressing both of dendrite growth and by-product formation.

The effectiveness of our method is demonstrated with an excellent cycling stability as long as 500 hr at a current density of 10 mA cm^{-2} *and an areal capacity of 10 mAh* cm^{-2}*. The laser irradiation technique represents a scalable,* *cost-effective solution for high-performance Zn anodes in ZIBs, ensuring longer battery life and greater efficiency. It paves the way for offering a compelling alternative to more expensive and complex techniques of depositing the passivation layer for Zn metal anodes.*

Continuous Lithium-Ion Extraction via Fuel Cell Desalination *Cansu Kök[1,2], Lei Wang[1,2], Jean Gustavo Ruthes[1,2], Antje Quade[3], Matthew Suss[4,5,6] and Volker Presser[1,2,2]; [1]INM-Leibniz Institute for New Materials, Germany; [2]Universität des Saarlandes, Germany; [3]Leibniz Institute for Plasma Science and Technology, Germany; [4]Technion–Israel Institute of Technology, Israel; [5]– Israel Institute of Technology, Israel; [6]Israel Institute of Technology, Israel*

With the rising demand for lithium in various applications and the global shift towards sustainable technologies, there is increasing interest in eco-friendly and cost-effective extraction methods. Various direct lithium-ion extraction technologies are being applied or are in development; however, a significant need remains for more sustainable systems and materials that minimize the use of additional chemicals and simplify the process.[1] Ceramic membranes have garnered significant interest due to their high ionic conductivity, excellent chemical compatibility with various materials, high electronic resistance, and good thermal stability.[2] This study introduces a continuous lithium-ion extraction method utilizing a multi-channel fuel cell desalination system with the lithium selective-ceramic membrane powered by oxygen and hydrogen gases as energy carriers. As feedwater and gases are supplied to the system, Li^+ ions migrate into the catholyte channel through a lithium-selective membrane, contributing to the formation of dissolved LiOH. Concurrently, Cl^- ions pass through the anion exchange membrane into the anolyte channel, where they combine with H^+ ions to produce aqueous HCl.[3] To enable lithium-ion selectivity, We incorporated a lithium superionic conductor ceramic membrane into the fuel cell desalination system. The ceramic membrane, $Li_{1+x}Al_xGe_{2-x}(PO_4)_3$ (x=0.5, LAGP), enabled the selective separation of Li^+ ions toward the other cations from the lithium-ion-containing feedwater. The concentration of all cations was determined using an inductively coupled plasma optical emission spectrometer (ICP-OES), and selectivity factors were investigated in two feed waters: seawater and mine water. The selectivity factors between Li^+ and Na^+ ions were found to be $K_{Ptc\text{-}seawater}$ (10.2), $K_{Ptc\text{-}minewater}$ (3.8), $K_{TiO2/Ptc\text{-}seawater}$ (20.5), and $K_{TiO2/Ptc\text{-}minewater}$ (6.0), respectively. We also coated titania-deposited platinum electrodes with atomic layer deposition to enhance the system's stability and durability. Transmission electron microscopy confirmed that the titania layer was uniformly coated on the electrode surface. Performance tests on the fuel cells using mine water and seawater demonstrated that the titania coating significantly improved selectivity and purity. When using the PtC catalyst with a purity level of 75% in seawater, the lithium-ion extraction rate achieved was 0.017 $mg/cm^2/h$. With the TiO_2/PtC catalyst, the extraction rate was 0.011 $mg/cm^2/h$, achieving a purity level of 95%. Additionally, the process generated 0.6 Wh of electricity per gram of lithium extracted.

Effects of Lattice Vacancies on Properties of $LiBO_2$ Material as Cathode Coating of Li-Ion Batteries *Carson Ziemke[1], Narendirakumar Narayanan[1], Ha M. Nguyen[1], Sebastian Amaya-Roncancio[2], John Gahl[1], Yangchaun Xing[1], Thomas Heitmann[1] and Carlos Wexler[1]; [1]University of Missouri, United States; [2]Universidad de la Costa, Colombia*

$LiBO_2$ is a wide band-gap insulator and a promising surface coating for stabilizing high-voltage cathodes in Li-ion batteries [1,2,3]. Despite its potential, uncertainties remain regarding the functional mechanisms of this coating [4]. Specifically, the transport of lithium ions and electrons through $LiBO_2$ in the presence of lattice vacancies is crucial for its design and development. This study employs density functional theory (DFT) calculations to investigate the effects of oxygen and boron vacancies on lithium diffusion and electronic band structures in both tetragonal (t-LBO) and monoclinic (m-LBO) polymorphs of $LiBO_2$ crystals. Our findings establish fundamental insights into this material and contribute valuable benchmarks for understanding insulator coatings in general. Regarding lithium diffusion, our study reveals distinct impacts of oxygen and boron vacancies on the energy barrier for lithium migration (E_m) in the two polymorphs. Oxygen vacancies decrease E_m in m-LBO but increase it in t-LBO, whereas boron vacancies significantly reduce E_M in both polymorphs, enhancing Li-ion diffusion coefficients. Analysis of electronic band structures using DFT indicates that both vacancy types introduce defect levels within the band gap, reducing the band gap (E_g) and transforming $LiBO_2$ into degenerate semiconductors. In conclusion, our study suggests that generating boron vacancies in $LiBO_2$ could potentially improve its lithium-ion conductivity. However, such vacancies may compromise the electronic insulation properties of the coating. Optimization strategies are therefore essential to achieve coatings with desired functional characteristics.

Ackowledgment
The authors acknolwedged the research fundings from the Materials Science and Engineering Institute, the University of Missouri-Columbia for supporting the computing resources for this work.

Investigations of Coupled Dynamics of Mobile Ions and Anharmonic Phonons in Solid Electrolytes *Olivier Delaire; Duke University, United States*

The design of new solid-state electrolytes (SSEs) hinges on identifying and tuning relevant descriptors. While static structural descriptors have been correlated with fast diffusion, the host framework flexibility and vibrations and their complex dynamic coupling with mobile ions remain less studied. Phonons describe the atomic dynamics in *crystalline materials and provide a basis to encode possible minimum energy pathways for ion migration but anharmonic effects can be large in SSEs. Identifying and controlling the pertinent phonon modes coupled most strongly with ionic conductivity, and assessing the role of anharmonicity, could therefore pave the way for discovering and designing new SSEs via phonon engineering. Here, we investigate phonons in a series of halide and sulfide fast Na+/Li+ ion conductors, using a combination of neutron scattering, ab-initio molecular dynamics (AIMD), and machine-learning molecular dynamics (MLMD). Using inelastic neutron scattering (INS) and MD simulations, we find that soft anharmonic phonon modes play an important role in facilitating ionic hops, reflecting the softness in the potential energy surface. Further, the quasi-elastic neutron scattering (QENS) measurements, supplemented with large-scale MD simulations, probe the diffusivity and the diffusion characteristics. These results offer detailed microscopic insights into the dynamic mechanism of fast ion diffusion and provide an avenue to search for further Na+/Li+ solid electrolytes. These results will also be contrasted with studies of coupled dynamics of anharmonic phonons and fast diffusion of mobile ions in other superionic systems.*

High-Throughput Virtual Screening of Polymer Electrolytes with Molecular Dynamics Simulations *Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States*

Polymer electrolytes have been proposed as solid-state electrolyte materials for Li-ion batteries, with preferrable mechanical and safety properties over current liquid electrolytes. However, polymer electrolytes have relatively low ionic conductivity at room temperature. Exploring the chemical design space of polymer electrolytes in the lab is cumbersome, typically requiring synthesis of new monomers, their polymerization and their evaluation as electrolytes. The number of potential monomers and potential polymers to explore is too large for pure experimental techniques.

Molecular dynamics simulations (MD) can be used to estimate the properties of hypothetical polymers before they are made, but they are rarely used in high-throughput. Here, we will discuss a discovery campaign to explore the scalability of MD simulations for self-driving computational discovery of polymer electrolytes. The workflow includes selection of force field parameters for novel monomers or salts, the assembly of homo- or hetero-polymer chains and the automated construction of amorphous simulation boxes. Then, MD simulations at the 100-ns are performed and ionic conductivity is estimated from analysis of the MD trajectories. Our platform successfully recapitulates the conductivities of over a dozen experimentally known polymers. Lastly, we explore the role of glass transition temperature (Tg), and particularly the discrepancy between Tg values measured experimentally and those estimate from MD simulations, as a source of error in the calculation of conductivity.

Machine Learning-Accelerated Discovery of Sustainable Redox-Active Polymers for Next-Generation Batteries *Subhash V.S. Ganti[1,2], Lukas Woelfel[1] and Christopher Kuenneth[1,2]; [1]Universität Bayreuth, Germany; [2]Bavarian Center for Battery Technology (BayBatt), Germany*

The current reliance of electric batteries on transition metals, which require extensive mining and contribute to greenhouse gas emissions, presents a significant environmental challenge. Redox-active polymer-based batteries offer a promising alternative with a lower carbon footprint, but their development is often hindered by issues such as high dissolution rates and low electronic conductivity, requiring time-consuming and expensive experimentation. To address these challenges, we harness the power of polymer battery informatics, utilizing advanced machine learning (ML) techniques to accelerate the discovery and optimization of suitable redox-active polymers for battery applications. Our data-driven approach employs proxy properties and transfer learning to enhance model accuracy and efficiency, outperforming random searches and baseline models. By training our ML model on a comprehensive dataset of redox-active polymer-based batteries and their associated properties, such as voltage and specific capacity, we can effectively screen a vast library of candidate polymers to identify those with the highest potential for battery applications. These top candidates are passed on to experimentalists for validation and further development, paving the way for a new generation of sustainable and high-performance redox-active polymer batteries.

Early Prediction of the Failure Probability Distribution for Energy Storage Technologies Driven by Domain-Knowledge-Informed Machine Learning *Stephen J. Harris, Maher Alghalayini and Marcus M. Noack; Lawrence Berkeley National Laboratory, United States*

There is a growing focus on sustainable energy sources and storage systems. The challenge with such emerging systems is their need to be warrantied for around 15 years with just a year of early testing. This requires accurate data extrapolation and estimation of the failure distribution. Physics-based approaches can be overwhelmed by the complexity of degradation, and pure data-driven approaches are inherently unable to extrapolate beyond the testing data. Here, we propose a framework for a hybrid approach for technology-agnostic customizations of a Gaussian process for stochastic and domain-knowledge-informed failure distribution predictions. We equip the Gaussian process with customized non-stationary kernels, heteroscedastic noise models, and prior-mean functions to allow for accurate extrapolation with high accuracy. Furthermore, we minimize testing time with a novel experiment-stopping criterion, which can significantly reduce the required data. Our framework could revolutionize energy-storage testing, enabling the rapid development of new technologies.

Machine Learning Assisted Electrode Development for Next Generation Batteries *Brindha Ramasubramanian[1,2,1], Pawan Kumar[2], Seeram Ramakrishna[1] and Vijila Chellappan[1]; [1]National University of Singapore, Singapore; [2]Agency for Science, Technology and Research, Singapore*

In response to the growing demand for sustainable battery technologies, we developed a novel methodology to *optimize and fabricate electrodes for next-generation metal-ion batteries. Our approach combines high-throughput experimentation with machine learning (ML) algorithms to accelerate the optimization of specific capacity and cycle life of batteries. To develop a proof of concept, we focused on nanoporous polymer-carbon (NPC) materials, known for their high surface area and tunable properties. We prepared 150 different NPC cathode combinations using automated tools, allowing us to generate a diverse set of samples quickly and efficiently for property evaluation. Each of these samples was then subjected to experimental testing to assess their electrochemical, spectral, and morphological properties using cyclic voltammetry, Raman spectroscopy, and electron microscopy. These techniques provided a wealth of data on the behavior and characteristics of each NPC combination under various conditions.*

The experimental data collected from the testing phase was used to train a newly developed ML framework. This model was designed to analyze the data, identify patterns, and predict the most promising NPC combinations for aluminum-ion storage. Key features of the ML framework included training on both literature and experimental data to enhance its predictive accuracy, refining synthesis conditions to optimize the electrochemical properties of the NPC materials and identifying new combinations of precursors and synthesis methods to identify high-performance cathodes. The ML-guided approach led to the discovery of several new high-performance electrode materials, including fluorine-based precursors, multi-metallic structures, and polymer composites. Using the synthesis conditions and material combinations suggested by the ML framework, we experimentally fabricated NPC-based hybrid cathodes, which were then tested to validate their performance.

The ML-optimized NPC cathodes demonstrated high performance in aluminum-ion storage systems, achieving a specific capacity ranging from 197 to 250 mAh g^{-1} at a current density of 500 mA g^{-1}, a high coulombic efficiency of 97% over 10,000 cycles, and long-term stability with performance maintained above 150 mAh g^{-1} for over 5,000 cycles. Our novel methodology, combining high-throughput experimentation with machine learning, has proven effective in developing high-performance NPC cathodes for next-generation Al-ion batteries. This approach not only accelerates the discovery and optimization of new materials but also provides a framework for future advancements in battery technology. Continuous refinement and application of this machine learning-assisted methodology can help develop efficient, durable, and high-performing electrodes for next-generation electrochemical energy storage devices commercially.

Machine Learning of Force Fields for Li-Ion Conductors *Oleksandr Voznyy[1], Salatan Duangdangchote[1,2], Alexander Davis[1] and Kareem Abdel Hafez[1]; [1]University of Toronto, Canada; [2]National research council of Canada, Canada*

In this work, we evaluate multiple state-of-the-art graph neural networks and compare their performance on the Li-ion molecular dynamics tasks with the goal of accurately prediction ionic diffusivity and conductivity values. Apart from accuracy of predictions of energies and forces, we add the task of predicting the RDF after a molecular dynamics run, as well as the conductivity per se.
We start by comparing three materials with similar composition but different crystal structure and conductivities and chose the most transferable model. Surprisingly, we find that equivariance does not necessarily improve the model.
Secondly, we find that the majority of pretrained models (e.g. OC22 or MACE) fail dramatically on the Li ion conduction. We thus create our own dataset of 1000 Li-containing materials and train our model on it.

11:00 AM EN08.09.08

Revealing the Proton Slingshot Transport Mechanism in Solid Acid Electrolytes with Machine Learning

Molecular Dynamics *Menghang (David) Wang[1], Jingxuan Ding[1], Grace Xiong[2], Ni Zhan[3], Cameron J. Owen[1], Albert Musaelian[1], Yu Xie[1], Simon Batzner[1], Nicola Molinari[1], Ryan Adams[3], Sossina M. Haile[2] and Boris Kozinsky[1]; [1]Harvard University, United States; [2]Northwestern University, United States; [3]Princeton University, United States*

Rotation-assisted diffusion has been proposed as a prevalent mechanism in various superionic Li-ion and proton conductors. While polyanion rotation (PR) has long be recognized to correlate with high ionic mobility, its precise role in proton conduction, its coupling with the surrounding environment, and its dynamics at nanosecond scale have remained elusive. We investigate the superprotonic phases of solid acid compounds CsH_2PO_4 and $CsHSO_4$, elucidating the detailed proton conduction mechanism using nanosecond molecular dynamics simulations driven by equivariant neural network force fields. Our results demonstrate that PR alone does not carry proton across sites. Instead, the combination of PR and active O-H bond reorientation creates a proton slingshot mechanism that governs long-range proton motion. In addition, PR exhibits dynamics on multiple time scales and activation energies, which have not been captured from previous sub-nanosecond simulations. A stronger correlation between PR and surrounding proton bonding is observed in CsH_2PO_4 compared to $CsHSO_4$, with distinctive rotational dynamics beyond mere rate differences. Our findings provide a detailed understanding of the proton conduction mechanism and PR dynamics in solid-acid compounds, offering new insights into the enhanced ionic mobility facilitated by PR.

11:15 AM EN08.09.09
Modelling Messy Materials—Amorphous and Polycrystalline Solid Electrolytes *James A. Quirk and James A. Dawson; Newcastle University, United Kingdom*

Using case study examples, we will demonstrate how computational techniques can be used to model messy solid electrolyte materials which are rich in defects and disorder. These results are connected to experiment to gain an understanding of ionic diffusion mechanisms, thus informing the material design.

Disordered systems pose unique challenges for computational modelling due to the size of the simulation cells required. This is especially vexing, given that solid electrolytes are usually highly defective and disordered materials. This may be by design, by introducing disorder as a means to enhance ionic diffusivity. Alternatively, it may be a side effect of synthesis; for example, the pressing of powders will produce a polycrystalline sample with many grain boundaries which can impede diffusion.

Sulfide solid electrolytes are a particularly promising technology. We show that an amorphous thiosilicate with composition $5Li_2S$-$3SiS_2$ shows excellent ionic conductivity. By simulating NMR, we confirm the structure of the polyanions present in the material, allowing us to determine that the geometry of the polyanion is the origin of the low barriers to diffusion. [X. Hao, J. A. Quirk et. al., Adv. Energy Mater. 2024, 2304556.] Beyond this, we have produced models of polycrystalline and glassy Li_6PS_5Cl. These models agree well with experimental observations and show encouraging tolerance towards defects.

11:30 AM EN08.09.10
Enabling the Reversible Cycling of F-Ions at Room Temperature *Brent C. Melot; University of Southern California, United States*

The geopolitics associated with Li have begun to create severe supply chain pressures that are driving the price of essential precursors for rechargeable Li-ion batteries to new highs. This volatility makes expanding the deployment of Li-ion batteries at larger scales challenging, despite their many advantages in terms of large operating potentials and slow self-discharge rates. While a tremendous amount of work has explored replacing Li with more abundant *cations like Na or Mg the possibility of harnessing negatively charged anions like fluoride, has largely been overlooked because trying to move anions around through closely packed lattices is tantamount to playing a game of atomic Jenga®. This talk will present our group's recent work developing new materials, based on defect-ordered forms of the fluorite structure, that accommodate reversible F-ion (de)insertion at room temperature. Results from device characterization, including operando X-ray diffraction and online electrochemical mass spectrometry, will be discussed in combination with density functional theory calculations to demonstrate the potential of these materials to enable new methods of energy storage based on highly sustainable chemistries.*

AI-Guided Understanding and Design of Solid-Solid Interfaces in Batteries *Venkata Surya Chaitanya Kolluru, Nina Andrejevic, Haili Jia, Yiming Chen and Maria K. Chan; Argonne National Laboratory, United States*

Solid state electrolytes have potential to widely replace liquid electrolytes in rechargeable Li- and Na-ion batteries due to improved safety and energy density. In addition to ionic conductivity and electrochemical stability window, stability with the anode and the cathode is of utmost importance for a potential solid electrolyte. Therefore, it is necessary to predict and determine phase decomposition or unknown phase formation at the electrode electrolyte interfaces. Using AI-guided generative modeling, as implemented in FANTASTX, we sample structures from the relevant chemical system and compare their stability and match to experimental data, where available. We also compare the structures generated by FANTASTX using sampling methods such as genetic algorithm and basin-hopping in the original and transformed structure spaces where the latter is obtained using neural-network based models such as variational auto encoders (VAEs). Finally, we discuss ML-based approaches which allows us to detect impurity phases and bonding from core-level spectroscopy.

Interface Design for All-Solid-State Lithium-Sulfur Batteries *Manas Likhit Holekevi Chandrappa, Jianbin Zhou, Ping Liu and Shyue Ping Ong; University of California, San Diego, United States*

Lithium-sulfur batteries (LSBs) are one of the most promising energy storage technologies due to the low cost and high abundance of S. However, polysulfide shuttling and the intrinsically low electronic conductivity of the S cathode pose severe challenges to their commercialization. In this talk, I will discuss potential strategies to mitigate these drawbacks via interface design in an all-solid-state LSB (SSLSB) architecture. Using DFT calculations and machine learning potentials, we show that sulfides are generally the most stable solid electrolytes and buffer layers for SSLSBs. We also demonstrate that the β-Li_3PS_4(100) surface tends to form interfaces with S_8 with 2D channels and lower activation barriers for Li diffusion. Finally, we also discuss a novel sulfur cathode chemistry that is healable via periodic heating and exhibits high electronic conductivity. These advances pave the way to the realization of practical LSBs.

2:30 PM EN08.10.03

A Data-Driven Framework to Accelerate the Discovery of Hybrid Cathode Materials for Metal-Based

Batteries *Ahmed H. Biby, Benjamin S. Rich, Nicholas R. Singstock and Charles B. Musgrave; University of Colorado Boulder, United States*

Selecting materials for hybrid cathodes, which involve a combination of intercalation and conversion materials, has gained interest due to their combined synergistic and compromised properties that are not attainable by their homogeneous counterparts. Herein, we present a data-driven framework for discovering hybrid cathode materials for metal-based batteries. This framework systematically explores the potential materials space for any given working ion, evaluates the candidate's stability, and identifies the growth modes/adsorption of the components for a stable hybrid cathode. To demonstrate the application of the framework and its various possible outcomes, we performed a case study whose main design objective was to discover hybrid cathode materials with an average gravimetric energy density surpassing that of the widely used high energy density NMC333 cathode material. The framework identified $LiCr_4GaS_8$*-*Li_2S *as a promising hybrid cathode material that achieves an average energy density of 1,424 Wh/kg (on a lithiated cathode basis) that exceeds NMC333's maximum theoretical energy density of 1,028 Wh/kg. Furthermore,* $LiCr_4GaS_8$*-*Li_2S *has several desirable features: 1) the lithiated and delithiated intercalation and conversion phases are thermodynamically stable; 2) the marginal volume change of the intercalation material upon (de)lithiation mitigates the high-volume change of the conversion material; 3) the conversion material possesses high energy density that ameliorates the low energy density of the intercalation material; 4) the intercalation material can act as both a conductive additive and immobilizer of S to mitigate sulfur species shuttling, while actively contributing to the energy density of the cathode; 5) the intercalation material serves as an ideal support for the soft sulfur species and finally, 6) we anticipate that the life span, self-discharge, mechanical integrity, and capacity fading are better than those of conventional Li-S batteries. The developed framework was instrumental for exploring materials within the enormous potential hybrid cathode material space with pre-defined battery material design objectives.*

Phenomenology of Lithium Dendrite Suppression in Solid Electrolytes Through the Inclusion of Ferroelectric Materials *Changmin Shi, Seunghyun Kim, Angus Kingon, Brian Sheldon and Yue Qi; Brown University, United States*

Li dendrite penetrates solid electrolyte (SE) beyond a certain critical current density (CCD) in Li metal-based SSBs, resulting in electrical shorting issue, especially under fast charging conditions. This has strongly limited the ability to develop viable fast-charging, high-energy-density solid state batteries (SSBs).

Multiple strategies have been reported to mitigate dendrite formation in SSBs. These have included engineering the dielectric properties of the SE to control transport and interface reactions. While the results indicate a direct impact of polarization on performance, reported results have not yet demonstrated critical current densities and lifetime improvements sufficient to invoke commercial interest.

In the light of this we set out to develop a composite PVDF-based SE system to utilize in conjunction with a Li metal anode that could mitigate dendrite formation and achieve high current densities and cycle life. Our innovation has resulted in a remarkable increase in the CCD to the extent that our cells ceased operation due to reaching the upper voltage limit of the battery tester, rather than encountering electrical shorting issues. At the end, we speculate upon the mechanisms, which can be due to a coupled piezoelectricity, mechanics, and electrochemistry effects.

3:30 PM EN08.10.05

Covalent Organic Frameworks for High-Performance Lithium Metal Batteries *Yoonseob Kim; Hong Kong University of Science and Technology, Hong Kong*

Polymers are ubiquitous in our daily life—plastic bags, clothes, house furniture, electronic devices, vehicles, etc. The number of applications is countless. One of the recently developed polymers with high porosity and crystallinity, called porous crystalline polymers, includes covalent organic frameworks (COFs). The unique features of those porous polymers, permanent porosity, and crystallinity make them essential in energy engineering applications. COFs with ionic functional groups can transport ions (e.g., Li^+*,* Na^+*, or* Zn^{2+}*) rapidly and reliably. Those ionic COFs (iCOFs) are incorporated in energy devices for enhanced transport and safety, outperforming known electrolytes and enabling the next-generation batteries. A primary focus is to make solid-state and single-ion-conducting iCOFs for all-solid-sate Lithium metal batteries. For this goal, we developed new iCOFs, such as the ones bearing hypervalent nodes, redox-active moieties, or three-dimensional network topologies. We proved that the iCOFs-based batteries have significantly improved safety while keeping the same high performance as those with liquid electrolytes. The iCOFs we have developed showed the highest* Li^+ *conductivity of 9.8 mS* cm^{-1} *at r.t. and a transference number of 0.92. The solid-state batteries with iCOFs installed cells showed 188 mAh* g^{-1} *at 0.25 C. These findings demonstrate the promise of using redox-active anionic COFs for electrochemical energy storage devices. Adopting such all-solid-state rechargeable batteries will render electric vehicles more robust, safe, and affordable, ultimately leading to improved environmental conditions (Advanced Materials **2021**; J. Am. Chem. Soc. **2023**; Advanced Energy Materials **2024**). Overall, porosity, periodicity, tailorability, and modularity advantages make them the next-generation materials for sustainable energy engineering.*

3:45 PM EN08.10.06

Heterogeneous Doping via Nanoscale Coating Impacts Mechanics of Li Intrusion in Brittle Solid Electrolytes *Xin Xu; Arizona State University, United States*

Lithium metal electroplating and short-circuiting limit fast charging in solid-state batteries, yet the mechanisms and methods to regulate lithium intrusions are not well-understood. In this work, we discover that nanoscale heterogeneous Ag^+ *doping dramatically affects lithium intrusion in* $Li_{6.6}La_3Zr_{1.6}Ta_{0.4}O_{12}$ *(LLZO), a brittle solid electrolyte. We generate nanoscale* Ag^+ *doping by thermally annealing a 3-nm-thick metallic film. The metallic Ag undergoes Ag-Li ion exchange, completely disappears, and diffuses into LLZO bulk and grain boundaries to a depth of 20-50 nm. Density functional theory calculations predict this Ag-Li ion exchange exhibits negligible impact on electronic properties. Mechanically, nanoindentation experiments (n = 69) show a fivefold increase in the force required to fracture* Ag^+ *surface-doped LLZO (*Ag^+*-LLZO), providing direct evidence that surface modification due to* Ag^+ *incorporation prevents crack opening. Conducting 121 plating experiments via operando microprobe scanning electron microscopy, we further confirm that the* Ag^+*-LLZO surface exhibits improved lithium plating even under a large local indentation stress of 3 GPa. Surprisingly, microprobe plating reveals that* Ag^+ *increases the diameter of plated Li at failure by more than 4 times, demonstrating its role in enhancing the defect tolerance of LLZO. Our study reveals a chemo-mechanical mechanism via surface heterogeneous doping, complementing the present bulk design rules to prevent mechanical failures in solid-state batteries.*

4:00 PM EN08.10.07

Dual-Functional Molecular Design Enabling Conformal Electrodeposition of Polymer Networks (EPoN) as Electrolyte Interphases for 3D Solid-State Batteries *Wenlu Wang, Anton Resing, Keith A. Brown and Joerg G. Werner; Boston University, United States*

Interfaces between materials of various functionalities are omnipresent in solid-state energy-storage devices and partially determine the device performance and degradation due to interfacial incompatibility, instability, resistance, and loss of contact over cycling. Electrolyte-type interphases that bridge battery components and materials with disparate functions, such as the active electrode materials and electrolytes, could overcome some of these detriments. Additionally, 3D thin-film solid-state batteries as promising candidates for high-performance microscale power sources require 3D ultrathin solid electrolyte interphases, as they take advantage of both short ion diffusion distances for high rate and the third dimension for high material loading and energy density. Important characteristics of such electrolyte-type interphases are their capability of electronic insulation and the physical separation of incompatible materials while allowing for ion transport. However, a key challenge of obtaining such functional interphases in batteries is their conformal deposition as thin and uniform coatings on 3D electrode architectures.

Here, we introduce the electrodeposition of polymer networks (EPoN) as a general approach to uniformly coat a wide range of polymers with varying functionalities on non-planar conductive materials. Conceptually, EPoN utilizes electrochemically activated crosslinkers as polymer end groups or pendant groups to confine their network formation exclusively to the material surface upon charge transfer, yielding a passivating and self-limiting growth of conformal and uniform coatings with tunable submicron thickness on conductive materials. Specifically, choosing poly(ethylene glycol) (PEO) as the Lithium-ion conducting backbone, we showed that our rational molecular design enables the conformal electrodeposition of ultrathin functional coatings with solid polymer electrolyte properties on 3D structured electrodes that allow designer interphases in various solid-state battery architectures and chemistries.

Tailored Ion Transport in $Li_{3-3y}Ho_{1+y}Cl_{6-x}Br_x$ via Anion-Mixing and Lithium Vacancies *Bright O. Ogbolu, Tej Poudel and Yan-Yan Hu; Florida State University, United States*

The growing demand for dependable energy storage solutions emphasizes the need for advancements in the field. All-solid-state lithium-ion batteries (ASSLBs) offer promising advantages such as higher energy density, lower costs, and improved safety. Halide solid electrolytes are noteworthy for their broad electrochemical stability window and compatibility with high-voltage cathodes. This study reports the halide series $Li_{3-3y}Ho_{1+y}Cl_{6-x}Br_x$ ($0 \leq x \leq 3$; $0 \leq y \leq 0.09$), synthesized using a co-melting method, achieving a high ionic conductivity of ~3.79 mS/cm at 25 °C, with a low activation energy of ~ 0.32 eV. High-resolution powder x-ray diffraction analyses reveal mixed-anion-induced phase transitions accompanied by enlarged bottlenecks for ion transport, increased vacancies, and favorable redistribution of Li^+ ions, facilitating the creation of new energy-efficient migration pathways. Solid-state $^{6,7}Li$ nuclear magnetic resonance and relaxometry investigations unveil enhanced ion dynamics with bromination, achieving a Li^+ motional rate neighboring 116 MHz. Bond valence site energy analysis sheds light on preferred Li^+-ion transport pathways, particularly in structural planes devoid of Ho^{3+} blocking effects. These findings offer valuable insights into the intricate correlations between structure and ion transport, laying the foundation for designing high-performance fast ion conductors for ASSBs and diverse applications in energy storage, separation, and actuation.

Kinetics in Li Plating onto Ag-C Porous Interlayer in Li-Free Solid-State Batteries *Se Hwan Park and Kelsey B. Hatzell; Princeton University, United States*

Li-free solid-state batteries, which contain no excess Li metal initially, are considered promising next-generation energy storage systems due to their high energy density and enhanced safety. However, heterogeneous Li plating onto the current collector leads to early failure and low energy efficiency. Porous interlayers positioned between *the current collector and solid electrolyte have the potential to guide uniform Li plating and improve electrochemical performance [1]. In this configuration, both the electrochemical reduction of Li ions and mechanical deformation, which allow Li metal to flow into the porous interlayer, occur simultaneously [2]. These complexities make understanding Li plating kinetics challenging. Factors such as stack pressure, interlayer composition, current density, and the mechanical response of the interlayer can influence Li deposition kinetics. This study explores how these factors impact Li movement through the interlayer and the morphology of Li electrodeposits. We employed a porous Ag-C interlayer with two different Ag particle sizes and observed Li plating behavior under various stack pressures and current densities. While Ag nanoparticles in the interlayer can facilitate Li movement, they can also induce internal stress, leading to void formation that impedes Li flow. Nanostructure analysis using cryo-FIB are combined with chemomechanicl modeling to uncover the mechanical interaction of interlayer during the alloying reaction between Ag and Li. When comparing the morphology of Li electrodeposits at different conditions, morphological changes correlate with the creep strain rate over Li ion flux. The electrochemical performance is determined by the morphology of Li electrodeposits rather than the Li plating current density.*

Understanding the Factors Affecting Li Dendtire Formation in the Garnet-Type Solid Electrolytes

Chunggi Jung, Abin Kim and Byoungwoo Kang; Pohang University of Science and Technology, Korea (the Republic of)

The demand for rechargeable Li batteries having more safety and higher energy density has been increased to meet the strong demand of novel applications such as electric vehicles and energy storage systems. In this aspect, Li ion batteries containing typical liquid electrolytes have fundamental limitations because liquid electrolytes can act as fuels in thermal runaway behavior leading to a fire or an explosion of battery and can be decomposed at high potential (> 4.5V) leading to the restricted use of high potential cathodes. To address these problems, there are several approaches. One of promising approaches is to apply proper oxide-based solid electrolytes (SEs) instead of liquid electrolytes because they can enable to deliver superior safety with Li metal and to achieve high energy density simultaneously. Among solid electrolytes, garnet-type solid electrolytes such as Li7La3Zr2O12 (LLZO) show great promise for solid-state Li metal batteries because of their chemical stability with Li metal and their high Li ionic conductivity.[1,2] However, oxide-based solid electrolytes have suffered from the Li dendrite formation and propagation inside SE in using Li metal as an anode because of the formation of short circuits that can pose a major obstacle to the commercialization of LLZO.[3,4]
In this study, we try to understand the factors affecting Li dendrite formation and propagation in the garnet-type LLZO SE with respect to materials' properties such as electrical properties and mechanical integrity, and interfacial properties. To achieve this, different samples that have different materials properties such as bulk and grain boundary and different surface properties were prepared. By using these samples, dominant factors affecting the short-circuit of Li metal inside SE have been understood. Finally, we will discuss about the correlation of the Li dendritic behavior with the critical current density, which is the important factor for using the solid electrolyte in real applications.

Molecular Dynamics of Phase Transformations in Barocaloric Layered Materials *Marc L. Descoteaux[1], Faith E. Chen[1], Malia B. Wenny[2], Daniel Laorenza[1], Craig Brown[2], Jarad A. Mason[1] and Boris Kozinsky[1,3]; [1]Harvard University, United States; [2]National Institute of Standards and Technology, United States; [3]Robert Bosch Research and Technology Center, United States*

Layered materials leveraging the order-disorder phase transition of hydrocarbon chains have been shown to exhibit significant barocaloric effects with promise for applications in thermal energy storage and conversion [1, 2]. While the material design space of barocaloric layered materials is large, a complete understanding of how a given layer structure, composition, and hydrocarbon chain length influence the nature of the barocaloric effect is currently lacking due to limited data quantifying the molecular motions responsible for the resultant entropic changes.

In this work, we perform a computational study with molecular dynamics (MD) simulations of a hybrid organic-inorganic perovskite and a di-n-alkylammonium halide salt which have experimentally presented significantly different barocaloric properties and phase-change behavior despite containing hydrocarbon chains of the same length and exhibiting the same transition temperature. To understand the source of these differences with a resolution on the atomic-scale, we use the E(3)-equivariant machine learned force field Allegro [3], trained with an on-the-fly active learning framework based on the Bayesian force field Flare [4]. This approach enables MD simulations of barocaloric layered materials with the accuracy of density functional theory to be scaled to large systems and long timescales.

The computational results are benchmarked against known experimental properties of the phase change and supplemented with computed and measured quasi-elastic neutron scattering data. Overall, the work realizes a fully atomistic description of these materials and quantifies their structural and conformational dynamics, developing understanding which improves our capability to rationally design barocaloric materials with desired properties for thermal energy management.

Boosting Volumetric Capacity of $LiFePO_4$ Cathode Material for Electric Vehicles via Spray Drying Process

Jae-Ho Park[1], Seokhun Kim[1], Hao Zhen[2], Seoung-Bum Son[1], Yasuo Ito[2], Jianguo Wen[1] and Youngho Shin[1]; [1]Argonne National Laboratory, United States; [2]Northern Illinois University, United States

The recent vigorous commercialization of electric vehicles (EVs) has driven an increase in the specification requirements for LIBs used in EVs. These requirements include high energy density, high-rate capability, long cycle life, low raw material cost, and environmental friendliness. In response to these demands, there is significant attention on the continuous development of cathode materials, with lithium iron phosphate ($LiFePO_4$, LFP) prominently standing out among them due to its relatively low production cost and stability. Despite its advantages, when compared to other cathode material groups, LFP suffers from low electronic conductivity of 10^{-9} S cm^{-1}. Efforts to improve electronic conductivity have focused on nano-sizing LFP particles, with subsequent carbon coating proving effective in further enhancing electronic conductivity and enabling superior rate capability. While nano-sized LFP has successfully enhanced its intrinsic performance, applying nano-sized LFP to EVs brings new challenges. Nano-sizing LFP particles significantly reduces the volumetric capacity within the electrode, resulting in a decrease in practical capacity at the cell level, ultimately limiting the mileage of EVs. Therefore, the development of LFP cathode materials for EVs requires a completely new approach to particle design.
In this study, to fabricate LFP cathode material suitable for EVs, primary particles of LFP precursor at sizes in the hundreds of nanometers were synthesized using the continuous supercritical hydrothermal method. Subsequently, secondary particles of LFP precursor at sizes in the tens of micrometers were manufactured using the spray drying process. Each process is completed in less than 5 minutes, making it the fastest synthesis method for producing LFP precursor and a highly appropriate synthesis method for mass production. Additionally, by incorporating a carbon source during the spray drying process, high internal electronic conductivity paths were established within the secondary particles. To determine the ideal temperature for carbon coating and LFP phase formation, the optimal sintering temperature for carbon-coated granulated LFP (G-LFP@C) was identified. Electrochemical properties, including rate capability and long-term cycling retention at various current densities, showed that G-LFP@C exhibited excellent performance with high volumetric capacity. The details will be discussed at the conference.

EN08.11.03

Underlying Factors for Improved Performance of P2/O3 Biphasic Layered Oxides for Sodium Ion Battery

Archana Kaliyaraj Selva Kumar[1], Katherine Mazzio[1,2] and Philipp Adelhelm[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin, Germany

Sodium ion batteries (SIBs) are emerging as a viable alternative to lithium ion batteries (LIBs) due to comparable electrochemical properties. Recently, increased industrial interest in large-scale SIB production has bolstered their commercial prospects.However, the disparity in the performance of SIB when compared to LIBs is majorly due ion-size which makes insertion/desertion process kinetically less favorable. The ion insertion/desertion

process during the charge-discharge cycle is accompanied by phase transitions on the cathode side. These transitions contribute to distinct challenges on the electrochemical performance, stability and cyclability. For instance, $LiCoO_2$ shows exceptional energy density and cycle life making it the most commercialized cathode material for LIBs. In contrast, $NaCoO_2$ faces issues due to multiple irreversible phase transitions during the cycling process[1]. Transition metal Layered oxides (TMO_2) have been regarded as the top choice for cathodes materials. They are classified into different phases, most represented are P2 and O3 depending on the stacking of close packed TMO_2 layers. The letters O and P denote octahedral and prismatic sites occupied by Li/Na ions while the numbers 2 and 3 denote the number of repeating TMO_2 layers[2].
Empirically, P2 phase (Na_xTMO_2, 0.6<x0.7) shows higher rate capabilities and lower capacity when compared to O3 phase (Na_xTMO_2, 0.8<x<1) attributable to difference in Na content and diffusion pathways[3, 4]. Composite biphasic cathode materials, harness synergistic benefits from both phases exhibiting reversible structural changes that outperform individual phase counterparts. This emerging focus on novel composite materials shows promise but lacks answers for fundamental questions on the changes in the chemical environment of the TMs with varying Na content and the reasons for observable reversible phase transitions in composite materials versus individual P2/O3 phases. In this work, we have studied $Na_xMn_{0.5}Fe_{0.25}Ni_{0.25}O_2$ (Na_xMFN)with increasing x value from 0.67 to 0.95. We have observed the transition from pure P2 phase (x=0.67) to biphasic P2/O3 (x= 0.75, 0.8 and 0.85) phase and pure O3 phase (x=0.95) from X-ray diffraction (XRD) analysis. The best performing composition is as expected, $Na_{0.85}$MFN with initial capacity values nearing 200 mAh/g with good cycling stability. Operando wide angle X-ray scattering (WAXS) technique showed the phase transitions which was compared with the results from ex-situ extended X-ray absorption fine structure (EXAFS) analysis showing changes in the chemical environment of the TMs. Interestingly, strain at the phase boundary of the intergrowth structure during the Na-insertion/desertion was observed. These results gave us deeper understanding on the phase transitions and improved electrochemical performance of biphasic composite material with optimal Na content.

EN08.11.05

Design of an Aprotic Solid-State Zn-Ion Battery *Benjamin H. Leifer, Yogeshwaran Agilan and Joshua W. Gallaway; Northeastern University, United States*

In this work we demonstrate the design of a solid-state Zn-ion battery with an aprotic solid electrolyte. The solid electrolyte is based on PVDF gelled with carbonate, similar to a solid-state Li-ion electrolyte recently reported by Khudiyev, et al.[1] This electrolyte is thermally drawable at 200 C and appropriate for use in a solid-state fiber battery. Zn-ion batteries could be an attractive alternative to Li-ion in some applications. Zn has good domestic sourcing and is more atmospherically stable than Li. Its cost is $2.99/kg as opposed to over $14/kg for Li metal. For the application of fiber batteries, Zn would allow the use of a metal wire anode, which would not be possible with Li.

The Zn-ion electrolyte had maximum room temperature conductivity of 1.8 mS/cm when using 0.5 M ZnTFSI.

Electrolytes using Zn triflate had lower conductivity and were only semi-translucent due to incomplete dissolution of the salt. A Zn|Zn symmetric cell showed stable cycling over 500 hours, and we calculated a Zn-ion transference number of 0.41. In designing a full cell, several cathode active materials were assessed with varying success. Three different polymorphs of MnO_2 showed specific capacities far below theoretical. Of these, ��-MnO_2 had the highest capacity; ��-MnO_2 had a lower capacity; and ��-MnO_2 had virtually no reversible capacity. In contrast, Mo_6S_8 Chevrel achieved the theoretical capacity of 128.8 mAh/g that corresponded to the intercalation end member $Zn_2Mo_6S_8$.[2] However, Chevrel can only achieve full capacity at an elevated temperature of 50 C. This demonstrates the concept of a rechargeable aprotic solid-state Zn-ion battery. Previous reports of reversible Zn intercalation in ��-MnO_2 may be due to intercalation of H^+ from residual H_2O that could be present if atmospheric control was not robust.

Simulation of Solid Electrolyte Interface in Anode-Free Batteries

Juliane Fiates[1,2] and James A. Dawson[1,2]; [1]Newcastle University, United Kingdom; [2]Faraday Institution, United Kingdom

Anode-free lithium metal batteries represent promising candidates for achieving high-energy-density storage capacities. However, their limited cycle life, attributed to the heterogeneous deposition of lithium and the formation of dendrites, poses challenges that must be addressed. The Solid Electrolyte Interface (SEI) plays a crucial role in determining the capacity of these batteries. Consequently, strategically controlling the evolution of the SEI on the anode surface emerges as a key approach to attain desired properties and enhance performance in these devices [1].

Our proposed talk aims to shed light on the understanding of the SEI formation mechanism, with a specific focus on the degradation reactions of the electrolyte. The methodology employed for studying SEI evolution is based on classical molecular dynamics simulation using the REACT package. This approach enables the simulation of large-scale systems and longer periods compared to ab initio simulations [2]. The results can serve as an auxiliary tool for screening and selecting appropriate electrolytes that effectively guide SEI formation towards desired properties. Furthermore, an atomistic depiction of the SEI significantly contributes to an enhanced understanding of experimental observations. In conclusion, our research aims to make a substantial contribution to the selection of optimal electrolytes for SEI modulation and to improve the capabilities of anode-free batteries.

EN08.11.08

***Microalgae Based Carbon-Sulfur Composite Cathodes for Lithium Sulfur Batteries** Arenst Andreas Arie; Parahyangan Catholic University, Indonesia*

Due to the high energy density of 2600 Wh/kg, which is 5~6 times, sulfur can be used as an active cathode material in lithium sulfur (LiS) batteries. So, the LiS batteries can be applied for electric cars and electronic products. However, the main problem of LiS batteries is the dissolution of polysulfide in the electrolyte during charging and discharging process, which is known as shuttle effects. It can cause a siginificant capacity during cycling due to the loss of active materials in the cathode. In order to minimize the shuttle effects, strategies such as application of carbon sulfur composite cathode materials was applied. The biomass are natural carbon precursors to prepare composite cathode materials which has good porosity and large surface area. The porosity and large surface area can be used to trap polysulfide via chemical and physical adsorption in cathode. Here, porous carbon materials were prepared using microalgae by two methods, pre-carbonization (MPC) and hydrothermal treatment (MPC/HT), in a pre-treatment procedure. Brunauer–Emmett–Teller analysis showed that the surface area and total pore volume of the MPC/HT are 2200 m^2/g and 2.13 cm^3/g, higher than those of the MPC (1550 m^2/g and 1.08 cm^3/g). The MPC/HT-S with a sulfur content of 87.6 wt.% exhibited a higher initial specific capacity and better cycle retention than those of the MPC-S (78.8 %). Hydrothermal treatment with sulfuric acid catalyst was found to be an effective method to minimize the shuttle effect and low conductivity. The enhanced electrochemical property of MPC/HT-S is attributed to the improved specific surface area of the MPC/HT and proper sulfur loading content, which effectively facilitated the intimate contact between sulfur and conductive carbon matrix and physically confined lithium polysulfide intermediates.

EN08.11.09

***Free Stand Lithiophilic Composite as Anode Electrode in Li Metal Batteries** Sara Hamed, Filipp Obrezkov and Tanja M. Kallio; Aalto University, Finland*

Metallic lithium is demonstrated as one of the most attractive high energy density anodes for lithium batteries. However, it faces a great challenge in realizing practical applications because of uncontrollable lithium dendrite formation, dead lithium generation, capacity decay, and poor coulombic efficiency, which gives rise to internal short circuit, safety hazards and short cycle life. To address these issues, three dimensional hosts can be applied to realize uniform Li nucleation. Here we report a carbon-based 3D skeleton (SiO2/CNT/CP) with SiO2 nanoparticles anchored carbon nanotubes (CNTs) coated on carbon paper (CP) to induce uniform Li plating in lithium metal batteries. SiO2 in the skeleton supplies abundant nucleation sites which lead to enhance lithophilicity. Furthermore, the ingenious hierarchical structure promotes uniform Li plating by equalising the current density distribution. The obtained SiO2/CNT/CP electrodes exhibit an excellent Coulombic efficiency of 99.99% at 1 mA cm-2 after 580 cycles while a symmetric cell shows a low voltage hysteresis of 40 mV without notable fluctuation for over 1250 h.

EN08.11.10

***An Anode for Lithium-Ion Batteries Based on a Carbonaceous Silicon Oxycarbide (SiOC) Composite with High Electrochemical Performance** Dillip K. Panda[1], Nawraj Sapkota[1], Gangadhar Jella[2], Ravindran Sujith[2], Apparao M. Rao[1] and Rajendra K. Bordia[1]; [1]Clemson University, United States; [2]Birla Institute of Technology and Science, Pilani – Hyderabad Campus, India*

Anodes based on silicon oxycarbide (SiOCs) have attracted significant attention due to their outstanding theoretical capacity and structural stability. Their use in Li-Ion batteries is, however, challenged by their low *electronic conductivity. The present study synthesized a SiOC composite containing graphene nanoplatelets (GNP) and rGO chemically modified graphene oxides. Both composites showed significant improvements in electrochemical performance. The conductivity of SiOC composite electrodes has been enhanced, ion diffusion lengths have been shortened, and charge-transfer resistance has been reduced. An approximately 1000 mA h/g capacity was obtained for SiOC-rGO composite at a current density of 0.37 A/g, significantly higher than that for SiOC. In addition, the composite anodes demonstrated a capacity of 700 mAh/g at 0.744 A/g after 800 cycles.*

EN08.11.11

Synergistic Influence of Anode Composition and Electrolyte Interactions in Sodium-Ion Cells *Pooja Ranganathan[1], Susmita Sarkar[2], Bairav S. Vishnugopi[1] and Partha P. Mukherjee[1]; [1]Purdue University, United States; [2]Stanford University, United States*

Sodium-ion batteries (SIBs) present a promising low-cost alternative to lithium-ion batteries due to the extensive availability of sodium resources. However, several challenges need to be addressed for SIBs to achieve commercial viability, particularly concerning the anode materials. Hard carbon, a popular choice of anode in SIBs, can facilitate highly reversible sodium storage through complex diffusion pathways and storage sites. However, a major challenge with this intercalation type anode is the insufficient storage capacity and low coulombic efficiency. On the other hand, tin (Sn) alloys with sodium at a high specific capacity (847 mAh/g), undergoing phase changes during electrochemical operation. The complication pertaining to Sn is due to its vulnerability to particle deformation and consequent volume expansion. This work investigates the synergistic role of anode compositions and electrolyte interactions on the electrochemical performance of sodium vanadium phosphate (NVP) based sodium-ion cells. A comparative analysis of the specific capacity retention among the anode composites was carried out with carbonate ester ($NaClO_4$ in PC: FEC (10%v/v)) and ether ($NaPF_6$ in diglyme) electrolytes. Further, an amalgamation of hard carbon and Sn as the anode is demonstrated to be a potential approach toward achieving high reversibility and specific capacity in SIBs.

EN08.11.12

Sulfonated Poly(Ether Ether Ketone) as Enhanced Separators for Lithium-Ion Batteries *Ling Wei Hwang, Sung Hwa Hong, Sara Mohaenitaromsari, Yu-Chen Sun, Meysam Salari and Hani E. Naguib; University of Toronto, Canada*

Separators in batteries are porous membranes that insulate the positive and negative electrodes from direct contact while accommodating electrolyte to facilitate ion transportation. It is desirable for the separators to have high thermal stability to prevent melting or shrinkage during battery operation. To this end, poly (ether ether ketone) (PEEK) is a potential candidate due to its superior heat resistance compared to commercial polyolefin separators. However, the employment of PEEK as battery separators is hampered by its poor solubility in organic solvents, preventing the use of well-developed separator fabrication techniques, such as electrospinning. To address this, we introduced negatively charged groups (i.e., sulfonic acid) to the PEEK polymer backbone, which is known to improve the solubility of the polymer. Then, we developed a nonwoven porous separator based on the sulfonated PEEK via electrospinning. The advantages of using electrospun fibers include the ultra-high surface area and the nano-porous structure, which can further enhance ionic exchange. While sulfonated PEEK (SPEEK) membranes have been studied for filtration applications such as water treatment, their potential in battery separator applications has yet to be demonstrated, as the ionic exchange process of SPEEK in electrolytes is not fully documented. Hence, in this study, the effect of sulfonation on lithium-ion conductivity and battery performance was explored. Aside from PEEK, other common polymers such as polystyrene (PS) and polyethylene (PE) can also be modified through sulfonation, imparting these typically non-conductive materials with ionic characteristics. Therefore, the findings from this study will accelerate the understanding of how the sulfonation process can be *used for tailoring material properties and micro/nanostructure, thereby expanding their applications.*

Apart from enhancing solubility, sulfonation of PEEK may also influence other separator properties (e.g., hydrophobicity and ionic conductivity), which strongly depend on the degree of sulfonation (DS) of PEEK. Studying the degree of sulfonation will help pave the way for the modification, stabilization, and selection of PEEK separators towards enhancing the safety and electrochemical performance of lithium-ion batteries. In this study, we synthesized PEEK with different DS by varying the reaction conditions. The sulfonation process was characterized by Fourier-transform infrared spectroscopy (FTIR) and X-ray photoelectron spectroscopy (XPS). Then, we fabricated the separators by electrospinning the SPEEK. Different separator thicknesses were fabricated via different processing times, and the morphology was characterized by scanning electron microscopy (SEM). We have demonstrated that there is a strong correlation between the degree of sulfonation, which leads to changes in morphology and therefore the battery performance. As a result, the overall battery performance was enhanced. We believe the findings from this work will pave the way for future studies on the degree of sulfonation and its enhancement of battery safety.

EN08.11.13

Liquid Metals with In Situ Polymerized Electrolyte for Anode-Free Lithium Metal Batteries *Sangbaek Park; Chungnam National University, Korea (the Republic of)*

To address the safety and energy density challenges of conventional Li-ion batteries, anode-free or zero-lithium excess configurations using only a current collector in the anode part have been developed. However, major challenges such as rapid Li dendrite growth, low Coulombic efficiency, safety issues, and thickness problems hinder the practical application of anode-free batteries (AFBs) using liquid electrolytes (LEs) and solid electrolytes (SEs). Herein, we report on potential AFBs using polymer electrolyte (PE) and a Li metal-free anode. The current collector surface is modified by coating a nanocomposite layer comprising carbon and various liquid metal nanoparticles. We observe that the polymerization depends on the solvent composition and the concentration of Li salt, and that cells containing polymerized electrolyte show better performance compared to conventional LEs. Liquid metals (LMs) serve as materials that rapidly alloy with Li, reducing the nucleation energy barrier for uniform Li deposition. Finally, AFBs with an Ag-C composite on the current collector were fabricated and compared with our concept using LMs-C composite to examine differences in cell performance and working mechanism. We believe that our investigation can contribute to future studies related to AFBs using polymer electrolytes and composite interlayers for practical applications.

EN08.11.14

Improving the Electrochemical Utilization of Oxide-Based LISICON-Type Solid Electrolyte for All-Solid-State Li Ion Battery Through Doping *Junhyung Park, Seungjun Woo and Byoungwoo Kang; Pohang University of Science and Technology, Korea (the Republic of)*

As the solution of the environmental pollution problem, fossil fuels need to be replaced with eco-friendly energy. Accordingly, the demand for electric vehicles (EVs) and energy storage systems (ESSs) has been steadily increasing. Li-ion batteries (LIBs) have been considered as the most important energy storage technology because of their higher energy density than other batteries such as Ni-Cd, Lead acid batteries, etc. Many studies have been focused on electrode materials, separators, and electrolytes in the cell platform with liquid electrolytes in order to increase the energy density of LIBs. However, it is gradually approaching a physiochemical limit to further increase the energy density of LIB with liquid electrolytes and safety issues that are related to liquid electrolytes have got severed in large scale systems such as EVs and ESSs. To overcome these problems and issues, all-solid-state batteries with oxide-based solid electrolytes (SEs) have been paid a lot of attention as a next generation energy *storage platform to simultaneous achieve both high energy density and superior safety. Among oxide based SEs, lithium superionic conductor (LISICON) have several advantages over others with respect to superior compatibility with high capacity electrode materials such as high Ni layered materials partly due to a low sintering temperature (700 °C) and good wetting property with Li metal anode. Low sintering temperature of LISICON SE can enable to use co-sintering process for integrating composite electrodes with LISICON SE layer resulting in very nice interfacial contact and low resistance. As a result, the LISICON SE based solid-state Li metal cell can be operated at room temperature. (Seungjun Woo, Byoungwoo Kang, Journal of Materials Chemistry A, 10.43, 23185-23194) Even with these fascinating properties, the LISICON-type SE still has poor Li ionic conductivity (~ 4.0×10^{-6} S/cm), and thereby the electrochemical utilization of the SE in ASSB is not trivial. In this study, we tried to increase the Li ionic conductivity of the LISICON-type SE by using doping. The electrochemical stability of doped-LISICON was evaluated to confirm whether the advantages of LISICON were maintained. Furthermore, we discuss about the effect of the dopants on fascinating compatibilities of LISICON-type SE.*

EN08.11.15

Improving Electrochemical Performance of High Ni Layered Materials by Adding High Valence Elements

Gi-Yeong Yi, Hyunmo Ryu and Byoungwoo Kang; Pohang University of Science and Technology, Korea (the Republic of)

Compared to the $LiCoO_2$, a high Ni layered material has been spotlighted in terms of price and capacity.[1,2] However, such a high Ni layered material suffers from poor cycle stability that can be severely affected by the cracks caused by a large volume change during the charge/discharge process because created cracks easily provide a new surface and side reactions such as the decomposition of electrolytes easily occurs especially in the surface.[3] To suppress this capacity fading, several approaches such as coating process and a doping strategy have been in progress.[4,5] Typically, a high valence metal doping significantly affects the Li/Ni disordering because the doping of high valence metal causes the reduction of Ni^{3+} to Ni^{2+} and the increased amount of Ni^{2+} easily induces the replacement of Li+ ions in Li layer resulting in the increase in the degree of the cation-disordering. The increase in the cation disordering can improve the structural stability of the layered oxides, especially at the end of charge state while the kinetic of the Li can be decreased due to blocking of the Li channel in Li layer. [7]

In this study, we simultaneously changed both bulk and surface properties of the high nickel cathode material by adding a high valence metal. To understand the improved electrochemical properties, bulk properties and surface properties of the doped material have been separately investigated with respect to the effects such as the kinetic of multiple phase transformation and polarization on the improved electrochemical performance. Furthermore, we will discuss about the meaning of these findings and understandings and the way to implement these things for further improving electrochemical performance.

Unlocking High-Performance Post-Lithium-Ion Batteries with Structural Modifications in Prussian Blue Analogues

Trakarn Yimtrakarn[1,2] and Watchareeya Kaveevivitchai[1,2]; [1]National Cheng Kung University, Taiwan; [2]Hierarchical Green-Energy Materials (Hi-GEM) Research Center, Taiwan

Large-scale energy storage systems require safe, low-cost, and efficient battery technologies. Zinc-ion batteries (ZIBs) and sodium-ion batteries (SIBs) have emerged as promising post-lithium-ion candidates due to their inherent safety, environmental friendliness, and inexpensive metal. Prussian blue analogues (PBAs) such as sodium manganese hexacyanoferrate (NMHCF) and metal-doped iron hexacyanoferrate (FeNiHCF) have gained significant attention for their electrochemical tunability, simple synthesis procedure, low material costs, and enhanced structural integrity.

This study focuses on two key strategies, defect engineering and metal doping, to enhance the performance of PBAs for post-lithium-ion batteries (PLIBs). For ZIBs, NMHCF was prepared by precisely controlling the iron lattice vacancies in the Prussian blue structure. The role of lattice vacancies and coordinated water on its performance in non-aqueous ZIBs was systematically investigated. Optimizing the degree of vacancies significantly enhanced the electrochemical properties of NMHCF, providing insights into zinc-ion intercalation and the impact of defect engineering on material performance. For SIBs, the metal-doping strategy in FeNiHCF, where the nitrogen-coordinated iron was doped with nickel, was employed. This approach delivered a high capacity of 148 mAh g^{-1} at 10 mA g^{-1} and a remarkable reversible capacity of ~55 mAh g^{-1} at an ultra-high current density of 25.6 A g^{-1} with minimal capacity decay (0.02%) over 1000 cycles. These unprecedented improvements are attributed to enhanced structural stability, electronic conductivity, and redox activity at the low-spin (carbon-coordinated) iron center.

Through in-situ and ex-situ characterizations, the stabilizing effects of defect engineering in NMHCF and metal doping in FeNiHCF on the chemical, physical, and electrochemical properties of PBAs were revealed. These findings highlight the potential of NMHCF and FeNiHCF as cost-effective and high-performance cathode materials for PLIBs. Structural modifications can unlock the hidden potential of PBA materials, paving the way for sustainable and scalable energy storage solutions.

EN08.11.17

Stabilizing Effect of Polycrystalline Diamond on Anodic Electrodes for Li Ion Batteries

Julio Saldaña[1], Elida I. de Obaldia[1], Enrique Quiroga[2], Orlando Auciello[3] and Daniel Villarreal[3]; [1]Universidad Tecnológica de Panamá, Panama; [2]Benemérita Universidad Autónoma de Puebla, Mexico; [3]The University of Texas at Dallas, United States

This study addresses the issue of rapid degradation and limited efficiency of lithium-ion batteries (LIBs), crucial devices for energy storage due to their high energy density, low weight, and low self-discharge rate. In this context. The use of ultrananocrystalline diamond (UNCD) films and unique electrically conductive grain boundary nitrogen-incorporated ultrananocrystalline diamond (N-UNCD) on superficies de Natural Graphite (NG)/cooper (Cu) anodes is investigated to enhance the stability of capacity energy vs. charge/discharge cycles, safety and performance of LIBs with the new anodes.

The primary objective of this research is to evaluate the stabilizing effect of UNCD and N-UNCD coatings on NG/Cu anodes in half-cell lithium-ion configurations. The study aims to determine how the UNCD and N-UNCD coating improve the performance of half-cells considering specific capacity, coulombic efficiency, and inherent

electrochemical processes such as solid electrolyte interface (SEI) formation and charge transfer.

Half-cell LIBs were assembled with different anode configurations, namely: NG/Cu, currently used in commercial LIBs, UNCD/NG/Cu, and N-UNCD/NG/Cu, alongside a metallic lithium reference electrode. Characterization of these cells involved techniques such as lithiation and delithiation cycles, specific capacity measurements, coulombic efficiency assessments, and electrochemical impedance spectroscopy (EIS). Additionally, distribution of relaxation times (DRT) and equivalent circuit models (ECM) were employed to analyze the electrochemical processes of the studied half-cells and compare their resistances to identify correlations indicative of the effect provided by the UNCD and N-UNCD coatings on the anode of a half-cell LIB.

The use of UNCD and N-UNCD coatings on graphite anodes significantly contributes to improve the stability and performance of LIBs' half-cells. The findings suggest that such coatings could serve as a viable solution to extend the lifespan, safety and efficiency of LIBs, crucial for the advancement of sustainable energy technologies.

EN08.11.18

The Thin Non-Stoichiometric Sn-O Layer Enabled Tunable Zn Plating Position for Anode-Free Zn Aqueous Batteries *Yuxuan Zhang, Fei Qin, Dong Hun Lee and Sunghwan Lee; Purdue University, United States*

Rechargeable Zinc-ion batteries (RZIBs) are regarded as the most promising candidate for large-scale energy storage and wearable electronics due to their low cost, high theoretical capacity (820 mAh g^{-1} or 5,855 mAh cm^{-3}), high safety, and environmental friendliness.[1]

Nevertheless, the practical energy densities of RZIBs are significantly limited by the use of excessive Zn metal anodes (with a thickness of 50–200 μm), resulting in a Zn utilization ratio (ZUR) of less than 5% due to the nearly unlimited zinc reservoir. The thickness of the Zn metal must be less than 10 μm, enabling a Zn utilization ratio higher than 80% according to the calculation.[2] However, the poor reversibility facing conventional Zn anode mainly led by the dendrite growth and the water-induced erosion makes it impossible to apply Zn anode with high ZUR for practical applications.[3]

Constructing an artificial protection layer on the Zn anode is an important approach to achieving the reversible Zn ion plating/stripping process by regulating the Zn plating either on or beneath the protection layer uniformly.[4] However, the thickness of the artificial protection layer (generally higher than 1 μm) is too thick for the required thickness of Zn metal foil (less than 10 μm) to be used in the practical application. More importantly, the preferred Zn plating position of a protection layer with the appropriate thickness for thin Zn metal foil is still inconclusive.[5]

Herein, we successfully controlled Zn plating positions by constructing the stoichiometric tunable Sn-O compounds thin layer (~80 nm) on Zn metal foil. The two different Zn plating behaviors have been systematically investigated by combining both experimental and theoretical results and a generalizable understanding of tuning the Zn plating positions has been proposed. During the electrochemical test, the Zn plated beneath the protection layer realizes long-term cycling over 3000 h at 1 mA cm^{-2} and over 600 h with a ZUR of 85.7%. We further employed the corresponding protection layer in the anode-free system by building the protection layer on Cu foil. The average Coulombic efficiency of the modified Zn||Cu cell achieved 99.7% after 1000 cycles at 20 mA cm^{-2} with a capacity of 10 mAh cm^{-2}. The full cell based on $ZnMn_2O_4$||modified-Cu delivered a capacity retention of 87.6% after 200 cycles, paving the way for high energy density RZIBs for practical applications.

EN08.11.19

Electronic Ionic Polymer Composite-Based Interface via Boosting Zinc Deposition and Transportation for Highly Stable Zn Metal Anodes

Yanghyun Cho[1], Jongha Hwang[1], Song Chi Keung[1], Myung-jun Kwak[2] and Woo-Jin Song[1,1,1]; [1]Chungnam National University, Korea (the Republic of); [2]Korea Electronics Technology Institute, Korea (the Republic of)

Zinc metal with high volumetric and specific capacities (5855 Ah L^{-1} and 820 mAh g^{-1}) is low-priced (0.5 – 1.5 \$ lb^{-1} of Zn metal vs. 8 – 11 \$ lb^{-1} of Li metal) and abundant in the earth (79 ppm of Zn metal vs. 17 ppm of Li metal). Typically, even though Zn metal, unlike alkaline metals such as Li and Na, exhibits more inert in aqueous systems, aqueous Zn ion batteries (AZIBs) are thermodynamically unstable in aqueous electrolytes due to the lower reduction potential of Zn (-0.76 V vs. SHE) than H^+/H_2 (0 V vs. SHE). As shown in the reaction, because E_{Zn}^{2+} (-0.76 V) is lower than E_H^+ (0 V), hydrogen evolution reaction (HER) has a higher tendency to occur before the Zn deposition reaction. Since HER can compete with the Zn deposition reaction, the reduction of Zn metal during the cycling is accompanied by water decomposition, resulting in a rise in the electrolyte's hydrogen ion concentration index (pH). When Zn metal is in contact with the electrolyte, the change of local pH can produce electrochemically non-conductive byproducts. The passivation of the surface accelerates the growth of dendrites and hinders Zn^{2+} diffusion. These reactions are interdependent, so for an ideal Zn anode, only reversible oxidation/reduction reactions should occur at the interface.

Therefore, modifying the Zn surface to prevent inappropriate side reactions with electrolytes to inhibit the continued production of by-products is preferred. Introducing 3D structural designs and artificial solid electrolyte interphase (SEI) layers tends to extend the lifespan of AZIBs by forming dense deposition structures. Another strategy involves incorporating materials with strong crystal orientations to control Zn deposition behavior effectively. Gradual Zn deposition in the planar direction can regulate internal stress and prevent charge accumulation. However, under high current densities, increased Zn^{2+} flux disrupts uniform ion transfer during deposition/desorption cycles, leading to internal stress and charge accumulation. These issues can alter the deposition structure and growth pattern of Zn. Furthermore, the complex and costly processes still require significant refinement for practical applications. While numerous studies have addressed the reversibility of Zn anodes from several perspectives, the complex correlation between the electrode and interface and cell performance has yet to be studied. Therefore, substrates with strong orientation relationships should be designed to control the active atoms to alleviate local charge accumulation and enable sufficient ion transfer.

In this work, we proposed a mixed electronic-ionic transport polymer composite (referred to as EIPCs) overlayer to relax internal stress and sufficient ion transfer by facile spin-coating process. The EIPCs-based interface is composed of poly (acrylic acid) (PAA) and graphene oxide (GO) at the electrode-electrolyte interface. The synergy effect of rapid Zn ion diffusion dynamics and electric field regulation effectively mitigated the typical surface Zn deposition and volume fluctuations. The growth of dendrites along the (002) basal plane exhibited lower surface energy and chemical activity, suppressing side reactions. In addition, the water-solved polymer (PAA) forms hydrogen bonds with the functional groups of graphene oxide to build a compact and well-aligned 2D stack. As a result, low interfacial resistance and high (002) preferential orientation further facilitate rapid plating/stripping during the cycle. The Zn@EIPCs with synergistic effect achieved improved anode performance with a long lifespan (>1500 h) and high current density (20 mA cm^{-2}). We also conducted a full-cell test with different cathodes ($Zn_{0.25}V_2O_5$, I_2) to confirm its versatility. The novel EIPCs interface design, dynamically suppressing dendritic formation, can significantly enhance the stability of AZIBs and other aqueous energy storage systems.

Self-Assembled CuO Nanostructures with Single Crystalline Nanorods—Synthesis and Electrochemical Performance

Mushtaq Ahmad Dar[1], Hany Sayed Abdo[1], Nabeel H. Alharthi[1] and Dong Wan Kim[2]; [1]King Saud

University, Saudi Arabia; [2]Korea University, Korea (the Republic of)

In recent years, large-scale self-assembly of meso-, micro-, and nanostructured components has garnered significant interest due to their promising applications in various fields. The potential of self-assembled nanostructures, particularly those of metal chalcogenides, is noteworthy and has been receiving growing attention. Oxide nanostructured materials are also greatly interesting for their fundamental properties and technological applications. Recently, it was discovered that metal oxide electrodes show outstanding electrochemical properties as anode materials for lithium-ion batteries. This finding has practical implications-the electrodes demonstrate excellent specific capacity, extended cycle life, and a relatively low self-discharge rate, making them highly suitable for energy storage technologies. This further highlights the potential of self-assembled nanostructures and equips the audience with valuable knowledge in this area. The self-assembly of CuO nanorods has led to the creation of unique sea urchin-like CuO nanostructures, which remain remarkably stable even under rigorous ultrasonication at ~650 watts. Transmission electron microscopy revealed these structures consist of CuO 'nano-pillars' approximately 125 nm wide and 700 nm long. X-ray photoelectron spectroscopy confirmed the formation of CuO. The single crystalline nanorods exhibit impressive electrochemical performance, with a specific capacity of about 428 mAh. g^{-1} after 24 cycles. A mechanism for the formation of the sea urchin-like CuO structure has been proposed.

This project was funded by the National Plan for Science, Technology, and Innovation (MAARIFAH), King Abdulaziz City for Science and Technology, Kingdom of Saudi Arabia, Award Number (2-17-02-001-0053).

EN08.11.22

Electrolyte-Swollen Polymer Films Enhancing Native Solid Electrolyte Interphase on Lithium Metal Anode

Keonwoo Choi[1], Hyunsub Song[1], Jaehyeong Bae[2], Il-Doo Kim[1] and Sung Gap Im[1,3]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of); [3]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

The lithium (Li) metal has been regarded as one of the most promising anode materials for rechargeable Li batteries thanks to its high theoretical specific capacity (3860 mAh g^{-1}) and low redox potential (-3.040 V vs the standard hydrogen electrode). However, the Li metal shows its inherent instability and high reactivity with electrolytes, leading to the formation of instantaneous and indiscriminating solid-electrolyte interphase (SEI) layers. The resultant fragile SEI can be broken and regenerated during repetitive discharge-charge cycles, thus provoking severe corrosion of Li metal anode, excessive electrolyte depletion and accumulation of substantial SEI layers. The inhomogeneous Li-ion migration within the irregular interphase can cause drastic growth of lithium metal dendrites and dead lithium, resulting in rapid capacity decay, poor battery lifetime, and even safety hazards. Herein, we demonstrate the electrolyte-swellable polymer thin nanolayer directly on Li metal anode by using initiated chemical vapor deposition process. The ultra-thin poly(dimethylaminomethyl styrene) (pDMAMS) layer, with a thickness of 100 nm, exhibits swelling behavior with a significant volumetric increase of 264 % under a commercial carbonate electrolyte. The corresponding expanded polymer matrix enables the formation of favorable native SEI layers within the framework, while simultaneously allowing efficient transport of Li ions. The electrolyte-swollen soft scaffold provides for Li_2O-free and Li_2CO_3-rich native SEI layers with homogeneous distribution of SEI components, achieving a remarkably high Li-ion transference number of 0.95 and ionic conductivity of 6.54 mS cm^{-1}. The pDMAMS-coated Li metal anodes prolong the battery lifetime by 550 % in Li-Li symmetric cells and 600 % in full cells coupled with practical high-nickel cathode of $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ in comparison to uncoated Li metal anodes. The electrolyte solvogel system is thoroughly investigated through in-depth profile analysis of SEI layers and precise manipulation of electrolyte-phobic repeating units in pDMAMS/electrolyte-phobic copolymers. This dual-purpose solvogel approach offers a fresh perspective on

stabilizing the interface between the Li metal anode and the liquid electrolyte, making it widely applicable in next-generation rechargeable batteries. Furthermore, it is expected to provide impetus for advancing beyond Li-ion technologies through a novel design of SEI layers.

EN08.11.23

Inorganic Protective Interlayer Based on Solution-Phase Synthesis for Anodic Interface in Li Metal All-Solid-State Batteries

Seong Gyu Lee, Gyu Hyeon Lee, Dayoung Jun and Yun Jung Lee; Hanyang University, Korea (the Republic of)

All-solid-state batteries (ASSBs) featuring lithium (Li) metal and sulfide solid electrolytes (SEs) have garnered significant interest due to their high energy density and non-flammable properties. However, the unstable anodic interface between the SE and Li metal has hindered their commercial development. In this study, we developed an inorganic protective interlayer for Li metal, comprising a Li-alloy and Li halide (LiX) within a Li_2S-P_2S_5 glass ceramic matrix, using a solution-phase synthesis method. This protective layer was synthesized via a solution-phase process with a specific precursor ratio of sulfide solid electrolyte components, with the addition of metal halide, ensuring complete dissolution. Application of this precursor solution to Li metal resulted in a dense, void-free protective interlayer, ensuring close contact at the anode, and facilitating rapid Li-ion transport through its components. This promotes stable Li metal deposition beneath the interlayer while preventing direct contact with the SE. The Li-alloy and Li halide-doped protective layer significantly enhances the electrochemical stability of the anodic interface through its physical barrier, chemical resistance, and fast Li-ion mobility. Consequently, this leads to improved electrochemical performance, with over 550 hours of stable Li deposition/stripping in a symmetric cell, compared to just 250 hours for cells with unprotected Li. When paired with a $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ cathode, the full ASSB exhibited remarkable capacity retention and coulombic efficiency, especially under high current conditions, effectively suppressing dendritic Li growth. This research highlights a straightforward and effective strategy for improving ASSB interfaces through the solution-phase synthesis of a protective layer that enhances Li-ion transport and interface stability. The protective interlayer's impact on the longevity and reliability of ASSBs marks a significant advancement towards their commercial viability, offering a promising pathway for developing next-generation high-energy-density batteries.

EN08.11.24

Heavier Alkali Metal Carbonphosphonitride Thermosets and Ternary Alkali Cyanides as Solid-State Electrolytes

Andrew Purdy[1], Kaitlyn I. Talamantez[1,2], Daniel M. Fragiadakis[1], Hunter O. Ford[1,3], Christopher A. Klug[1], Mark O. Bovee[1,3], Megan B. Sassin[1] and Brian L. Chaloux[1]; [1]U.S. Naval Research Laboratory, United States; [2]NREIP Intern, United States; [3]NRC Postdoctoral Associate, United States

We already demonstrated that lithium dicyanamide ($LiN(CN)_2$) reacts with phosphorus cyanides ($P(CN)_3$ or $RP(CN)_2$) in a 2:1 or greater mole ratio in an anhydrous aprotic mutual solvent to form a resin, which then cures at temperatures of 200-300 °C to a non-flammable Li-P-C-N ion conductor. When fully cured, those films have a low ionic conductivity, probably due to rigid crosslinking of the thermoset. We found previously that the sodium version Na-P-C-N is substantially more conductive than the Li-P-C-N materials. Post-cure treatment with diglyme also causes a dramatic conductivity increase, presumably by complexing the mobile alkali ions and plasticizing the material. For this work, we completed the entire alkali metal series by preparing A-P-C-N materials through A= K, Rb, and Cs, prepared composites of Na-P-C-N and sodium beta-alumina, and made efforts to prepare ternary cyanides of A(CN) or $AN(CN)_2$ (A = Li, Na, K, Rb, Cs) with $Al(CN)_3$ and $Ga(CN)_3$. The ratios of resin to ceramic and the conditions of preparation are varied to produce solid composite films for measurement, and the ionic conductivity and chain motions of these films are characterized by impedance and dielectric relaxation spectroscopy. Test cells with the heavier alkali metal are constructed and measured to evaluate electrochemical stability and

transference numbers. Additionally, solid state NMR is used to examine the compositional stability of the composite and the ion mobility between different ionic conductors.

EN08.11.26

NASICON-Type Sodium Iron Phosphate Cathodes from Scalable Spray-Flame Synthesis *Mohammed-Ali Sheikh[1] and Hartmut Wiggers[1,2]; [1]Universität Duisburg-Essen, Germany; [2]Center for Nanointegration Duisburg-Essen (CENIDE), Germany*

Sodium-ion batteries (SIB) are increasingly in focus of current battery research due to their potential low cost and the abundance of raw materials. While hard carbon is an established and cost-effective anode material, the search for suitable cathode materials for SIB remains a significant area of interest [1]. Lithium Iron Phosphate (LFP), one of the most viable cathode materials for Lithium-ion batteries, offers a theoretical capacity of 170 mAhg^{-1} [2]. The sodium-based analog Sodium Iron Phosphate (NFP), theoretically has a similar capacity [1]. However, its most stable crystal structure, maricite, is considered electrochemically inert due to its dramatically low ionic conductivity [3] and the electrochemical properties of NFP are highly dependent on its composition and morphology [3, 4]. In comparison, NASICON-structured polymorphs of NFP exhibit excellent cycling stability and rate capabilities. However, the high phosphate content in the NASICON polyanionic framework typically results in lower theoretical capacity [5, 6].

In this work, we report the production of different compositions of NASICON-type nano $NaFe_xPO_4$ (x = 1.2, 1, 0.75, 0.67, 0.5) using spray-flame synthesis (SFS). The synthesized NFP materials are characterized using transmission electron microscopy (TEM), X-ray diffraction (XRD), and Raman spectroscopy for structural and morphological characteristics. Elemental composition is analyzed via energy-dispersive X-ray spectroscopy (EDX). Thermal behavior is studied using thermogravimetric analysis (TGA) with simultaneous differential scanning calorimetry (DSC) and the NFP compositions are tested as cathodes in SIB half-cells.

The pristine materials consist of amorphous nanoparticles with a median diameter of around 12 nm. EDX analysis reveals a homogeneous elemental distribution with quantities close to the intended compositions. After a short annealing step for 1 hour at 600°C, the materials crystallize and, unexpectedly, all materials exhibit the rhombohedral NASICON structure. To our knowledge, no $NaFe_xPO_4$ with a higher Fe content than x = 0.75 has been reported yet. Initial half-cell tests show that NFP cathodes exhibit capacities close to their theoretical values, with capacity increasing with higher Fe content.

In conclusion, SFS presents a promising method for the scalable production of cathode active nanomaterials for SIB. This method holds significant potential, particularly for the compositional tuning of material classes, to fully utilize their capabilities for various applications.

Fluorine-Containing Materials Utilized in Electrochemical Energy Storage Devices *Stephen Budy; BCI, United*

States

The demand for high-performance electrochemical energy storage devices has driven the development of advanced battery technologies with improved energy density, safety, and cycling stability.[1] Utilizing fluorine chemistry to design battery components is a critical strategy to accomplish these requirements. Fluorine has emerged as a crucial element in achieving these goals with fluorinated materials being employed in a wide range of battery applications, including separators, solid and liquid electrolytes, electrolyte additives, solvents, binders, and protective layers for electrodes.[2]

The utilization of fluorine extends across various critical components of electrochemical energy storage devices. Fluorinated electrolytes, for instance, exhibit improved conductivity and stability, thereby enhancing the efficiency and lifespan of lithium-ion batteries. These electrolytes contribute to mitigating issues such as dendrite formation and electrolyte decomposition, which are critical for the long-term performance and safety of batteries. Fluorinated electrodes represent another significant application area. Materials like fluorinated carbons and metal fluorides offer higher specific capacities and improved cycling stability compared to conventional materials. Fluorine doping or incorporation into electrode structures enhances their electronic conductivity, ion diffusion kinetics, and structural stability under cycling conditions. This results in batteries with increased energy densities, faster charging capabilities, and longer cycle life, meeting the growing demand for high-performance energy storage solutions.[3]

However, despite the promising advantages, the widespread adoption of fluorine-containing materials in electrochemical energy storage devices faces challenges. These include cost considerations, scalability of synthesis methods, and potential environmental impacts associated with fluorine-containing materials.[4] Addressing these challenges requires continued research and development efforts aimed at optimizing material synthesis, improving performance metrics, and ensuring sustainability throughout the lifecycle of these technologies.

Herein, we provide an overview of the diverse roles and significant impacts of fluorine-containing materials in enhancing the performance, efficiency, and safety of these crucial technologies. The role of fluorine chemistry is driving innovation and shaping the future of electrochemical energy storage technologies. High ionic conductivity over 10^{-3} S cm^{-1}, superior mechanical performance, and robust LiF-rich interphases at both the Li metal anode and the cathode are observed. Fluorinated solid electrolyte interphase (SEI) helps to enhance the cycle stability of batteries.

Illuminating the Route to High-Performance Zn-Ion Batteries—A Study on Electrochemical Properties of Laser-Treated Anodes *Anzelms Zukuls[1], Ramona Durena[1], Nikita Griscenko[1] and Leonid Fedorenko[2]; [1]Riga Technical University, Latvia; [2]Lashkaryov Institute of Semiconductor Physics, Ukraine*

Due to the rapid development of humankind, inevitable environmental changes are occurring, prompting the search for alternative and friendlier technologies to mitigate these impacts. To improve conditions in our constantly evolving global ecosystem, solutions involving the use of renewable natural resources for energy production are being proposed. A key challenge in realizing a sustainable future is the issue of energy storage, given the irregular production of green energy. Numerous technologies for safe energy storage have been *suggested, demanding greater focus and development. Among these technologies, electrochemical energy storage in rechargeable batteries stands. Alongside the widely used lithium-ion battery technologies, research is also exploring alternative options like Na^+, Zn^{2+}, and Ca^{2+} ion batteries [1-4]. As scientists gain a deeper understanding of battery processes, new opportunities for advancing battery technology emerge. Rechargeable zinc-ion aqueous batteries have garnered renewed interest due to their potential for large-scale storage applications. In this study, we modified the surface of Zn electrodes through laser irradiation, employing two different laser wavelengths (266 nm and 1064 nm) and two irradiation mediums (air and water atmospheres) to prepare the anode surfaces. For sample comparison, measurements were performed in the "TSC Surface" (from rhd instruments) measuring cell using a 3-electrode configuration. Sample studies were performed in 1M KOH electrolyte solution using Ag/AgCl electrode as reference electrode and Pt electrode as counter electrode. The samples were characterized using Raman spectroscopy, scanning electron microscopy, cyclic voltammetry, and impedance measurements. Results indicate that laser processing can increase the specific surface capacitance of the samples by up to 30%. The observations reveal that laser-modified electrodes exhibit more efficient ZnO growth and Zn plating in an alkaline electrolyte medium. Laser-irradiated surfaces (during Zn plating and ZnO growth), have significantly lower charge transfer resistance compared to normal Zn plates. Also, irradiated samples have much less ZnO residue after Zn plating than the non-irradiated Zn surface. In general, the laser treatment contributes to the increase of the electrode capacity compared to the unmodified Zn sample.*

Mechanics of Flexible and Wearable Electronic Energy Systems *Nadeem Qaiser and Nazek El-Atab; King Abdullah University of Science and Technology, Saudi Arabia*

The role of mechanics in various advanced energy systems is crucial since the device's efficacy mainly depends on the mechanical integrity of the system. For instance, the working of energy storage systems including Lithium-on batteries (LIB) consists of a complex chemo-mechano-electro process. This work will cover how the electrodes of LIBs respond to the diffusion of Li-ions. The diffusion-induced-stresses (DIS) play a critical role in the cyclic life as well as the high energy density of the battery. The extensive FEM analysis revealing fracture conditions, DIS, and volumetric expansion, followed by experimental investigations will be discussed. Our study shows how DIS stresses evolve and what methods can be utilized to mitigate these stresses, which in turn enhances the performance of LIBs. Brief details of current recent research trends i.e., 2D materials-based LIBs will also be discussed.

Supercharging the Solid State—Argyrodites as Electrolytes in Lithium-Ion Batteries *Cade Alaniz[1], Austin Shotwell[1] and Annalise Maughan[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States*

Lithium-ion all-solid-state batteries (ASSBs) offer the potential to meet rising energy storage demands by enabling *a safer, more energy dense option for consumer and industrial applications. Replacing the liquid electrolyte with a solid ion conductor significantly reduces flammability and mechanical instability and have been proposed to stabilize high-capacity lithium metal anodes. However, solid state electrolytes (SSEs) that can simultaneously meet the demand for high Li-ion conductivity and electrochemical stability with lithium metal are few and far between. Halide argyrodites such as Li_6PS_5X (X = Cl, Br) have garnered attention for their high ionic conductivities that can compete with current liquid electrolytes. However, many sulfide argyrodites suffer from narrow electrochemical stability windows that do not permit their use with high voltage cathodes or lithium anodes. Here, we have developed a new compositional family of mixed oxide-sulfide argyrodites and determined the relationships between composition, ionic conductivity, and electrochemical stability with lithium metal. Through X-ray scattering, Raman spectroscopy, and a suite of electrochemical measurements, we develop fundamental relationships between composition, structure, and electrochemical behavior of this new family of argyrodites.*

Advancing Aqueous Trivalent Metal Batteries by Realizing Planar Indium Plating with Ultrahigh Efficiency and Long Lifespan *Songyang Chang; University of Puerto Rico at Río Piedras, Puerto Rico*

*Aqueous trivalent metal batteries represent a compelling candidate for energy storage, due to the intriguing three-electron transfer reaction and distinct properties of trivalent cations. However, little research progress has been achieved with trivalent batteries, due to the inappropriate redox potentials and drastic ion hydrolysis side reactions. Herein, we selected an appealing yet underrepresented trivalent indium as an advanced metal choice, and we revealed the crucial effect of substrate on its plating mechanism. When copper foil is used, an indiumophilic InCu alloy interface can be in-situ formed upon plating, which exhibits favorable binding energies and low diffusion energy barriers for indium atoms. Consequently, a planar, smooth, and dense indium metal layer was uniformly deposited on the copper substrate, leading to outstanding plating efficiency (99.8-99.9%) and exceedingly long lifespan (6.4-7.4 months). The plated indium anode was further paired with high-mass-loading Prussian blue cathode (2 mAh cm^{-2}), and the full cell (N/P = 2.5) delivered an excellent cycling life of 1000 cycles with 72% retention. This work represents a significant advancement in the development of high-performance trivalent metal batteries.**Aqueous trivalent metal batteries represent a compelling candidate for energy storage, due to the intriguing three-electron transfer reaction and distinct properties of trivalent cations. EN08.11.32
Epitaxial Thin Film Growth and Elemental Substitution of Perovskite Hydrides $MLiH_3$ *Erika Fukushi[1], Fumiya Mori[1], Kota Munefusa[1], Takayuki Harada[2] and Hiroyuki Oguchi[1]; [1]Shibaura Institute of Technology, Japan; [2]National Institute for Materials Science, Japan*

Hydrides are compounds in which a negatively charged hydride ion (H^-) is bonded to other elements, making them promising for developing functional materials with unique hydrogen-derived properties. These properties, *including hydrogen storage, high-temperature superconductivity, and hydride-ion conduction, hold potential for creating energy-saving materials like superconducting power cables and innovative energy devices such as batteries and fuel cells. To this end, perovskite hydrides, known for their structure-sensitive properties and high elemental substitution capabilities, offer an ideal platform for investigating and developing exotic hydride materials. In this study, we use the radical hydrogen (H-radical) reactive infrared laser deposition method to synthesize $MLiH_3$ (M: Sr, Ba) perovskite hydride epitaxial thin films. We determined the optimum conditions in our experimental setup for growing well ordered, single-phase $MLiH_3$(100) thin films. We demonstrate the potential of perovskite hydride epitaxial thin films for future materials exploration by measuring the intrinsic hydride-ion (H^-) conduction of a $SrLiH_3$(100) thin film. In this study, we also added Na and other elements to the thin film to demonstrate that it is possible to control the properties of $MLiH_3$ epitaxial thin film by substituting elements, which is one of the strengths of perovskite.*

$MLiH_3$ thin films were synthesized by infrared laser deposition on $MgAl_2O_4$(100) or $LaAlO_3$(100) substrates in a vacuum chamber with a back pressure of about 1.0×10^{-8} Torr. Normal hydrogen gas and H-radical gas were supplied as reactive gases during film deposition. The starting material was a pellet made by mixing and pressing MH_2 and LiH powders. NaH and other powders were added to the pellets for elemental substitution experiments. The crystallinity and orientation of the obtained films were evaluated by X-ray diffraction (XRD) measurements, the surface morphology by optical microscopy, and the H^- conductivity by AC impedance measurements.

Epitaxial thin films were obtained for both $BaLiH_3$ and $SrLiH_3$ when the films were deposited in the conditions; the substrate temperature was 150°C and the reactive gas was H-radical. In a larger amount in the reaction atmosphere, H-radicals also improve the quality of the product perovskite hydride epitaxial thin films. For the $SrLiH_3$(100) epitaxial thin film, we used electrochemical impedance measurements to observe intrinsic hydride-ion conduction. The shapes of the resulting Nyquist plots were almost semicircular, in agreement with the H^- conduction in the $SrLiH_3$ crystal. This result demonstrated that epitaxial thin films can provide a suitable platform for observing intrinsic H^- conduction. Our measured conductivity of the $SrLiH_3$(100) epitaxial thin films was about one-fifth of the value reported in a previous powder study.

We tried Na substitution into $MLiH_3$ epitaxial thin films and found an improvement in H^- conduction. This is thought to be due to the substitution of monovalent Na for the divalent M site, which created vacancies in the H site for charge compensation and facilitated H^- migration. This result suggests that the control of physical properties by substitution, which is unique to perovskite, is also possible in the epitaxial thin film.

In conclusion, this study provides a methodology for future exploration of exotic hydrides where the physical properties of the desired hydride will be measured using the epitaxial thin film platform. In addition, this study provided insight into how to use epitaxial films as a platform to control their physical properties by elemental substitution.

Rate Performance Investigation of an Iron-Doped Mn-Based Tunnel Type Cathode Containing Sodium, Lithium and Titanium for Low-Cost Li-Ion Batteries

Axel B. Gambou-Bosca, Wen Zhu, Sergey Krachkovskiy and Chisu Kim; Hydro-Québec, Canada

While Cobalt-free layered cathode materials such as NMA ($LiNi_{1-x-y}Mn_xAl_yO_2$) have garnered increased attention for applications in high energy density Li-ion batteries, the raw material cost of nickel is not immune to market fluctuations; thus, it would be advantageous to safeguard against it in the future. In this sense, Li+/Na+ exchange ion has been extensively explored as an effective method to prepare high-performance Mn-based layered cathodes for Li-ion batteries. In this work, tunnel type $Na_xLi_yFe_{0.16}Mn_{0.65}Ti_{0.19}O_2$ with $0<x<0.44$ and $0<y<0.65$ has been prepared by solid-state synthesis followed by Li+/Na+ ion exchange and cycled to a high (4.8 V vs. Li/Li+) cut-off voltage to achieve high energy density. However, long-term cycling at a higher upper cut-off voltage exacerbates harmful surface and bulk degradation mechanisms that compromise the overall lifetime and thermal stability of *the cell. Herein, in situ operando X-ray diffraction, SEM-EDX, solid-state NMR and electrochemical tests are combined to get more insight into the structural changes affecting the rate performance of the new cathode material.*

Printed MXene-MoWS2 Asymmetric Micro-Supercapacitors for Flexible Energy Storage Devices *Animesh Mandal and Samit K. Ray; Indian Institute of Technology Kharagpur, India*

Micro-supercapacitors (MSC), renowned attractive for their exceptional power density and remarkable longevity, possess the potential to function as integrated power reservoirs within electronic systems. The interdigitated architecture of the MSC devices mentioned reported here is fabricated by the utilization of a specifically engineered mask and screen printing process on a flexible and transparent substrates. The electrodes are constructed using two key
materials: titanium carbide MXene (Ti 3 C 2 T x) and Molybdenum Tungsten Disulfide (MoWS2) . MXene, a 2D layered material, enables rapid ion diffusion within the interdigitated electrode structure, while MoWS2 consists of nanoparticles.
MoWS2 and MXene asymmetric micro-supercapacitor (MoWS2/Mxene A-MSC) described here operates in an aqueous electrolyte at a potential range of 0-1.8 V and maintains 72% of its initial capacitance even after one thousand charging cycles. Additionally, it boasts an energy density of 117.6 mW. H. cm -3 with the highest record power density of 1285.7 mW. cm -3. Molybdenum Tungsten Disulfide (MoWS2) and Ti 3 C 2 T x -MXene MSC to function in aqueous electrolytes, the study highlights the promising approach of employing Ti 3 C 2 T x -Mxene as the negative electrode and MoWS2 as the positive electrode in asymmetric architectures to enhance both the energy and power densities
of micro-supercapacitors.

EN08.11.35

Low Energy Synthetic Graphite from Natural Gas as Anode Material for Li-Ion Batteries *Daniel Lwanzo Paluku[1], Joseph Stiles[1,1], Maha Yusuf[1,2], Jonah Erlebacher[3], Craig Arnold[1,1] and Mohd Shaharyar Wani[1,1]; [1]Princeton University, United States; [2]Adlinger Center for Energy and Environment, United States; [3]Johns Hopkins University, United States*

Synthetic graphite is the industry standard anode material in lithium-ion batteries (LIBs). It offers several advantages such as long battery cycle life and high theoretical capacity. However, the production of synthetic graphite is energy-intensive, resulting in increased greenhouse gas emissions and carbon footprint[1,2]. Therefore, alternative low-energy carbon synthetic routes to graphite manufacturing are crucial to minimize carbon footprint of battery making.[3]
In this work, we present electrochemical viability of synthetic graphite (SG) obtained by the removal of metal from metal-carbon composites synthesized from the reduction of natural gas with metal chloride.[4] We evaluate the electrochemical behavior of SG under a range of cycling rates (C/10, C/2, 1C, 2C, 10C), and compare its behavior with that of a wide range of commercial synthetic graphite materials. Our results demonstrate the viability of SG as an alternative low energy-intensive carbon anode material for LIBs showing favorable performance as compared to commercial synthetic graphite produced through high energy methods.

Deconvoluting Surface and Bulk Charge Storage Processes in Redox-Active Oxides by Integrating Electrochemical and Optical Insights

Luhan Wei and Qiyang Lu; Westlake University, China

Redox-active transition metal oxides (TMOs) are pivotal in enhancing electrochemical energy storage and conversion technologies, encompassing applications in supercapacitors, batteries, and electrolyzers. As electrode materials, redox-active TMOs facilitate charge storage through redox processes at different length scales, from surface pseudo-capacitive-like behavior (i.e., surface process) to bulk battery-type ion intercalation (i.e., bulk process). Understanding these processes is crucial for optimizing energy storage and conversion devices due to their coexistence in real applications. However, the significant kinetic differences between surface and bulk processes pose challenges for explicit deconvolution and quantitative analysis. Although recent studies combining operando physical characterizations with electrochemical testing have shown promise in visualizing and validating the kinetic behaviors of surface and bulk processes, there remains a lack of methodologies that can simultaneously provide a quantitative interpretation of these processes based on physico-electrochemical responses within a unified physical framework. This framework requires a refined electrochemical model capable of accurately reconstructing the overall redox-active behavior by properly describing the individual contributions of surface and bulk processes. Achieving this level of precision remains a significant challenge for existing models.

In this study, we propose an integrated approach that combines operando electrochemical and optical techniques to disentangle the contributions of surface and bulk processes. Using birnessite δ-MnO_{2-x} *as a model system, we account for surface pseudo-capacitive-like layers (denoted as* L_{Surf}*) and employ a refined model that incorporates both the kinetic parameters of surface reaction rate (denoted as k) and bulk chemical diffusion coefficient (denoted as D). This methodology enables the deconvolution of electrochemical and optical responses corresponding to surface and bulk processes based on the same set of kinetic parameters, thereby precisely elucidating the variations in electrochemical kinetics and operando optical properties for each process within a consistent physical framework. Our method provides a robust framework for investigating the complex interplay of kinetic factors in redox-active TMOs, offering valuable insights for designing and optimizing a wide range of electrochemical technologies.*

EN08.11.37
A Novel Biphasic O3/P2 Layered Na-Transition Metal Oxide Based Cathode with Earth Abundant T_M***-Ions with Long-Term Cyclic Stability for Na-Ion Batteries***

Sravan Kumar Bachu, Hugh B. Smith and Iwnetim I. Abate; Massachusetts Institute of Technology, United States

Layered transition metal oxides cathodes are ideal candidates for high energy density commercially deployable

Na-ion batteries. While O3-type layered $Na_xT_MO_2$s (T_M => transition metal ion) with high starting Na-content (of ~1 per formula unit; x) offers high specific capacity, they suffer from cycling instability. On the other hand, P2-type layered $Na_xT_MO_2$s exhibits better electrochemical cycling and environmental stability but have lower Na-content, which would hinder their specific capacity in Na-ion full cells. Combining the synergistic effects of both, the present work aims to design and develop a high Na-content Bi-phasic O3/P2 $Na_xT_MO_2$ composition with different phase fractions by varying the calcination temperature. A novel biphasic O3/P2 Fe-Mn based $Na_xT_MO_2$ been successfully synthesized via solid state, exhibited the first discharge capacity of ~178 mAh/g with an exceptional cycling stability of ~90% capacity retention after 100 cycles at C/10 in a voltage window of 1.5-4.2 V vs. Na/Na^+. Furthermore, the exceptional cycling stability exhibited by this material is also supported by negligible phase transformations and volume change during electrochemical cycling as observed in in-situ synchrotron XRD studies. The electrochemical performance of the as-developed cathode material was also investigated in Na-ion 'full' cell configuration by coupling with commercial hard carbon based anode. The Na-ion 'full' cells have exhibited a 1st cycle reversible capacity of ~160 mAh/g with an average voltage of ~3 V, almost comparable to that of LFP/graphite 'full' cells (~150 mAh/g; 3.2 V), which is a significant step forward towards the commercialization of this material. In summary, this work demonstrates the successful development of Fe-Mn based O3/P2 biphasic cathode with an appropriate phase fractions exhibiting exceptional cycling performance both in Na-ion 'half' and 'full' cells.

EN08.11.38

Building a Rechargeable Voltaic Battery Via Reversible Oxide Anion Insertion in Copper Electrodes *Jose F. Florez Gomez, Songyang Chang and Xiangyong Wu; University of Puerto Rico at Rio Piedras, United States*

Voltaic pile, the very first battery built by humanity in 1800, plays a seminal role in battery development history. However, the premature design leads to the inevitable copper ion dissolution issue, which dictates its primary battery nature. To address this issue, solid-state electrolytes, ion exchange membranes, and/or sophisticated electrolytes are widely utilized, leading to high costs and complicated cell configuration. Herein, we build a rechargeable zinc−copper voltaic battery from simple and cheap electrolyte/separator materials, thus eliminating the need to use the above components. Notably, our battery leverages the Zn4SO4(OH)6.xH2O precipitation in ZnSO4 electrolytes, a common side reaction in zinc batteries, to provide a "locally alkaline" environment for copper electrodes. Consequently, oxide (O2−) anion insertion takes place and readily transforms copper to copper(I) oxide (Cu2O) without any copper ion dissolution issue. Therefore, this battery realizes a high capacity of ∼370 mA h g^{-1} and a long cycling of ∼500 cycles. Our work provides an innovative approach to stabilize anion insertion in metal electrodes for energy storage.

EN08.11.39

Boosting Stability and Storage Capacity of Prussian White Cathodes Using Carbon Nanotube Composites in Sodium-Ion Batteries *Wangchae Jeong, Inbeom Lee and Jaekook Kim; Chonnam National University, Korea (the Republic of)*

This study presents a new cathode material for sodium-ion batteries (SIBs), specifically a Prussian white ($Na_2MnFe(CN)_6$) combined with carbon nanotubes (PW–CNT), synthesized using a chelating-agent-assisted co-precipitation technique to manage defect formation and enhance electrochemical stability. Traditional Prussian white cathodes used in SIBs face several issues such as excessive lattice defects, irreversible phase changes, and structural instability, which result in inconsistent performance. Our research introduces a novel method for synthesizing cathode materials by integrating carbon nanotubes (CNTs) and a chelating agent, which play crucial roles in regulating moisture levels during the formation process.

Incorporating CNTs into the synthesis creates a conductive carbon framework that not only maintains the *structural stability of the cathode but also improves its electrochemical properties by enabling more efficient electron and ion transport. The chelating agent used in the process helps control the moisture content, a critical factor that influences defect formation and the overall stability of the material.*

The electrochemical performance of the PW–CNT composite cathode was extensively evaluated in SIB setups. The cathode demonstrated an impressive reversible capacity of 133 mAh g$_{-1}$ at a discharge rate of 10C, which is nearly 30% higher compared to conventional Prussian white cathodes and about 1.2 times greater than traditional Prussian blue cathodes. This substantial increase in capacity highlights the effectiveness of the combination of the Prussian white matrix with carbon nanotubes, further improved by the moisture-regulating properties of the chelating agent.

Additional testing of the PW–CNT composite cathode in a coin-type full cell with a hard carbon anode showed outstanding long-term cycling stability, with the cathode retaining around 58% of its initial capacity after 1500 cycles at a 1C rate. This durability indicates the material's robustness and its potential for long-term energy storage applications.

This research not only advances our understanding of how material composition, synthesis conditions, and electrochemical performance interact in battery technologies but also demonstrates the promise of the PW–CNT composite in significantly improving the reliability and efficiency of SIBs. By addressing the limitations of traditional Prussian white cathodes through advanced material engineering, this work lays the groundwork for future innovations in SIB technology, potentially leading to more efficient and sustainable energy storage solutions. The benefits of these advancements are broad, affecting applications such as electric vehicles, portable electronics, and grid energy storage, thereby underscoring the importance of cutting-edge cathode materials in the development of battery technology.

A High-Current Initiated Formation Strategy for Improved Cycling Stability of Anode-Free Lithium Metal Batteries

Kangning Cai[1,2]; [1]Tsinghua Shenzhen International Graduate School, China; [2]Tsinghua-Berkeley Shenzhen Institute, China

Anode-free lithium metal battery (AFLMB) is considered as one of the most promising candidates for next-generation high-energy-density rechargeable lithium battery. Improving the reversibility of lithium plating/stripping on bare anode current collector is the key to enabling AFLMB. Herein, we develop a high-current initiated formation strategy to improve the cycling stability of AFLMB by regulating the Li nucleation and growth behavior. A great number of ultrafine Li nanospheres with uniform and dense distribution are deposited on the anode current collector during the initial Li deposition at very high current density (10~30 mA cm^{-2}). These Li deposits serve as electrochemically active sites and manifest fast kinetics for lithium plating/stripping with enhanced exchange *current density, which successfully guide uniform dendrite-free Li nucleation/growth. Preferential decomposition of anions in the electrolyte under high current also induces the formation of robust inorganic-rich SEI, which facilitates the interfacial charge transfer and alleviates parasitic reactions. By simply changing the formation strategy, the average Coulombic efficiency of Li||Cu half cells is elevated from 96.8% to 98.5% at 1 mA cm^{-2} for 200 cycles and the capacity retention of Cu||LiFePO$_4$ anode-free cell is impressively improved from 34.5% to 54.7% after 100 cycles. Besides, the time consumed for formation process is effectively reduced by 10.5% after adopting the high-current initiated formation strategy, which could greatly improve the formation efficiency and holds great potential for practical application in AFLMB.*

EN08.11.41

The Importance of Achieving Intimate Contact In All-Solid-State Batteries *Dongkyu Lee and Dong-Joo Yoo; Korea University, Korea (the Republic of)*

All-solid-state batteries (ASSBs) have gained significant interest as an attractive alternative to traditional lithium-ion batteries (LIBs) due to their improved safety and potential for higher energy density. Among the various types of solid electrolytes (SEs) including oxide-based and polymer SEs, sulfide-based SEs have attracted the most attention, largely due to their high ionic conductivity and electrochemical stability. However, the commercialization of ASSBs is being hindered by several unresolved challenges, namely various side reactions at electrode-electrolyte interfaces, dendritic behaviors at the anode, and poor interfacial contact. To note, the contact issue is unique to ASSBs compared to LIBs, and therefore has not been investigated deeply. While the high ductility of the sulfide-based SEs enables plastic deformation of SE particles to fill the voids between SE particles, when SEs contact materials of higher strength, the lack of deformation in SEs leads to the formation of voids at material interfaces. Herein, the impact of intimate contact in sulfide-based ASSBs is highlighted. By investigating pellet, wet-processed, and dry-processed electrodes, we quantified a crucial factor, 'coverage' – the areal ratio between SE-contacted CAM surfaces to the CAM surfaces. Coverage is a key factor since lithium-ion can only be conducted through SEs to be intercalated into the CAM. Through a simplified single-particle two-dimensional electrochemical model, we were able to visualize the effects of coverage on the behaviors of lithium-ions inside the CAM during operation. In cases of low contact coverage, especially at high C-rates, the lithium-ion kinetics are limited by solid-state diffusion within the CAM particles, rather than by ionic conduction at SEs. Electrochemical tests were conducted to demonstrate the effects of coverage on internal resistances and rate capabilities in lab-scale pressure-cells, hence emphasizing the importance of intimate contact at the CAM-SE interface.

Intimate contact at the lithium metal-SE interface is less challenging to achieve compared to the cathode side owing to the decent ductility of lithium metal. However, incorporating bare lithium metal as the anode material is very challenging due to the dendritic growth of lithium metal. To suppress this, many studies have been conducted to introduce a protective layer between the anode-SE interface, including metallic, organic, and inorganic layers. Here, we were able to fabricate a compact nano-silicon (nSi) layer through in-situ lithiation sintering. One of the key features of the nSi layer is the of intimate contact at the nSi-SE interface induced by the compact layer. The nSi-Li layer enables a very reversible stripping/plating of lithium metal with exceptional critical current density (CCD) and areal capacity, proven through electrochemical analyses at a pouch-cell scale. In contrast, the composite layer fabricated using micro-silion (μSi) did not achieve the same level of enhancement as the nSi layer. Through a two-dimensional electrochemical model, we were able to attribute one of the reasons behind the disparity in performance to the degree of intimate contact. The limited contact induces high localized current densities, resulting in a shorter cyclability and lower CCD. In conclusion, these studies highlight the importance of achieving ideal morphological traits in ASSBs by modifying fabrication processes and material selection, with the specific focus on achieving intimate contact at both the CAM-SE interfaces and the protective layer-SE interface.

EN08.11.42

Hybridization of Ester Solvents for Wide-Temperature Operation Lithium-Ion Batteries *Soung Jin Yang and Dong-Joo Yoo; Korea University, Korea (the Republic of)*

Carbonate-based electrolytes are commonly used in commercial Li-ion batteries (LiB). However, due to high melting point and de-solvation energy of carbonate solvents, such as Ethylene Carbonate (EC), Li-ion diffusion and charge transfer kinetics become sluggish at low temperatures. Herein, we introduce hybrid solvent with ester and ether functional group for wide temperature range operation. The unique oxygen spatial arrangement of such solvents allows for higher degree of electron-withdrawing effect compared to standard carbonates, leading to weaker binding energy with Li-ions. With the low melting point of hybrid solvents, the low solvation energy of hybrid solvents allows for faster charging even at subzero temperature. Several types of hybrid solvents were also investigated by changing the molecular weight, with different impact towards cell performance.

EN08.11.43

Probing Oxygen Redox and Charging Mechanism of LiNiO$_2$ *Jun Chen[1], Mikkel Juelsholt[2], Robert House[1] and Peter G. Bruce[1]; [1]University of Oxford, United Kingdom; [2]Columbia University, United States*

The demand of high-energy lithium-ion batteries boosts the interest in increasing Ni content in cathodes and/or raising charge cutoff voltage. In the drive to minimize the Co content from these cathodes, it is critical to understand the behaviour of the ultimate Ni-rich archetype, LiNiO$_2$. Substantial efforts have been made to understand the structural transitions of LiNiO$_2$ when Li is extracted, but there remains considerable debate over the extent of Ni oxidation and O-redox in LiNiO$_2$, particularly across the voltage plateau at 4.2 V. Herein, we perform a structural and spectroscopic study of LiNiO$_2$ to probe the extent of O-redox and determine its mechanism. We employ combined neutron and synchrotron X-ray powder diffraction analysis that takes account of the stacking faults, and quantified the Ni vacancies formed when the material is charged across the voltage plateau. Chemical analysis shows that the Ni absent from the bulk does not leave the particles. While in principle there is sufficient Ni$^{3+/4+}$ oxidation capacity to account for all the Li$^+$ removed on charge without O^{2-} oxidation, high resolution resonant inelastic X-ray scattering (RIXS) at the O K-edge confirms the presence of trapped molecular O$_2$, on charging across the plateau, which is accommodated Ni vacancy clusters. The atomic-resolution annular dark-field scanning transmission electron microscopy (ADF-STEM) demonstrates the core-shell nature of the charged particles, with a Ni-rich Rocksalt like shell approx. 5 nm thick. Ni L-edge XAS measurements in fluorescence yield mode implies the average oxidation state of Ni of less than +4, coexisting with the presence of O-redox at the top of charge whilst it does not necessarily imply the latter commences on charging before Ni is oxidised to +4. This offers comprehensive insights of structural and chemical behaviours of highly charge LiNiO$_2$ in lithium-ion batteries.

EN08.11.44

Laser-Graphitized Carbon Fiber-Based Stand-Alone Electrodes for High Performance LMFP Battery *Ritu Kumar and Mohini Sain; University of Toronto, Canada*

We report a novel approach for developing high-performance lithium manganese iron phosphate (LMFP) batteries featuring copper and aluminum current collector-free stand-alone electrodes. Utilizing graphite/carbon fiber and LMFP/carbon fiber, these electrodes are fabricated through a laser graphitization process combined with spray coating techniques. This innovative design reduces reliance on critical minerals like copper and aluminum while significantly enhancing the battery's overall energy density (a 23% increase), reducing weight (a 28% reduction), and lowering costs compared to conventional batteries with copper and aluminum current collectors. The battery, constructed in a highly flexible pouch cell format, demonstrates superior mechanical flexibility and improved electrochemical performance, particularly at elevated C-rates. It maintains over 80% capacity retention after 150 *cycles, indicating robust long-term stability. The introduction of this carbon fiber-based electrode structure, alongside the spray coating process, marks a significant advancement in battery technology, providing a forward-looking solution for efficient, flexible, and sustainable energy storage applications.*

EN08.11.45

Enhanced Electrochemical Performance of $Na_3V_{1.5}Cr_{0.4}Fe_{0.1}(PO_4)_3$ NASICON Cathode for High-Rate Sodium-Ion *Yesom Park, Sang bin Lee and Jaekook Kim; Chonnam National University, Korea (the Republic of)*

The increasing demand for sustainable energy storage systems has drawn significant attention to sodium-ion batteries (SIBs) as a viable alternative to lithium-ion batteries, due to the abundance and low cost of sodium resources. One of the key challenges in SIB development is the improvement of cathode materials, which typically suffer from lower ionic mobility and electronic conductivity. In this study, we developed a NASICON-structured $Na_3V_{1.5}Cr_{0.4}Fe_{0.1}(PO_4)_3$ (NVCFP) cathode material by dual-doping vanadium phosphate ($Na_3V_2(PO_4)_3$, NVP) with chromium (Cr) and iron (Fe). The dual-doping strategy significantly enhances the electrochemical performance of the material, particularly its high-rate capability and cycling stability.
NVCFP exhibited a discharge capacity of 71 mAh g^{-1} at a high current rate of 100 C and retained 95% of its initial capacity after 10,000 cycles. The improved performance is attributed to the synergistic effects of Cr and Fe co-doping, which enhance both structural stability and electronic conductivity. Cr doping facilitates a reversible V^{3+}/V^{5+} redox reaction at high voltage, improving the stability of the NASICON framework, while Fe doping introduces new electronic conduction pathways, boosting the overall conductivity of the material. Rietveld refinement and synchrotron X-ray diffraction (XRD) confirmed the successful incorporation of Cr and Fe into the crystal structure without compromising the phase purity of the material.
Density functional theory (DFT) calculations and electrochemical impedance spectroscopy (EIS) showed that NVCFP has lower charge-transfer resistance and improved Na^+ ion diffusion kinetics compared to undoped NVP. The material also demonstrated a lower energy barrier for Na^+ ion migration, contributing to its enhanced high-rate performance. Cyclic voltammetry (CV) results further indicated that NVCFP has a high pseudocapacitive contribution, particularly at high scan rates, making it suitable for high-power applications.
In full-cell configurations with a hard carbon anode, NVCFP demonstrated superior initial discharge capacity and cycling stability compared to undoped NVP. These findings highlight the potential of $Na_3V_{1.5}Cr_{0.4}Fe_{0.1}(PO_4)_3$ as a high-performance cathode material for sodium-ion batteries, offering a promising pathway for the development of large-scale, cost-effective energy storage systems.

Optimizing O3-Type Fe-Mn-Based Cathodes for Na-ion Batteries—Unveiling the Synergistic Impact of Chemical Co-Substitution *Arindam Ghosh, Rashmi Hegde, Keshav Kumar and Premkumar Senguttuvan; JNCASR,* *India*

Layered transition metal oxide-Na_xMO_2 (M = transition metal) is the most widely explored class of cathode materials in lithium and sodium-ion batteries (LIBs and SIBs).[1] The replacement of expensive Co and Ni with cheaper elements like Fe and Mn is appealing which can reduce the overall cost of the battery. Despite the higher operating voltage of Fe^{3+}/Fe^{4+} and the large specific capacity of Mn^{3+}/Mn^{4+}, issues like irreversible Fe-migration and Jahn-Teller distortion associated with Mn^{3+}/Mn^{4+} redox are yet to be overcome.[2,3] To improve the electrochemical performances, various cations (e.g., Li^+, Cu^{2+}, Mg^{2+}, Zn^{2+}, and Ti^{4+}) are partially substituted in the place of M.[4–6] Along this line, in search of better Fe-Mn-based cathodes, we selected an O3-type $Na[Fe_{0.50}Mn_{0.50}]O_2$ (NFMO) material and co-substituted Li^+ and Cu^{2+} in the transition metal layer to create a composition of $Na[Li_xCu_yFe_{0.50-(x+y)}Mn_{0.50}]O_2$ (NCLFMO) and compared their electrochemical performances. Both materials crystalize in a rhombohedral structure and Rietveld refinement and TEM analyses suggest an enhanced O-Na-O distance after the substitution. The NFMO and NLCFMO cathode display a capacity of 135 and 121 mAh g^{-1} in the potential window of 4.0-2.0 V vs Na^+/ Na^0 at 0.1 C rate, with an average voltage (V_{avg}) of 2.63 V and 3.31 V respectively, which leads to an increased energy density of 400 Wh kg^{-1} for NCLFMO.[7] Following the substitution, the capacity contributions of Mn and Fe become 20.2% and 79.8%, respectively, instead of 49.8% and 50.2% in NFMO. Clearly, it indicates a pronounced Fe^{4+}/Fe^{3+} redox along with a suppressed Mn^{4+}/Mn^{3+} redox activity. Additionally, chemical co-substitution significantly improves capacity retention, with NCLFMO retaining 98% of its initial discharge capacity after 500 cycles compared to 52% for NFMO. Faster Na^+-ion diffusivity from the galvanostatic intermittent titration technique (GITT) and reduced cell resistance from impedance spectroscopy support the enhanced performances of NCLFMO cathode. In-situ XRD measurement reveals a reversible O3-P3-O3 phase transition during cycling and ex-situ x-ray absorption spectroscopy analysis confirms a prominent Fe^{4+}/Fe^{3+} redox with a suppressed Mn^{4+}/Mn^{3+} redox during charge-discharge cycling. More significantly, NCLFMO remains air-stable, retaining its structure and electrochemical properties after exposure to air for 30 days. Finally, a full cell with precycled HC is fabricated, delivering a capacity of 105 mAh g^{-1} with a V_{avg} of 3.15 V in the potential window of 4.0-1.5 V at a 0.1 C rate. In conclusion, the (Li^+ + Cu^{2+})-co-substitution strategy improves the overall performance of the Fe-Mn-based layered oxide cathode, paving the way for developing better cathodes for commercial SIBs.

High-Performance Sn-TiC/C-CNTs Composite Anode for KIBs—Stress Mitigation and Electrochemical Performance Enhancement *Inbeom Lee, Wangchae Jeong and Jaekook Kim; Chonnam National University, Korea (the Republic of)*

As the global demand for lithium-ion batteries (LIBs) continues to rise, potassium-ion batteries (KIBs) have emerged as a promising alternative due to the abundance and low cost of potassium. However, the development *of efficient KIB anode materials faces significant challenges, particularly in managing large volume changes and stress propagation during cycling.*

This study investigates the potential of Sn-TiC/C-CNTs composite anodes to address these issues, focusing on the mitigation of stress propagation and improvement of electrochemical performance. Using high-energy ball milling, Sn particles were combined with a TiC/C-CNTs matrix to form a robust composite with enhanced mechanical and electrical properties. The inclusion of carbon nanotubes (CNTs) and titanium carbide (TiC) in the matrix improves electrical conductivity and mitigates microcrack formation, resulting in better cycling stability and capacity retention compared to pure Sn anodes.

The Sn-TiC/C-CNTs composite exhibited a reversible capacity of 315.89 mAh g^{-1} after 50 cycles, showing significant improvement over Sn and Sn-TiC/C anodes. Detailed electrochemical tests, including cyclic voltammetry and impedance spectroscopy, confirmed the superior performance of the Sn-TiC/C-CNTs anode, highlighting its potential for high-performance KIBs.

Theoretical modeling and phase analysis further elucidated the underlying mechanisms of stress relaxation and volume expansion management within the composite anode. This study demonstrates that the integration of Sn with TiC/C-CNTs matrix provides a promising strategy for enhancing the stability and performance of alloy-type anodes in KIBs, paving the way for the development of more reliable and efficient potassium-ion batteries.

EN08.11.48

Electrochemical Performance of Lithium-Ion Batteries Using Si-Based Alloys as Anode Materials

Jong-Min Seo[1], Jeong-Yun Yang[1], Eun Seok[1], Jae-Won Kim[2], Ji-Yong Kim[2], Jaewook Sung[2], Soong-Keun Hyun[2] and Goo-Hwan Jeong[1]; [1]Kangwon National University, Korea (the Republic of); [2]Inha University, Korea (the Republic of)

Silicon (Si) is a promising element as an anode material for lithium-ion batteries (LIBs) due to its exceptionally high theoretical capacity (~3579 mAh/g). However, in practical applications, Si anodes face significant challenges due to substantial volume expansion (~300 %) during lithiation, which leads to structural degradation and rapid capacity fading. We present here an innovative approach to the development of Si-based alloys as anode materials synthesized by a melt spinning process. Finally, we propose a unique approach to significantly enhance electrochemical performance.

In this study, we introduced a copper (Cu) as an alloying element into the silicon matrix for the purpose of enhancing electrical conductivity and structural stability, and reducing the volumetric change that occurs during cycling. The melt spinning (MS) process ensures the uniform distribution of Cu within the silicon matrix by rapid quenching of molten Si alloys. We optimized the size of inclusions affecting enhanced structural stability of the Si alloys by mitigating volumetric changes during charge-discharge cycles. Furthermore, we anticipate that the addition of Cu will improve electric conductivity, as the melt spinning process can yield a homogeneous Cu dispersion with fine microstructures. This should suppress the capacity fading typically observed in traditional silicon anodes due to their volume expansion during the cycling.

Following the MS synthesis of the Si-based alloys, ball milling was employed to produce small and uniform particles with an optimized particle size of 5.6 μm (D50). Structural characterization using scanning electron microscopy (SEM) and X-ray diffraction (XRD) revealed the formation of fine intermetallic particles, which will provide enhanced mechanical stability to the silicon matrix. The electrochemical characterization was performed *using galvanostatic charge-discharge tests with the Si alloy-graphite composite electrode in a 2023 coin-type cell. The Si alloy demonstrated an initial reversible capacity of 505.6 mAh/g at a current density of 0.2C, with a coulombic efficiency of 92.75%. The cell demonstrated high cycling stability, retaining over 88% of its initial capacity after 30 cycles. The addition of Cu to the alloy matrix has resulted in enhanced charge transport and reduced volume expansion, thereby enhancing the overall structural integrity of the anode materials as expected. This study demonstrates that Cu-containing Si alloys produced by the MS technique enhance the electrochemical performance of LIBs. The incorporation of Cu has proved beneficial in improving both electrical conductivity and structural stability, particularly by alleviating volume expansion issues of the anode. This has resulted in enhanced cycling stability and capacity retention. The present work demonstrates that Cu-containing Si alloys are well-suited for high-performance LIB applications. Further work is underway, with a focus on the further development of Si alloys and the scale-up of the melt spinning process for commercial production.*

EN08.11.49

Effects of Magnesiothermic Reduction Process on SiO_x Anode Materials for Lithium-Ion Batteries *Jeong-Yun Yang, Eun Seok and Goo-Hwan Jeong; Kangwon National University, Korea (the Republic of)*

As regulations on internal combustion engine vehicle have been tightened due to the recent climate crisis, the development of lithium-ion batteries (LIBs) and other electric vehicle batteries is actively undergoing. A LIB consists of an anode, a cathode, an electrolyte, and a separator. Among them, high capacity and energy density in the anode materials are crucial for development. Graphite has been used as a representative anode material, allowing Li insertion and extraction during charging and discharging. However, its energy density improvement is limited by its low theoretical capacity (372 mAh/g). Thus, there is an ongoing need to develop high performance anode materials.

Silicon has a theoretical capacity about 4,200 mAh/g much higher than that of graphite. However, a critical issue with Si anodes is capacity reduction due to significant volume expansion and contraction (300% or more) during the alloying and dealloying processes of Li. To address this challenge, extensive studies has been dedicated to silicon-based anode materials. Among these, the synthesis of SiO_x ($0 < x < 2$) particles have attracted much attention due to their ease of synthesis, high chemical and structural stability, and reasonable cost. Additionally, the expansion issue in anode materials is mitigated by the formation of lithium oxides during the initial charging/discharging cycles.

We utilized a magnesiothermic reduction reaction (MRR) process, a widely used method for synthesizing silicon oxide particles. The reaction, $SiO_2 + 2Mg \rightarrow Si + 2MgO$, involves the simple mixing and reduction of SiO_2 particles with Mg powder, producing SiO_x ($0 < x < 2$) particles. Since the reaction is exothermic, SiO_2 can be converted to SiO_x ($0 < x < 2$) at a lower temperature compared to conventional methods. Additionally, the reduction process results in smaller SiO2 particles, which can alleviate volume expansion during cycling and potentially extend the lifespan of LIBs by reducing structural degradation in anode electrodes.

We synthesized SiO_x particles through the MRR process and employed them as an anode material for high-capacity LIBs. Sodium silicate solution and tetraethyl orthosilicate were employed as precursors for SiO_2. Spherical SiO_2 particles, approximately 100-500 nm size, were synthesized using a sol-gel method. After mixing the synthesized SiO_2 with Mg power, SiO_x ($0 < x < 2$) particles were obtained through the MRR process under an argon and hydrogen gas mixture. Standard characterization methods, such as SEM, XRD, Raman spectroscopy, and XPS, were used to analyze the particle's shape, crystallinity, and chemical composition.

After optimizing the anode composition of graphite and SiO_x particles, we fabricated a half-cell for electrochemical characterization. We observed a significant increase in initial discharge capacity with the increase of reduction temperature. Finally, we will present a comprehensive analysis of the relationship between silicon content in the particles, charge capacity, and capacity retention rate to elucidate the effects of the MRR process.

EN08.11.50

Visualizing Na Metal Plating and Solid Electrolyte Failure in Seawater Batteries *Jihun Cho and Youngsik Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Among the various types of batteries, the rechargeable seawater battery (SWB) has emerged as a promising alternative to lithium-ion batteries due to its limitless capacity, cost-effectiveness, and thermal stability, all facilitated by the abundant seawater cathode. To take advantage of the extremely high cathode capacity, SWBs consider using sodium (Na) metal as an anode material, which offers superior specific capacity and the lowest potential level. However, metal plating at high rates can lead to the formation of metal dendrites, resulting in the failure of the ceramic NASICON solid electrolyte and eventually causing a short circuit in the SWB.

In previous research on seawater batteries, several strategies have been proposed to suppress metal dendrites. Firstly, using liquid electrolytes facilitates contact between the metal and solid electrolyte. This prevents the localized increase in current, which is common with poor solid/solid contacts, thereby effectively inhibiting the growth of metal dendrites.

Secondly, employing anolyte (NaBP) which has an intrinsic redox potential is another approach. This anolyte participates directly in the redox reactions, suppressing side reactions and SEI layer formation, which in turn prevents localized metal growth. Additionally, the high electronic conductivity of NaBP allows the dissolution of dead metal separated from the electrode during the discharge process, improving the Coulombic efficiency and reversibility of the metal anode.

Although these strategies are effective in suppressing metal dendrites, the problem of solid electrolytes breaking due to metal dendrites still occurs. To further suppress this issue, it is necessary to understand the metal dendrite features in seawater batteries. Particularly on the anode side of seawater batteries, multiple interfaces exist, and the appropriate strategy may vary depending on the interface causing the problem.

In this study, the metal dendrites of seawater batteries (SWB) are primarily investigated using X-ray computed tomography (XCT) visualization, which can directly reveal the failure state. The results show that metal plating occurs at the NASICON/liquid electrolyte interface, and high-current plating leads to uneven metal accumulation. These plating phenomena are discussed in the context of the charge transfer pathway in SWBs, particularly focusing on the role of the electro-conductive liquid anolyte. The principles of mechanical failure in NASICON solid electrolytes are also described, referencing prior research on all-solid-state batteries. Consequently, we suggest a potential solution to prevent dendrite failure at high current densities, which primarily targets the release of metal accumulation on the NASICON surface.

EN08.11.51

A Self-Healing and Recyclable Polyurethane-Based Solid-State Polymer Electrolyte Enabled by a Diels-Alder Dynamic Network *Xiaoyu Du; University of Puerto Rico, China*

Compared with liquid electrolytes, solid-state polymer electrolytes (SPEs) with better thermal, mechanical stability and processablilty are urgently required for the development of next-generation flexible energy storage devices. Herein, a series of polyurethane-based solid polymer electrolytes (PUBSPE) with cross-linking structure were prepared by Diels-Alder reaction. The hydrogen bonding between the urea groups and dynamic Diels-Alder reaction endows the solid polymer electrolyte with excellent self-healing ability without external stimuli at room temperature. The PUBSPE also displays good liquid affinity and superior recyclable properties, which provide a practical idea for the design of multifunctional polymer electrolytes. Although the cross-linking solid polymer electrolytes films display unsatisfied ionic conductivity about 10 S cm at 60°C, the ionic conductivity value of the self-healing and recycled PUBSPE were close to their pristine one. The wide working voltage window of PUBSPE (>5.0 V) indicate that they can meet the requirements of most cathode materials. Moreover, the Li|PUBSPE|LiFePO maintained a good coulombic efficiency (> 98.0 %) throughout all the cycle at 60°C, and the flexible cells can *successfully light the blue diode under harsh conditions. This work provides new insights and concepts to design flexible, reliable, and safe polymer electrolytes for electronic devices at high-temperature*

EN08.11.52

In-Situ Acrylate Polymerization in 3D Porous Single-Ion Polymers for Superior Lithium-Metal Battery Performance *Tapabrata Dam, Asif Javid and Chan-Jin Park; Chonnam National University, Korea (the Republic of)*

Incorporating polymer-based solid electrolytes into next-generation lithium-metal batteries (LMBs) is crucial for enhancing energy density and improving safety. Polymer electrolytes offer several advantages, including cost-effectiveness, ease of processing, improved mechanical properties, flexibility, shape moldability, and stability at higher voltages. However, challenges such as inadequate ionic conductivity at ambient temperatures, anion polarization, and a low Li^+ ion transport number hinder the development of polymer-based solid electrolytes. To address dual-ion conduction, single-ion conductive polymers (SICPs) have emerged as a promising alternative, where only lithium ions migrate, resulting in a higher lithium-ion transference number. Despite their potential, SICPs face challenges like complex synthesis, poor film-forming properties, and limited ionic conductivity due to reduced lithium-ion dissociation, which restrict their use in LMBs. In contrast, ether oxygen-rich polymers, such as polyethylene oxide and poly(dioxolane), are widely employed for their ability to effectively dissociate salts, enhancing conductivity.

In this study, we investigate a combination of SICPs and ether polymer network (EPN)-based separators to overcome challenges in polymer electrolyte membranes by leveraging the advantageous properties of each polymer type. The combination of a 3D network-based SICP and an EPN electrolyte membrane ensures consistent distribution of Li^+ ion source sites and ion-conducting segments, promoting delocalized Li^+ transport. The partially sulfonated PVDF-HFP-based SICP and ether oxygen-containing EPN enhance ionic conductivity, electrochemical stability, and mechanical strength. The optimized SICP-EPN membrane achieves an ionic conductivity of ~10^{-4} S cm^{-1}, an electrochemical stability window of 4.9 V, and a lithium-ion transference number of ~0.6 at 30 °C. Dynamic mechanical analysis reveals a storage modulus of approximately 1 MPa. In Li│SICP-EPN│NCM811 coin cells, the specific discharge capacity reaches 122 mAh g^{-1} after 250 cycles at a C/2 rate and 30 °C, with a capacity retention of 82% and an average Coulombic efficiency of 99.4%. Interfacial studies indicate an organic-inorganic mixed interface layer, where the top surface consists mainly of organic components, providing flexibility, while the bottom surface contains inorganic-rich compounds such as Li_3N and LiF, which enhance mechanical strength and lithium-ion transport properties.

This work represents a significant advancement in developing cost-effective, high-energy-density LMBs with improved cycle life and safety. The in-situ polymerized SICP membrane addresses key challenges in LMB technology, including interfacial stability, lithium dendrite suppression, and ion transport efficiency. Furthermore, the methodology presented here can be extended to other battery chemistries and polymer electrolyte systems, offering a versatile platform for improving the performance of next-generation energy storage devices.

EN08.11.53

Fluorine Segment Integrated Copolymer Electrolyte for Enhanced Electrochemical Stability in High-Voltage Lithium Metal Batteries *Asif Javid, Wu-Young Goh and Chan-Jin Park; Chonnam National University, Korea (the Republic of)*

In recent years, the increasing application of secondary batteries in electric vehicles (EVs), portable electronics, and flexible wearable devices has driven the demand for innovations in high-energy-density batteries. Lithium metal batteries (LMBs) incorporating solid-state polymer electrolytes (PEs) are promising candidates for meeting the growing energy needs of advanced energy storage systems. However, polymer electrolytes face several challenges, including low ionic conductivity, a narrow electrochemical stability window, and interfacial instability,

which limit their compatibility with high-voltage cathode materials in LMBs.
This study presents a novel strategy to overcome these limitations by tailoring the polymer backbone at the molecular level, thereby enabling highly tunable chemical functionalities. A fluorine-functionalized copolymer was synthesized via in-situ polymerization, composed of polyethylene glycol methyl ether acrylate (PEGMEA) and 2,2,2-trifluoroethyl methacrylate (TFEMA). The copolymers with fluorinated functionality exhibit high oxidation resistance, exceeding 5 V vs. Li/Li$^+$, and promote the formation of an inorganic-rich hybrid interphase. Electrochemical assessments demonstrate that the optimized fluorinated copolymer achieves an ionic conductivity of 0.329 mS cm^{-1} and a lithium-ion transference number of 0.64 at ambient temperature, attributed to the anion immobilization effect. The Li│PE│NCM811 cell, assembled via in-situ polymerization, delivers a specific discharge capacity of 181.5 mAh g^{-1} at a 0.1C rate and maintains a capacity retention of 84.41% with an average Coulombic efficiency of 99.4% after 150 cycles at 0.5C. Additionally, the Li│PE│Li symmetric cell demonstrates stable cycling performance for over 1000 h. This work introduces a new approach for the rational molecular design of polymer electrolytes, achieving excellent electrochemical properties suitable for high-voltage lithium metal batteries.

EN08.11.54

Composite Polymer Electrolytes with Li_2SO_4-Infused 3D SiO_2 Fillers for Enhanced All-Solid-State Battery Performance *Min-Ho Lee, Seung-Ju Baek and Chan-Jin Park; Chonnam National University, Korea (the Republic of)*

The growing adoption of electric vehicles (EVs) has significantly increased the demand for energy-dense and safe lithium-ion batteries (LIBs). Although conventional LIBs with organic carbonate-based liquid electrolytes are widely used, they present serious safety concerns, such as short circuits, electrolyte leakage, and thermal runaway. Solid-state batteries (SSBs) have emerged as a promising alternative, with composite polymer electrolytes (CPEs) attracting attention due to their ability to combine the mechanical strength of ceramic materials with the flexibility of polymers, thereby enhancing thermal stability and energy density. The incorporation of ceramic fillers into polymer electrolytes helps to address key challenges such as low ionic conductivity at room temperature and poor interfacial contact between the electrode and electrolyte.
In this study, we developed a cost-effective and highly conductive CPE system by integrating a three-dimensional ceramic framework filler with fiber-shaped Li_2SO_4/SiO_2. Ether oxygen-based polymers are known to improve ionic conductivity due to their ability to readily dissociate salts. Here, we employed a 1,3-dioxolane monomer as a precursor to synthesize the polymeric matrix, which synergistically enhances ionic conductivity at room temperature. The thermally activated in-situ polymerization process reduces interfacial resistance at both the solid electrolyte and cathode-electrolyte interfaces.
The developed CPE exhibits excellent electrochemical properties, including a high ionic conductivity of 0.29 mS cm^{-1} at room temperature, a lithium-ion transference number of 0.68, and electrochemical stability up to 4.91 V vs. Li/Li$^+$ at 30 °C. These characteristics are crucial for ensuring the long-term stability and high efficiency of solid-state lithium metal batteries (SS-LMBs). A Li│CPE│$LiFePO_4$ cell demonstrated stable cycling performance, achieving a discharge capacity of 128 mAh g^{-1} after 200 cycles at a 0.5C rate and 30 °C, retaining 88% of its initial capacity. This high cycling stability, combined with favorable electrochemical characteristics, underscores the potential of the developed CPE for future applications in high-energy-density SS-LMBs.

EN08.11.55

Isovalent Multi-Component Material Design for Stabilizing Cubic-$Li_7La_3Zr_2O_{12}$ with Excellent Li Mobility *Han Uk U. Lee and Sung Beom Cho; Ajou University, Korea (the Republic of)*

The cubic phase of $Li_7La_3Zr_2O_{12}$ (LLZO) is promising candidate for replacing traditional liquid-state electrolytes, due *to their high ionic conductivity, high chemical stability to Li metal, and a wide electrochemical window. However, under ambient conditions, the tetragonal phase is the ground state, while the cubic phase can be stabilized above 650°C. To address this polymorphic issue, doping strategies have been widely attempted. However, conventional aliovalent dopants frequently results in a reduction in Li ion mobility and the induction of undesired phase transformations. In this study, we propose a novel multi-component doping strategy to stabilize the cubic phase of LLZO while maintaining high Li ion mobility. The practical isovalent ions and their combinations are screened using density-functional theory (DFT) calculations and ab-initio molecular dynamics (AIMD) simulations, identifying the most stable multi-component alloy configuration that can stabilize the robust cubic phase of LLZO. Our results demonstrate that the* $Li_7La_3(Zr, Hf, Ce, Ru)_2O_{12}$ *composition achieves a stable cubic phase at low temperatures, which we was further validated through experimental synthesis. This proposed doping strategy has the potential to advance the development of high-performance all-solid-state batteries.*

EN08.11.56

Tailoring Laminar Li_3VO_4 (LVO) for Superior Cycle Life (>6000 cycles) in Aqueous Zinc-Ion Batteries

Tejveer S. Anand, Aashish Joshi, Akshita Sharma, Amit Gupta and Madhusudan Singh; Indian Institute of Technology Delhi, India

Vanadate compounds like Li_3VO_4 *(LVO) exhibit vital properties that make them a compelling alternative to traditional MnO and Prussian blue analogues for aqueous zinc-ion batteries (AZIBs), owing to their structural stability, long cycle life, and superior capacity [1]. In this work, we employed a scalable surfactant-free sol-gel method, offering a more efficient synthesis route than conventional solid-state and hydrothermal techniques, to produce LVO with a laminar morphology [2]. To achieve the desired phase of LVO, ammonium metavanadate (Sigma-Aldrich) was dissolved in 2-methoxyethanol to form solution-P, while lithium acetate dihydrate was dissolved separately in the same solvent to create solution-Q. Solution-Q was dropwise added to solution-P with continuous stirring for 48 hours at 60 °C. The resulting gel was then annealed at 800°C for 4 hours to obtain a pure phase of LVO. Powder X-ray diffraction (XRD) confirmed that LVO crystallizes in an orthorhombic structure with the Pmn21 space group [3], and Rietveld refinement provided the lattice constants: a = 5.448 Å, b = 6.327 Å, and c = 4.949 Å. UV-Vis spectroscopy revealed that LVO possesses a broad band gap of 3.95 eV, characteristic of a semiconducting material. High-resolution transmission electron microscopy (HRTEM) and selected area electron diffraction (SAED) showed sharp diffraction spots, indicating high crystallinity and the presence of a laminar flake-like morphology observed from FESEM. For electrode preparation, the LVO active material was mixed with Super P carbon black, multi-walled carbon nanotubes (MWCNTs), and a PVDF binder in NMP solvent in a 7:2:1 ratio to form a slurry. This slurry was coated onto pre-carbonized carbon cloth (heated to 1300 °C under nitrogen) and dried under vacuum at 80 °C for 24 hours. The electrodes were punched out and assembled into CR2016 cells using an aqueous electrolyte composed of 2 M* $ZnSO_4$ *and 0.5 M* $Zn(CF_3SO_3)_2$ *in distilled water. Cyclic voltammetry (CV) tests on the LVO||Zn half-cell revealed one oxidation peak at 1.06 V and two reduction peaks at 1.03 V and 0.602 V at a scan rate of 0.1 mV/s. At a higher scan rate of 1 mV/s, a slight increase of 3.7 % in oxidation potential and a reduction potential deviation of -11.1%* (V^{5+}/V^{4+}) *and -1.9 %* (V^{4+}/V^{3+}) *were observed. A shouldered peak appeared at 1.22 V at 0.5 mV/s, possibly indicating a biphasic mechanism during the vanadium redox process. The LVO||Zn half-cell (mass loading ~1.28* mg/cm^2*) demonstrated an initial capacity (Biologic BC810 battery cycler/Neware) of 54.71 mAh/g with a coulombic efficiency (CE) of approximately 99.68% and retained a capacity of 36.81 mAh/g (CE ~ 99.87%) after 6000 cycles when cycled at 0.5 A/g between 0.15 V and 1.6 V. At a lower current density of 0.075 A/g, the cell exhibited a discharge capacity of 71.63 mAh/g (CE ~95.96%) and retained 61.09 mAh/g after 200 cycles. When cycled at 0.1 A/g for an additional 1000 cycles, the cell maintained a capacity of 56.27 mAh/g, achieving an overall retention of ~91 %. However, reducing the discharge potential from 0.15 V to 0.1 V caused a significant decline in capacity retention over 5000 cycles, with the cell delivering 186.72 mAh/g in the first cycle and retaining only ~26.6 mAh/g with an average CE of 99.73 %. Additional ex-situ studies, including time-of-flight* *secondary ion mass spectrometry (ToF-SIMS), are being conducted to investigate the spatial distribution of Zn-ions and various other fragments in solid-electrolyte interphase (SEI) layer for a more comprehensive understanding of the degradation mechanisms.*

Scale up of High Temperature Polyimide and Polyolefin Dielectrics, Film Processing and Testing *Mohak Desai[1], Jiahao Mao[2] and Jing Hao[1]; [1]University of Connecticut, United States; [2]Purdue University, United States*

Dielectric polymers used in electrical and electronic systems require withstanding high electric field and elevated temperature. o-polyoxachloronorbornene (o-POClNB) and polyetherimide (PEI) are two such polymers chosen for scaling up as they have demonstrated excellent dielectric performance at high electric field and high temperature (between 150°C to 200°C) operating range. These polymers have also high enough molecular weight to be able to make entanglements in polymer chains. Polymer samples were used for mechanical testing and solution processing for film casting. The large-scale polymer films would undergo further extensive dielectric testing. The o-POClNB Thermal, mechanical and dielectric properties of these polymers showed the possible melt processibility when synthesized at a larger scale. Scaling up of these polymers would help in understanding cost, evaluation of morphology and structure property relationship with dielectric and thermal properties for high energy density capacitors and other energy storage devices. Replacement of biaxially oriented polypropylene (BOPP) for capacitor application is very important especially at operational temperature above 100°C with potential impacts over broad range of NAVY applications in pulse power and marine electronics.

Understanding and Controlling Material Structure and Reactivity in Beyond Li-Ion Systems *Lauren Marbella; Columbia University, United States*

Beyond Li-ion technologies have the potential to diversify the suite of chemistries that can address our energy storage needs in the next few decades. However, we still do not know if the decades of research dedicated to optimizing Li-ion battery performance is transferable to more earth abundant chemistries, such as K-ion batteries. In this talk, I will discuss our efforts to understand why canonical electrolytes from Li-ion batteries (e.g., fluoroethylene carbonate additives) fail when applied to beyond Li systems. In addition, I explore how we can potentially leverage the lower reactivity of PF_6-based electrolytes that is observed upon moving down the periodic *table from Li to Na and K. Insight from these results indicate that electrolyte engineering in beyond Li-ion systems may be an entirely new undertaking and that with these changes, we also have to consider all other components of the battery (electrode materials, solvents, and the resulting solid electrolyte interphase structure).*

9:30 AM EN08.12.03

Resolving the Zn^{2+} Solvation Structure and Transport Properties of $ZnCl_2$ Electrolytes Using Neural Network Potential from Salt-in-Water to Water-in-Salt *Chuntian Cao[1], Arun Kingan[2], Ryan C. Hill[2], Jason Kuang[2], Lei Wang[1,2], Chunyi Zhang[3], Matthew R. Carbone[1], Hubertus van Dam[1], Shinjae Yoo[1], Esther S. Takeuchi[2], Kenneth J. Takeuchi[2], Xifan Wu[4], Milinda Abeykoon[1], Amy Marschilok[2] and Deyu Lu[1]; [1]Brookhaven National Laboratory, United States; [2]Stony Brook University, The State University of New York, United States; [3]Princeton University, United States; [4]Temple University, United States*

Aqueous zinc-ion batteries (ZIBs) are of great interest for next-generation energy storage applications due to their low cost, intrinsic safety, and environmental friendliness. $ZnCl_2$ solutions are a promising electrolyte for aqueous zinc ion batteries. We have performed a combined computational and experimental study of the structural and dynamic properties of aqueous $ZnCl_2$ electrolytes with concentrations ranging from salt-in-water (SIW) to water-in-salt (WIS). By developing a neural network potential (NNP) model, we perform molecular dynamics (MD) simulations with ab initio accuracy but at much larger length and time scales. The calculated NNP structural and dynamic properties of $ZnCl_2$ electrolytes are in good agreement with pair distribution function (PDF) experiments and conductivity measurements.

The MD trajectories provide a comprehensive picture of the Zn^{2+} solvation shell structure, with a range of $Zn(H_2O)_xCl_y$ first solvation shell species and their populations. The NNP solvation structures are validated by the structure factors of $ZnCl_2$ solutions obtained from the PDF experiment. Multiple co-existing solvation motifs of $Zn(H_2O)_xCl_y$ were determined through this analysis. Dynamic properties dictated by the multi-stage charge carrier characteristics are deciphered and will be described, including differences in Zn^{2+} and Cl^- diffusion within the SIW and WIS regimes.

Through microscopic insights of the structural and dynamic properties of $ZnCl_2$ electrolytes, we aim to reveal the underlying mechanism of the ion transport process and inform further studies on ion transport, desolvation energy, and electrode-electrolyte interface structures.

Accessing Mg-Ion Storage in V_2PS_{10} via Combined Cationic-Anionic Redox with Selective Bond Cleavage

Matthew Wright[1,2,2], Todd W. Surta[2], Jae Evans[2], Jungwoo Lim[2], Hongil Jo[2,2], Cara Hawkins[2], Mounib Bahri[2], Luke Daniels[2], Ruiyong Chen[2], Marco Zanella[2], Giannantonio Cibin[3], Alan Chadwick[4], Matthew Dyer[2], Nigel Browning[2], John Claridge[2], Laurence J. Hardwick[2,2] and Matthew Rosseinky[2]; [1]University of California, Santa Barbara, United States; [2]University of Liverpool, United Kingdom; [3]Diamond Light Source, United Kingdom; [4]University of Kent, United Kingdom

Magnesium batteries attract interest as alternative energy-storage devices because of elemental abundance and potential for high energy density. Development is limited by the absence of suitable cathodes, associated with poor diffusion kinetics resulting from strong interactions between Mg^{2+} and the host structure. V_2PS_{10} is reported as a positive electrode material for rechargeable magnesium batteries with fast insertion kinetics. Cyclable capacity of 100 mAh g^{-1} is achieved with Mg^{2+} diffusion of 7×10^{-11} - 4×10^{-14} cm^2 s^{-1}. The fast insertion mechanism results from combined cationic redox on the V site and anionic redox on the $(S_2)^{2-}$ site; enabled by reversible cleavage of S–S bonds, identified by X-ray photoelectron and X-ray absorption spectroscopy. Detailed structural characterisation *with maximum entropy method analysis, supported by density functional theory and projected density of states analysis, reveals that the sulfur species involved in anion redox are not connected to the transition metal centres, spatially separating the two redox processes. This facilitates fast and reversible Mg insertion in which the nature of the redox process depends on the cation insertion site, creating a synergy between the occupancy of specific Mg sites and the location of the electrons transferred.*

10:30 AM EN08.12.05

Ab Initio Insights to Metal Passivation—A Study of Diffusion and Defect Formation in Zirconia and Alumina

Mackinzie S. Farnell[1], Jianli Cheng[2], Jimmy-Xuan Shen[3,3] and Kristin A. Persson[2,1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Lawrence Livermore National Laboratory, United States

First principles calculations based on density functional theory have enabled digital workflows to drive materials discovery forward; however, these workflows still have many limitations. One issue is that current workflows are unable to account for metal passivation. Metal passivation refers to the process by which metals form oxide layers that protect the material and prevent corrosion; this process is necessary for materials to be stable in air. Whether an oxide layer forms can be determined thermodynamically with Pourbaix diagrams, but the kinetic characteristics of the oxide, such as how fast it will grow and what thickness it will reach, are not well characterized with first principles. To work toward a first principles understanding of metal passivation, we look to the Point Defect Model [1]. The model offers atomic level insights into passivation and suggests that defect formation and diffusion are responsible for the growth of passive films. To test this idea in zirconium and aluminum, we calculated defect formation energies and diffusion in amorphous oxides for both metals. Since the materials are modelled as amorphous, defect calculations were performed for several different atomic sites and the formation energy varied by as much as 4 eV. Using defect formation energies and diffusion, we calculated defect conductivity for oxygen vacancies in the structures and compared this to oxide thickness measurements found from a literature review. Defect conductivity was correlated with oxide thickness, such that a slower defect conductivity was associated with a thinner oxide forming. These results are consistent with our expectation that growth of the passive film will be affected by how much energy it takes to form a defect and how quickly species can move through the film. This knowledge offers a potential path forward for incorporating passivation into digital materials discovery.

Designing Heteroatom-Doped Iron Phosphide Core-Shelled Structures as Freestanding Anodes for Sodium and Potassium-Ion Batteries

Kwadwo Asare Owusu and Kevin M. Ryan; University of Limerick, Ireland

Energy storage devices (ESDs) are essential for advancing renewable energy integration, reducing dependence on fossil fuels in electricity generation, and developing electric vehicles and wearable technologies. Lithium-ion batteries (LIBs) currently dominate the ESD market, but their high cost per watt-hour and limited lithium resources present long-term challenges.

Alternative battery chemistries, notably sodium-ion batteries (SIBs) and potassium-ion batteries (PIBs), are considered promising complements and potential LIB replacements [1, 2]. They offer cost-effectiveness, abundant sodium and potassium resources, and worldwide distribution of these elements. Additionally, their compatibility with aluminum makes them appealing options for constructing economically viable and safe ESDs. Nonetheless, the performance of SIBs and PIBs is hampered by the sluggish diffusion of Na^+ and K^+ within electrode materials. Overcoming this limitation is a critical challenge in developing Na and K-batteries. Among potential electrodes,

phosphorous boasts a high theoretical capacity, but it suffers from poor cycling and substantial volume expansion during charge storage [3, 4].

This research focuses on the design of core-shell FeP microcuboids on freestanding carbon cloth substrates, aiming for high-capacity (up to 800 mAh g^{-1}), long-cycle anodes for sodium- and potassium-ion batteries [5]. The synthesized FeP microcuboids display unique physical and morphological characteristics that facilitate efficient sodium-ion storage. Featuring a porous core enveloped by a 10 nm carbon shell, they provide an increased surface area, promote rapid Na^+ diffusion, and mitigate significant volume changes during cycling. The incorporation of heteroatoms such as fluorine and nitrogen enhances both electronic conductivity and structural stability, benefiting both sodium and potassium storage.

11:00 AM EN08.12.07

Investigation of Ruddlesden Popper-Type Oxide as an Intercalation Based Cathode Material for All-Solid-State Fluoride-Ion Batteries *Vanita Vanita[1], Aamir I. Waidha[1], Sami Vasala[2], Pascal Puphal[3], Roland Schoch[4], Pieter Glatzel[2], Matthias Bauer[4] and Oliver Clemens[1]; [1]Universität Stuttgart, Germany; [2]European Synchrotron Radiation Facility, France; [3]Max Planck Institute for Solid State Research, Germany; [4]Universität Paderborn, Germany*

Increasing use of Lithium-ion batteries (LIBs) has led to and will further lead to the depletion of lithium reserves. In response, investigations are being done on other cations (Na^+) and anions (F^-, Cl^-)[1] as shuttling ions for battery systems. Recently, fluoride ion batteries (FIBs) are considered to as an alternative for all-solid-state batteries[2], for which cells based on conversion-based cathode materials can provide high specific capacity at the cost of fast capacity fading on cycling[3, 4]. This can be understood from the fact that the conversion mechanism involves large degree of atom organisation, changes in chemical bonds and massive volume changes upon cycling. This has been shown to be prevented by using intercalation-based cathode materials, which drastically reduce the volume changes due to the possible intercalation and de-intercalation of ions from the host lattice[5]. This not only led to higher cycling stability but also facilitates the lowering of overpotentials[6]. In this respect, different second-generation intercalation-based materials have been derived from initially studied materials[5-7], among which Ruddlesden-Popper type $La_2Ni_{0.75}Co_{0.25}O_4$ have been identified for improved cycling performance[8] and further $LaSrMnO_4$ / $La_1Sr_2Mn_2O_7$ are under investigation.
In this study, we explore the structural changes of $La_2Ni_{0.75}Co_{0.25}O_4$ / Pb-PbF_2, $LaSrMnO_4$ / Pb-PbF_2 and $La_1Sr_2Mn_2O_7$ / Pb-PbF_2 cells during fluoride intercalation and de-intercalation by using X-ray diffraction (XRD) and electrochemical characterization methods. By X-ray diffraction analysis of cells cycled to different cut-off conditions, reveal an increase of the unit cell along the c-axis and contraction in the ab-plane. The detailed complex reaction behaviour of the phase, focusing on changes in the oxidation states and co-ordination environments of Ni and Co in $La_2Ni_{0.75}Co_{0.25}O_4$ was studied via X-ray absorption spectroscopy (XAS). Under optimized operating conditions, we achieved a cycle life of 120-cycles at a critical cut-off capacity of 40 mAh.g^{-1} and over 400-cycles under a pressure of 452 MPa. The average Coulombic efficiencies ranged from 85% to 90% for the cell operated without pressure and 95 % to 99 % for the cell operated under pressure for $La_2Ni_{0.75}Co_{0.25}O_4$ / Pb-PbF_2 cells. Therefore, $La_2Ni_{0.75}Co_{0.25}O_4$ stands out as one of the promising cycling-stable high-energy cathode

materials for all-solid-state FIBs, offering improved capacity [8, 9].

Rechargeable Alkaline MnO$_2$ Cathodes for Grid Storage—Mechanism of Bi Modifier *Eric K. Zimmerer and Joshua W. Gallaway; Northeastern University, United States*

The rechargeable Zn-MnO$_2$ alkaline battery is one of the few capable of meeting the extreme cost requirements needed for global integration of battery storage in the power grid. Modifying the MnO$_2$ cathode with Bi allows it to cycle reversibly between layered Mn oxides -MnO$_2$ and Mn(OH)$_2$ without detrimental formation of Mn$_3$O$_4$. This provides a cathode capacity of 617 mAh/g, which modeling has shown to enable energy storage costs below \$50/kWh. However, commercial adoption requires a more complete understanding of the variables that affect the performance of the alkaline MnO$_2$ cathode. This talk will present an updated understanding of the mechanism of the Bi-modified alkaline MnO$_2$ cathode.

The alkaline MnO$_2$ cathode achieves a full two-electron cycling reaction. This is a 2-step electrochemical process: the Mn^{4+}/Mn^{3+} step occurs via proton insertion/extraction while the Mn^{3+}/Mn^{2+} step occurs via dissolution/precipitation. While Bi modification prevents the rapid failure of the alkaline MnO$_2$ cathode due to Mn$_3$O$_4$ formation, a gradual decline in capacity is still observed (~25% over 100 cycles). To better understand where this capacity loss comes from, greater understanding of the electrochemical mechanism is needed. Because the cycling materials are poorly crystalline, techniques other than diffraction were needed. We used operando extended X-ray absorption fine structure (EXAFS) to characterize the first cycle of alkaline MnO$_2$ electrodes with and without Bi additive. Data shows that when Bi is not included Mn$_3$O$_4$ forms during the Mn^{2+}/Mn^{3+} step of the first charge, suggesting it forms via aqueous complexing of which is blocked by Bi additive. This means Bi is not structurally incorporated in the material during cycling, which was further confirmed by comparison to synthesized Bi-doped -MnO$_2$ which was found to have a local coordination unique and distinct from a rechargeable cathode. Post-mortem TEM of particle cross-sections confirmed that Bi is concentrated around particle surfaces and its effect on cycling is largely interfacial.

Atomic-Scale Mechanisms of Superionic Conduction and Interfacial Phenomena in Sulfide Electrolytes for Lithium Batteries *Varun Shreyas, Saransh Gupta, Meghnath Jaishi, William Arnold, Hui Wang and Badri Narayanan; University of Louisville, United States*

Rechargeable solid-state lithium metal batteries (SSLMBs) offer tremendous promise as energy-dense and safe energy storage solution for electric vehicles, mobile computing, and portable electronics. Particularly, SSLMBs utilizing sulfide electrolytes (e.g., prototypical Li_7PS_6 *argyrodites) have garnered a lot of attention owing to their remarkable Li-ion conductivity (~*10^{-3} *S/cm), elastic stiffness (~30 GPa), and low flammability. Nevertheless, sulfide electrolytes remain far from commercial SSLMBs due to longstanding issues with slow Li-ion conduction under ambient conditions, and parasitic side reactions at the Li-anode. These problems stem from a lack of fundamental understanding of the atomic-scale processes underlying ion conduction, charge transport, structural evolution, and interfacial reactions (e.g., dendrite growth, electrolyte decomposition, etc.) in SSLMBs. Using halogen-doped Li-argyrodite as a representative system, we address this crucial knowledge gap by integrating density functional theory (DFT) calculations, machine learning (ML), and ab initio/classical molecular dynamics (AIMD/ CMD) simulations. Specifically, using AIMD simulations, we find that fluorine-containing argyrodite electrolytes that simultaneously offer enhanced (a) Li-ion conduction facilitated by unique Li-disorder induced by fluorine and other halogen co-dopants, and (b) stability against the Li-anode owing to the formation of a stable solid-electrolyte interface containing conductive species (*Li_3P*), alongside LiCl and LiF. Furthermore, we employed a large database of energies, atomic forces, charges, elastic/thermal properties, energetics/pathways for key reactions, obtained using DFT calculations to train an accurate reactive force field (ReaxFF) for Li/P/S systems. The newly developed ReaxFF can accurately capture (a) structure, energetics, and dynamics across multiple length scales, (b) thermal properties, (c) interfacial reactions, and synthesis pathways, (d) mechanical properties, (e) ion transport, (f) and atomistic response to environment (temperature, pressure, etc.) Importantly, molecular dynamics simulations based on the newly developed model reveal interfacial reactions at electrified interfaces. We will discuss these results in the context of accelerating the design of novel solid-state electrolytes for long-lived, stable, and high-energy-density lithium batteries.*

1:45 PM EN08.13.02

The Synthesis of Zr-Doped $Li_{3-x}In_{1-x}Zr_xCl_6$ ***with Ultrahigh Ionic Conductivity for All-Solid-State Lithium-Ion Batteries*** *Jinzhao Fu and Yan Wang; Worcester Polytechnic Institute, United States*

All-solid-state lithium-ion batteries (ASSLBs) are an important milestone for the future of energy storage because of their capability of impressive energy density and outstanding safety. However, oxide and sulfide solid-state electrolytes (SSEs) suffer either low ionic conductivity or poor chemical stability. In contrast, halide-based SSEs, are promising as candidate materials owing to high conductivity, good stability, and broad cathode compatibility. Though element doping of the SSEs is an effective and common approach to further improve their electrochemical properties, dopant exploration, and optimization through solely experimental trials are costly and time-consuming. For this aspect, computational simulations for dopant element and concentration screening are adopted in this research, and zirconium is selected as a suitable dopant for Li_3InCl_6*. The synthesized* $Li_{2.75}In_{0.75}Zr_{0.25}Cl_6$ *exhibited Li ionic conductivity of 5.82 ×* 10^{-3} *S/cm at room temperature, which is the highest among reported halide SSEs. The ASSLB formed with* Li_2CoO_2*-*$Li_{2.75}In_{0.75}Zr_{0.25}Cl_6$*-Li/In delivers a high initial capacity of 129.3 mAh/g. Conclusively, this work provides an effective approach that combines computational modeling and experimental verification for the* *development of halide SSEs with improved stability and conductivity. The successful design approach and compelling results provide further possibilities and capabilities for future SSE research.*

2:00 PM EN08.13.03

Holistic Assessments of New Sodium Superionic Frameworks *Lauren N. Walters[1], Yuxing Fei[2], Bernardus Rendy[2], KyuJung Jun[2], Mouhamad Diallo[2], Xiaochen Yang[2], Tara P. Mishra[1], Matthew J. McDermott[1], David Milsted[1] and Gerbrand Ceder[2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States*

The discovery of tunable superionic conducting frameworks is necessary for the development of next generation solid state batteries. To this end, we present a computational-experimental materials exploration strategy leveraged to comprehensively reintroduce the sodium conducting framework, $Na_4TiP_2O_9$ (NTP). We utilize high-throughput computational screening to probe chemical and structural substitutions on the text-mined NTP parent structure. We validate (meta)stable NTP candidates through application of synthesis selection algorithms employed by an experimental autonomous laboratory. Our expansive data set of synthesis trials allow us to propose simple but powerful generalized synthesis methodology rules for $Na_xMP_2O_9$. Finally, we highlight the structural, chemical, and conductivity characterization of realized compounds. Our work is a testament to the powerful interplay of data-driven computation and experimentation, particularly when applied to research on new superionic conduction frameworks for energy storage advancement.

2:15 PM EN08.13.05

Synthesis of Li Ion Conducting NLZSP($Na_{3-x}Li_xZr_2Si_2PO_{12}$) Solid Electrolyte Through Novel Electroreforming Method and Its Application *Jongwoo Kim and Youngsik Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Among lots of candidates of solid electrolytes, materials of NASICON type have high ionic conductivity, are inexpensive, and are stable in the atmosphere, making them suitable for various applications. History of lithium ion conducting NASICON type material starts from 1980's and currently LATP which has Ti^{4+} replaced with Al^{3+} is widely used for its high ionic conductivity. However, Ti based NASICON material is unstable in contact with the Li metal due to reduction of Ti^{4+} to Ti^{3+}. This reduction produces by-products that hinder ion conduction and cause cracks in the electrolyte, limiting the use of NASICON materials in diverse configurations.

To overcome this reduction problem, many researchers have tried replacing Ti ions with Zr ions, which have a more stable oxidative state. However, simply replacing titanium ions with zirconium led to several issues. This work suggests a novel electrochemical method to create Zr-based Li-ion conducting NASICON($Na_{3-x}Li_xZr_2Si_2PO_{12}$) material from Na-based NASICON($Na_3Zr_2Si_2PO_{12}$) material. There are two sites where mobile ions occupy in the NASICON structure. The M1 site is where the space is shared with ZrO_6 octahedra, and the M2 site is the space between two tetrahedral sites. Since the bond length between the mobile ion and oxygen in the M1 site is constant, cations in the M1 site help maintain the structural skeleton. Cations in the M2 site can be easily extracted and inserted for electrochemical activity due to the diverse ion-oxygen bond lengths.

In this work, Na in Na-based NASICON material was selectively exchanged with Li, and some ions were partially substituted to ensure structural stability. The system built for ion substitution using an electrochemical method has been named the 'electroreforming' process. To verify the characteristics of the solid electrolyte produced by this process, it was first demonstrated that Na was exchanged with Li using an electrochemical method. Structural analysis confirmed the insertion of lithium ions into the NASICON structure, showing ion conductivity three orders of magnitude higher compared to samples synthesized using conventional solid-state methods. Secondly, it was *verified that it works well as a lithium-conductive ceramic membrane after modification. In a Li metal symmetric cell, it operated for over 100 hours and exhibited lower overpotential compared to conventional electrolytes. Additionally, it was applied in a new system for recovering lithium from spent batteries, the 'electrochemical lithium recycling system,' where it functioned as a stable lithium-conductive membrane in aqueous solutions.*

This study proposes a simple electrochemical method to modify structurally stable Na-based NASICON-type membranes to Li-based membranes. Additionally, it presents alternative application strategies for the modified solid electrolyte beyond battery systems.

2:30 PM EN08.13.06

Fast Lithium-Ion Diffusion in Weakly Bound van der Waals Frameworks *KyuJung Jun[1,2] and Gerbrand Ceder[2]; [1]Massachusetts Institute of Technology, United States; [2]University of California, Berkeley, United States*

We discover that ultrafast Li-ion diffusion can be achieved in materials with van der Waals-bonded layered structures. Using fine-tuned CHGNet, an accurate and efficient universal graph neural network potential model, we predict that the room-temperature ionic conductivity in this framework reaches up to 14.7 mS/cm in the undoped structure, and by introducing excess lithium stuffing, increases up to an order-of-magnitude higher predicted conductivity of 234 mS/cm, which is one of the highest lithium ionic conductivity ever predicted for inorganic materials. While high ionic conductivity often comes at the expense of thermodynamic stability owing to the occupancy of high-energy lithium sites, this material exhibits excellent thermodynamic stability and is a ground state in the phase diagram. The ultrahigh lithium-ion conductivity originates from the combination of the structural advantage originating from van der Waals bonds and its activated diffusion networks via lithium stuffing. We prove that the soft c-directional van der Waals bonding allows both ultrahigh ionic conductivity and exceptionally low defect formation energy to add excess interstitial lithium ions. In addition, lithium stuffing in its diffusion network creates face-sharing octahedral configurations with strong lithium-lithium interactions, corresponding to an activated local environment. The homogeneity of the diffusion network allows the percolation and non-dissipation of the activated local environment to create an activated diffusion network, enhancing the ionic conductivity to a record-high value upon lithium stuffing. Guided by the features of van der Waals structures, we perform high-throughput screening to discover 10 additional novel lithium superionic conductors, verified by long time-scale molecular dynamics simulations using fine-tuned CHGNet. Our work opens an exciting path towards a new class of low-dimensional lithium superionic conductors.

Describing Ionic Conducting Sodium Halides Using the Perovskite Toolbox *Xabier Martinez de Irujo Labalde and Wolfgang Zeier; University of Münster, Germany*

Na-ion solid electrolytes are currently being investigated as promising candidates for solid state batteries. Due to the scarcity of the Li metal in the current Li-ion technology and the safety issues of liquid batteries, the scientific interest has been shifted to alternative ways with the desire to meet the demands for high energy density capabilities in solid state batteries.[1,2] Chalcogenides and oxides materials have been thoroughly studied. Although both families show a reasonable transport performance, they lack electrochemical stability, mechanical stability and/or easy processing.

In this context, halides stand out as promising candidates since they combine large stability windows with good mechanical deformability. Recently, Na-containing ternary chlorides with nominal composition Na_xMCl_6 (M^{3+} = In^{3+},

Y^{3+}, Zr^{4+}, Nb^{5+} or Ta^{5+}) have been experimentally found as promising ionic conducting electrolytes.[3] The fact that some of them crystallize in a perovskite structure make those particular systems an unparalleled framework to search for novel ionic conductors and to get deeper insights in the structure-transport properties relationships.

Here we have performed different cationic and anionic substitutions on the $NaTaCl_6$ perovskite-related material. The relationship between the crystal structure and ionic transport properties in those materials was investigated by means of X-ray diffraction, pair distribution function analyses, nuclear magnetic resonance, quasi-elastic neutron scattering and impedance spectroscopy. By fully analysing those materials using the perovskite toolbox, we hope to offer a reliable guidance to improve the structure-property relationships in the current halide electrolyte materials.

Computational Investigations of Features for Predicting Ionic Conductivity in Multivalent Solid Electrolytes

Samuel M. Greene and Donald Siegel; The University of Texas at Austin, United States

Solid-state batteries based on the redox of multivalent ions (Mg^{2+}, Ca^{2+}, Zn^{2+}, etc.) may offer improved safety and performance relative to today's Li-ion batteries. A significant challenge hindering their development is the sluggish mobility of multivalent ions in most solids. Computational methods for efficiently predicting conductivity can accelerate the discovery of faster ion conductors. Direct first-principles calculations of conductivity are expensive and difficult to automate, which has prompted a search for other properties related to conductivity that are easier to calculate or measure. Previous studies have identified features related to the electronic charge density and phonon spectrum that are correlated with energy barriers for ion migration in monovalent conductors. Results from our first-principles simulations demonstrate that these features are not well correlated with energy barriers for multivalent ion migration. I will discuss potential reasons for this lack of correlation and propose modifications that are found to improve correlations. These findings quantify the promise of using such features to efficiently screen for better multivalent ion conductors.

Unveiling Phase Formation Mechanisms in Over-Stoichiometric Rocksalt-Type Li Superionic Conductors

Yu Chen, Xinye Zhao and Gerbrand Ceder; Lawrence Berkeley National Laboratory, United States

Rationalizing synthetic pathways is crucial for material design and property optimization, especially for polymorphic and metastable phases. Over-stoichiometric rocksalt (ORX) compounds, characterized by their face-sharing configurations, are a promising group of materials with unique properties for energy storage application; however, their development is significantly hindered by challenges in synthesizability. Here, taking the recently identified Li superionic conductor, over-stoichiometric rocksalt Li–In–Sn–O (o-LISO) material as a prototypical ORX compound, we systematically investigate the mechanisms of phase formation. By combining ex situ and in situ synchrotron X-ray diffraction, solid-state NMR, TEM, and ab initio calculations, we reveal that the spinel-like phase with unconventional stoichiometry forms as coherent precipitates from the high-temperature-stabilized cation-disordered rocksalt phase. This process prevents direct phase decomposition and kinetically locks the system in a metastable state with desired face-sharing Li configurations. This insight enables us to further enhance the ionic *conductivity of o-LISO to exceed 1 mS cm^{-1} at room temperature via synthetic optimization. Our work offers valuable perspective on the rational synthesis of ORX materials and highlights important opportunities of unraveling synthesis mechanisms in complex material optimization.*

Targeted Grain Boundary Modifications to Overcome Conductivity and Stability Challenges in Lithium Solid-State Electrolytes *Hyunwon Chu[1,2], Thomas Defferriere[1], Harry Tuller[1] and Jennifer L. Rupp[2]; [1]Massachusetts Institute of Technology, United States; [2]Technische Universität München, Germany*

With the growing demand for energy-dense batteries, inorganic solid-state electrolytes have sparked academic and industrial interests owing to their inherently high energy densities and better safety. Among these, Li-garnet LLZO ($Li_7La_3Zr_2O_{12}$) and Li-perovskite LLTO ($Li_{0.33}La_{0.56}TiO_3$) have emerged as frontrunners based on their promising bulk properties. Not only do these oxides improve existing battery systems, but they also enable the applications of energy-dense anodes and high-voltage cathodes. Despite the promise, grain boundaries in both materials hinder ionic conduction and promote electronic conduction, reducing the local ionic-to-electronic transference number. This impacts key battery performance metrics such as power density and overall lifespan. A mechanistic understanding is a key prerequisite for developing strategies to improve detrimental grain boundary interfaces. In this study, we show that low transference numbers at Li oxide grain boundaries arise from space charge formation. Charged point defects tend to segregate and accumulate at the grain boundaries leading to excess charges, which create Schottky-type potential barriers (measuring 0.15 V for LLZO and 0.32 V for LLTO at 20 °C). These barriers cause a depletion of ionic carriers and an accumulation of electronic carriers in the adjacent space charge layers. Our space charge model provides a clear explanation for the thermodynamic origins of low ionic conductivity in LLTO and high electronic conductivity in LLZO at the local boundaries. In light of these insights, we propose new electrolyte design principles for tailoring the local defect chemistry, carrier density, and transport dynamics of Li ceramic grain boundaries: First, by selectively choosing the sintering atmosphere (oxygen partial pressure), we influence intrinsic defect equilibrium and lower space charge accumulation at the grain boundaries. Second, by using aliovalent doping (donor dopants), we introduce net-opposite extrinsic charges that counterbalance the intrinsic space charge at these grain boundaries. Collectively, the fundamentals guide engineering strategies leading to control of local potentials at grain boundaries, enabling four times faster ion conduction for Li-perovskite LLTO and a threefold improvement in short-circuit current limit for Li-garnet LLZO.

Designing Flexible Electronics for Next Generation IoT and Autonomous Sensors *Ravi Silva; University of Surrey, United Kingdom*

Flexible electronics allows for "human-wearables" and "building-skins" to monitor both humans and buildings such that we can better assist society in the health and well-being of our people and assets. To achieve this non-invasively with sustainability in mind nano-scale designs are being developed that are manufacturable and inexpensive. All these systems will need wireless power. If these platforms can be produced on flexible and reconfigurable formats, its energy systems could become ubiquitous and be deployed in many other fields. This talk will expand on the nanoscale design of systems for future wearables including the IoT plus its synthesis for human compatible bioelectronics.

Within this concept, we examine routes in which energy-scavenging sources can be built into multifunctional platforms. Powering of such devices to allow for autonomous functionality as well as for use in wearables is explored. We will examine organic (OPV) and perovskite (PSC) material systems that can be used to scavenge energy, with power conversion efficiency that now approaches 20% for both PM6/Y6 and metal halide-perovskite solar, that can operate both outdoors and indoors. We also show developments in triboelectric nanogenerators (TENGs) that can be used to power such devices with enhanced power conversion efficiency. These can also be used for sensing both normal and sheer stress in autonomous sensors, suitable for the prevention of diabetic peripheral neuropathy via smart insoles that can operate energy autonomously. Smart contact lenses, photodetectors, glucose and temperature sensors, with high detection sensitivity, good biocompatibility and mechanical robustness will be part of the future devices that allow for better assisted living. Flexible mesh electrode options for bioelectronic platform demonstrates how cardiac tissue engineering can be used in in-vivo applications showing its potential in monitoring disease progression and potential pharmaceutical validation in transplant or in the repair of damaged heart tissue.

We further examine use of large area hybrid detectors that overcome attenuation limits associated with photon scattering to give flexible, broadband high sensitivity X-ray detectors that can be powered for portability remote operations. These allow for future high definition imaging, coupled to therapeutics.

A future world with wearables and flexible electronics will enable assisted living to support modern societies. We hope such systems can be now designed and produced to improve the quality of life in everyday activities.

11:00 AM EN09.01.02
Super-Flexible Wearable, Ultra-Light Weight, Self-Powered a-Ga_2O_3/Paper-Based UV-C Photodetector
Govind Gupta[1,2]; [1]Council of Scientific & Industrial Research–National Physical Laboratory, India; [2]Academy of Scientific & Innovative Research, India

The development of a highly flexible and lightweight wearable self-powered ultraviolet-C photodetector (UVCPD) utilizing an amorphous-Ga_2O_3 (a-Ga_2O_3) film grown on paper substrates (glossy, parchment, and 75 GSM) is reported. The morphology, flexibility, optical characteristics, and photodetection capability of the sputtered a-Ga_2O_3 on paper substrates are thoroughly investigated. The fabricated device demonstrates an ultra-high responsivity of 20.96 mAW^{-1}, a high specific detectivity of 1.04×10^{10} Jones, a low noise equivalent power of 4.71×10^{-12} $WHz^{-1/2}$ with a rapid response speed of 65/67 ms under self-powered conditions at an optical illumination of 266 nm. The superior performance of a-Ga2O3/paper-based devices is attributed to surface roughness, porosity, microfibrous structure, and enhanced light absorption. The device showcases outstanding flexibility, bending endurance (>600 cycles), and deformability and exhibits stable performance over two months. The fabricated device could be utilized in biomedical applications as a wearable device designed to mitigate the adverse effects of UVC radiation, known for its potential to induce various harmful health conditions. Demonstrating self-powered, high-performance, and biodegradable paper-based UVCPD devices opens up new avenues for the next generation of wearable and flexible optoelectronic devices.

11:15 AM EN09.01.03
Multi-Tasking Flexible Sensor with Reservoir Computing Monitoring Water Droplet Dynamics *Naruhito Seimiya[1], Seiji Wakabayashi[2], Haruki Nakamura[1], Guren Matsumura[3], Kohei Nakajima[4] and Kuniharu Takei[1]; [1]Hokkaido University, Japan; [2]Osaka Prefecture University, Japan; [3]Osaka Metropolitan University, Japan; [4]The University of Tokyo, Japan*

Water droplets impacting a solid surface show different behavior depending on the angle of impact or the volume of water droplets. If sensor that monitors this impact behavior with time can be developed, it may be able to obtain information on the impacted water droplets, applying as a rain sensor to acquire precipitation and wind velocity. To achieve this rain sensor based on water dynamics monitoring, this study proposes a simple, low-cost resistive type multi-tasking flexible sensor that can be placed on a variety of surfaces such as an umbrella, roof, and car. Fabrication process is briefly explained. First, Polyimide (PI) film was exposed by CO_2 laser to generate laser-induced graphene (LIG), which is multilayered and defective graphene confirmed by Raman spectroscopy. The LIG layer was then transferred from PI film to a polydimethylsiloxane (PDMS) elastomer film. The surface of PDMS/LIG and PDMS were textured by CO_2 laser to form microscopic irregular surfaces that reproduce the Lotus effect. The textured LIG/PDMS has superhydrophobic surface with a contact angle (CA) of 179±0.1°and a sliding angle (SA) of 2.8±0.5° while the textured PDMS has a CA of 176±3.9° and a SA of 9.2±0.6°. This superhydrophobic surface controls the impact behavior of water droplets and enables continuous measurement of their impact dynamics. The sensing mechanism for the impact behavior of water droplets was studied by the relationship between the impact behavior of water droplets and the resistance value. The water droplets hit on the sensor spread rapidly in a radial pattern, then receded and left out from the sensor surface. The resistance at the moment of impact of the water droplet is the lowest and then gradually increases. The minimum resistance value was found to be smaller as the drop height increased or the sensor tilt decreased. This result shows the resistance value decreases as the force acting in a vertical direction to the sensor surface increases. This force also increases the amount of water *droplets sinking into the microscopic irregular surfaces of the sensor, increasing the contact area between the droplets and the sensor surface. As the result, electrical resistance is changed depending on the condition of water droplet, which is the sensing mechanism. This sensing mechanism makes it possible to measure different time series data depending on the impact behavior of water droplets due to changes in water volume, wind velocity, and sensor tilt.*

Time series data of resistance changes in the impact dynamics of water droplets were obtained for volumes from 10 μL to 40 μL, wind velocities from 0 m/s to 5.0 m/s, and sensor tilt angles from 0° to 60°. These time series data were analyzed using reservoir computing, which is one of the recurrent neural networks, to estimate the volume of water droplets and wind velocity at each sensor tilt. For each tilt, the volume and wind velocity estimation results were obtained with relatively low normal mean square error (NMSE) <0.2 and <0.25, respectively. This result indicates that this sensor has the potential to be used as a sensor to acquire precipitation information by attaching this sensor on a variety of objects. Importantly, this single sensor can estimate multiple information of volume and wind velocity as a multi-tasking simple sensor system.

In conclusion, we developed the multi-tasking rain sensor to obtain rain perspiration and wind velocity from the dynamic change of water droplet behaviors. By developing a resistive-type flexible sensor and reservoir computing algorithm, water droplet volume and wind velocity at each sensing angle were successfully extracted with relatively high accuracy. Although there are a lot of things to apply to the real rain/weather sensor system, this may contribute to a new class of flexible sensor integrated with machine learning potentially for low power consumption due to less number of sensors.

11:30 AM EN09.01.04

Machine Learning-Assisted Data Interpolating Flexible Temperature Sensor Array *Haruki Nakamura[1], Ryota Ezaki[2], Guren Matsumura[2], Chia-Chen Chung[3], Yu-Chieh Hsu[3], Yu-Ren Peng[3], Akito Fukui[2], Yu-Lun Chueh[3], Daisuke Kiriya[4] and Kuniharu Takei[1]; [1]Hokkaido University, Japan; [2]Osaka Metropolitan University, Japan; [3]National Tsing Hua University, Taiwan; [4]The University of Tokyo, Japan*

Flexible sensors, which can be installed even on nonplanar objects, are expected to collect many datasets for data analyses. Among them, flexible temperature sensor is promising for application of environmental monitoring, healthcare, and robotics. To realize temperature sensor platforms for such applications, sensor stability, reliability, and high sensitivity are necessary to analyze datasets precisely. Furthermore, low power consumption of sensor system is another challenge, which in general each sensor consumes power to operate it, resulting in huge power consumption for Internet of Things. Although many temperature sensor concepts have been reported previously, the sensor that combine such characteristics has yet to be fully developed. To address these challenges, we aim to realize low power, high stability, and high spatial-resolution mapping of temperature distribution using solution-based V_2O_5 nanowire network-based flexible temperature sensor combining with machine learning system. Solution-based process allows to economically fabricate large-scale sensor on a flexible substrate. To make highly stable and relatively high temperature sensor sensitivity, inorganic V_2O_5 nanowire network was selected to form thin film on a flexible substrate. Furthermore, this sensor has almost no hysteresis behavior for temperature sensing. For low power consumption concept, data interpolation is applied to predict the data between sensors with reservoir computing (RC), realizing that low power consumption can be achieved due to less number of sensors required. This enables real-time highly spatial resolution detection of temperature distribution and contact position.

First, fundamental characteristics of the temperature sensor were conducted. Resistance change was measured against temperature changes from 25 to 60 °C by using an environmentally controlled oven. During the measurement, resistance of temperature sensor decreases with increasing temperature due to V_2O_5 nanowire properties. Temperature sweeps (increasing and decreasing) were also conducted to discuss hysteresis of the sensor. To find optimal conditions of the sensor, all measurements were tested by changing annealing

temperature conditions from room temperature to 250 °C after V_2O_5 nanowire network formation. The results show that smaller hysteresis is realized when annealing temperature increases. In particular, the sensor annealed at 250 °C shows good properties of sensitivity of ~ -1.5 %/°C and sensitivity difference (i.e. hysteresis) of ~ 0.024 %/°C between temperature sweeps. The long-term reliability of the sensor was evaluated by subjecting it to thermal cycles between 25 °C and 60 °C for over 110 hours in the environmentally controlled oven. During the first 20 hours, the resistance values increased slightly by 0.5 %, corresponding to 0.33 °C fluctuation. However, after 20 hours, the sensor stabilized with no observable resistance shifts, indicating high stability of temperature sensor.
For the data interpolation using RC, the sensors were placed on each side of the cube. A total of six temperature sensors were used to create a device that can simultaneously measure temperature changes on a cube shape. By optimizing the algorithm, detections of temperature and tactile position were successfully detected with recall value of ~90% for temperature (60~100°C) and ~93% for tactile position. Interpolation technique enables temperature and tactile detection not only on the surface where the sensor is placed, but also on the edges of the cube between the sensors.
In summary, this study demonstrated temperature sensing system that combines solution-based process of V_2O_5 nanowire and RC analysis. By optimizing fabrication process and data processing algorithm, temperature and tactile sensing were achieved with high stability, high sensitivity, low hysteresis, and high spatial resolution, which is potentially used for next class of low-cost and low power sensing system.

11:45 AM EN09.01.05
Inorganic Nanowires Based Stretchable Sensors for Wearable Applications *Dhayalan Shakthivel and Ravinder Dahiya; Northeastern University, United States*

Robust stretchable sensors (temperature, strain, optical, pressure etc.) are the critical components of wearable electronic systems health monitoring and wellness applications. In these applications the sensors are expected to show stable performance under bending, stretching and other mechanical loading conditions. While commonly explored organic and inorganic-organic hybrid materials based sensors meet these requirements, their modest performance (e.g., mobility, conductivity) and stability hinder their wider use. In this regard, the inorganic semiconductors nanowires (NWs), 2D materials, metallic NWs etc. are attractive owing to their distinct physical and chemical properties. Further, inorganic semiconductors based flexible/stretchable sensors can be developed using novel transfer/printing techniques. The current work demonstrates inorganic metallic and semiconducting NWs based stretchable strain sensors and photodetectors (PDs) on Ecoflux substrate with stable performance under high cyclic loading conditions. The functional components of both the strain and UV sensors are based on inorganic nanomaterials on an eco-friendly substrate. Silver (Ag) NWs have been used to fabricate stretchable strain sensor that displayed good linearity in the low strain range (< 40%), high cyclic stability beyond 5000 and fast response time (~200 ms). The sensor has been integrated over human finger to evaluate the bending strain for applications in smart gloves and robotics. The fabrication methodology has been extended to develop a ZnO NWs based stretchable UV dosage monitor for human skin health monitoring applications. The UV sensing device configured as metal-semiconductor-metal structure on Ecoflux substrate displayed stable performance over 10,000 cycles. The sensor exhibited good characteristics of responsivity (77 A/W), and detectivity (6.6 x 10^{13} jones) for UV light, at par or better than common organic and hybrid stretchable PDs.

SESSION EN09.02: Flexible Triboelectrics
Session Chairs: Ying-Chih Lai, Ravi Silva and Husnu Unalan
Monday Afternoon, December 2, 2024
Hynes, Level 3, Ballroom A

*1:30 PM *EN09.02.01*

Untethered, Autonomously Self-Healable and Self-Powered Actively-Perceiving and Energy-Harvesting Triboelectric Skins and Their Applications in Soft Robotics *Ying-Chih Lai; National Chung Hsing University, Taiwan*

Soft robots with organism-like adaptive bodies have shown great potential in vast robot-human and robot-environment applications. Developing skin-like sensory devices (that are e-skins) enables them to naturally sense and interact with environment. It would be better if the capabilities to feel can be active like real skin. However, conventional e-skins are developed using passive sensing technologies, including resistive, capacitive, and optical types. Such passive sensors suffer from limited materials, poor scalability, complicated architectures, scant stretchability, large driving-voltage, and huge power dissipation in large-area uses. Those drawbacks greatly hinder the development of untethered and deformable robotic skins.
In this talk, we will present diversified cutting-edge self-powered triboelectric skins (tribo-skins) [1-6] with various fascinating attributes, including autonomous ability of self-healing (30 min, 100% efficiency at 900% strain) [3], omnidirectional stretchability (>900%) [1-4, 6], transparency (88.6%) [3], environmental-inert (−30 to 60 °C) [4, 6], and electromagnetic and biomechanical energy-harvesting ability [5]. The tribo-skins can actively sense proximity, contact, and pressure to external stimuli via self-generating electricity. The driving-energy comes from natural triboelectrification effect involving a cooperation of contact electrification and electrostatic induction. We will demonstrate the first actively perceivable and responsive soft robots using the untethered and ultra-stretchable tribo-skins.[1,2] The perfect integration of the tribo-skins and soft actuators enables soft robots to perform various actively sensing and interactive tasks including actively perceiving their muscle motions, working states, textile's dampness, and even subtle human physiological signals. The diversified self-powered tribo-skins with various desired attributes will be introduced. Last, we will demonstrate a transparent, self-healing, and self-powered perceiving soft robotic hand. These works will inspire lots of great ideas and show tremendous potentials of wearable/stretchable/deformable electronics, artificial e-skins, smart interfaces, and soft robots.

2:00 PM EN09.02.02

Triboelectric-Driven (bio)Mechanical Sensors Based on 2D Materials and Textile Platforms *Ievgeniia Kovalska[1], Jack Routledge[1], Rocco Cancelliere[2] and Monica Craciun[1]; [1]University of Exeter, United Kingdom; [2]Università degli Studi di Roma Tor Vergata, Italy*

Healthcare and well-being are on the brink of revolution with the integration of self-powered sensing technology in textiles. Key to this revolution is triboelectric nanogenerators (TENGs), leveraging the interplay of utilized materials' electronegativity and electrostatic induction. These devices harness untapped energy by converting human activities and physiological signals (like walking, breathing, heartbeat), along with vibrations from sounds and *machinery, into green electricity. TENG (bio)sensors offer a promising self-powered and eco-friendly alternative to battery-powered devices, perfect for wearable healthcare and environmental monitoring.*

In my presentation, I will discuss our advancements in developing flexible, mechanically robust, lightweight, and resilient TENG (bio)sensors for practical application demands. I will show how we create textile TENGs using 2D materials and their heterostructures as both active sensing layers and electrode materials. One highlight of our research is a novel textile beeswax TENG capable of harvesting acoustic energy, functioning as a sound detector or self-powered microphone. This device can also act as an acoustic hybrid energy harvester, converting acoustic pollution and mechanical vibrations, such as those from working engines, into usable electrical energy.

Additionally, I will demonstrate the application of 2D material heterostructures in wearable TENG biosensors for continuous monitoring of physiological signals. These sensors detect various volatile organic compounds, including acetone and styrene, as well as cortisol levels in sweat, which are associated with various diseases. Furthermore, I will discuss the potential of these sensors to detect elevated body temperatures, as they exhibit responses to temperature changes.

2:15 PM EN09.02.03
Gas-Mask-Integrated Multi-Sheet Flutter Triboelectric Nanogenerator for Self-Powered Emergency Response System *Deokjae Heo[1], Myunghwan Song[1], Jinkee Hong[2] and Sangmin Lee[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)*

Gas masks are crucial personal protective equipment used in hazardous environments, and gas-mask wearers should always be prepared for emergencies to ensure better safety and survival. Considering that sudden or long-term emergencies can occur at any time, a self-powered gas-mask system must be established for a continuous power supply to emergency-related electronics or for reliable self-powered sensing. Nevertheless, a comprehensive analysis and the demonstration of a gas-mask-integration design that considers breathing resistance, electrical output generation, and practical application together remain challenging. This study developed a gas-mask-canister-integrated inhalation-driven multi-sheet flutter triboelectric generator (MF-TEG) and ultimately realized a self-powered emergency response gas-mask-system (S-ERG) for the first time. The MF-TEG was mechanically and electrically analyzed and optimized for various design variables based on the average peak voltage and root mean square output measurements. A gas-mask canister with the MF-TEG produced a stable electrical output (62 V, 500 Hz) for every inhalation, and its inhalation resistance was 7 % lower than the permissible level, although the canister was compact. Personal environmental monitoring and wireless location tracking were achieved with the S-ERG in the charging mode successfully using high-capacitance capacitors and commercial electronics. A self-powered chemical warfare agent (CWA) sensing mechanism was developed and analyzed for various relevant variables based on peak voltage, output response, and electrical resistance measurements. A real-time personal CWA alert system was realized with the S-ERG in the sensing mode, equipped with a signal-processing unit, via LED illumination.

2:30 PM EN09.02.04
Wet Spun Composite Core-Shell Fibers with Titanium Disulfide Nanosheets for Triboelectric Nanogenerators *Onur Demircioglu[1], Sumeyye Kandur[1], Ali D. Ucar[1], Murathan Cugunlular[1], Mete Batuhan Durukan[1], Doga Doganay[1], Melih O. Cicek[2] and Husnu E. Unalan[1]; [1]Middle East Technical University, Turkey; [2]University of Twente, Netherlands*

Triboelectric nanogenerators (TENGs) covert motion energy into electrical energy by frictional electrification. The simplicity of the triboelectrification mechanism, coupled with a relatively high-power output and straightforward *fabrication techniques, renders these devices easily adaptable for a wide range of applications. In this work, TENG performance of core-shell fibers fabricated through the wet-spinning method was investigated [1]. Conducting core fiber, working as the current collecting electrode, consisted of thermoplastic polyurethane/carbon black (TPU/CB) mixture. The conductivity of the core was measured as 3.6 S/m at the composition of 50% CB and 50% TPU. Dielectric shell layers consisted of composites with TPU. First, conductive two-dimensional titanium disulfide (TiS_2) nanosheets were used in these composites. Afterwards, in order to improve the TENG output, TiS_2 nanosheets were oxidized to obtain insulating TiO_2 nanosheets within the composites. These fibers were fabricated with TiS_2 nanosheet concentrations of 5, 25 and 50 wt.% within the shell layer. Triboelectric performance of TPU/CB-TPU/TiS_2 and TPU/CB-TPU/TiO_2 core-shell fibers were evaluated for their energy generation and harvesting capabilities, as well as their potential use in sensors. Due to the use of TPU both in the core and shell layers, fibers were highly flexible and stretchable. Our results show that these core-shell fibers can be used in various triboelectric applications, including wearable and health monitoring systems, highlighting their potential in IoT environments like real-time human motion and structural health monitoring.*

2:45 PM EN09.02.05

A Self-Powered, Flexible, Multi-Materials 3D-Printed Triboelectric Nanogenerator-Based Force Sensor

Shingirirai Chakoma, Xiaochang Pei, Jerome Rajendran, Anita Ghandehari, Jorge Alfonso Tavares Negrete and Rahim Esfandyarpour; University of California, Irvine, United States

Traditional flexible force sensors, often based on piezoresistive, capacitive, piezoelectric, or triboelectric effects, face substantial challenges. These include the necessity for multiple electronic components and complex circuitry to digitize sensing signals, dependency on batteries, poor conductivity, and high fabrication costs. Developing sustainable, self-powered flexible force sensors capable of transducing force without the need for additional active electronic circuitry remains a significant challenge. In this study, we developed a self-sustaining, flexible, multi-layered, and multi-nanomaterial 3D-printed triboelectric nanogenerator (TENG)-based force sensor that operates independently of external power sources. Our TENG device is based on Styrene-ethylene-butylene-styrene (SEBS) and MXene/Polyaniline (PANI) composite, chosen for their excellent triboelectric properties, flexibility, and suitability for 3D printing. To address the conductivity issues posed by MXene oxidation due to its highly reactive surface functional groups, we introduced PANI, a conductive polymer capable of forming a protective layer for MXene. Our TENG device achieves a peak voltage of 600V with a sensitivity of 5.8 V/N and can deliver an output power of 0.8 W/m^2 at a force of 50 N and an 8 Hz contact frequency. This development paves the way for substantial progress in self-sustainable and multimodal force-sensing technologies.

Innovative Strategies for High Current Output of Triboelectric Nanogenerator via Electrostatic Discharge

Seh-Hoon Chung[1], Jinkee Hong[2] and Sangmin Lee[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

Triboelectric nanogenerator (TENG) is one of the promising energy harvesting technologies that can easily convert a mechanical energy input to an electric energy output. As the TENGs have several advantages like simple design, low weight, and high applicability, TENGs are expected to harvest the abandoned small and random mechanical energy such as body movement, low velocity wind, etc. However, TENGs can only generate low current output of *about few microamperes by its fundamental working mechanism. Even though general TENGs can generate relatively high voltage of about 100 to 200 V, the low current output of TENGs limits the application field of TENGs. Therefore, it is necessary to fabricate a new working mechanism of TENGs that can generate high current output for broadening the application field of TENGs.*

In this regard, we propose innovative strategies for designing high current TENGs using the electrostatic discharge (ESD) effect. As there are several methods to regulate the ESD, we demonstrate the three other strategies of occurring ESD inside the device, using dielectric lubricant oil, and utilizing ion channel to occur the ESD outside of the TENG device. With these strategies, the peak current outputs of TENGs are measured from 85 mA to 15 A which is significantly higher than the current output of general TENGs. Based on the high current output of ESD based TENGs, it was able to utilize the ESD based TENGs for various applications such as powering 200 to 2000 series or parallel connected LEDs, charging lithium-ion battery and high capacitance capacitors, turning on commercial devices such as hygrometer, radio, and generating hydrogen with electrolysis. We expect that these strategies can expand the application field of TENGs and lead the use of TENG in real life.

The Unified Theory of Triboelectric Nanogenerators—A Pathway to Practical Applications *Randunu Devage Ishara G. Dharmasena; Loughborough University, United Kingdom*

Background

Triboelectric nanogenerators (TENGs) convert mechanical movements into electrical pulses using triboelectric charging and electrostatic induction. TENGs are categorized as either contact-mode or sliding-mode architectures, and a wide range of device designs have been introduced for each of these categories. Due to high instantaneous power (>500 W/m^2) and energy conversion efficiency (>50%) [1], TENGs are considered a leading power source and a sensing technology for future wearable electronics, especially in health monitoring applications.

Designing efficient and reliable TENGs for practical applications has been challenging due to lack of detailed knowledge on their theory and optimization. The classical theoretical models for TENG use idealised assumptions such as parallel-plate capacitor approximations which deviate from real-world devices, making it difficult to accurately simulate or optimise their output generation. We introduced the distance-dependent electric field (DDEF) model, causing a paradigm shift from classical models to Maxwell's equations based electric field modelling for TENG [2,3,4]. This model, for the first time, demonstrated accurate modelling of non-planar TENGs and the optimisation of all primary parameters which govern their output behaviour. However, this initial model was restricted to contact-separation mode TENGs.

Herein, for the first time, we present the unified DDEF theory which can accurately represent both contact and sliding mode 3D TENGs. We compare the output trends of different TENG working modes using this theory to assess their relative performances. A series of optimisation techniques is derived to improve electrical outputs and to reduce internal impedances, which are critical for future TENG applications.

Methods

Gauss's law is used to model the electric field behaviour of finite charged surfaces via analytical methods to derive the unified DDEF equation, which is applied to triboelectric contact surfaces and electrode interfaces to evaluate the electrode potentials [4]. These potentials are modelled against the relative movement between the triboelectric surfaces, which is used to assess the charge, current, voltage and power outputs from the TENG. This unified DDEF model is combined with the Norton's theorem and TENG power transfer theory to maximize electrical outputs and minimize internal impedance [2]. The theoretical results are validated experimentally to assess the effectiveness of these predictions.

Results and discussion

The experimental and theoretical results indicate a close match, proving the accuracy of the unified DDEF model.

This new theory, for the first time, encompasses all possible TENG configurations via a single electric field equation, allowing a common platform for TENG performance comparison. The results indicate that, at constant speed movements, contact-mode TENGs perform relatively better than the sliding-mode TENGs. The optimisation techniques derived here improves the power generation and reduce impedance of the TENG by over 60 times [3], creating a step increase in efficiency and bringing them closer to real-life applications.

Triboelectric-Electromagnetic Hybrid Energy Harvester for Functional Light-Emitting Diodes Inserted Portable Devices *Yu-Seop Kim[1], Yoonsang Ra[1], Chungyeon Cho[2], Sangmin Lee[3] and Dongwhi Choi[1]; [1]Kyung Hee University, Korea (the Republic of); [2]Wonkwang University, Korea (the Republic of); [3]Chung-Ang University, Korea (the Republic of)*

Light-emitting diode (LED) is currently being used in various fields thanks to its unique advantages, such as long lifespan and cost-effectiveness, in comparison to conventional incandescent light bulbs that use relatively high electrical energy. Functional LEDs can emit visible, infrared (IR), and ultraviolet (UV) light, depending on the length of the wavelength range from 275 to 850 nm. Visible LEDs are essential for electronic device displays and lighting. IR LEDs, which emit longer wavelength light, are used in infrared communication, sensing, and medical health care. UV LEDs, which emit ultraviolet rays with a shorter wavelength than visible light, are used in material processing, security, and sterilization. Functional LEDs with various wavelengths have great potential when used in portable electronic devices due to diverse and versatile functionality, in addition to the advantages of energy efficiency. Here, the consideration of a suitable power supply method is essential, as functional LED inserted portable electronic devices need to operate multiple LEDs simultaneously or fully depending on demand without an external power supply. In this regard, research on self-powered portable energy harvesters that are grid independent is highlighted to maximize the advantages of portable electronic devices with functional LEDs. This can increase the possibility that portable electronic devices with functional LEDs can be used in a variety of fields from daily life, security, and healthcare to industry. In this study, we propose a portable triboelectric-electromagnetic hybrid energy harvester (P-THE) for the operation of functional LEDs that emit light with various wavelengths, including IR, visible, and UV. P-TEH can drive functional LEDs using biomechanical energy to serve a portable and extensive purpose. To enhance electrical output, a planetary gear train is introduced to convert low-frequency biomechanical energy from human motion into high-frequency rotational movement, which is a major factor for electrical power output. Triboelectric nanogenerator (TENG) based on the coupling of triboelectrification and electrical charge induction have the advantages of diverse material selection and a simple operating mechanism. One of the notable advantages of TENG is that it can generate high electromotive force. Electromagnetic generator (EMG), which has successfully utilized with its long history, can produce high current output. Considering the characteristics of TENG and EMG, we experimentally demonstrated successful hybridization of TENG and EMG, showing that it is possible to provide both high electromotive force and high current for functional LED operation on demand. P-TEH can operate 250 visible light LEDs, 50 IR LEDs, and multiple UV LEDs using biomechanical energy. Furthermore, demonstrations of various applications, such as healthcare prototype devices with IR LEDs, identification of counterfeit documents, and material processing with UV LEDs, are presented. Consequently, P-THE is expected to extend the range of applications of future portable electronic devices in various fields without an external power source.

Wearable Triboelectric Nanogenerator (Copper TENG) Based Energy Harvester for Biosensing Applications

Seema Powdel, Michelle Livojevic, Yuchen Shao and Manisha Gupta; University of Alberta, Canada

Energy harvesters have emerged as a promising technology, offering a sustainable alternative to traditional battery-powered systems. Recent trends in energy harvesting technology are focused on increasing power efficiency and integration in daily use applications. Triboelectric nanogenerators (TENGs) have shown a wider and a green approach to harness mechanical energy from environment and convert it into usable electrical power. This research highlights on the design and fabrication of a simple and low-cost TENG designed with copper mesh and polydimethylsiloxane (PDMS) focusing on its ability to sense mechanical force and convert it to electrical power/energy. Here, we have developed a fabrication method the fabrication method, which is simple yet efficient, without using complex chemical/mechanical processes, making it economical, sustainable and accessible. The copper, known for its excellent conductivity and flexibility, serves as an electrode to offer charge collection and transfer. We have utilized the commercially available copper mesh with different thickness for this. PDMS, a biocompatible polymer, provides high elasticity to maximize the effect of triboelectric effect. The copper mesh and PDMS are arranged in a contact separation working mode with a PDMS wall (which behaves like an air gap). This PDMS wall separates the conducting bottom copper electrode and insulator middle PDMS thin layer. The design adopts a box-and-a-lid configuration where the copper mesh along with the PDMS wall forms the box structure and the top copper electrode along the middle PDMS layer forms the lid of the device structure. The device is encapsulated with top and bottom layers of PDMS and when the triboelectric layers come in contact, they produce a change in electric potential and induce electrostatic induction to generate electrical power [1]. Experimental data demonstrates that the copper mesh-PDMS TENG can generate open circuit voltage ranging from 1 to 10 V even with gentle tapping with finger. The test devices are made with a PDMS wall of thickness 2 mm and the top and bottom PDMS encapsulating layers are made 1mm thick. The TENG device shows a linear relationship of applied pressure with voltage under constant controlled force and human finger tapping. A power density ranging from 12 μW/m2 can be achieved using 100 μm and 150 μm thick copper mesh with application of controlled constant force. The copper-TENG device shows a good potential for mechanical energy harvester as it can detect small changes in external pressure applied on it and its performance remains stable even after 4000 cycles. The device can be adhered onto the skin as it is lightweight and flexible. The future work is aimed at optimizing the device design for generating higher power capacity and integrating an energy storage element for making it suitable for powering low-power wearable biosensing devices and for IoT applications.

Aluminum Foil Crumpled Ball Based Triboelectric Nanogenerator for Ultralight, Low Noise, Highly Durable Self-Powered Portable Device *Kyunghwan Cha, Sunghan Kim and Sangmin Lee; Chung-Ang University, Korea (the Republic of)*

Recently, as modern society became more industrialized and the global population explodes, the world is facing a large amount of waste materials, which causes environmental problems such as soil pollution, air pollution, and water pollution Among the waste materials, aluminum foil, which is widely used for food, cosmetics, tobacco, and chemical products owing to its distinctive advantages of cheap, lightweight, good thermal conductivity, impermeability, and wide adaptability, occupies a significant proportion and the amount of waste foil is increasing with its usage. For example, estimates suggest that in Europe, almost 860,000 tons of aluminum foil has been produced per year. Also, in China alone, the amount of aluminum foil production is 3.65 Mt in 2017. Many of those aluminum foil is thrown as waste in a damaged state with contaminant materials and difficult to recycle, accordingly, most of waste foils are landfilled or incinerated, resulting in many harmful effects to nature environments. Accordingly, converting the waste aluminum foil into useful things may provide a new platform for addressing the environmental problems.

In this regard, triboelectric nanogenerator (TENG), which converts ambient mechanical energy into electricity via contact electrification and electrostatic induction, is a promising option owing to its attractive characteristics, such as simple fabrication, wide material availability, and versatile operation modes. Although several research have hitherto been conducted to fabricate TENG utilizing aluminum foil, the conventional structures, especially plate to plate type, are disadvantageous to use recycled foil because used aluminum foils are generally wasted in state of torn and wrinkled, and commonly thrown away with contaminant materials. Furthermore, as electrical output performances of typical plate to plate type TENGs, which produce electricity by contact-separation process of different materials, are significantly affected by surface state of materials, these deformed and contaminated foils may have a negative influence on output performances. Therefore, for effectively utilizing these recycled aluminum foils into TENG, a novel structural design strategy, which can generate electricity through these deformed and contaminated foils, is highly desired.

In this work, aluminum foil based crumpled ball TENG (AFCB-TENG) was proposed. Here, the aluminum foil which was commonly wasted as garbage is recycled, crumpled in a ball shape, generates electricity and powers electronics. Owing to the innovative crumpled foil design, AFCB-TENG exhibits the outstanding characteristics, such as ultralight, low noise, and highly durable, which is significantly advantageous and qualified as sustainable power sources. For generating high electrical output, AFCB-TENG was fabricated by air-breakdown model, which produces electricity via direct electron transfer in strong electric field. Therefore, AFCB-TENG achieved the high output performances, such as output peak voltage of 648 V, current density of 8.1 mA/cm^3, and optimum power density of 162.7 mW/cm^3. In addition, for maximizing the output performances, the structure of AFCB-TENG was quantitatively optimized according to various design parameters. The optimized AFCB-TENG demonstrated its high performances while driving 500 LEDs and powering 30 W commercial lamps. This work provides an innovative guideline for fabricating TENG with outstanding characteristics while not polluting our nature environment.

High Direct Current Output Through Flexible Film Triboelectric Generator Employing Wind Power *Ji Woong Hur[1], Sangmin Lee[1] and Jihoon Chung[2]; [1]Chung-Ang University, Korea (the Republic of); [2]Kumoh National Institute of Technology, Korea (the Republic of)*

Amongst various energy harvesting technologies, triboelectric generators (TEGs) are one of the promising energy harvesters in limelight due to its advantages such as simple structure, great deal of possibilities for various materials, high voltage output. However, frictional damage is the topmost challenge since TEG utilizes contact electrification from repeated contact and separation on the surfaces of two materials. To decrease the frictional wear, flexible materials can be applied, but the efficiency of electrical output would be greatly lowered. In this study, the flexible arch-shaped film TEG (FAS-TEG) is introduced to decrease frictional force by applying moderate normal force and increase the contact area with films of flexible triboelectric materials. and metal-to-metal contact between the fixed and moving electrodes causes ampere-level electrostatic discharge which can generate *high direct-current output of 1.7A. FAS-TEG can charge a 100 μF capacitor to 1.74 V for 200 s with wind power even without a rectifying circuit and it could power commercial a thermohydrometer. Finally, FAS-TEG can be further developed to be the promising power source for future electronics.*

SESSION EN09.03: Self-Powered and Low-Power Printed/Flexible Sensors II

Suomi Printed Intelligence—Fully Printed Flexible Electronics—Low Voltage TFTs and Novel NDR Devices
Paul Berger[1,2]; [1]Tampere University, Finland; [2]The Ohio State University, United States

Finland (or Suomi in Finnish language) is a vast landscape of forests that fuels a vibrant timber and paper industry. Finns grow trees in the same way farmers grow wheat, except saplings planted now will be harvested by a daughter or son 25-30 years later. Some of the largest paper companies have roots in Finland, such as UPM. UPM began exploring adding value to their paper by printing electronics atop biodegradable paper. This helped foster a very vibrant printed electronics community within Finland, which has been recognized as a vital technology represented on the Finnish government's technology roadmap. Within this Finnish roadmap is the Printed Intelligence Infrastructure (PII) consortium that infuses significant capital investments, uniting universities and government labs (Oulu, Tampere, Åbo Akademi and VTT). This talk will highlight this Finnish research community and focus on specific accomplishments by the Laboratory for Future Electronics (LFE) team at Tampere University. Currently growing at 18% annually, it has been predicted that by 2030, there will be 50 billion connected devices which should all operate and integrate smoothly with the Internet but also provide a vast spectrum of services in e.g. healthcare, smart homes, industry automation, and environmental monitoring. As the "Internet of Things" (IoT) or "Internet of Everything" (IoE) continues to grow, the number of connected objects will grow at explosive rates. For this to be possible, a paradigm shift from current approaches based on rigid silicon CMOS where batteries are used will be required. In the future, IoT objects will have to be extremely low-cost, flexible and thin (and in some cases also stretchable and/or biodegradable) in order for these ubiquitous electronics to be unobtrusive. In addition, these distributed devices must harvest their energy from other means than batteries, as massive numbers of batteries mean massive end of life, toxic waste disposal and recycling issues. Because they will be manufactured by low temperature, low-cost mass manufacturing processes, they will be ultra-low cost and able to be put on thin, flexible carriers that make them able to be truly put anywhere.
Finland is also the birthplace of atomic layer deposition (ALD), which has become ubiquitous for advanced silicon CMOS. And ALD also has great virtue to reduce energy consumption for autonomously-powered IoT solutions by lowering voltage and improving performance. This talk will place emphasis on active devices, like low-voltage thin film transistors (TFT) with threshold voltages below 1 volt and mobilities in excess of 10 cm^2/V sec and sub-threshold slopes down to 100-110 mV/dec; and a new class of polymer tunnel diodes that manifest with a room temperature negative differential resistance (NDR), enabling hybrid TD-TFT circuits. And this talk will also place these electron devices into perspective within the system-level ensemble that leverages both energy scavenging from the environment and local energy storage.

8:30 AM +EN09.03.02
Towards Edible Electronic Systems for Biomedical and Food Monitoring Applications *Mario Caironi; Istituto*

Italiano di Tecnologia, Italy

Edible electronics envisions a technology that is safe for ingestion, environmentally friendly, and cost-effective. Differently from "ingestible" electronics, it aims at realizing electronic devices that are degraded within the body after performing their function, either digested or even metabolized, thus removing any retention hazard. Edible electronics could potentially target a significant number of biomedical applications, such as remote healthcare monitoring, and of applications for food quality monitoring as well, such as edible electronic tags directly in contact with food. Here I will first give an introduction to this emerging field and propose long-term opportunities in terms of environmentally friendly smart technologies, remote healthcare monitoring, along with the challenges ahead. Then, I will report on our recent progress in the development of edible electrolyte-gated field-effect transistors, and of edible logic circuits made with them, as well as on edible sensors for the monitoring of parameters in the gastro-intestinal tract and of conservation of perishable food. I will also share perspectives for adoption of such edible components in future edible electronic systems, both in terms of power requirements for edible energy storage devices and of communication strategies.

9:00 AM EN09.03.03

Multimodal Flexible Sensors for Minimally-Invasive and Real-Time Plant Monitoring *Masaki Teramoto[1], Satoko Honda[2] and Kuniharu Takei[1]; [1]Hokkaido University, Japan; [2]Osaka Metropolitan University, Japan*

In recent years, global population growth has accelerated the food crisis, especially in developing countries. Smart agriculture, which integrates agriculture and Internet of Things (IoT), is attracting attention as one way to overcome this problem. Efficient management of crops at all times and remotely leads to improve crop productivity and quality. Many soil sensors and plant wearable sensors have been developed to promote smart agriculture. In particular, growth rate monitoring of plant is focused by using sensors, which is an important indicator of plant healthcare. However, to realize the smart agriculture, most likely more plant information needs to be monitored simultaneously, which have yet to be reported to date. If the growth rate and soil condition can be measured simultaneously, it should be possible to analyze the correlation between them for more efficient and healthier crop cultivation. To conduct this challenge, this study aims to develop a multimodal integrated flexible sensor sheet consisted of a strain sensor to measure plant stem growth rate, an impedance sensor to measure soil moisture, and a pH sensor to measure soil pH.

The flexible strain sensor was fabricated by mixing carbon black (CB), polydimethylsiloxane (PDMS), and Ecoflex. Kirigami structure was applied to the sensor film to dramatically reduce the load on the plant due to sensor expansion and contraction, as well as to allow minimal-invasive measurements that do not interfere with respiration and photosynthesis at the stem surface. While Young's modulus without kirigami structure was ~5 MPa, the one for a sensor with kirigami structure was ~41 kPa, which 120 times softer sensor was realized. The maximum strain measurement range of the sensor was 259 % with a gauge factor (GF) 1.15 in the strain up to 40 %, and GF = 1.75 in the strain range between 40 %-55 %. In the strain more than 55 %, GF increased exponentially. Since PDMS and Ecoflex have a high coefficient of thermal expansion, their temperature characteristics were examined to determine the effect of changes in environmental temperature. The resistance change ratio of the strain sensor was 5.8% when the ambient temperature was varied from 15°C to 40°C, suggesting that a temperature sensor is required to integrate with this sensor sheet to measure growth rate of plant accurately in the future.

Impedance sensor was fabricated by printing Ag and CB electrodes on PET film. Soils with different mass moisture contents were prepared, and the impedance was measured by inserting the sensors into each soil. The impedance at 0 % moisture content of the soil was about 800 kΩ, and the impedance decreased with a sensitivity of 1.95 kΩ/% between 0 %-160 %. The impedance reached about 20 kΩ at 340 % moisture content, and the value did not change at higher moisture contents.

The pH sensor was fabricated by printing a CB electrode and an Ag/AgCl reference electrode on PET film and forming a pH detection film, polyaniline (PANI), on the CB electrode by a cyclic voltammetry method. When the potential difference was measured by placing it on solutions of different pH, a strong negative correlation was obtained, with a sensitivity of 14.9 mV/pH.
It is worth to note that all three sensors were characterized with commercially available sensors as control experiments. All results were well matched between these flexible sensors and commercial sensors. After confirming the consistent results using the developed flexible sensors, as a proof-of-concept for multimodal plant sensor sheet, three sensors were integrated on a PET film. Demonstration experiments were conducted using soybean seedlings and succeeded in real-time measurements of these information.
In conclusion, this study developed multimodal flexible sensor sheet to monitor plant healthcare. Although further studies are required to realize smart agriculture, this sensor sheet may help to open a way to monitor real-time plant information.

9:15 AM EN09.03.04

Sustainable Fully Inkjet-Printed Humidity Sensor Based on Ionic Liquid and Hydroxypropyl Cellulose *Mikel Rincón Iglesias[1,2], Peter Krebsbach[2,3], Daniela Correia[4], Cristian Mendes-Felipe[1], Senentxu Lanceros-Mendez[1,5] and Gerardo Hernandez-Sosa[2,3]; [1]BCMaterials, Spain; [2]Karlsruhe Institute of Technology, Germany; [3]InnovationLab, Germany; [4]Universidade do Minho, Portugal; [5]Ikerbasque, Basque Foundation for Science, Spain*

The current digitalization entails the implementation of sensors to collect information from the surrounding environment, in every facet of society. Among the environmental factors, the monitoring of humidity levels is essential in agricultural productivity, food and drug storage, comfort levels, ecosystems, or meteorology, among others. Due to the ubiquity demand of those sensors, certain requirements need to be met, such as being lightweight, flexible, stretchable, efficient, low cost, and of simple fabrication. However, sustainability concerns may arise from the use of non-degradable and synthetic materials in temporary or disposable electronics. This work focuses on the development of advanced humidity sensors using water-soluble cellulose derivatives and ionic liquids to meet performance requirements while promoting sustainability.
We fully inkjet printed a humidity sensor composed of hydroxypropyl cellulose (HPC) as a matrix comprising a 50 wt.% of the ionic liquid: 1-butyl-3-methylimidazolium tetrachloronickelate(II) ($[Bmim]_2[NiCl_4]$). Further, the ionic liquid used presents a color change from transparent when hydrated to blue when relatively dehydrated. The developed ink based on these materials was dissolved using only water and ethylene glycol. The sensor consists of two layers: i) a silver interdigitated electrode (IDE) printed on a cellulose diacetate substrate and ii) the formulated ink printed on the IDE as an active layer.
The relative humidity (RH) was measured by recording the impedance moduli at different frequencies (10^{-1}–10^{6} Hz). The sensor exhibits a linear response in the range between 30% RH and 90% RH with low hysteresis. Moreover, the color change has been monitored by UV-Vis spectroscopy where a linear increase of the transmittance was detected for decreasing RH at ≤ 30%, making it an electrical and a visual sensor. Therefore, this sensor allows to electrically measure the humidity levels in normal conditions and visually indicates exceptionally dry conditions. Thus, it can find applications to conserve water in agriculture or prevent the burning of stubble that can cause forest fires.

9:30 AM EN09.03.05

Wearable Full-Organic Radiation Detector for Real-Time Dose Monitoring During Radiation Therapy *Ilaria Fratelli[1,2], Laura Basiricò[1,2], Andrea Ciavatti[1,2], Matteo Verdi[1], Sabrina Calvi[3,4], Sara Maria Carturan[5,2], Antonio Valletta[3,4], Alberto Aloisio[6,7], Felix Pino[2,5], Marcello Campajola[7], Sandra Moretto[5], Luca Tortora[3,4], Matteo Rapisarda[3,4], Massimo Chiari[2], Stefania De Rosa[3], Stefano Bertoldo[2], Olivia Cesarini[2], Francesco Tommasino[8,2], Ettore Sarnelli[7], Luigi Mariucci[3,4], Paolo Branchini[3,4], Alberto Quaranta[8,2] and Beatrice Fraboni[1,2]; [1]Università di*

Bologna, Italy; [2]INFN, Italy; [3]Istituto Nazionale di Fisca Nucleare, Italy; [4]CNR, Italy; [5]Università degli Studi di Padova, Italy; [6]University Federico II, Italy; [7]Istituto Nazionale di Fisica Nucleare, Italy; [8]Università di Trento, Italy

Mechanical flexibility, portability, low cost of fabrication, scalability onto large areas and human tissue equivalence are crucial properties which make organic and hybrid semiconductors excellent candidates for the development of wearable personal dosimeters. Among others, their employment in the medical field (i.e. during proton therapy treatments) to monitor in real-time and in-situ the dose delivered to the patients during radiotherapy is extremely promising.

Here, we present the results achieved with an innovative fully-organic detector, where a flexible phototransistor (OPT) based on dinaphtho[2,3-b:2',3'-f]thieno[3,2-b]thiophene (DNTT) is coupled with a plastic scintillator based on polysiloxane (i.e. homopolymer polymethylphenylsiloxane and polyvinylphenyl-co-phenylmethyl). The ion beam induced luminescence spectra of the scintillators under irradiation with 2 MeV protons and the UV–vis absorbance spectrum of the DNTT film show a significative overlapping, assuring spectral matching between the light emitting sensor (siloxane scintillator) and the photoconverter (DNTT sensitized OPT). Besides, the coupling between the two components of the detector perfectly preserve the mechanical flexibility and conformability of the device. In fact, this detector demonstrated mechanical flexibility down to a curvature radius of RC = 0.5 cm and low power operation (VDS = VGS = -1 V), assessing its potential employment as a personal dosimeter with high comfort and low risk for the patient.

The detector has been firstly tested under 5 MeV proton beam to reproduce the end-of-range conditions typically present at the border of the target during the prostate cancer treatment. We carried out these tests at LABEC ion beam center (Firenze, Italy). We irradiated the devices with subsequent 10 s cycles of irradiation varying the fluxes of particles in the range of $(10^6 \div 10^{10})$ $H^+s^{-1}cm^{-2}$*. The photocurrent leads to a steep increase upon irradiation which is proportional to the proton flux.*

We present a kinetic model able to precisely reproduce the dynamic response of the device under irradiation and to provide further insight into the physical processes controlling it. By this model, the response of the detector, the rise and fall dynamic, and the progressive build-up of a persistent photocurrent are correctly reproduced. The two components identified in the response under proton flux (a swift and a persistent one) were attributed to two kinds of photo-induced defects with different mean values of the distribution of the recovery activation energies. It was demonstrated experimentally and confirmed by the computational analysis that the fast response is recurring, independently from the persistent current drift, thus assessing the suitability of the here proposed devices as a real-time proton detector.

Then, to assess the use of this technology as personal dosimeter, the detecting system has been tested in actual clinical conditions employing an anthropomorphic phantom mimicking the human pelvis, and a therapeutic proton beams provided by the TIFPA proton therapy center (Trento, Italy) typically employed for prostate cancer treatment (energy in the range [70-200] MeV). The wearable detector has been placed in two different positions: (i) centered on the target of the beam (i.e. in the prostate position) and decentered from it, in the region surrounding the tumor (i.e. the rectum which is one of the organs at risk that would benefit from a real-time monitoring of the impinging radiation). The dynamic curve shows that this device is able to monitor in-situ and in real-time the presence/absence of radiation for the accurate recording and mapping of the dose delivered during a treatment plan. Finally, the detector has been characterized as dosimeter when placed centered in the target position demonstrating dose linearity and providing a stable response even after hard and long-lasting proton irradiation (up to 2 x 10^{10} *protons, 30 min of operation).*

9:45 AM EN09.03.06

Colloidal Crystals Based Time-Temperature Integrators *Markus Retsch, Marius Schöttle, Thomas Tran and Harald Oberhofer; Universität Bayreuth, Germany*

In the realm of advanced materials, the autonomous and manipulation-free recording of temperature states over extended periods is gaining critical importance for, e.g., battery safety assessments. Our research introduces a novel concept for time–temperature integrators (TTIs) utilizing colloidal crystals, which provide a versatile and effective optical readout for low-tech visual inspections.
The innovative approach leverages two key features of colloidal crystals. First, the film-formation kinetics of these crystals can be precisely controlled by blending particles with distinct glass transition temperatures (Tg). Second, by creating a linear gradient of these particle mixtures within the colloidal crystal, we enable a localized and gradual readout mechanism. Specifically, tailor-made latex particles, uniform in size but with varying T_g, create a homogeneous photonic stopband. The disappearance of this opalescence directly correlates with the local particle ratio and the specific time-temperature exposure, offering a straightforward and visual indication of thermal history.[1] *This material is capable of autonomously recording isothermal heating events.*
Increasing the complexity of the colloidal particle mixtures introduces a redundancy of film formation kinetics. We use these in the form of an array of colloidal crystal spots to train an artificial neural network to learn the individual time and temperature dry sintering kinetics. This approach allows for a machine learning-enabled precise and independent measurement of time and temperature parameters, using only a standard smartphone camera for readout.[2] *Our findings highlight the significant potential of integrating machine learning in materials science to enable novel forms of functional devices.*

Microfabricated Bioresorbable Flexible Passive Sensor Nodes for Strain Monitoring *Levent Beker; Koç University, Turkey*

This talk introduces a batch-compatible photolithography-based microfabrication approach for creating highly miniaturized biodegradable sensors on flexible substrates. Up to 1600 devices can fit within a 1 cm^2 footprint. A capacitive strain sensor on a poly(glycerol sebacate) (PGS) substrate, crucial for implantable and wearable applications, demonstrates the method. The sensor measures changes in the gap between interdigitated electrodes (IDEs), showing stable capacitance under various strains (5%, 10%, 15%). Wireless operation and rapid degradation in PBS (1 M, pH ≈ 12) are confirmed. This scalable process offers versatile, high-density biodegradable sensors for real-world applications.

11:00 AM EN09.03.08
Design of Thermochromic Polydiacetylene-Based Dielectric for Soft Stretchable Sensors *Fatemeh Motaghedi, Tricia B. Carmichael and Simon Rondeau Gagne; University of Windsor, Canada*

Polydiacetylene (PDA) is a conjugated polymer with alternating ene-yne moieties, known for its distinct and rich optical properties. Synthesized through the topochemical photopolymerization of 1,3-butadiyne-containing precursors, polymer can be formed via a 1,4-addition reaction when exposed to UV light. The synthesis process is simple and regioselective, resulting in high-purity PDA products without the need for catalysts or chemical initiators. Notably, PDAs can undergo a blue to red phase transition in response to various external stimuli, such as pH, temperature, chemical exposure, molecular bonding, or mechanical stress. This thermochromism is directly *attributed to a a change in backbone conformation, going from planar (blue phase) to nonplanar (red phase). This unique thermochromism made PDAs particularly promising for chemo- and biosensing applications. Despite these features, the rigid backbone of PDAs can limit solubility and processibility, posing challenges for their application in organic electronics.*

To address these limitations, our group developed novel soluble and processable PDA materials by synthesizing 1,3-butadiyne-containing oligosiloxane precursors. The resulting materials, after photocrosslinking to form PDA, were found to be soluble in common organic solvents and easily processable into thin films. Additionally, these crosslinked siloxane-PDA materials exhibited good optoelectronic properties and interesting thermochromism. Upon synthesis and optical characterization, we used these new crosslinked materials as a dielectric in a capacitive temperature sensor, thus enabling the detection of temperature through another mechanism (optical and electronic sensing). This dual-sensing mechanism from the same materials is particularly interesting for smart packaging and wearable sensing, where multiple readout can be used simultaneously to monitor small temperature changes. In this presentation, we will discuss the design and synthesis of the new materials and their application in dual-mode temperature sensing. Various properties of the PDA polymer characterized using techniques such as Raman spectroscopy, differential scanning calorimetry, thermogravimetric analysis, and UV-vis Spectroscopy will also be discussed.

Printed Carbon Nanotube-Based Sensors for Real-Time and Continuous Gas Detection in Simulated Human Gut Microbiota Systems *Sahira C. Vasquez Baez, Martina Aurora Costa Angeli, Luisa Petti and Paolo Lugli; Free University of Bozen-Bolzano, Italy*

To enable sensors to operate effectively beyond controlled laboratory environments, a methodical reverse engineering approach is crucial, tailored to the unique demands of specific applications. In vitro simulators of the human gastrointestinal tract serve as invaluable platforms for studying the influence of dietary factors on gut microbiota, necessitating continuous monitoring of microbial-produced gases. However, these simulators often lack integrated, continuous gas monitoring capabilities in their harsh environments. Here, we showcase the seamless integration and inline use of fully printed carbon nanotube (CNT)-based chemiresistive gas sensors, incorporating a thin polydimethylsiloxane membrane, within the Simulator of the Human Microbial Ecosystem (SHIME). We detail our selection of materials, optimization of fabrication processes, and operational protocols for these sensors. Our results demonstrate the sensors' ability to monitor gas production phases continuously in the anaerobic, highly humid, and acidic conditions of the SHIME system over extended periods (up to 16 hours) with minimal saturation. This work advances the field by establishing a practical and tailored sensor for real-time *monitoring of gaseous biomarkers in in vitro systems like SHIME. The integration of low-cost, low-energy-demand printed flexible gas sensing systems highlights their transformative potential in food biotechnology, promising energy-autonomous sensing solutions.*

11:30 AM EN09.03.10

Electrolyte-Gated Field Effect Transistors-Based Sensors for Nanoplastics Detection—Use of Different Fabrication Techniques and Semiconductor Materials to Investigate Sensors Sensitivity *Giulia Elli[1,2], Manuela Ciocca[1], Bajramshahe Shkodra[1], Malavika Manju Sudheer[2], Giorgio Mattana[3], Benoît Piro[3], Despina Fragouli[2], Paolo Lugli[1] and Luisa Petti[1]; [1]Free University of Bozen-Bolzano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Université Paris Cité, France*

Plastics accumulating in the environment are nowadays of big concern for aquatic systems and for the living organisms populating them. In this context, nanoplastics (NPs) are considered the major and most dangerous contaminants because of their small size and their active surface, which brings them to interact with a variety of other molecules. Despite the importance of detecting NPs, currently available methods rely on bulky and expensive techniques, such as spectroscopy.

The aim of this work is to advance the field of electrochemical sensors in the context of environmental monitoring, by demonstrating that they can be employed for the detection of NPs. In particular, we investigated the use of a novel, fast, and easy-to-use electrolyte-gated field-effect-transistor (EG-FET) based sensor for the detection of polystyrene NPs (PS-NPs) – chosen as model material.

First, random networks of carbon nanotubes (CNTs) were selected as the semiconducting material of choice, considering their ability to form non-covalent interactions with PS-NPs. Indeed, in our CNT EG-FETs (EG-CNTFET) devices, interaction between NPs and CNTs caused a change in the electric double layers. Changes of on current (I_{ON}) (compared to a baseline value) were calculated and the corrected I_{ON} ($^*I_{ON}$) was obtained. A linear increase in the $^*I_{ON}$ of the EG-CNTFETs, with a sensitivity of 9.68 μA/(1mg/ml) and a linear range of detection from 0.025 to 0.25 mg/ml were observed. A π-π interaction was hypothesized to take place between the two materials, as indicated by X-ray photoelectron spectroscopy analysis. Using artificial seawater as electrolyte, to mimic a real-case scenario, a linear increase in $^*I_{ON}$ was also observed, with a sensitivity of 6.19 μA/(1mg/ml), proving the possibility to use the developed sensor in more complex solutions, as well as in low concentrations.

Next, the production and characterization of more complex NPs solutions, resembling more realistic environmental conditions, were evaluated. It was proved that NPs absorbed mercury ions (Hg^{2+}) on their surface, with a binding capacity of 2.04 %. This more complex NPs solution (NP-Hg complexes) was used to evaluate the EG-CNTFET sensitivity. No clear differences compared to pure NPs solution were observed, showing that the developed sensors could be used even with a more complex analyte.

Finally, a different semiconductor material, poly[2,5-(2-octyl-dodecyl)- 3,6-diketopyrrolopyrrole-alt-5,5-(2,5-di(thien-2-yl)thieno [3,2-b] thiophene)](DPP–DTT), was ink-jet printed, to use electrolyte-gated organic field-effect-transistor (EGOFETs) for this application. A linear increase in the $^*I_{ON}$ of the EGOFETs, with a sensitivity of 1.3 μA/(1mg/ml) and a linear range of detection from 0.01 to 0.25 mg/ml were observed. Further enhancement of the EGOFET sensors, by utilizing a peptide as biorecognition element, were then evaluated. Through cyclic voltammetry, a decrease of current in the reduction peak was observed, with increasing peptide concentrations, proving the effective grafting of the peptide on the gate electrode. With electrochemical impedance spectroscopy, an increase in Z (impedance) was observed with increasing peptide concentrations, which correlates to an increase in the charge transfer resistance. With peptide concentration of 10 μg/ml, an increase of 1500 % compared to bare gold was shown. The developed functionalization protocol is now being transferred to a final EGOFET device, and studies on the sensitivity are being conducted.

This study offers a starting point for future exploitation of electrochemical sensors for NP detection and identification.

11:45 AM EN09.03.11

Elevating Healthcare—Flexible Electrochemical Sensing of Cytokines in Sweat for Wearables *Moritz Ploner[1], Bajramshahe Shkodra[1], Antonio Altana[1,1], Lara Franchin[2], Mattia Petrelli[1], Anna Tagliaferri[1], Daniele Resnati[3], Alessandro Paccagnella[2], Stefano Bonaldo[2], Paolo Lugli[1,1], Martina Aurora Costa Angeli[1] and Luisa Petti[1]; [1]Free University of Bozen-Bolzano, Italy; [2]Università degli Studi di Padova, Italy; [3]Empatica, Italy*

In recent years, wearable devices have become essential tools in our daily lives, supporting a variety of activities ranging from human-machine interfaces to health monitoring. Especially the application of wearable sensors in healthcare allows for continuous, minimally invasive monitoring of human health indicators in accessible biofluids like sweat. Among the various biomarkers measurable in sweat, cytokines are particularly compelling for health monitoring as they are essential signaling proteins that play a key role in understanding immune activity and diagnosing diseases like sepsis, diabetes, and cancers. Given the strong correlation between sweat and blood levels, the continuous and quantitative detection of sweat cytokines via wearable devices offers valuable insights into both physiological and pathological conditions, thereby enhancing human healthcare.

While various biosensing techniques for cytokine detection exist, our work focuses on a flexible screen-printed carbon-based three-electrode (SPCE) electrochemical platform, due to its accuracy, sensitivity, miniaturization, and continuous monitoring capabilities, enabling low-cost, accessible, and highly performing wearable monitoring. Due to the low physiological levels of cytokines in sweat (pg/mL range), achieving sensitive detection requires meticulous geometric optimization of the transducer. Here, we detail the fabrication and geometric optimization of the SPCE platform (i.e., active area and electrode distance), through experimental and simulated electrochemical validation via electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV). The geometrical optimization findings indicate that an increase of 300% in the active area leads to a doubled peak current during CV. Additionally, for integration into wearables, a compact configuration appears optimal. Decreasing the distance between WE and CE by half results in a 60% increase in current density in the electrolyte, thus contributing to increasing peak currents and reduced diffusive effects observed during experimental CV. Moreover, the electrochemical reaction occurs solely on the WE, leading to a higher current density in the electrolyte and thereby enhancing sensitivity.

Following geometrical optimization to boost sensitivity, the WE is modified with electrodeposited gold nanoparticles (AuNPs) to improve electron transfer and increase the surface area, while biofunctionalization with thiolated aptamers ensures selective detection of interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF-α), two critical cytokines. Results show that detection occurs in artificial sweat under constant flow conditions, utilizing a microfluidic system designed for wearable applications.

The sensor successfully detects IL-6 and TNF-α within their physiological sweat ranges of 5 to 15 pg/mL and 9 to 362 pg/mL, respectively, with a limit of detection of 0.2 pg/mL for both analytes, using EIS. Importantly, the sensor exhibits a negligible response to non-specific analytes, ensuring high selectivity.

In comparison to other works, which employ more complex and costly materials, our work emphasizes simplicity and cost-effectiveness, as we use simple AuNP-modified SPCEs. Moreover, we apply EIS to detect cytokines in artificial sweat without additional redox reporters, a novel approach that significantly advances biosensor technology, making it ideal for integration into wearable devices designed for sweat-sensing applications, however necessitates a wearable electronic readout suitable for on-body use. Achieving this integration necessitates advancements in low-power electronics and energy harvesting technologies, enabling continuous energy-autonomous sensing without frequent recharging. This integration enhances user convenience and enables on-body applications, thereby paving the way for self-sustaining, high-performance wearable health monitoring devices that have the potential to elevate human healthcare.

Direct Ink 3D Writing of Thermoelectric Materials and Devices *Jae Sung Son, Seungjun Choo, Jungsoo Lee, Seong Eun Yang, Keonkuk Kim and Hyunjin Han; Pohang University of Science and Technology, Korea (the Republic of)*

Thermoelectric (TE) power generation can provide a unique solution to convert this dissipated, wasted heat into useful energy, that is, electricity. The performance of thermoelectric modules, typically composed of cuboid-shaped materials, depends on both the materials' intrinsic properties and the temperature difference created. Despite significant advancements in the development of efficient materials, macroscopic thermal designs capable of accommodating larger temperature differences have been largely underexplored because of the challenges associated with processing bulk thermoelectric materials. At this moment, three-dimensional (3D) printing technology can maximize the flexibility in the design and fabrication of TE modules into more efficient structures. Herein, we present the 3d direct ink writing fabrication of various thermoelectric materials and power generators. The particle-based colloid inks were formulated to exhibit desired rheological properties through the electroviscous effect, tailored by the surface charges. The printed thermoelectric materials exhibit comparable thermoelectric properties to those of materials synthesized by conventional metallurgical methods. Furthermore, combined with the finite element modeling, the macroscopic geometries are designed and realized by the 3D printing processes, leading to significant enhancements in the temperature difference within devices and the resulting output powers. The proposed approach paves the way for designing efficient thermoelectric power generators.

2:00 PM EN09.04.02
Nanostructured Sb_2Te_3 and Ag_2Te Films on Polyvinylidene Fluoride Membranes for Near-Room-Temperature Thermoelectric Heat Harvesting in Mechanically Flexible Devices *Ankit Kashyap[1,2], Geetu Sharma[2], Divya Rawat[1], Debattam Sarkar[3], Niraj Kumar Singh[1], Conner Wallace[2], Kanishka Biswas[3], Ganpati Ramanath[2] and Ajay Soni[1]; [1]Indian Institute of Technology Mandi, India; [2]Rensselaer Polytechnic Institute, United States; [3]Jawaharlal Nehru Centre for Advanced Scientific Research, India*

There is a great deal of interest in high figure-of-merit (ZT) thermoelectric materials for applications such as power generation from waste heat, solid-state refrigeration to support efficient photovoltaic conversion, and heat management in nanoelectronics. High room-temperature ZT in metal chalcogenides demonstrated through nanostructuring and doping have evinced interest in their integration with flexible substrates for powering consumer electronic devices[1, 2]. Here, we demonstrate the integration of nanostructured thin films of Ag_2Te and Sb_2Te_3 nanostructures with polyvinylidene fluoride (PVDF) membranes for generating micro-volt-level electric fields. Ag_2Te nanowires and Sb_2Te_3 nanoplatelets were obtained by either rapid microwave-stimulated surfactant-assisted synthesis or chemical conversion of Te nanowires without a surfactant. Both processes are efficient and amenable to scaled-up production. Micrometer-thick films of these layers were formed on PVDF by vacuum filtration, drying, and cold pressing. Both individual and bilayers of these materials remain mechanically resilient to flexing. The Ag_2Te-based device with Cu contacts generated ~2.3 mV from a human finger touch, and ~18 mV with a 50 K temperature gradient[3], while devices with nanostructured Ag_2Te/Sb_2Te_3 bilayers exhibited ~2.5 mV, and ~28 mV, respectively. This talk will describe the key factors of materials synthesis and processing that play a defining

role in the stability and performance of these flexible mV-harvesting devices. In particular, the roles of solvents, drying rate during film formation, size, and nanostructure shape will be discussed along with strategies to enhance mechanical flexibility and the thermoelectric properties. Our findings are relevant to scalable manufacturing of flexible thermoelectric devices for low-temperature energy harvesting. <!--![endif]---->

2:15 PM EN09.04.03
Direct Ink Writing of PEDOT:PSS Aerogels for Thermoelectric Applications in Soft Electronics *Hasan E. Baysal, Tzu-Yi Yu and Francisco Molina-Lopez; KU Leuven, Belgium*

Soft electronics, characterized by their mechanical softness and stretchability, mimic the form factor of biological systems, offering significant potential for applications in soft robotics, wearable electronics, biomedical devices, and tissue engineering.
Powering wearable electronics remains a significant challenge that could be addressed by thermoelectric (TE) materials, which can generate electrical power from temperature gradients between the body temperature and the environment. Organic thermoelectric (OTE) materials, especially conducting polymers like PEDOT:PSS, are abundant, sustainable, and inherently soft, making them ideal for wearable applications. PEDOT:PSS aerogels, due to their highly porous structure, offer ultra-low thermal conductivity that enhances the temperature gradient across the material, improving the efficiency of TE power generation. Moreover, the lightweight of aerogels reduces the overall device mass, making them ideal for portable and wearable applications. By requiring ≈90% less material compared to dense structures, aerogels offer a cost-effective and sustainable solution for TEs.
Traditional fabrication techniques of planar OTE fall short for the production of emerging soft electronics that extend beyond flat surfaces . Direct Ink Writing (DIW) emerges as a key method for additive manufacturing of complex, three-dimensional structures essential for soft electronics. Developing OTE inks suitable for DIW without compromising their mechanical and thermoelectric performance remains challenging.
To address this, we developed a PEDOT:PSS paste with suitable rheology for DIW. To ensure material shape retention, the printed parts were lyophilized, resulting in a flexible and conducting aerogel with high TE performance. The paste formulation allows to balance electrical conductivity and mechanical stretchability of the 3D printed OTE aerogels. Our DIW process enabled the fabrication of complex, three-dimensional structures that are mechanically robust, maintain their shape, and can be integrated on stretchable substrates.

2:30 PM EN09.04.04
A Facile Method to Improve Adhesion Between CNT Films and Substrates for Better Thermoelectric Performance *Chongyang Zeng and Emiliano Bilotti; Imperial College London, United Kingdom*

Doping methods are common applied to improve the electrical conductivity of CNT films or change the type of CNT films (p-type to n-type) to construct devices with p-n legs. However, the beneficial effect of increasing electrical *conductivity, by a common p-type dopant of $FeCl_3$, will disappear after a heat treatment at 150 °C for 1 h (necessary for activating the self-folding). Moreover, CNT films doped with $FeCl_3$, had a poor adhesion to the electrode substrate for device fabrication. Therefore, it would be desirable to find new additives that can promote CNT films to achieve better adhesion and higher electrical conductivity simultaneously, without increasing the thermal conductivity. PEDOT:PSS is a common conductive polymer that is widely applied in organic solar cells, TE devices and stretchable devices. It has low thermal conductivity, favourable environmental stability and flexibility but relatively low electrical conductivity. Strategies like adding organic polar solvents (e.g. DMSO, ethylene glycol (EG) or acid treatment (e.g. formic acid (FA), sulfuric acid (H_2SO_4) have been used to improve PEDOT:PSS electrical conductivity.*

In this work, PEDOT:PSS-doped CNT films were fabricated by drop casting PEDOT:PSS solutions on the surface of CNT films. p-p conjugate interactions between PEDOT:PSS and CNT are beneficial to improve the TE properties (e.g. electrical conductivity) of the composites. In addition, PEDOT:PSS has been previously reported to act as an adhesion promoter between organic semiconductors (e.g. P3HT) and certain substrates (e.g. UV/ozone-activated polydimethylsiloxane (PDMS), fullerene films). A new self-folded TE device based on CNT/PEDOT:PSS films has been fabricated. The open circuit voltage and output power of this device were 93 mV and 85 µW at a temperature gradient of 80 K, higher than the device without adding PEDOT:PSS (86 mV and 42 µW).

This work provides a new and simple approach to achieve better TE performance by exploring the role of PEDOT:PSS as a dopant and adhesion promoter for CNT films, and offers inspirations for fabrication and applications of new flexible p-type TE materials, for instance in the wearable electronics field.

2:45 PM EN09.04.05

3D Printing of Conductive Polymer Aerogel Thermoelectric Generator with Tertiary Doping *Terek Li[1], Yuhang Huang[1], Jia Xi Chen[1], Yu-Chen Sun[1], Omid Aghababaei Tafreshi[1], Zia Saadatnia[2,1] and Hani E. Naguib[1]; [1]University of Toronto, Canada; [2]Ontario Tech University, Canada*

The rapid advancement of conductive polymer aerogel for thermoelectric application has predominantly depended on the use of performance-enhancing additives for improvement in electrical performance. Meanwhile, the intrinsic capability of the polymer matrix is often overlooked, and control over aerogel geometry remains limited. This arises from the challenges in fabricating conductive polymer aerogel film and the absence of an effective doping technique that does not compromise the aerogel's fragile microstructure due to induced capillary stress. Herein, 3D printing is combined with a tertiary doping process to simultaneously enable synthesize of conductive polymer aerogel with controlled geometry, high electrical conductivity of over 10 Scm- 1, low thermal conductivity of <100 mWm-1K-1, while increasing the thermoelectric output by four times compared to pristine aerogel. The result of this work opens new opportunities to enhance the performance of conductive polymer without relying on additives by unleashing the full potential for conductive polymer matrix.

3:30 PM *EN09.04.06

High-Throughput Printing of High-Performance and Flexible Thermoelectric Devices for Energy Harvesting and Energy Autonomous Sensors *Yanliang Zhang; University of Notre Dame, United States*

Thermoelectric devices offer tremendous opportunities in direct conversion of waste heat into electricity and solid-state refrigeration with no moving parts or environmental emission from refrigerants. To realize its broad applications in energy harvesting and thermal management, significant advances are required to not only increase thermoelectric figure of merit zT but also improve the mechanical flexibility and reduce the manufacturing time and cost. Here, we present novel and scalable ink based printing methods that enable high-throughput

development and low-cost manufacturing of thermoelectric materials and devices.
An aerosol based high-throughput combinatorial printing (HTCP) method is developed to accelerate the discovery and optimization of high-efficiency thermoelectric materials. The HTCP was employed to print thermoelectric materials with gradient doping, and
investigate the role of sulfur doping level in bismuth telluride based materials. This leads to rapid discovery of the optimal doping level, yielding a printed n-type material with high room-temperature power factor of 1774 μW/mK^2.
Sintering is a very critical process in controlling the microstructures and properties of printed thermoelectric materials. We demonstrate a machine learning assisted high-throughput printing and ultrafast (< 1 second) photonic flash processing method that produces silver selenide based flexible films with room temperature zT > 1, which is among the highest in flexible materials. The films show excellent flexibility with 92% retention of the power factor (PF) after 1000 bending cycles with a 5 mm bending radius.
Highly scalable and low-cost extrusion printing and screen printing processes were applied to transform high-efficiency thermoelectric particles into high-performance devices. The thermoelectric power factor in our printed p-type materials reaches 3500 μW/mK^2, which is among the highest in the best reported values in printed TE materials in the last decade. This results in highly competitive room temperature ZT of 1.3. The scalable printing methods can enable film-based devices manufactured with the optimum thicknesses and form factors to realize very competitive performance/cost ratio compared with commercial bulk devices. Moreover, the film-based devices offer mechanical flexibility and adaptability to curved surfaces, making it advantageous for a much broader range of applications than the rigid bulk devices. A fully printed wearable thermoelectric generator generates an electrical power density of 0.5 mW/cm^2 and 26.6 mW/cm^2 at temperature difference of 10 K and 70 K, respectively.
The highly scalable and cost-effective printing technology is poised to become a game changer to unlock the immense potential for thermoelectric devices to play an important role in energy harvesting and enable energy-autonomous sensing systems.

4:00 PM EN09.04.07
Aramid Nanofibers Reinforced Bismuth Telluride Films for Wearable Thermoelectric Generator *Kun Zhang and Xinyi Chen; Donghua University, China*

In this work, we use aramid nanofibers (ANF) to ehance the thermoelectric and mechanical performances of bismuth telluride (Bi_2Te_3) based composite materials. Using aramid nanofibers (ANF) with exceptional mechanical properties and thermal stability as an innovative organic binder, ANF/Bi_2Te_3 composite films were prepared by using the screen-printing method. Attributed to the formation of three-dimensional (3D) ANF network through hydrogen bonding in dispersion, ANF can enhance the dynamic stability of ANF/Bi_2Te_3 thermoelectric ink shows, which lays a foundation for subsequently preparing high-performance ANF/Bi_2Te_3 films. Meanwhile, experimental results show that a small quantity of ANF can simultaneously optimize the thermoelectric performances of commercial Bi_2Te_3. When the ANF content is 0.1wt%, the power factor of composite film achieves the maximum value of 3373.8 μW/m.K^2, which is 1.29 times that of pure Bi_2Te_3 film. Multiple characterization and theoretical calculations were utilized showing the attribution of such prominent thermoelectric properties to a significant increase in the effective carrier mass induced by interaction between ANF and Bi_2Te_3. Furthermore, benefiting from robust ANF network and strong interaction between two phases, the mechanical performance of Bi_2Te_3 matrix was enhanced simultaneously.

4:15 PM EN09.04.08
Brush-Printed Thermoelectric Generators *Bokai Zhang; KU Leuven, Belgium*

Organic thermoelectric materials (OTEs) present distinct advantages such as cost-effectiveness, large-area *processing capabilities, material abundance, and flexibility. However, their widespread adoption is limited by inherent performance constraints. While research has largely concentrated on novel materials and doping strategies, molecular ordering—a proven technique for enhancing organic transistor performance—remains underexplored in OTEs.*

Our objective is to establish a versatile approach for enhancing the performance of thin-film OTEs by inducing anisotropic molecular conformation changes and increasing crystallinity through brush printing. We developed a protocol for the well-known P-type polymer PEDOT and systematically studied the effects of coating speed and film thickness. We hypothesize that the directional capillarity effect induced by the brush bristles will promote the elongation and connectivity of PEDOT-rich domains. Anisotropic performance is expected at the mixed regime of coating, which can lock in place the aligned polymer chains while maintaining relatively high crystallinity.

The induced nanoscale morphological changes significantly enhanced the conductivity along the printing direction without compromising the Seebeck coefficient, resulting in a 270% improvement in power factor compared to similar spin-coated samples. We will apply a similar protocol to less-explored emerging N-type polymers, thereby introducing a novel method to produce high-performance OTE generators that encompass both P-type and N-type conducting polymers.

4:30 PM EN09.04.09

Soft and Highly Conductive Structured Materials for Wearable Thermoelectric Devices *Jiraphat Khongthong, Mohsen Mohammadi, Nara Kim and Klas Tybrandt; Linköping University, Sweden*

The incorporation of thermoelectrics in wearable technology has attracted considerable attention with the potential of energy harvesting for powering electronic devices and providing sustainable thermal comfort for human body. Local thermoelectric generating/cooling can be achieved by conventional bismuth telluride p- and n-type thermoelectric pellets, but there is a need for uniform distribution of electric current and heat over large areas with soft and stretchable conductors in wearables. However, current technologies have limitations in terms of low electrical and thermal conductivity, and softness which result in impractical devices. Here, we develop a novel class of soft structured materials that combines the unparalleled performance of conventional metals with the unique electromechanical properties of emerging stretchable composites. By employing a new structural design, the high performance stretchable conductor circumvents the weakness of conventional kirigami materials and serpentine design, and demonstrates superior conductivity with low sheet resistance, high stretchability, and low effective Young's modulus. The conductors allow for seamless integration of thermoelectric coolers and heat sinks into clothing to facilitate wearable technology for efficient large-scale applications.

4:45 PM EN09.04.10

Intrinsically Stretchable and Printable Thermoelectric Materials for Highly Sustainable Thermal Energy Harvesting *Doojoon Jang[1] and Heesuk Kim[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)*

Thermoelectric (TE) materials have the potential to capture and convert waste heat from low-grade thermal sources into electricity for solid-state energy harvesting. Despite the significant advances in TE energy conversion efficiency through material-level discoveries, diversification of heat sources presents a barrier to sustainable thermal energy harvesting from arbitrarily shaped and deformable targets, such as the human body. To address such challenge, the TE materials are expected to flawlessly accommodate the applied strains and deformation through improved intrinsic stretchability without undermining the TE properties. However, efforts to enhance the stretchability of high-zT inorganic TE materials or inherently flexible TE polymers often result in compromised TE *properties due to the introduction of plasticizing agents. Stretchable TE generator designs can only partially complement the intrinsically insufficient material stretchability, at the clear expense of limited material selection and manufacturing processes. Likewise, the empirical trade-off between the material mechanical reliability and TE efficiency presents a formidable hurdle towards flawless thermal energy conversion with high mechanical reliability under harsh operating environments.*

In this study, we introduce an innovative approach to restructure and hybridize single-walled carbon nanotube (SWCNT) networks to achieve simultaneous facilitation of mechanical reliability and TE efficiency. Low-molecular-weight polymeric dopants can allocate greater free volume within the SWCNT network, while concurrently promoting its electrical conductivity, and the resulting restructured film can be stretched up to 100% with more homogeneously size-controlled microcracks. Moreover, incorporation of ionic liquids with high dielectric constants alleviates the aggregation of π-π interacting SWCNT bundles to further improve the film stretchability to ≥170%. As a consequence of SWCNT debundling and SWCNT-polymer heterointerfaces, phonon scattering is further intensified to considerably suppress the lattice thermal conductivity for enhanced TE figure of merit (zT >0.1). Such exceptional deformability and programmable viscoelasticity allow for our restructured SWCNT to be directly printed into three-dimensional structures at micrometer-scale resolution to achieve soft TE generators with an unprecedented pair of exceptional mechanical reliability and TE harvesting efficiency. Our ingenious strategy promises to spark innovations in leveraging thermal energy for a broad range of practical applications encompassing wearable electronics and Peltier thermoregulation.

Enhancing Slide Electrification by Polarization of Electret Materials *Shalini Shalini[1], Pravash Bista[2], Sajjad Shumaly[2], Chirag Hinduja[2], Dhiman Mallick[1], Ankur Goswami[1], Hans-Jürgen Butt[2] and Rüdiger Berger[2]; [1]Indian Institute of Technology Delhi, India; [2]Max Planck Institute for Polymer Research, Germany*

Sliding electrification is the spontaneous charge separation when water droplet moves over the hydrophobic surface [1, 2]. Sliding electrification has been explored for various fluoropolymers (PFOTS, PTFE etc.)[3] and non-fluorinated polymers[4]. For fluoropolymers and non-fluoropolymers surfaces a highest drop charge of approximately ~2 nC has been reported[5]. Fluoropolymers are electret materials, which can be pre-charged by polarization. However, slide electrification effects were not investigated for defined polarization states. Using a defined polarization state offers the possibility to increase the efficiency of charge separation significantly. Therefore, we investigated how pre-charged hydrophobic surfaces impact sliding electrification. The hydrophobic surface has been used in this study that is Cyclic Transparent Optical Polymer (CYTOP) fluoropolymer. CYTOP has the capability to store the negative charge for months[6]. We applied an intense electric field of -6 MV/m for 15 min to a ~500 – 600 nm thick CYTOP film. For this field strength causes a corona discharge where dipoles orient near the surface[7, 8]. The advancing and receding contact angles of pre-charged CYTOP (PCC) were 85° and 65° respectively, for non-charged CYTOP (NCC) film 112° and 102° respectively. Consequently, contact angle hysteresis (CAH) was observed around 10° and 20° for NCC and PCC surface, respectively. Sliding electrification *experiments revealed a drop charge of approximately ~1.2 nC corresponding to a drop discharge current of ~6 μA on for the NCC surface. However, the drop charge increased on the PCC surface to ~8.3 nC that corresponds to a drop discharge current of ~100 μA drop current. Therefore, using pre-charged CYTOP surface results in an eight-fold higher drop charge than any other reported slide electrification charge for 45 μL volume drops. The drastic increment in drop charge shows the discernible impact of pre-charge CYTOP surface. I will discuss how slide electrification can be used to power energy-autonomous sensing systems.*

Enhancing Energy Applications Through Self-Doped Conducting Polymers and Nanostructured Composites—Synthesis, Characterization and Performance

Dana Kanzhigitova, Perizat Askar, Aslan Tapkharov, Salimgerey Adilov and Nurxat Nuraje; Nazarbayev University, Kazakhstan

This study shows the creation, analysis, and utilization of conducting polymer nanostructures, such as self-doped conducting polymers, V_2O_5 inorganic templates, and polyaniline derivative nanostructures, for energy-related purposes. The self-doping mechanism in polymers introduces charged functional groups into the polymer backbone, leading to a substantial improvement in electrical conductivity and stability, without depending on external dopants. Nanostructures are created by engineering polyaniline derivatives, which have become known for their environmental stability and adjustable electrical properties. The key findings indicate that these self-doped conducting polymers and polyaniline derivative nanostructures possess exceptional conductivity and stability, making them very suitable for uses in the energy sector.

Hybrid thin films were synthesized by chemically polymerizing vanadium pentoxide (V_2O_5) and polypyrrole (PPY) to form composites. The use of p-toluenesulfonic acid as a dopant improved the sensing capacities, enabling the *detection of minor changes in current resulting from low levels of hydrogen exposure (5-250 ppm) at normal room temperature. The latency was 42 seconds, however the recovery time was 37 seconds, demonstrating quick and efficient working.*

By implementing specific chemical modifications, the self-doping effect is utilized to improve the conductivity and biocompatibility of these polymers. This enhancement makes them ideal for a range of applications, such as serving as cathode material in batteries and providing stable counter electrodes for dye-sensitized solar cells (DSSCs). This study enhances the overall comprehension of conducting polymers and nanostructured materials, hence creating new opportunities for the advancement of next-generation energy applications.

EN09.05.03

Fully Organic p-n Diode Using Polarity Switching in Single Conjugated Polymer-Dopant System *Eunsol Ok and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)*

Investigations into organic semiconductors (OSCs) often encounter limitations with n-type charge transport due to the environmental vulnerability of n-type materials. Developing stable and high-efficiency n-type OSCs is crucial for devices relying on p-n junctions in complementary and logic circuits. This research introduces polarity switching, an unusual phenomenon caused by doping p-type conjugated polymer (CP) film in high doping level, and then the main charge carrier type switches from p to n depending on the doping level. The polarity switching is implemented only with inherently stable p-type CP and p-type oxidizing agent as dopant. In this study, the polarity switching is validated with the electric properties changing from p to n-type via Seebeck coefficient analysis, AC Hall measurements, field-effect transistor mobility, and energy level shift using photoelectron spectroscopy. Further molecular structural changes induced by doping are examined through grazing-incidence wide-angle X-ray scattering, with a detailed analysis of oxidation state changes in the dopant ions via X-ray photoelectron spectroscopy. These results demonstrate a direct relationship between an increase in delocalized polarons and a reduced bandgap, leading to band-like transport. Additionally, the study reveals orientation changes in the crystalline structures due to dopant interactions with the CP backbone chains. This research successfully culminates in the development of a vertical homojunction organic diode with a rectification ratio in the tens of thousands, enhancing our understanding of polarity switching and paving the way for novel applications that allow versatile charge carrier type manipulation within a single p-type CP-dopant system. Furthermore, the p-n diode array, utilizing parylene C as the substrate, is versatile enough for use in creating soft, flexible, and transparent devices, suitable for modern wearable, human-friendly technology. Notably, the bridge rectifier circuit, using four p-n diodes, facilitates the rectification of alternating current into output, enabling its seamless integration into electronic and household appliances.

EN09.05.04

Advanced Materials for Energy Efficient Printable Electronics *Rodrigo F. Martins, Suman A. Nandy, Guilherme Ferreira, Manuel Mendes and Elvira Fortunato; NOVA School of Science and Technology, Portugal*

With the growing smartness in electronic manufacturing worldwide, printed electronics capture attention because of their ability to overcome the limitation of traditional high-cost manufacturing approach which is mostly based on rigid silicon substrate. Moreover, has a great potential to offer biodegradable and recyclable solutions, by choosing low-cost substrate for printing devices, that may be recycled and/or naturally degraded in nature. This is a way forward to minimize the electronic waste (e-waste) caused by the ever-increasing number of disposable electronic devices. Relevantly, "printing electronics on paper" technology is rapidly developing in both research and electronic industry fields during the last decade. [1]
For a plethora of applications, the printed devices and systems on foils require to be powered autonomously. To

do so, within a sustainable approach green energy source should be exploited, such as photovoltaics thermo and mechanic energy harvester exploiting as much as possible the different materials performances as well design and architecture of the same.
The development of stable, cost-effective, non-toxic, and eco-friendly printable devices for energy powering electronic printed devices on foils, such paper that are extremely lightweight, affordable, readily customizable, thin, flexible, and disposable are discussed in this presentation.

EN09.05.05
Navigating Bias Stress Effects for Organic Transistor Sensor Design *Manikanta Makala[1], Maciej Barlog[2], Derek Dremann[1], Salahuddin Attar[2], Edgar Gutiérrez Fernández[3,4], Mohammed Al-Hashimi[2] and Oana D. Jurchescu[1]; [1]Wake Forest University, United States; [2]Texas A&M University, Qatar; [3]European Synchrotron Radiation Facility, France; [4]University of Warwick, United Kingdom*

Electronic sensors play a key role in modern society, enabling the detection and monitoring of various physical, chemical, and biological processes. Organic field-effect transistors (OFETs) have emerged as a versatile platform for the development of this technology. However, their long-term stability and reliability are often compromised by bias stress effects, which occur upon prolonged operation. While progress has been made in the development of p-type devices, there is still a pressing need for the advancement of stable n-channel OFETs. In this work we improved the operational stability of n-type devices by utilizing the new class of donor-acceptor polymers materials based on indacenodithiazole (IDTz) and diketopyrrolopyrrole (DPP). Chemical tailoring of the electrode surface resulted in tunable charge transport and the demonstration of electron and hole injections with mobilities exceeding 1 cm^2/Vs. We implemented a double layer polymer dielectric to achieve a high tolerance against bias stress and stressed the devices for 1000 min at constant DC conditions ($V_{GS} = V_{DS} = 60V$). These conditions are much more aggressive than only repeated cycling of the devices and more appropriate for applications where the transistor must provide current for long periods of time. Our OFETs exhibited negligible changes in mobility and a threshold voltage (Vth) shift = 0.5 V. Intriguingly, our findings reveal that performance and bias stress stability are not directly related when different side chain orientations are introduced on polymer backbone. Polymers with branched side chains exhibited slightly more notable degradation (average shift in mobility is 9 percent, and Vth = 1.2 V), although the polymer with branched side chain gave the highest mobility. In this presentation we will also describe the effect of annealing along with the structural importance of polymer and evolution of trap density of states in device stability, information of which gives clue on degradation pathways. In summary, our results provide a framework to better understanding and mitigating bias stress effects in OFETs, a crucial step for the development of stable and reliable organic electronic sensors.

EN09.05.06
Efficient Organic Photovoltaic Modules for Indoor Applications *Seunghyun Rhee and Seo-Jin Ko; Korea Research Institute of Chemical Technology, Korea (the Republic of)*

In recent decades, the expansion of Internet of Things (IoT) devices has been substantial, leading to their pervasive integration into various facets of daily life. These indoor IoT devices necessitate extremely low power consumption, typically within the range of 1-300 μW, and thus require a sustainable power source. Organic photovoltaics (OPVs) emerge as an ideal power solution, aligning well with these low-power demands and offering numerous benefits. These benefits include optimal absorption wavelengths for indoor light sources, the potential for vibrant color realization, and flexible form factors. Despite the significant advancements in indoor OPVs, the development of high-performance indoor OPV modules is crucial for their practical application.
This study focuses on the manufacturing process of organic photovoltaic (OPV) modules designed for high performance in indoor applications. Leakage currents, resulting from internal defect states, pose a significantly

greater challenge in indoor OPVs compared to outdoor 1 Sun illumination conditions. To address this issue, we employed various large-area film fabrication techniques, such as doctor-blading, bar-coating, and slot-die coating, followed by laser scribing for precise etching of large area organic film. The fabricated large-area organic films demonstrated a defect-free quality, making them well-suited for the implementation of large-area OPV modules in indoor settings.

EN09.05.07

Enhanced β-Phase Formation and Dipole Moment in Poly(Vinylidene Fluoride) (PVDF) Films—Influence of Fabrication Processes and Hot-Pressing

Minyeong Cheon and Su-Chul Yang; Dong-A University, Korea (the Republic of)

Poly(vinylidene fluoride) (PVDF) is extensively utilized in applications such as pressure sensors, actuators, and energy harvesters due to its favorable piezoelectric properties. This study investigates the impact of different fabrication processes and subsequent hot-pressing on the β-phase formation and dipole moment in PVDF films. The PVDF films were prepared using doctor-blading, spin-coating, and electrospinning techniques to analyze their β-phase conformation and polymeric crystallinity.

The results indicated that the electrospinning process significantly enhanced the β-phase fraction, reaching up to 83.8%, due to the high stretching effect. This was further improved slightly through hot-pressing, which also enhanced polymeric crystallinity. The hot-pressed electrospun PVDF films demonstrated a maximum output voltage of 6V, showcasing their potential in practical applications.

SEM analysis revealed that the electrospun PVDF films exhibited small pores between nanofibers before hot-pressing, which disappeared after the process, resulting in a dense structure. The 12 wt% electrospun PVDF films achieved the highest β-phase fraction and dipole moment due to the combined effects of effective polymer chain stretching and pore volume during hot-pressing.

This research underscores the importance of the fabrication process and post-treatment in optimizing the piezoelectric properties of PVDF films, providing valuable insights for the development of high-efficiency piezoelectric devices. This study was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF), funded by the Ministry of Education (NRF-2022R1F1A1071566).

Keywords: Poly(vinylidene fluoride), β-phase fraction, Polymeric crystallinity, Dipole moment, Electrospinning, Hot-pressing, Doctor-blading, Spin-coating

EN09.05.08

The Role of Oxygen Insertion on Performance of A-D-A-Type Non-Fullerene Acceptors (NFA) in Organic Solar Cells

Wejdan A. Althobaiti[1], Yakun He[1], Julien Gorenflot[1], Wisnu T. Hadmojo[1], Sandeep Sharma[1], Weimin Zhang[1], Shahidul Alam[1], George Harrison[1], Shadi Fatayer[1], Iain McCulloch[2], Thomas D. Anthopoulos[1], Martin Heeney[1] and Frédéric Laquai[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]University of Oxford, United Kingdom

Charge transfer (CT) in bulk heterojunction (BHJ) organic solar cells (OSCs) can occur through two pathways: photo-induced electron transfer from the donor (D) to the acceptor (A), controlled by the electron affinity (EA) offset, and photo-induced hole transfer from the acceptor to the donor, governed by the ionization energy (IE) offset. Here, we report the synthesis of a novel non-fullerene acceptor (NFA) coded TPTI-BT, whose properties were first predicted by computational chemistry before the material was synthesized: i.) high ionization energy, creating sufficient IE offsets with many typical donor materials, and ii.) large acceptor quadrupole moment (QM), facilitating interfacial charge transfer and separation. However, despite these allegedly favorable properties for high device performance, TPTI-BT exhibited surprisingly moderate device performance, in particular when

compared with the structurally-related and efficient acceptor O-IDTBCN. In fact, the chemical structure of TPTI-BT is very similar to that of O-IDTBCN, it contains only two additional oxygen atoms in the donor core of the A-D-A-type acceptor backbone structure. Interestingly, this causes TPTI-BT to exhibit overall lower device performance. We present a comparative study of these two NFAs (TPTI-BT vs. O-IDTBCN) and elucidate the origin of the lower performance of the TPTI-BT acceptor caused by the modification of the chemical structure upon insertion of two additional oxygen atoms.

EN09.05.09

Molecular Aspects of Deformability in Printed Organic Semiconductors *Robert Ramji[1], Andrew T. Kleinschmidt[1], Darren J. Lipomi[2,1] and Tod A. Pascal[1]; [1]University of California, San Diego, United States; [2]University of Rochester, United States*

The structural rigidity and electronic properties of semiconducting polymers are fundamentally influenced by their backbone geometry. As we push the boundaries of flexible and stretchable electronics for the next generation of sensing systems, understanding and controlling the physical and thereby the electronic structure of π-conjugated polymers becomes a crucial part of advancing these technologies. Rational design of new material compositions for energy-autonomous devices will require advanced theoretical approaches, including simulation of these material systems at the nano and micro scales with molecular dynamics (MD). However, due to the limitations of conventional methods like classical force fields, existing torsional scan (TS) methods for parameterizing inter-monomer torsional potentials fail to accurately represent the behavior of conjugated polymers with significant steric hindrance, leading to unusably distorted energy calculations. We introduce a more precise method based on isolating the energy associated with electron delocalization (DE) that decouples delocalization energy from other nonbonded interactions, providing more accurate estimates of backbone rigidity. Our method significantly improves the modeling of polymers like PNDI-T, demonstrating more accurate planarization energy calculations, and further allows for a general exploration of the difference in energy associated with electron delocalization between various backbone conformations. We extend our initial work to explore the effects of both dihedral and improper torsions on electronic properties. Our findings indicate that while improper torsion generally disrupts electron delocalization, certain configurations may enhance orbital overlap, reducing the energetic cost of certain conformations, suggesting pathways to maintain conjugation even under high torsional stress. This approach not only refines current computational models but also enhances the understanding of the mechanical and electronic behavior critical for developing advanced materials in flexible and stretchable electronics.

EN09.05.11

Amplifying Touch Using 3D ZnO Tetrapods for Tactile and Haptic Intelligence *Parth Pandit[1], Mahesh Y. Chougale[1], Deepak Dubal[1], Yogendra K. Mishra[2], Graham Kerr[1] and Ajay K. Pandey[1]; [1]Queensland University of Technology, Australia; [2]University of Southern Denmark, Denmark*

In the era of virtual and augmented reality, the quest for wearable tactile sensors that can relay and resolve physical interactions akin to the human sensory receptors and provide haptic feedback are becoming increasingly important. Inclusion of pressure sensors in soft and textured forms can also help bionic devices, and aid positively in diagnostics and rehabilitation of gait movement and plantar fasciitis in geriatric patients[1].Their multifunctional role is often suited to double up as energy-harvesters- capable of converting external kinetic energy into electrical energy via microstructural changes [2].
In this work, we present piezoelectric properties of a composite film of Polyvinylidene fluoride (PVDF) and 3D Zinc oxide tetrapods (ZnT). Zinc oxides are emerging as ideal materials for piezoelectric applications due to their superior piezoelectric properties, flexibility, and stability. PVDF stands out for its flexibility and biocompatibility. By integrating these materials, we created tactile sensors that are not only highly sensitive but also serve as energy

harvestor, making them suitable for self-powered wearable sensing applications[3]. Electrical characterization of these composite devices shows the piezoelectric voltage produced increases as a function of ZnT loading. Their operational stability, reliability and effectiveness in monitoring different types of physical interactions including whole body weight bearing and detection of foot movement are examined. These advancements could pave the way for the integration of flexible, highly sensitive, and self-powered pressure sensors into future healthcare, haptic feedback systems, and robotic technologies[4].

Photocatalytic Inks Based on TiO_2 Nanomaterials for Water Remediation

Christian A. Palacios Torrez[1,2], Angélica Orona Navar[1] and Jose M. Romo-Herrera[1]; [1] Universidad Nacional Autónoma de México, Mexico; [2] CICESE, Mexico

Wearable devices are a current reality and its development deserves great attention. Transferring the properties of nanostructures into textiles could have a great impact on society's every day life. Moreover, heterogeneous photocatalysis has gained attention in recent years as a method to clean water, due to its great potential for the mineralization/breakdown of organic pollutants via advanced oxidation processes (AOP) [1]. Most materials used for research in this field are employed in either powder form or supported over a rigid substrate, both of which are unsuitable for large-scale applications. Our work aims to evaluate the photocatalytic efficiency of textiles printed with screen-printable inks based on TiO_2 *nanomaterial pigments, proposing them as a promising alternative for large-scale remediation of water bodies.*

A screen-printing paste has been designed with a commercially available TiO_2 *powder (80% anatase; 20% rutile) used as the active pigment. A second set of* TiO_2*-based materials were obtained via the reduction of the commercial powders in presence of Al, following a procedure reported by Wang et al. [2]. These pastes were obtained by mixing the pigments with polymeric binders and a plastifier, using a mixture of water and ethanol as solvent. As-obtained pastes/inks were used to screen-print patterns onto different textile substrates. Angle-contact measurements of the different pastes were analyzed to explore their wettability properties, while microscopic profiles of the cross section of the dried patterns allowed to monitor and optimize their viscosity. The* TiO_2*-based inks exhibited good viscosity for screen-printing onto cotton and glass fiber substrates. The adherence and physical stability of the printed patterns has been evaluated.*

Photocatalytic tests were performed via the degradation of a dye under various light conditions in presence of the screen-printed textiles and compared to the pigments in their powder form as reference. This result should be important data to evaluate the performance at a laboratory level for the use of TiO_2*-based inks in large-scale water remediation.*

Tailoring the Alkyl Side Chain of DPP-Based Conjugated Polymer for Improved Thermoelectric Performance

Byoungwook Park; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Conjugated polymers (CPs) have recently garnered significant attention as thermoelectric materials due to their low thermal conductivity, high potential for scalable production via solution processing, and excellent mechanical deformability. However, despite these attractive attributes, CPs generally exhibit inherently low electrical conductivity, which impedes the thermoelectric performance of devices. Additionally, there is a notable lack of systematic investigations into the molecular design of CPs aimed at optimizing their thermoelectric performance. In this work, we designed and synthesized novel DPP-based conjugated polymers with precisely controlled alkyl side-chain lengths. Utilizing these newly synthesized polymers, we fabricated thermoelectric devices and evaluated their electrical conductivity and thermoelectric performance under various doping conditions. The fundamental aspects of the electrical, morphological, and structural properties of the synthesized polymers are discussed. Notably, we elucidated novel insights into the doping efficiency and electrical conductivity characteristics as influenced by the length of the alkyl side-chains in CPs, thereby demonstrating the systematic development of thermoelectric devices based on the structural design of CPs.

EN09.05.14
Liquid-Metal-Printed Ultraconductive Two-Dimensional Oxides for Multimodal Wearable Bioelectrodes

William J. Scheideler, Md Saifur Rahman and Anand P. Tiwari; Dartmouth College, United States

Conducting oxides are a critical high-performance material for next generation displays, solar cells, and wearable sensors, but their high process temperatures and poor mechanical properties have limited use in printed flexible electronics. We propose to overturn these limitations of inorganic oxides via ultrafast, low-temperature fabrication of durable wearable electrodes via liquid metal printing. We demonstrate solvent-free, vacuum-free printing of highly flexible two-dimensional (2D) conducting oxides for wearable multimodal bioelectrodes. Our robotic liquid metal printing process based on Cabrera Mott surface oxidation deposits ultrathin (2 – 10 nm thick) 2D indium tin oxide (ITO) with excellent transparency (> 95%) and superlative conductivity (> 1300 S/cm) on par with sputtered films. In a significant advance over past printed oxides, we leverage hypoeutectic In-Sn alloys for printing 2D ITO at less than 140 °C, allowing deposition on polymer substrates including PET, PEN, and polyimide. XPS, XRD, AFM, and HRTEM characterization reveals the efficacy of Sn-doping, the highly crystalline nature of 2D oxides, and the large, platelike grains formed by the liquid metal reaction environment. We further demonstrate a significant enhancement to bending strain tolerance for 2D ITO (down to 2 mm bending radius), high scratch resistance exceeding the durability of traditional PEDOT electrodes, and low contact impedance to skin as a wearable bioelectrode compared with control Ag/AgCl gel electrodes. Finally, we utilize the conductivity and transparency of

2D ITO for synchronous, multimodal measurements via electrocardiography (ECG) and pulse plethysmography (PPG). Collectively, these results represent an order of magnitude improvement in the performance of printed metal oxides and introduce a promising material set for display-integrated electrodes and multimodal biometrics.

EN09.05.15

Photonically Cured Solution Deposited Hybrid Transparent Conducting Electrode Fabricated with Methods Scalable to Web Speeds > 10 m/min

Justin C. Bonner[1], Bishal Bhandari[1], Robert Piper[1], Cynthia T. Bowers[2], Melinda A. Ostendorf[2], Garret Vander Stouw[3], Julia Huddy[4], William J. Scheideler[4] and Julia W. Hsu[1]; [1]The University of Texas at Dallas, United States; [2]Air Force Research Laboratory, United States; [3]Energy Materials Corporation, United States; [4]Dartmouth College, United States

Transparent conducting electrodes are used in many applications such as LEDs, displays, and solar cells. Ideal transparent conducting electrodes have low sheet resistance, high transmittance, and low surface roughness. This work demonstrates a roll-to-roll (R2R) compatible process to fabricate hybrid transparent conducting electrodes on PET. Roll-to-roll manufacturing at a commercial scale requires flexible substrates that can be conveyed at processing speeds > 10 m/min. Solution deposition via blade coating, gravure, or flexographic printing can be performed at a high speed with low capex cost. However, thermal annealing is too slow and can damage PET; thus, we adapt photonic curing for post-deposition processing. Photonic curing uses a xenon flash lamp to deliver micro-to-millisecond light pulses onto the sample and heat specific films via light absorption. High temperatures can be achieved in the film processed using photonic curing with the PET substrate staying at low temperatures because the short light pulse can be of high intensity and low energy. This work applies photonic curing to make hybrid transparent conducting electrodes that consist of a multi-scale Ag network of metal bus lines (MBLs) and nanowires (AgNWs), overcoated with indium zinc oxide (IZO) on PET. We achieved an average transmittance > 80%, sheet resistance < 15 ohms/sq, and surface roughness < 5 nm. The AgNWs and IZO are blade coated at a 1.5 m/min speed and photonically cured at speeds > 10 m/min. TEM cross sections and SEM images show IZO planarizing MBLs and AgNWs.[1] Bending tests are performed to show the material can be conveyed over 2” diameter rollers. XPS analysis shows metal oxide conversion after photonic curing. The process is then adapted to gravure/flexographic printing at speeds up to 60 m/min to further demonstrate scalability. Perovskite solar cells are fabricated on top of these hybrid TCEs and benchmarked against commercial TCEs.

EN09.05.16

Enhanced Strain Resistance of Fractal Fiber Laser-Induced Graphene for Flexible Electrodes via Annealing and Oxygen Plasma Etching

Yanru Chen[1,2], Yixin Liu[2], Yuhan Liu[2], Jiaqi Liu[2], Liuyang Han[2] and Yuzhen Li[2]; [1]University of California, San Diego, United States; [2]Tsinghua University, China

1. Introduction
Laser-induced graphene (LIG) is a low-cost, three-dimensional (3D) porous carbon material with excellent electrical properties, fabricated via laser direct writing (LDW). Its easy fabrication makes LIG suitable for applications ranging from healthcare wearables to soft electronics that need flexible, stretchable materials with good stress resistance. However, LIG's natural brittleness limits its strain resistance. To address this, we propose a dual treatment strategy of annealing and oxygen plasma etching to enhance the strain resistance of LIG.

2. Method
A 6 mm × 6 mm square LIG pattern was prepared on a polyimide film using a 10.6 μm carbon dioxide (CO_2) infrared laser with a power of 3.6 W and a speed of 90 mm/s. The LIG was then modified through a 25-minute oxygen plasma etching process and a 4-minute low-temperature annealing at 180°C, resulting in a fractal fiber structure.

3. Result and Discussion

LIG was prepared through the LDW technique. We defined energy density E_d (mJ/mm) as follows:

$E_d=P_{laser}/V_{laser}$

where P_{laser} is the laser power, and V_{laser} is the laser scanning speed.

Data show that increasing E_d leads to greater LIG thickness, lower sheet resistance, and reduced resistivity. Scanning electron microscope (SEM) images of LIG surface morphologies were analyzed under a constant E_d (4.0 mJ/mm) with varying P_{laser}. As laser power increased from 3.6 W to 6 W, LIG's entangled fiber structure transitioned into a layered, uniform 3D porous structure. Thus, P_{laser} = 3.6 W and V_{laser} = 90 mm/s were chosen for fabrication, yielding a fibrous morphology that maintains good electrical interconnectivity through lateral slippage under tensile or bending strain.

To enhance strain resistance, we optimized LIG's microstructure using low-temperature annealing and oxygen plasma etching. A 4-minute 180°C annealing treatment repaired surface oxidation defects in the graphene and reduced internal stress, enhancing mechanical performance. Oxygen plasma etching then introduced defects and pores, increasing surface roughness. This combined treatment balanced structural integrity with microstructural modifications, enhancing LIG's overall mechanical performance and strain resistance.

SEM images revealed changes in LIG's microstructure after treatment. After 25 minutes of oxygen plasma etching (ET 25), the LIG structure was significantly degraded, with almost no intact fibers. Conversely, 4 minutes of low-temperature annealing at 180°C (AT 4) resulted in a denser fiber structure. Following AT 4 and ET 25, the microstructure became rougher, forming multiple filamentous structures within each fiber while maintaining the overall fiber morphology as fractal microfibers ranging from hundreds of nanometers to a few nanometers. XPS data showed increased C-C bonds (from 68.62% to 78.85%) and decreased C-O, and C=O bonds after dual treatment, while Raman spectroscopy indicated good graphitization with low I_D/I_G values.

We studied the strain resistance of LIG patterns transferred to polydimethylsiloxane films, preparing three samples: untreated LIG, AT 4 treated, and AT 4 followed by ET 25 treated. Stretching tests showed similar gauge factors (GF, calculated as $GF=\Delta R/(R_0\times\varepsilon)$) of approximately 14 for untreated and AT 4 treated samples. However, LIG treated with AT 4 and ET 25 exhibited a lower GF of 7.43, demonstrating superior strain resistance with minimal changes in electrical performance.

4. Conclusion

Considering both mechanical stability and electrical performance retention, we chose manufacturing parameters of P_{laser} = 3.6 W and V_{laser} = 90 mm/s, with LIG treated by 4-minute low-temperature annealing followed by 25-minute oxygen plasma etching. This process produces fractal fiber LIG with high strain resistance, ensuring mechanical reliability and stable electrical performance for LIG electrodes in stretchable devices, meeting the requirements for flexibility and durability in practical use.

EN09.05.17

Development of Microwave and Millimeter Wave Absorber with Flexible Hexaferrite-Rubber Sheets *Geon-Yeong Park[1], Youn-Kyoung Baek[2], Jae-Hee Heo[1] and Young M. Kang[1]; [1]Korean National University of Transportation, Korea (the Republic of); [2]Korea Institute of Materials Science, Korea (the Republic of)*

With the rapid development of information and communication technology (ICT) and the increasing integration and multifunctionality of automotive electronics, the frequencies of electromagnetic (EM) waves generated by electronic devices are becoming more diverse, extending beyond microwaves to millimeter wave bands. This trend highlights the importance of EM wave absorption technology to mitigate potential malfunctions and signal degradation. EM wave absorption typically relies on the dielectric loss and magnetic loss mechanisms of materials. One effective method for absorbing frequencies over GHz ranges is the utilization of ferromagnetic resonance (FMR) of magnetic materials. FMR is directly proportional to the magnetic anisotropy of magnetic

materials. Most metallic and ceramic magnetic materials do not have sufficient magnetic anisotropy, so their FMR band cannot exceed the GHz range. M-type hexaferrite materials, with the basic chemical formula (Ba, Sr)$Fe_{12}O_{19}$, exhibit high crystal magnetic anisotropy and an FMR frequency around 50 GHz. La-Ca-Co substituted M-type hexaferrite, known for high-performance ferrite magnets, have even higher crystal magnetic anisotropy, leading to higher FMR frequencies above 50 GHz and are expected to absorb even higher frequency bands.
In this study, we synthesized powders of $SrFe_{12}O_{19}$ (SrM), the basic composition of M-type hexaferrite, and $Sr_{0.2}La_{0.4}Ca_{0.4}Fe_{9.75-x}Al_xCo_{0.25}O_{19}$ (SLCAM) with x = 0, 0.2, and 0.4, considered high-performance permanent magnet compositions, using the solid-state reaction method. We measured the M-H curves of the sintered samples using a vibrating sample magnetometer (VSM) and evaluated their magnetic properties. The powdered samples were combined with nitrile butadiene rubber (NBR) to create flexible absorber sheets. The crystal phases and microstructures of the sheets were analyzed using X-ray diffraction (XRD) and a scanning electron microscope (SEM). The high-frequency complex permittivity and complex permeability of each sample were measured in the 33–75 GHz range using a vector network analyzer and a free space measurement system, and the reflection loss (RL), indicating EM wave absorption capability, was calculated based on transmission line theory.
All samples were synthesized in a single-phase M-type hexaferrite structure. Compared to the x = 0 sample, the x = 0.2 and 0.4 samples had larger grains and increased c-axis orientation in the sheet. The FMR frequency (f_r), identified by the peak of the imaginary part of the permeability, was 48.5 GHz for the SrM sample and 63.3 GHz, 66.2 GHz, and 68.5 GHz for the SLCAM samples with x = 0, 0.2, and 0.4, respectively. The SrM-rubber sheet showed a minimum RL (RL_{min}) of -33.5 dB at 49.7 GHz with a thickness of 0.37 mm. The x = 0, 0.2, and 0.4 sheets, with a thickness of ~0.3 mm, showed RL_{min} values of -35.0, -38.8, and -43.0 dB at frequencies of 63.2, 66.3, and 68.5 GHz, respectively. The substitution of Al increases the f_r and the frequency of RL_{min}, corresponding with the f_r increase. The maximum EM wave absorption frequency band (Δf), satisfying RL < -10 dB, was 45.0–53.4 GHz for SrM, and 52.9–75 GHz, 50–75 GHz, and 59–74.2 GHz for the x = 0, 0.2, and 0.4 samples, respectively. The x = 0.2 sheets showed very promising results, demonstrating extremely wideband absorption characteristics, capable of absorbing 99% of EM waves over the entire V-band (50–75 GHz) range. The Al-substituted La-Ca-Co M-type hexaferrite-rubber sheets, with a highly flexible thickness of 0.3 mm that can be bent or folded without damage, exhibited excellent wideband EM wave absorption characteristics in the microwave and millimeter wave bands, indicating their potential as highly promising materials for EM wave absorbers in automotive and various electronic device systems.

EN09.05.18

Thermal Drawing of Graphene-Polyvinylidene Fluoride Fibers for Self-Powered Sensing *Md Sazid Bin Sadeque[1], Mahmudur Rahman[1,2], Md Mehdi Hasan[3,1] and Mustafa Ordu[1]; [1]Bilkent University, Turkey; [2]University of Southampton, United Kingdom; [3]University of Massachusetts Amherst, United States*

Triboelectric nanogenerators (TENG) harvest low-frequency mechanical and biomechanical energy by the combined effect of triboelectrification for generating surface charge and electrostatic induction for guiding electrons through an external circuit. Ferroelectric polyvinylidene fluoride (PVDF) has excellent triboelectric properties due to its highly electronegative fluorine ions, high dielectric constant non-toxicity, flexibility, low processing temperature, and resistance to environmental effects. The high dielectric constant of PVDF results in spontaneous polarization, increasing triboelectric charge density in the friction layer. Incorporating 2D materials into PVDF promotes the electroactive phase transition of the polymer. Graphene and its derivatives have been extensively used as 2D materials with wearable TENG devices owing to their exceptional electrical properties. This work examines the performance of thermally drawn PVDF fiber at varying graphene nanoplatelet (GNP) concentrations (1%, 3%, and 5wt%). The 5% GNP-PVDF fiber showed maximum improved electrical performance with increased open circuit voltage and short circuit current 1.41 and 1.48 times, respectively, compared to the pristine PVDF TENG fiber. The fabric GNP-PVDF TENG demonstrated a maximum power output of 32.14 μW at a *matching load of 7 MΩ while the power density was 53.57 mW m^{-2}. The TENG fabric was employed for biomotion monitoring and analysis. The devised TENG remained stable in harsh conditions such as high/low temperature, alkaline medium, multi-washing cycle, and extended usage cycle.*

NSF Nanoscale Science and Engineering Center for High-rate Nanomanufacturing, Northeastern University
Contact: Ahmed Busnaina (a.busnaina@northeastern.edu)

With the rising demand for more complex electronics as well as custom electronics (ASICS), the time required for manufacturing has increased exponentially over the past few decades. Today, the overall processing time of a chip is 8-12 months or more. Additive manufacturing of electronic components, although it is still at the development stage, provides a fast, low cost and sustainable alternative to the conventional semiconductor manufacturing approach. This paper introduces a scalable, fully additive, directed-assembly-based process for printing silicon based Metal-Oxide-Semiconductor Field-Effect-Transistor (MOSFET) at high throughput (one layer per minute for a 4-inch substrate regardless of minimum feature size). The assembly process used is fast fluidic directed assembly which utilizes colloidal suspensions of metallic, dielectric and dopant inks to print MOSFETs. This technique utilizes surface energy and fluidic motion to direct the particles the circuit pattern areas on the substrates. Furthermore, the additive nature of the processes results in 1000x reduction in materials use and orders of magnitude less power and water. The printing of silicon MOSFET using a silicon substrate requires P doping (using Boron) and N doping (using Phosphors). In this paper, we introduce a novel approach that allows controlled doping of miniaturized electronic devices using fast fluidic assembly over chemically engineered Si wafers. In this paper, we introduce a novel approach that allows controlled doping of miniaturized electronic devices using fast fluidic assembly over chemically engineered Si wafers. This requires a doping process that requires the printing of the liquid dopants where the source and drain are followed by encapsulation and a precisely-controlled thermal process using Rapid Thermal Process (RTP) up to 900-1000 C to allow the thermal diffusion of the dopant atoms inside the substrate with desired depth. The process takes about 2 minutes and can be controlled to obtain the desired dopant penetration depth into the silicon wafers as well as the correct concentration profile. This is followed by printing of the gate dielectric and gate. The dielectric is also printed using low K dielectric (SiO2). The process allows the fully additive fabrication of the FET devices without the use of high vacuum etching or oxide growth techniques. The MOSFET output curve showed that Vd was swept between 0-1 V, with increasing the gate voltage from 0-24 V with 4 V increments
The output curve resulted from the simulation is similar to the I-V characteristic curve achieved experimentally with negligible drain current at zero gate voltage, confirming that the transistor is operating in enhancement mode as observed experimentally and indicating a working according to the design parameters.

Influence of Energetic Disorder in Doped Conjugated Polymers on Doping Efficiency and Charge Transport

Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Doping in conjugated polymers has recently gained attention because of its ability to freely control electrical conductivity and energy levels. Sophisticated engineering approaches and state-of-the-art doping techniques aimed at improving performance have enabled both p-type and n-type doped conjugated polymers to achieve conductivities of over 1000 S/cm. Despite the progress in the electrical conductivity, the influence of the fundamental physical quantities in conjugated polymers on the doping process has not yet been sufficiently investigated. Conjugated polymers exhibit high degree of structural disorder (including crystallinity, chain conformation, chain configuration, orientation, and impurities), which leads to substantial energetic disorder, manifesting as a widened distribution of the density of states. Moreover, structural disorder induced by the incorporation of a significant amount of dopants and Coulomb interactions between charged particles have a potential to further increase energetic disorder in doped polymer films. In this talk, I will present research findings on the conflicting effects of the energetic disorder in conjugated polymers on the charge generation and charge transport processes during doping. In the first part, I will discuss the effect of energetic disorder in conjugated polymers on the generation of free charges and doping efficiency during the doping process. Specifically, I will present that increased energetic disorder can activate bound charges into free charges and enhance doping efficiency, which were observed in poly(3-hexylthiophene-2,5-diyl) (P3HT) films of exhibiting different energetic disorder by modulating crystallinity. In the second part, I will discuss the excellent transport properties that can arise from the extremely suppressed energetic disorder in chemically doped systems, facilitated by the torsion-free main chain structure of indacenodithiophene-co-benzothiadiazole (IDTBT). Our results suggest that adequate consideration of conflicting perspectives on energetic disorder, and finding a balance between them, can be critical to enhance the final electrical properties of doped conjugated polymers.

Biocompatible Triboelectric Nanogenerator for Self-Powered and Wearable Temperature Sensing Application

Raheel Riaz, Nasim Golafshan, Santanu Patra and Anja Boisen; Technical University of Denmark, Denmark

*The body temperature is an essential aspect of us human beings and other warm-blooded animals for maintaining various physiological conditions of the body. It has been reported that the body's core temperature has an effect on enzyme function and nervous system's performance. Besides that, raise in temperature indicates the onset of various pathogenic disorders. The onset of hypothermia (loss of body temperature maintenance) affects heart and nervous system's functions. Thus, it is essential to track the body's temperature. Currently, available products for sensing temperature are based on chemometric and digital methods. While using the chemometric thermometers can be hazardous for the end users (as they use poisonous materials like Mercury), the digital counterparts require batteries for operation and become an environmental hazard. Besides that, these commercially available temperature sensors are not designed as user friendly for continuous monitoring of the body temperature. Triboelectric nanogenerators **(TENGs)** have proved to be an innovative and groundbreaking self-powered biomedical sensing method that leads its way to be used for temperature sensing application. These nanogenerators rely on the contact between two materials and produces electrical output by reciprocating to material's surface morphology. The alteration in the morphological aspects of materials can be induced by the change in temperature (as it can cause softening/hardening, expansion/contraction of materials), resulting in the change in electrical output of TENG devices. In this work, we have utilized this property of materials and TENG to*

*fabricate our biocompatible self-powered temperature sensor **(BeST)** based on TENG devices. BeST utilizes a chitosan-based flexible film as a positive triboelectric layer while Polyimide (Kapton) is used as a negative triboelectric film. The **BeST** devices were fabricated using Kapton and Chitosan films separated from each other by a 3D printed polymer separator (about 2 mm thick), this separator avoids the contact between the two triboelectric layers in the absence of applied compressive force. On the application of compressive mechanical forces, the **BeST** devices produced open-circuit voltages **(V_{OC})** of **116.8-141.75 V** and short-circuit current of **80-140 nA**. The devices were subjected to mechanical cycles at different temperatures of 25, 30, 35, 40 and 45 degrees Celsius. When studying the relationship between temperature and electrical output, the **BeST** demonstrated excellent linearity with an **R^2** value of **0.9906** or **99.06 %** for open circuit voltages **(V_{OC})** and **0.9880** or **98.8 %** for short circuit current **(I_{SC})** respectively. This paves the way for utilizing these **BeST** devices in temperature sensing applications in wearable, ingestible and implantable paradigms.*

***High-Endurance Zinc Ion Supercapacitors with Wide Temperature Tolerance** Tse Nga Ng; University of California, San Diego, United States*

Metal ion capacitors are hybrid electrochemical cells that bridge the divide between batteries and electrochemical capacitors, enabling them to provide high energy densities at rapid charging or discharging rates. These devices combine a redox metal anode, similar to that found in batteries, to enhance the capacity for charge storage and an electric double-layer cathode that allows fast kinetics and sustains high power density. The first metal ion capacitors were based on lithium and sodium ions, but potential safety hazards associated with these metals prompted the search for other alternatives. In particular, zinc ion supercapacitors (ZICs) emerge as an appealing choice with advantages of environmental safety, a high theoretical capacity as a divalent system, and an abundance of zinc reserves unaffected by geopolitical factors.

However, zinc ion cells are currently limited by the imbalance in the utilization ratio between the metal anode and the cathode. This imbalance, used to compensate for dendritic loss upon redox cycling, restricts the overall energy density and poses a significant barrier to commercialization. This study presents a new scalable approach to tackle the dendritic issue at the anode and increase the capacity of the cathode by redox polymers, to achieve anode-free supercapacitors with more balanced utilization ratios and a wide temperature tolerance. The resulting zinc ion supercapacitor demonstrated state-of-the-art energy and power densities with 84% capacity retention after 50,000 cycles, and operated down to a low temperature of -60°C. The mechanistic findings in this report provide the design guidelines for zinc ion supercapacitors with high cumulative capacities and extended cycle lifetime to minimize maintenance costs, crucial for high-endurance applications such as in un-interruptible power supplies and energy-harvesting systems.

9:00 AM EN09.06.04

***Safe and Deformable Li-Ion Battery Based on a High-Voltage Hydrogel Electrolyte** Peisheng He[1], Jong Ha Park[1], Chao Fang[2], Anju Toor[3] and Liwei Lin[1]; [1]University of California, Berkeley, United States; [2]The Hong Kong University of Science and Technology, China; [3]Georgia Institute of Technology, United States*

Safe and deformable soft batteries are desirable for future wearable electronic devices. However, current Li-ion batteries on the commercial market are rigidly packaged and hermetically sealed to prevent moisture penetration and the leakage of toxic and flammable organic electrolytes. Since the modulus of elasticity and gas permeability of materials are inextricably linked, stretchable batteries often experience significant performance degradation over time in the ambient due to inevitable moisture penetration. Furthermore, the polymer-based flexible packaging materials can be easily damaged resulting in electrolyte leakage that poses significant safety concerns.

Here we report a non-toxic, aqueous hydrogel electrolyte instead of its organic counterpart that is demonstrated to 1) enable highly safe operations due to its non-toxic and non-flammable nature; 2) alleviate the moisture penetration problem from the outside environment; (3) have a high-voltage working window of ~2.97V; and (4) allow the construction of stretchable batteries by using elastic polymer packaging materials instead of rigid hermetic seals. The prototype batteries have shown good stretchability (50% strain) and flexibility (radius of curvature < 2mm) to enable conformal attachments to a wide range of geometric surfaces. The prototype battery also shows outstanding cyclic stability, retaining ~90% of the original capacity after 100 cycles for over 2 months in the ambient environment without using any rigid hermetic sealing package. Finally, a prototype battery with a self-healing elastomer package remains functional after being punctured by a needle 5 times at different locations in the package. Furthermore, it can recover >90% of its capacity after being cut through by a razor blade and subsequently healed at 70 for 10 minutes. Such safe and highly stretchable batteries would be useful for several wearable electronic applications such as blood glucose monitoring, hearing rate monitoring, temperature monitoring, wireless charging, smart clothing, etc.

9:15 AM EN09.06.05

3D Printing of Li-Ion Batteries by Fused Filament Fabrication for In-Space Applications *Félix Bourseau[1,2], Sylvie Grugeon[1,2], Ugo Lafont[3] and Loïc Dupont[1,2]; [1]Université de Picardie Jules Verne, France; [2]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), FR CNRS 3459, Hub de l'Energie,, France; [3]European Space Research & Technology Centre Keplerlaan, Netherlands*

Additive manufacturing (AM) recently appeared as a new production process for energy storage devices. Indeed, it paves the way for 3D-designed electrodes and batteries resulting in improving the electrochemically active surface, power, and specific capacity (1). The growing need for micro-batteries and customizable devices also contributes to the outbreak of 3D printing in battery production. Recently, In-Space Manufacturing (ISM) has gained interest in AM processes thanks to their versatility, low cost, and ease of use (2). Fused Filament Fabrication (FFF) has been successfully deployed in the International Space Station to print spare parts and tools (3). 3D printing in microgravity of energy production and storage devices is the next challenge to take up to carry out the ISM approach.

Thus, this work aims to make in-space 3D printing of Li-ion batteries feasible. For seven years, our group has optimized composite filament formulations to successfully 3D print liquid-electrolyte Li-ion batteries by FFF (4). The challenging task of this study is to develop a solid polymer electrolyte with adapted electrode filaments suitable for microgravity 3D printing. We have created and characterized new formulations to obtain a process that fits the security requirements of the spacecraft's environment (5). The structuration of a dual-thermoplastic polymer matrix and process parameters were thoroughly investigated to obtain the best compromise between printability and electrochemical performances. 3D printing alleviating gravity constrain environments has been performed at European Space Agency (ESA) facilities (6) to demonstrate in-space printability and to understand microgravity's influence on the morphology and the performances of our 3D-printed batteries.

Studies and Characterization Of 3D Printed Ceramic Electrolytes for Batteries *Manon Faral, Audrey Laventure and Mickael Dollé; Université de Montréal, Canada*

Recent advances in 3D printing not only bring interest in the design of all-solid state battery components, but also support the optimization and study of processing properties. Thanks to its flexibility in terms of ink formulations and resulting architectures, this technique offers the possibility of creating customizable shapes that allow a new approach, not permitted by conventional manufacturing methods. However, challenges remain in optimizing formulations, printing parameters, and performance to develop and maintain a printable architecture before considering its integration into a system.

Due to the limited information available in the literature, the objective of this work is to investigate the properties of 3D printed ceramic electrolytes. The first part of the study focuses on evaluating the printability of various solid composite electrolytes with complex architectures. The direct-ink writing technique will be discussed, including the development of ceramic ink formulations with different compositions using a sacrificial polymer. The printability of these inks will be investigated by rheological studies. Other aspects will be related, such as the influence of thermal treatments and architectures on the structural (print fidelity) and electrical properties of the material. These properties are investigated using characterization methods such as XRD, SEM, optical profilometry, and EIS. These tests are performed to compare and optimize system properties, with an emphasis on the geometric deformations that occur during the sintering step after 3D printing.

The optimization of this proof-of-concept shows how the processing of ceramic electrolyte via 3D printing, will impact the structure, electrical properties, and thus the performances.

Building a Flexible High-Performance TENG from Waste Polystyrene Through Surface Structuring and Chemical Modifications *Linards Lapčinskis, Liva Germane, Mairis Iesalnieks, Raivis Eglitis, Artis Linarts and Andris Šutka; Riga Technical University, Latvia*

Triboelectric nanogenerator (TENG) is a promising route for harvesting green energy from motion and vibrations.[1] TENGs can be made from a wide array of materials and studies show that different surface modifications can increase energy density by almost 300%.[2-3] This study focuses on improving the triboelectric properties of recycled polystyrene (R-PS) films through a combination of physical and chemical surface modifications aimed at enhancing their performance in TENGs for sustainable energy harvesting. Polystyrene, commonly used in packaging, presents a significant environmental challenge due to its long decomposition period.[4] Recycling this material into TENGs provides an innovative pathway for waste management, transforming it into valuable energy-harvesting devices. In this work, R-PS films were subjected to surface modification to increase the triboelectric performance. Physical surface roughness was created using immersion precipitation, while chemical modification involved the introduction of self-assembled monolayers (SAMs), namely (3-aminopropyl)triethoxysilane (APTES), vinyltrimethoxysilane (VTMS), and 3-(trimethoxysilyl)propyl methacrylate (TMSPMA).
The roughness of the R-PS surfaces was confirmed by AFM and SEM, which revealed the formation of highly porous

surface structures contributing to increased triboelectric performance. FTIR and XPS were used to validate the chemical surface modifications, by confirming functional group characteristic of the applied SAMs. Water contact angle measurements demonstrated the increased hydrophilicity of the modified surfaces, further supporting the effectiveness of the chemical modifications.

Initial triboelectric tests were conducted in contact-separation mode against indium tin oxide (ITO) electrode, where SAM-modified films demonstrated significantly enhanced performance compared to pristine R-PS. APTES-modified films exhibited a positive surface charge, while films modified with TMSPMA and VTMS displayed a strong negative charge. The optimal combination of surface roughness and SAM modifications resulted in substantial improvements in the triboelectric output of the films. To further understand the underlying mechanisms, calculations were performed to estimate the net group charge for the SAM-modified films after bond scission. [5] Calculations revealed that heterolytic cleavage of Si–C bonds in the SAM molecules leads to the formation of charged species, which directly influence the observed surface charge polarity.

Two TENG prototypes, composed of matched and unmatched R-PS films were fabricated and tested under controlled conditions. The matched TENG, consisting of rough APTES/R-PS and smooth VTMS/R-PS, outperformed the unmatched TENG in terms of short-circuit current and charge density, reaching 23.9 μA and 1.52 nC cm^2*, respectively. Energy and power density calculation also indicated that the matched TENG achieved higher values across the chosen load resistances. Long-term durability tests, conducted over 100,000 contact-separation cycles, showed excellent stability, with minimal performance degradation.*

This research highlights the potential for recycled polystyrene to be repurposed into high-value triboelectric devices, addressing both environmental concerns and the growing demand for sustainable energy solutions. By combining surface roughness modifications with tailored SAMs, the study demonstrates a viable approach to enhancing the charge density and overall performance of TENGs made from recycled materials.

Layer-by-Layer Self-Assembling of Polyelectrolytes—From Ultrathin Ambipolar Capacitors to Wearable Label-Free Biosensors *Giuseppe Barillaro; University of Pisa, Italy*

Layer-by-layer (LbL) assembly is widely recognized for its effectiveness in coating substrates with polymers, colloids, biomolecules, and cells, offering superior control and versatility, especially on micro and nanostructured surfaces.

This presentation explores the application of LbL self-assembling of polyelectrolytes as a versatile technique in two key areas: ultrathin ambipolar capacitors and wearable label-free biosensors.

Polyelectrolytes, due to their charged nature, facilitate the sequential deposition of alternating nm-thick layers with complementary charges onto various substrates. This process ensures self-regulation of the thickness of both single and multilayer films, promoting uniformity and reproducibility, regardless of the hosting materials.

In the field of energy storage, this control has shown to be critical for developing ultrathin capacitors with ambipolar nature capable of operating across extended frequency ranges with high capacitance densities. These

advancements are pivotal for advancing flexible electronics and energy storage applications.
In biosensing, LbL assembly has been utilized to functionalize nanostructured materials with biocompatible polyelectrolyte layers engineered with biomolecules and/or emitting dyes, enabling the development of implantable and wearable sensors for real-time, label-free detection of analytes of clinical interest.

Mechanically Ductile Electronic, Electrochemical and Energy Devices Achieved by Materials Design and Multilayer Integration *Antonio Facchetti[1,2]; [1]Georgia Institute of Technology, United States; [2]Northwestern University, United States*

In this presentation we report the fabrication of mechanically deformable opto-electronic devices on various plastic and elastic substrates, including bio-derived ones. Thus, we describe organic and metal oxide thin-film transistors, OTFTs and MOTFTs, respectively, employed to fabricate circuits for backplane displays and driving/stimuli-sensitive elements of sensors. Furthermore, organic electrochemical transistors (OECTs) and OECT circuits with performance identical to those of glass substrates are demonstrated on PET and cellulosic substrates. Finally, stretchable organic solar cells using a combination of new photoactive materials and a combination of more ductile electrodes and interlayers are demonstrated and integrated with OTFT/OECT circuits for physiological recording.

Electrode Design Concepts for Intrinsically Stretchable and Sustainable Batteries *Aiman Rahmanudin[1,2], Mohsen Mohammadi[1,2] and Klas Tybrandt[1,2,3]; [1]Linköping University, Sweden; [2]Wallenberg Wood Science Center, Sweden; [3]Wallenberg Initiative Materials Science for Sustainability, Sweden*

High-capacity stretchable batteries are crucial for next-generation wearables to enable long-term operation and mechanical conformability with human users. However, in existing stretchable battery electrode designs, increasing the active material loading to yield higher capacity often leads to thicker and stiffer electrodes with poor mechanical properties.[1] Here, we will present a concept that decouples the electrochemical (redox-active material) and mechanical properties of the battery electrode by 1) designing an energy storage process that relies of diffusion of the redox active species within a porous conductive scaffold,[2] and 2) by engineering conductive redox-active fluids as electrodes for stretchable batteries.[3] The key innovation of the concept is that the mass loading of the active material and their resulting battery capacity is independent from the overall stiffness of the cell. Such a design enables thicker battery electrodes with higher capacities without a trade-off in mechanical properties. Considering the exponential growth of the internet-of-things devices by 2035, of which many will be wearables, adopting sustainable practices to mitigate the environmental impact of traditional energy storage solutions while advancing their mechanical functions and battery performance is urgently needed to meet the United Nations Sustainable development goals. Currently, majority of reported stretchable batteries predominantly use unsustainable battery chemistries (Li-ion and toxic organic electrolytes), expensive and finite metal current collectors, and non-biodegradable petroleum-based polymers such as fluorinated polymers, and elastomers such as silicones and styrene block co-polymers as either binders and/or encapsulation layers. To demonstrate the decoupled stretchable battery concept and address the environmental sustainability challenges, *biomass-derived materials were utilised to construct the battery from plant-based redox-active biomolecules (e.g., lignin), cellulose nanofibers as mechanical scaffolds and biodegradable elastomers as encapsulation layers. Ultimately, we hope that the work would inspire future stretchable battery designs that simultaneously addresses the mechanical, electrochemical, and sustainability considerations.*

Unconventional Designs for Soft and Stretchable Organic Batteries *Klas Tybrandt, Aiman Rahmanudin, Mohsen Mohammadi, Nara Kim and Reverant Crispin; Linköping University, Sweden*

Next-generation electronics will interface intimately with the human body. This requires devices with high degrees of conformability and autonomy, where integrated soft and stretchable batteries are an essential component. However, existing stretchable batteries are predominantly based on unsustainable transition metal-based active materials and use non-biodegradable petroleum-based elastomers. Such batteries cause environmental issues like waste generation upon disposal and the use of finite resources during manufacturing. Further, the mechanical properties of conventional battery designs tend to deteriorate with active material loading, making them too stiff for optimal conformability. To address these issues, here we present the development of several unconventional designs for soft and stretchable organic batteries. Such designs can decouple the electrochemical performance from the mechanical properties and allow for the use of active sustainable bio-based materials. One example is a stretchable and biodegradable organic battery employing sustainable plant-based materials with cellulose as a structural component in the electrode, separator, and current collector, and with redox-active biomaterials for energy storge and a biomass-derived biodegradable elastomer for encapsulation. Our 3D porous scaffold design allows for high mass loadings of redox-active biomolecules, in combination with a low Young's modulus. The full cell showed reversible electrochemical performance under stretching and is biodegradable.

High Performing Organic Photvoltaic Cells and Modules for Indoor Application *Donia B. Fredj and Sadok B. Dkhil; Dracula Technologies, France*

Harvesting indoor light to power electronic devices for the Internet of Things became a potential market to be explored.
In fact, a surge in the number of indoor appliances in various aspects of our daily life was observed making a strong development of the field of internet-of-things (IoT).
In the last few years, organic photovoltaic (OPV) devices are reaching impressive efficiencies (PCE) up to 20 % making them one of the most promising solar technology.
Importantly, OPV devices demonstrated high power conversion efficiencies as well as excellent stability under indoor conditions
As a result, Indoor photovoltaic has emerged as an important candidate for powering low consumption devices dedicated for the Internet of Things using in different fields such as electronics, sensing..
The rapid and exciting evolution of the OPV requires diversity in fabrication methods.
Among them, inkjet printing has aroused considerable attention as a printing electronic technology for large-scale printed flexible and stretchable electronics with many advantages.

Essentially, Inkjet printing has the advantage to provide freedom of forms and design on various substrates with good reliability, high time efficiency, a low manufacturing cost, low material usage comparing to other deposition techniques. These special characteristics have allowed inkjet to become an enabler of cost-effective attracting the researchers on functional devices such as photovoltaic solar cells (PV).
Nevertheless, a number of challenges must be overcome in this technique, including stability of inks to avoid the nozzle clogging, the wetting behavior, compatibility of viscosity, surface tension with printheads.
So, herein, in this work, we present all inkjet printed organic photovoltaic cells and modules with high efficiency for indoor application with freedom of shape and design fabricated by Dracula Technologies company.

Multifunctional Energy Generating Electronic Skin for Robotics and Wearables *Ayoub Zumeit, Abhishek Singh and Ravinder Dahiya; Northeastern University, United States*

Replicating the functioning of biological skin with touch, temperature sensing etc. is a challenging task. A number of attempts have been made to develop electronic-skin (e-skin), mimicking the morphology and functionality of biological skin. However, powering these sensor-laden systems to ensure continuous operation remains a big challenge. Herein, we present solar cells-based energy generating e-skin (solar skin) and demonstrate how the energy outputs of solar-cells can be innovatively processed for multimodal sensing. Two different approaches are followed. In the first, the generated electrical energy from solar skin under indoor light illumination is used for continuous powering of portable low-power devices. For instance, solar cells generate an energy surplus of >1mW (effective module area of 20 cm2) under white light illumination (4450 lux), which is used for the continuous powering of portable low-powered devices such as array of touch sensors. In the second approach, a solar skin without using dedicated sensors is developed to provide capabilities for touch, temperature, and proximity sensing. This is achieved by reading the variations and energy output patterns of the solar cells. Likewise, solar cells are used to sense multiple parameters including object motion, colour detection (from light wavelength), and ambient temperature (sensitivity about -1.8 mV/C). The accurate tracking of shadow sensing, for an object moving in horizontal and vertical directions with respect to the solar skin with varying speeds (1, 5, and 10 cm/s), we could obtain the information such as the velocity and acceleration of moving object. In this regard, the presented e-skin can also be seen to be having vision capability. The presented work opens exciting avenues into futuristic energy-autonomous e-skins that can "see" and "feel" without need of bulky and toxic batteries to power them.

2:00 PM EN09.07.02
Simulations of Piezoelectric Phononic Crystals for Soft Reconfigurable Devices *Alison H. Root, Tejas Dethe and Andrej Kosmrlj; Princeton University, United States*

Phononic crystals are periodic metamaterials whose structure interacts with elastic waves, making them a useful platform for vibration-based devices. Applications ranging from vibration damping to energy harvesting have been explored for a variety of phononic crystal systems. Piezoelectric phononic crystals are ripe for exploration in the vibrational energy harvesting sphere as they can combine the vibration collecting properties of phononic crystals *with the mechanical to electrical energy conversion of piezoelectric materials. With piezoelectric hyperelastic materials, we can also take advantage of large deformations to change the phononic properties of the crystal. Internally applied electric fields allow us to introduce defects to the crystal in a targeted fashion. By dynamically generating defects, a crystal's behavior can be tuned for its specific application, and even be used for multiple different devices depending on the applied electric field.*

We simulated a piezoelectric material in quasi-two dimensions undergoing large, nonlinear deformations due to an applied electric field to produce several fundamental crystal defects. Using modal analysis, we predicted the phononic properties of resonator and waveguide defects, and then further explored their behavior in time-domain simulations. We also simulated the behavior of simple devices that capitalize on these defect structures, designed with an eye toward concentrating phonons for vibrational energy harvesting applications.

This work was supported by NSF via the CAREER Award DMR-1752100 and Princeton's MRSEC DMR-2011750.

Enhancing the Piezoelectric Properties of Ultra-Thin ZnO Films on Flexible Substrates Using Atmospheric Pressure Spatial ALD

Hayri Okcu[1,2], Gustavo A. Ardila Rodriguez[2], Laëtitia Rapenne[3] and David Munoz-Rojas[1]; [1]Grenoble INP, France; [2]CROMA, France; [3]CMTC, France

Zinc oxide (ZnO), known for its abundance, low cost, ease of processing, and ecological benefits, holds significant promise as an alternative material for lead-free piezoelectric sensors and actuators. Despite these advantages, improving the piezoelectric properties of polycrystalline ZnO films deposited on inexpensive flexible substrates at low temperatures remains a challenge. This study addresses the critical question of whether it is feasible to enhance the piezoelectric properties of ZnO films deposited using a facile open-air method at relatively low temperatures without any epitaxial relationship. The significance of solving this problem lies in the potential to directly deposit enhanced piezoelectric ZnO films on flexible substrates using simple, cost-effective open-air methods. This advancement could significantly expand the application of ZnO piezoelectric films in large-area and roll-to-roll (R2R) systems, making them more accessible for diverse applications, including wearables, smart flexible materials, and various surface integrations.

The primary objective of this research is to optimize the texture and piezoelectric properties of ZnO at temperatures below 250 °C on inexpensive flexible substrates using atmospheric-pressure spatial atomic layer deposition (AP-SALD).[1] The study leverages the known relationship between c-axis preferentially oriented wurtzite ZnO structures and superior piezoelectric properties, focusing on the critical role of growth temperature in controlling film texture. Utilizing AP-SALD, we employed diethylzinc as the metal precursor, deionized water as the co-reactant, and nitrogen as the purging gas. The deposition process was systematically studied over a temperature range of 60 to 300 °C, on p-doped Si (100) substrates with a native oxide layer. Structural properties were analyzed using XRD, SEM, and TEM while vertical inverse piezoelectric properties were assessed with PFM. Key findings indicate that growth temperature has a strong impact on film texture. High-quality piezoelectric ZnO films with a three-fold improvement in piezoelectric amplitude and a high degree of phase polarization could be obtained after optimization. Notably, the optimal piezoelectric response was achieved within the 210 to 270 °C temperature range, with a (002) preferred orientation and an effective d_{33} piezoelectric coefficient of 4.1 pm/V. [2] Such higher piezoelectric response was observed in films of only around 200 nm thick. In conclusion, AP-SALD is demonstrated to be a viable and efficient method for controlling the structural and piezoelectric properties of thin ZnO films, enabling high-quality piezoelectric materials suitable for R2R applications. The study highlights the importance of texturization and thickness in enhancing the piezoelectric properties of self-textured ZnO films, advancing both fundamental understanding and practical applications in the field of piezoelectric energy-harvesting and sensing materials.

***Scalable and Stable Quasi-2D Lead-Tin Perovskite Solar Cell** Maria Antonietta Loi; University of Groningen, Netherlands*

Lead-tin (Pb-Sn) perovskites are a highly promising composition for single-junction and all-perovskite tandem solar cells due to their narrower bandgap and reduced toxicity. While the use of quasi-two-dimensional (quasi-2D) Ruddlesden-Popper phases has resulted in superior stability towards the environment and large improvement in the crystallization with respect to the 3D compositions, very little work has been done towards their deposition with scalable techniques. Here, $PEA_2(FA_{0.5}MA_{0.5})_4(Pb_{0.5}Sn_{0.5})_5I_{16}$ (n=5) with a gradient structure is successfully prepared for the first time by a two-step blade coating. Perovskite films which are treated with tin (II) acetate ($SnAc_2$) along with N, N-dimethylselenourea (DMS) exhibit a reduced number of surface traps and enhanced surface crystallization, owing to the in-situ formation of tin selenide (SnSe). Record devices with power conversion efficiency (PCE) of 15.06%, an open circuit voltage (V_{OC}) of 0.855 V, and negligible hysteresis are obtained. More importantly, the hydrophobic SnSe significantly protects the active layer from the environment. These devices retain 91% of the original PCE after 10 days in ambient air (30%-40% humidity) without encapsulation, and nearly no-degradation of the PCE is detected after over a month of storage in inert atmosphere, and under continuous MPP tracking for 15 hours.

4:00 PM *EN09.08.02
***Solution-Processed Ultra-Flexible/Stretchable Organic Photovoltaics for Wearable Applications** Kenjiro Fukuda[1] and Takao Someya[2,1]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan*

Organic photovoltaics (OPVs) have garnered attention as promising advanced wearable power generators for on-skin electronics, owing to recent improved high power conversion efficiency (PCE) exceeding 20% and their flexibility/stretchability. The large-scale production of such flexible OPVs and other optoelectronic devices can be achieved via all-solution processing without requiring vacuum processes. The usage of ultra-thin substrate films having thickness of 1 μm can enable minimized wearing load and increased power per device weight. Additionally, to secure the structural and functional integrity of the epidermal power generators, sufficient mechanical robustness must be ensured for withstanding the repeated tensile strains imposed on the devices by continuous body movements, thereby permitting long-term reliable operation. To meet this requirements, intrinsically

stretchable OPVs are important hot topic recently.
Here we show our recent progress of solution-processed ultra-flexible/stretchable OPVs and their potential applications for wearables. More specifically, we are currently focusing on interface engineering to improve the performance and stability of ultra-thin organic solar cells. By improving the adhesion of interfaces between functional layers, we could improve both mechanical robustness [1]and waterproof properties [2]. We control the wetting conditions of solution processed layers to make perfect interfaces of organic photoactive layers and liquid metal interface, enabling reasonable performance of OPVs and other optical devices [3]. Furthermore, we have succeeded in developing intrinsically stretchable OPVs using strain redistribution technology [4]. An additive to PEDOT:PSS transparent electrodes improved both crack onset train value and adhesiveness to the stretchable substrates. Thanks to these performances, the strain to the active layer could be redistributed to the beneath PEDOT:PSS layers, enhancing COS values of photoactive layers.
Using such OPVs as power sources, we have developed some applications for wearables. The one example is wearable bio-signal monitoring devices [3,5], and the other is rechargeable system of cyborg insects where a living insect is used as soft-robots for doing rescue tasks during disasters [6].

Mechanical-Electrical-Moisture Stable Ultra-Flexible Perovskite and Organic Solar Cells *Wallace C. Choy; The University of Hong Kong, China*

Flexible/foldable solar cells (SCs) have a lot of market potential for applications in photovoltaics integrated into buildings and wearable electronics because they are lightweight, shockproof, and self-powered. Additionally, solution-processed flexible/foldable perovskite SCs feature low cost, low carbon and low power consumption in production, shortened payback time, simple fabrication, and attractive power conversion efficiency (PCE) >20% (comparable to typical c-Si SCs). However, electrodes of organic/perovskite SCs such as widely adopted indium-tin-oxide (ITO) electrodes are formed by physical deposition methods (e.g., sputtering and thermal evaporation) which are high power consumption, large carbon footprint, and incompatible with high throughput production, thus hindering further development. Moreover, developing efficient flexible/foldable SCs with super-flexibility (foldability) is still challenging due to the poor mechanical durability of typical ITO electrodes.
We recently developed an in-situ solution-processed method (iSPM) to achieve a new class of foldable transparent electrodes (FTEs) composed of metal-oxide nanoparticles (MONPs) and silver nanowires (AgNWs) [1]. Strategically, the iSPM enables the fabricated substrate-integrated FTEs through the unique tri-system integration including (i) AgNW-AgNW, (ii) MONP-MONP, and (iii) AgNW-MONP systems. Based on the new electrode, the foldable perovskite and organic SCs with very good stability against multi-loading (mechanical-electrical-moisture) operation with folding radius as small as 0.75mm, humidity 85% and continuous electrical bias operations have been demonstrated. To further improve device performances, we have introduced several strategies to the perovskite and organic active layers including modulating the mixing Gibbs free energy [2], dielectric constant of the organic materials [3], and reconstructing subsurface lattice for stable perovskite [Joule 8, 1, 2024]. The PCE of the organic and perovskite SCs can reach over 19% [Nature Comm., 15, 2103, 2024] and 25.2% [Joule 8, 1, 2024].

4:45 PM EN09.08.04
Flexible, Self-Powering, Dual-Functional Organic Sensory Device for Smart Indoor Environments *Hyun Woo Ko[1,2], Suyeon Jo[1,2], Byoung-Soo Yu[2,3], Tae Hyuk Kim[1], Hyunwoo J. Kim[1], Jae Won Shim[1], Do Kyung Hwang[2,3,1], Ji-Hoon Kang[4] and Min-Chul Park[2,1]; [1]Korea University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]University of Science and Technology, Korea (the Republic of); [4]Inha University, Korea (the Republic of)*

This research advances the field of flexible electronics by introducing a groundbreaking flexible, monolithic dual-functional sensory device, leveraging a multi-component organic photoactive structure to simultaneously achieve effective energy harvesting and high-precision sensing capabilities. The core innovation lies in the seamless integration of dual organic photovoltaic (OPV) and photodetector (OPD) functionalities within a single flexible device, marking a pioneering achievement in the realization of true image sensing with substantial energy efficiency.

Addressing the significant challenges of operational efficiency and practicality, which have hindered the commercial viability of flexible indoor OPVs and OPDs for Internet of Things (IoT) applications, this study presents a device design that not only surpasses the current barriers of device efficiency but also offers a promising solution for sustainable indoor electronic devices. By meticulously optimizing the photoactive layer, this research has achieved a notable breakthrough in power conversion efficiency (PCE), reporting over 32% for rigid and 30% for flexible OPVs under standard indoor illumination conditions. This efficiency is underpinned by a sophisticated analysis of charge-carrier dynamics that ensures efficient molecular packing and an unprecedented free-charge generation yield.

The practical application of this research is further demonstrated through the development of a self-powering single-pixel image sensor, which operates effectively in commercial indoor settings without external bias, showcasing exceptional photodetector performance with a linear dynamic range exceeding 130 dB in photovoltaic mode. The study's comprehensive approach extends to the exploration of the chemical and optical properties of the organic photoactive layer, facilitating the high performance of the OPD. Devices fabricated under this structure exhibited broad responsivity peaks in the red and near-infrared (NIR) wavelength regions, signifying the versatility and broad applicability of the sensory device in various lighting conditions. The detectivity metrics further validate the device's ability to discern weak signals, highlighting its potential for advanced sensing applications.

Furthermore, the device's exemplary stability, maintaining a PCE of up to 90% even after 1800 hours without encapsulation under dim indoor lighting, points towards its reliability and longevity in practical applications. The combination of organic materials used in the photoactive layer not only enhances the device's efficiency but also significantly improves its flexibility. This flexibility allows for integration into various form factors and substrates, making it suitable for a wide range of applications in smart indoor environments. The flexible nature of the device enhances its mechanical robustness and enables innovative designs for IoT devices that can be seamlessly integrated into everyday objects. This durability, coupled with the device's high efficiency and dual-functionality, renders it a compelling candidate for future flexible indoor IoT devices and smart indoor environments.

In sum, this research not only sets a new benchmark for the performance of flexible, monolithic sensory devices but also offers a strategic pathway for the development of sustainable indoor electronics. The novel monolithic dual-functional sensory device, with its efficient energy harvesting and precise sensing capabilities, stands as a significant contribution to the field, guiding future research towards exploring the full potential of organic-based optoelectronic technologies for indoor applications.

Discovering Magnetoelasticity in Soft Matter for Self-Powered Bioelectronics *Jun Chen; University of California, Los Angeles, United States*

The magnetoelastic effect, also named as Villari effect and discovered in 1865 by Italian experimental physicist Emilio Villari, is the variation of the magnetic field of a material under mechanical stress. This effect is usually observed in rigid metal and metal alloys with an externally applied magnetic field and has been ignored in the field of soft bioelectronics for the following three reasons: the magnetization variation in the biomechanical stress range is limited; the requirement of the external magnetic field induces structural complexity and bulky structure, and there exists a gigantic mismatch of mechanical modulus up to six orders of magnitude difference between the rigid magnetoelastic materials and the soft human tissues. In 2021, we discovered the giant magnetoelastic effect in a soft solid polymer system, later in a liquid permanent fluidic magnet, which paves a fundamentally new way to build up intrinsically waterproof and biocompatible soft bioelectronics for diagnostics, therapeutics, and energy applications. Our group at UCLA is currently pioneering this research effort of harnessing giant magnetoelastic effect in soft systems for personalized healthcare and sustainable energy.

8:15 AM EN09.09.02

Solvent Evaporation Assisted Direct Ink Writing Using Polar Solvent for Flexible Polyvinyl Fluoride Piezoelectric Composites in Enhancement of Piezoelectric Properties *Aaron Rodriguez, Stephanie Gonzalez, Abdiel Cruz, Alexis Lopez, Sabina Arroyo, Yirong Lin and Anabel Renteria; The University of Texas at El Paso, United States*

The fabrication of 3D printing piezoelectric polymer sensors has been of great importance due to their low-cost fabrication, phase manipulation, flexibility, and great piezoelectric response. In this study, a printable ink of polyvinylidene fluoride (PVDF) has been synthesized to enable the fabrication of flexible piezoelectric devices using solvent evaporation assisted direct ink writing (DIW). Different weight percentages of barium titanate (BTO) – 10 wt.%, 15 wt.%, and 20 wt.%, - along with 5 wt.% of multi-wall carbon nanotubes (MWCNT) in a polar solvent solution of dimethyl sulfoxide (DMSO), with a PVDF to solvent ratio of 1:5.23 have been used to fabricate piezoelectric polymer sensors aimed at enhancing the polar phase of PVDF and achieve a high piezoelectric coefficient. In addition, by using solvent evaporation assisted DIW, it is possible to align BTO and MWCNT with each depositing layer, which contributed to the promotion of the polar phase of PVDF and therefore increase their piezoelectric properties. The results from these 3D printed composites showed that a phase transition of PVDF from non-polar α-phase to a polar phase can be acquired by using temperature of 80 °C and an electric field of 3kV by contact poling. Under controlled temperature and humidity conditions, the proposed PVDF/BTO/MWCNT composite shrinks about 10% while maintaining its flexibility. Furthermore, by fabricating PVDF with 20 wt.% BTO obtained the optimal piezoelectric coefficient (d_{33}) of 53.25 pC/N, while maintaining its flexibility with a young modulus of 4.87MPa.

8:30 AM *EN09.09.03

Photometric, Photovoltaic and Photoluminescent Approaches in Energy-Autonomous Sensing Systems *John A. Rogers; Northwestern University, United States*

From sensors of the health of the human body to monitors for the health of the natural environment, power supply represents a key challenge. This talk describes materials-oriented approaches that exploit ambient light as a mechanism for harvesting energy to support operation of these and related systems. Specific emphasis is on the synergistic and/or individual use of photometric schemes (i.e. those that use light as the basis for sensing), photovoltaic devices and/or photoluminescent materials. Examples span 'always-on' electronic light dosimeters for applications in dermatology, to light-triggered temporary cardiac pacemakers for postsurgical care, to wearable, wireless oximeters for health monitoring, to passive microfliers for distributed sensing of the environment.

9:00 AM *EN09.09.04

Flexible Perovskite Solar Cells and Supercapacitors Integrated in a Photocapacitor— A Route Towards Self-Powered Portable and Wearable Electronics *Francesca Brunetti; Università degli Studi di Roma Tor Vergata, Italy*

The conceptual idea of the integration of energy photovoltaic (PV) generation and storage systems in a single unit simultaneously is a powerful means to use energy more efficiently specially under discontinuous illumination, improving the system performance, reducing device size and weight. Lightweight, bendable integrated PV devices and storage systems can be used in various applications, such as transportable electronic chargers, flexible displays, biomedical devices, conformable sensors, and wearable electronic textiles, attracting significant attention both from the scientific and industrial community.
In this context, the emerging technology of flexible perovskite solar cells (f-PSCs) plays a fundamental role with a record power conversion efficiency above 25 %[1] under 1 sun illumination and furthermore, they reached remarkable efficiency of 32.5% under indoor illumination at 1000 Lux [2].
Flexible supercapacitors (f-SCs), on the other hand, are the best candidates for the storage in low power, portable electronics, as they offer several advantages over conventional Li-ion batteries (LiBs), such as lightweight, smaller size, longer life time (f-SC > 30,000 h vs battery > 500 h), and higher power density [3,5]. Their compactness not only facilitates portability and convenience for the end-user but also allows for better integration into diverse electronic ecosystems without imposing spatial constraints.
In this presentation, the fabrication of f-PSCs will be reported showing our latest results on the scaling up process from solar cells to modules using sustainable printing techniques [6-8]. We will also report on our latest results on f-SC fabricated on flexible paper substrates using sustainable materials and printing techniques [9].
Finally, the integration of the two devices will be shown in a in a hybrid photosupercapacitor. In this device, the supercapacitor showcases remarkable stability and a coulombic efficiency of 100%. Through a hybrid bifurcated structure designed to enhance their applicability, the supercapacitors were connected in series, and neatly layered on a paper substrate with the solar module strategically placed on top. The device quickly reached saturated voltage value with exposure to various light intensities such as 1 sun, 1000 lx, 500 lx and 200 lx and displayed a self-discharge beaviour which lasted more than two minutes. With peak overall and storage efficiencies determined to be 2.8% and 23% respectively. with an extensive potential window of 3.8 V, making it an prominent choice for real time application in electronic systems[10].

9:30 AM EN09.09.05
Organic Thermoelectric Ionogels for Self-Powered Multimodal Medical Sensors *Ya-Hsin Pai[1], Chen Xu[2], Renyang Zhu[1], Xinyi Ding[1], Shengqiang Bai[3], Ziqi Liang[1] and Lidong Chen[3]; [1]Fudan University, China; [2]Shanghai Changzheng Hospital, China; [3]Chinese Academy of Sciences, China*

In this contribution, a paradigm ionogel consisting of ionic liquid (IL) and PVDF-HFP composites is made, which inherently possesses dual-function ionic thermoelectric (iTE) and piezoelectric (PE) attributes. By harnessing these multifaceted features, we crafted fully self-powered, multimodal sensors for biomedical scenarios with corresponding needs. In a bio-simulated cardiac system, these sensors demonstrated superior minimum sensitivities for pressure changes and temperature variations, corresponding to fluctuations of blood pressure and core body temperature, respectively. Furthermore, we showcased their swift and sophisticated responses to various in vivo vital signs in a hemorrhagic shock scenario, where such a real-time monitoring device is crucial for emergency situations. In sum, the development of these advanced ionogel-based sensors holds great promise for revolutionizing clinical medicine. Their dual-functionality, self-powering capability, and high sensitivity make them ideal for real-time, continuous monitoring of patients' health, ultimately improving patient outcomes and advancing the field of medical diagnostics.

Solar Heating Modulated by Evaporative Cooling Provides Intermittent Temperature Gradients for Ionic Thermoelectric Supercapacitors *Mingna Liao; Linköping University, Sweden*

Solar heating is important for many applications but less attractive for concepts requiring intermittent heating, such as ionic thermoelectric supercapacitors (ITESCs). However, the heating process even at constant solar illumination can be converted to temperature oscillations through water infiltration and evaporation. Here, this process is demonstrated for a carbon nanotube-cellulose membrane and used to induce temporally varying temperature gradients across an ITESC, which enables continuous operation through repeated charge and discharge cycles. A temperature variation of 10 K can be generated on the top electrode, which leads to a variation in the temperature difference across the ITESC of 7.5 K. Precise control over charge and discharge durations can be achieved by adjusting the volume and interval of the added water. The concept of temporarily adjusting temperatures by evaporative cooling may be extended to create intermittent heating also for other heat sources that are typically constant.

Sustainable Solutions for Energy Autonomous Soft Sensing Systems *Martin Kaltenbrunner; Johannes Kepler Universität Linz, Austria*

Soft devices provide unique opportunities in our quest for a more sustainable future. Their adaptive and responsive nature renders them attractive for diverse application fields, ranging from wearables in health monitoring to exploration of extreme environments. Among the key issues to overcome for successful market adoption are untethered operation, high performance green materials and end-of-lifetime considerations in complex (soft) systems. This talk introduces solutions for solar-powered flexible and lightweight devices, from wearable sensors to energy-autonomous unmanned aerial vehicles that utilize stable and ultrathin perovskite photovoltaic cells with record specific power. Whenever (sun)light is not available, battery powered solutions remain in high demand due to their relatively high power and energy densities. We here introduce stretchable, yet degradable and printable forms of batteries for wearable sensors. Pushing the boundaries of sustainable electronics, we demonstrate new concepts for advanced fungal mycelium skins as biodegradable substrate material. With reduced surface roughness and improved mechanical stability, these naturally grown flexible circuit boards offer solutions for next-generation green sensor systems.

Enabling Continuous Visual Correction in Flexible Contact Lens Platforms *Andres Vasquez Quintero[1,2]; [1]Azalea Vision, Belgium; [2]Ghent University, Belgium*

Azalea Vision, a pioneer in ophthalmic innovation, is dedicated to enhancing visual quality and quality of life for individuals with challenging vision correction needs. This work will focus on our groundbreaking flexible contact lens platform designed to address the unique challenges faced by patients with irregular astigmatism.

The Unmet Need: Irregular Astigmatism *Irregular astigmatism, characterized by non-uniform corneal curvature, presents significant challenges for traditional vision correction methods. Patients often experience fluctuating visual acuity, ghosting, and discomfort, leading to diminished quality of life. Azalea Vision's innovative platform aims to revolutionize the management of irregular astigmatism by providing a personalized, continuous, and dynamic solution.*

Technology Overview *The core of our technology lies in the integration of thin-film electronics, liquid crystal cells, radio-frequency elements and micro-battery technology within a flexible contact lens platform. We leverage advanced thin-film fabrication techniques to create ultra-thin, flexible electronic components seamlessly integrated into the contact lens. This ensures optimal comfort and conformity to the eye's natural shape. Our proprietary* ***Active Light Management (ALMA)*** *technology is a dynamic vision enhancement system embedded within the contact lens. It utilizes liquid crystal elements to dynamically adjust the pupil aperture based on real-time visual input, correcting for the irregularities caused by astigmatism and providing personalized vision correction. To ensure continuous operation, the platform incorporates a micro-battery capable of powering the electronics for an extended period. A wireless charging system using RFID technology enables convenient, daily recharging, eliminating the need for frequent battery replacement.*

The Azalea Vision platform offers significant advantages over traditional correction methods for irregular astigmatism:

Personalized Correction: *The ALMA technology adapts to the unique corneal topography of each patient, providing tailored vision correction that evolves with the changing visual environment.*

Continuous Correction: *The platform operates continuously throughout the day, ensuring consistent visual clarity and reducing fluctuations in visual acuity.*

Enhanced Comfort: *The thin, flexible design of the platform ensures comfortable wear and minimal disruption to the natural blink cycle.*

Beyond vision correction, our platform holds immense potential for integrating various sensing capabilities. Future iterations could incorporate sensors for monitoring intraocular pressure, glucose levels, and other biomarkers, opening new avenues for personalized healthcare and disease management.

Azalea Vision's flexible contact lens platform represents a paradigm shift in the management of irregular astigmatism. By combining cutting-edge technology with a patient-centric approach, we strive to empower individuals with clear, continuous, and personalized vision, ultimately improving their quality of life. This presentation will delve deeper into the technical details, clinical potential, and future directions of this transformative platform.

11:30 AM EN09.09.09

Integrated Fingertip Wearable Microgrid System for Autonomous Energy Management and Metabolic Monitoring *Shichao Ding; University of California, San Diego, United States*

Practical wearable electronics platforms for non-invasive personal health monitoring require advanced sensing modalities and highly integrated electronic systems. However, these systems face limitations in long-term continuous healthcare monitoring due to inadequate energy supply, limited sensing system capabilities, user experience issues, complex circuitry regulation, and large device dimensions. By applying the wearable microgrid design concept, we present a wearable, wireless, energy-autonomous, multiplexed sweat sensing system that operates on the fingertip. This system utilizes a high-efficiency, self-voltage-regulated wearable microgrid, composed of enzymatic biofuel cells (BFCs) and silver chloride-zinc (AgCl-Zn) batteries, to harvest and store energy from natural perspiration without requiring any body movement or physical exertion. Critical design considerations, including accurate energy budgeting, compatible circuit regulation, and scenario-specific complementary characteristics, were employed to seamlessly create the energy microgrid and integrate it with the sensor array and microcontroller onto a single fingertip. The sensing modality combines an osmotic pump and paper fluidic system to continuously deliver natural fingertip perspiration to a sensor array for on-demand multi-metabolite sensing. Coupled with low-power electronics for signal acquisition and wireless data transmission, the system can be solely powered by natural fingertip perspiration while detecting glucose, ascorbate, lactate, and levodopa levels over extended periods. The integrated sweat monitoring system on the fingertip provides a solution for effortless, reliable, and self-sustainable comprehensive non-invasive metabolic monitoring.

11:45 AM EN09.09.10

System with Integrated Inhalation-Driven Triboelectric Nanogenerator for Monitoring User Respiration and Detecting Chemical Warfare Agents *Myunghwan Song[1], Jinkee Hong[2] and Sangmin Lee[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)*

With the advent of the Internet of Things (IoT) era, various sensors and small/portable electronics are being installed or embedded in physical objects, machinery, and equipment to detect certain events or changes. The increased integration of such sensors in daily life activities poses challenges in terms of continuously supplying power to each sensor and managing the power requirements because the batteries must be appropriately replaced or recharged. Furthermore, external batteries are associated with several limitations such as a large system weight, space occupation, and environmental pollution. To address these problems, several researchers have explored sustainable and renewable future energy sources that can help operate small/portable electronics or function as self-powered sensors. Considerable research has been performed on mechanical energy harvesting devices such as piezoelectric, electromagnetic, and triboelectric generators, which produce electrical energy from mechanical movement without environmental constraints. Triboelectric nanogenerators (TENGs), which are based on the principles of triboelectric effect and electrostatic induction, have attracted research interest owing to their high energy efficiency, compatibility with easily available materials, and low cost. However, most of the existing TENGs generate a low current output (~μA) and high voltage output (~V) owing to their high internal impedance. Recently, several researchers attempted to develop TENGs with a high current output (~mA) by incorporating novel structures, additional electrical layers or external circuits. However, such TENGs require a

large and automatic mechanical input for continuous electrical output generation, which limits its potential as a power source for small electronics in everyday life.
Moreover, since self-powered sensors are widely used in emergency situations (fire, chemical gas exposure accident, etc.), immediate reaction via continuous sensing is very important. Accordingly, respiration, which is a typical example of natural / continuous mechanical input source, has been utilized to operate TENGs. Film-flutter TENGs are representative respiration-driven TENGs and can produce a continuous electrical output from an extremely small respiration input owing to the low weight of the film and exploitation of the flutter phenomenon. However, the existing film-flutter TENGs exhibit a lower current output (nA–μA) and voltage output (mV–V) than other types of TENGs, owing to the influence of the irregular contact behavior and low contact force on the output. This limitation must be addressed for TENGs to be used as portable power sources. Specifically, TENGs that can derive a high current output (~mA) from a small respiration input must be established.
Considering these aspects, in this study, a novel inhalation-driven TENG (ID-TENG) with an amplified current output was developed for gas-mask-integrated self-powered multifunctional system. The mechanical structure of the ID-TENG was optimized by comparing the root-mean-square (RMS) voltage output in parametric experiments. The proposed ID-TENG is expected to function as a gas mask-integrated self-powered multifunctional system 1) auxiliary power source and 2) self-powered sensor. Specifically, the ID-TENG is expected to function as a self-powered user-position-indicating light. The stored energy of the ID-TENG can likely power a commercial Bluetooth tracker and wirelessly transmit the user location data. Moreover, the ID-TENG can potentially be used as a hybrid sensing system to examine the user respiration state and detect chemical warfare agents (GB, DMMP etc.) through the output waveforms.

SESSION EN09.10: Materials and Circuits Enabling Low Power Consumption
Session Chairs: Martin Kaltenbrunner and Andres Vasquez Quintero

Hynes, Level 3, Ballroom A

1:30 PM *EN09.10.01

Organic Semiconductors for Neuromorphic Biosensing *Francesca Santoro; Forschungszentrum Jülich/RWTH Aachen University, Germany*

The replication of neural information processing in electrical devices has been extensively studied over the years. The paradigm of parallel computing, which allows information to be simultaneously detected, processed, and stored, is required for numerous applications in many fields. In the case of brain-computer interfaces, another important requirement is the suitability of the device for communication with cells from structural and functional point of view. Organic semiconductors have been successfully used for neuronal interfaces ionic-to-electronic signal transduction, agile processing in 2D/3D fashion and biocompatibility. Many works have demonstrated the reproduction of neural plasticity mechanisms, such as short-term facilitation and long-term potentiation. In each device, the physical mechanism of transduction may be different, but it is known that the electrolyte plays a key role in the functioning of these devices, as it provides the ions responsible for the chemical transmission of information. Focusing on long-term memory, this can be reproduced in the organic electrochemical transistors (OECTs) with the oxidation of the neurotransmitter, as in the case of the biohybrid synapse. It is crucial to understand the influence of the material chemistry, electrolyte composition and neurotransmitter-mediated memory effect of the device, as long-term modulation is based on a change in the ionic balance between the electrolyte and the organic polymer.

This electrolyte composition (i.e., biogel) and neurotransmitter-dependency plasticity will be discussed also to consider the use of neuromorphic OECTs to be interfaced with living neurons to establish biohybrid synapses and neuronal networks. In fact, neurohybrid interfaces can be achieved through bidirectional closed loop communication with various neurotransmitters such us dopamine and glutamate.
Furthermore, I will discuss how conjugated polymers can be engineered with azopolymers and spyropirans (opto-sensitive polymers which switch from cis to trans conformation upon certain light exposure at characteristic wavelengths) to feature diverse optoelectronic short- and long-term plasticity. In fact, conductive polymers and light-sensitive surface coating can also enable electromechanical coupling with neuronal cells, enhancing the cell-chip coupling at different scales and favoring structural plasticity reaction in neuronal cells. These biomimetic materials will enable a new class of bioelectronic device used for neuronal interfaces towards their application in implantable probes.

2:00 PM *EN09.10.02
Next-Generation Sensing and Perception Enabled by Large-Area Electronics *Naveen Verma[1,2], Yue Ma[1], Xiaoyang Ma[1], Rakshit Pathak[1], Sigurd Wagner[1] and James Sturm[1]; [1]Princeton University, United States; [2]EnCharge AI, United States*

Next-generation sensing and perception applications, such as smart agriculture, industrial automation, and surgical rooms of the future, are characterized by complex environments, generating a vast, distributed, and interrelated array of embedded signals across modalities. Such smart environments motivate automated systems that generate robust and sophisticated responses to the complex and dynamic environmental state. This requires a generalized framework for perception, based on the co-design of algorithms and technology platforms for sensor fusion.

This talk starts by discussing such a framework, based on combining remote and embedded sensing. Remote sensing, such as vision, enables scalable data acquisition, across wide and dynamic fields of view, while embedded sensing, such as object-attached tags, enables multi-modal data acquisition with invariant association to embedded processes/objects. We present a class of deep-learning models for sensor fusion, that leverages the scale of remote sensing and the structure introduced by embedded sensing to enhance the robustness and efficiency of perception. The key principle for fusion is aligning spatially-dense remote-sensing feature maps with spatially-sparse embedded-sensing feature maps. This requires indexing a large number of distributed embedded point sensors by spatial location, to create feature maps.

We next discuss how Large-Area Electronics (LAE) provides a platform for spatially-distributed, physically-integrated embedded sensing arrays. In the past, this has been restricted to low-frequency form-fitting multi-modal tactile sensing sheets. We review hybrid systems, combining CMOS and LAE, that leverage in-sensor computing for scalable and efficient sparse-signal sensing from large-scale conformal sensor arrays. The architectures employ simple operations implemented by integrated thin-film-transistor (TFT) circuits to perform sensor data compression for scalable readout from the arrays.

More recently, we show how innovations in TFT technology, devices, and circuits, enable Giga-Hertz LAE systems, opening up wireless functionality. Such systems can achieve large radiative apertures, providing a high-degree of control over radiated signals, in the typical frequency range for low-power embedded radios (i.e., hundreds of MHz to few GHz). At the technology level, we leverage high-mobility zinc-oxide semiconductor for improved TFT transconductance. At the device level, we leverage source-drain self alignment, via backside exposure for photo-lithographic patterning through transparent zinc oxide, and conformal zinc-oxide deposition via atomic layer deposition for thick (low-resistance) bottom-gate electrode, to maximize TFT power-gain frequency (f_{MAX}). At the *circuit level, we leverage high-quality factor LAE inductors for resonant cancelation of TFT parasitic capacitances in the multi-GHz regime, to create radio-frequency switches and controllable oscillators.*

Based on these advances, we demonstrate LAE wireless systems having large radiative apertures for radiation-pattern control in wireless sensing. First, we demonstrate a GHz 3-element phased-array transmitter, with directional control realized by injection-locked LAE TFT oscillators. Second, we demonstrate a 2.4 GHz reconfigurable antenna, based on an 11x11 array of patch antennas, interconnected by TFT RF switches to control the surface-current distribution for frequency, polarization, and radiation pattern configuration. Third, we demonstrate a 2.4 GHz passive backscattering beamforming transmitter, leveraging the geometry of a van Atta array for directional frequency-shift-keying signal reflection to an active receiver. Together, these provide a picture for the required elements and technology pathways for realizing large-scale distributed multi-modal sensing and perception systems.

2:30 PM EN09.10.03

Patterning of Miniaturized Oxide TFTs with High-Resolution Reverse-Offset Printing for Low-Voltage IoT Applications *Fei Liu, Asko Sneck, Patrik Eskelinen, Olli Halonen, Kim Eiroma, Mika Suhonen, Henri Ailas, Henrik Sandberg, Ari Alastalo and Jaakko Leppaniemi; VTT Technical Research Centre of Finland Ltd., Finland*

Oxide thin-film transistors (TFTs) are key electronic components applied in display backplanes and flat panel X-ray detectors due to their high mobility, low off current, and low temperature processing. Their use in back-end-of-line (BEOL) applications, in highly sensitive biosensors, and in flexible integrated circuits (ICs) are also under active research. Oxide TFTs can be fabricated using vacuum processes, such as sputtering and atomic layer deposition (ALD), as well as through low-cost, solution-based processes including printing [1]. Critical to the implementation of such TFTs in flexible ICs for Internet-of-Things (IoT) and wearable applications are: (i) low-voltage operation (≤ 5 V) (enabling low power operation), (ii) small device size (≤ 5 μm) (avoiding impractically large circuit footprints and increasing yield), and (iii) high charge carrier mobility (≥ 10 $cm^2/(Vs)$) (enabling sufficient operation frequency and/or gain).

We have developed a versatile, high-resolution patterning method of thin films that is based on reverse-offset printing (ROP) of a polymer resist at μm-level resolution. The technique can be used to fabricate both solution- and vacuum deposited oxide TFTs down to 2.5 μm channel lengths. The steep sidewalls of the printed polymer allow it to be employed as a sacrificial layer to pattern vacuum-deposited metal (e.g., Al, Cu, Ti/Au) via lift-off process [2]. The patterned layers can be used both as gate and source/drain (S/D) contacts to the TFTs as well as sensor electrodes [3]. This can help to avoid problems (e.g. stability) associated with S/D-contacts that are printed with nanoparticle inks [4]. Moreover, we demonstrate that the same ROP resist can also be used as an etch mask to pattern a solution-processed, ALD-grown, or sputtered oxide semiconductor and gate dielectric thin films.

Here, we discuss the fabrication process and the electrical performance of n-type oxide TFTs with solution-processed In_2O_3 as well as ALD-grown ZnO and In_2O_3 semiconductors that are patterned using ROP down to 5 μm channel lengths. Depending on the semiconductor fabrication process and the device stack and geometry, we achieve TFTs that operate at ≤ 5 V and show ~3 – 10 $cm^2/(Vs)$ mobility, high ON/OFF-ratio $>10^7$, and turn-on voltage close to 0 V. By using unipolar pseudo-CMOS circuit topology, flexible ICs can be developed for IoT and wearable application, reducing the need for Si-chips. The use of benign and Earth-abundant materials palette, such as ZnO, enables the development of sustainable IoT sensor platforms.

Electrically Gated, Ultra-Broadband THz Amplitude Modulation via Solid-State Organic Electrochemical Devices

Jonathan Scott[1], Atsutse Kludze[1], Megan Santamore[1], Christina Kousseff[2], Iain McCulloch[1], Yasaman Ghasempour[1] and Barry P. Rand[1]; [1]Princeton University, United States; [2]University of Oxford, United Kingdom

Wireless systems for imaging, sensing, and communications continue to march onward into higher frequency bands for improved bandwidth, resolution, directionality, and other benefits. In this context, the THz regime (from 0.1 to 10 THz) has recently gained attention. However, THz radiation presents unique challenges regarding modulation and reconfigurability that are needed for many device applications. The so-called "THz gap" refers to the nascent state of development for the generation and manipulation of THz radiation. The necessary picosecond timescales place stringent requirements on the operation of THz devices that renders conventional materials and fabrication approaches less effective at higher frequencies. Consequently, most research on devices for the manipulation of THz radiation, such as 2D systems or periodic structures/metamaterials, rely on novel materials and complex fabrication techniques. Such approaches present additional challenges to solving the THz gap in scalability, reproducibility, and integration with existing technologies, hindering their widespread adoption.

Organic semiconductors have shown great promise in the context of facile processing and fabrication for scalable, large area devices. While organic semiconductor-based displays are well established, areas of active device research include organic electrochemical transistors (OECTs) and electrochromic devices (ECDs). Such devices utilize organic mixed ionic-electronic conductors (OMIECS) such as poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) as channel layers in contact with an adjacent electrolyte that provides mobile ions. When a bias is applied between the electrolyte and channel, ion migration is induced into the channel material, leading to charge compensation that can modulate conductivity. These reversible interactions are accompanied by significant color changes, leading to their use in ECDs. Such devices show unique properties, including low-voltage operation, chemical tunability, ability to interface with soft and flexible substrates, and ease of fabrication. Additionally, the conductivity of such polythiophenes can often be processed to near-metallic levels, allowing for high frequency operation.

In this talk, we demonstrate the use of electrochemical doping and de-doping processes in a thin channel of an OMIEC to electrically manipulate THz radiation across a 1 THz bandwidth. We demonstrate a fully solid-state device based on a gel electrolyte laminated onto a polythiophene thin film, achieving up to 75% modulation depth with a single layer. We also explore the electrochemical stability limits of such devices, as well as the response *times and long-time biasing capabilities. Further, we demonstrate the simultaneous DC, THz, and optical (i.e., electrochromic) switching behaviors of the films. These results show the promise of OMIEC-based devices for THz operation, opening new avenues for advanced applications in high frequency bioelectronics, sensing, and communication technologies.*

3:00 PM BREAK

3:30 PM EN09.10.05
Organic Mixed Conductors in Fully Direct-Written THz Metaoptics *Giorgio Ernesto Bonacchini[1,2], Cristiano Bortolotti[3,2], Federico Grandi[3,4], Matteo Butti[2], Francesco Modena[2], Lorenzo Gatto[3,4], Christina Kousseff[5], Iain McCulloch[5], Caterina Vozzi[4], Mario Caironi[2] and Eugenio Cinquanta[4]; [1]Università degli Studi di Padova, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Politecnico di Milano, Italy; [4]Consiglio Nazionale delle Ricerche, Italy; [5]University of Oxford, United Kingdom*

In the past two decades, the interest towards low-cost and portable terahertz (THz) metadevice technologies has surged thanks to the considerable promise that these electronic and hybrid electronic–photonic systems will likely play in upcoming sensing, imaging, and telecom applications[1]. Indeed, a wealth of metadevice platforms based on inorganic semiconductors (e.g. III-V compounds and silicon), 2D materials (e.g. graphene and transition metal dichalcogenides) have been proposed, along with those that rely on superconductors, metal oxides and liquid crystals[2,3]. Interestingly, the use of organic electronic materials in tuneable metastructures has not yet been pursued[4–6], and their THz properties are largely unexplored[7]. A possible explanation of this gap in both the scientific literature and technology is possibly due to the relatively low charge carrier mobilities and poor charge injection of organic semiconductors with respect to inorganic and layered materials[8]. This limitation has possibly originated the preconception that organic materials have no utility in high-frequency applications[9].
In this work, we challenge this point of view by demonstrating for the first time the use of organic electronic materials as tuning layers within reconfigurable THz metaoptics. Indeed, we show that the transmission of metallic metasurfaces resonating in the 0.5-0.75 THz range can be effectively modulated by an organic mixed ion-electron conductor (OMIEC) through a charge carrier screening effect, as previously demonstrated with inorganic semiconductors and layered nanomaterials[10,11]. In particular, we exploit the polymer p(g2T-TT), the prototype material of an emerging class of OMIECs characterized by conjugated polymer backbones that exhibit high hole (or electron) mobilities, while also displaying liquid-like ionic conduction thanks to their hydrophilic glycolated sidechains[12,13]. By optimizing the dissolution of p(g2T-TT) in high boiling point solvents, we are able to fabricate THz metadevices where both the metastructure and the active materials are processed solely by cost-effective and mass-scalable direct-writing techniques, namely inkjet printing and femtosecond laser writing, which are also compatible with large-area and plastic substrates[14]. Moreover, through time-domain terahertz spectroscopy performed on bare OMIEC thin-films, we show that the large conductivity modulations of these polymers, until now probed only at very low frequencies, are effectively preserved in the terahertz range, leading to optimal metadevice reconfigurability.
These results point to a new spectrum of applications for organic electronic materials in terahertz technologies, where their unique characteristics may lead to groundbreaking wireless bioelectronic and neuromorphic technologies[15,16].

Pervasive Electronic Devices Based on Unconventional Materials *Almudena Rivadeneyra, Francisco J. Romero, Carmen L. Moraila-Martinez, Sara Rojas, Victor Toral, Diego P. Morales and Encarnación Castillo; Universidad de Granada, Spain*

The ever-increasing use of technology in almost every aspect of our lives makes mandatory the investigation in innovative devices and novel fabrication techniques and materials that have not been traditionally used in the fields of electronics but that can give answer to many of the consequences of the omnipresence of electronics, especially related to the sustainability and circularity of electronics.

In this context, our group is advancing in the development of responsible devices based on printed electronics as fabrication techniques in combination with graphene derivates together with metal-organic-frameworks (MOFs), among other materials. One of our main focuses are on the design of the electronic devices with the minimum number of layers as well as minimizing the power consumption both at their fabrication and their end-of-life.

One example that combine the already mentioned scientific approach is the design and development of a moisture sensor manufactured by just laser scribing of a cork substrate, defining a conductive meandered layout based on nanostructured graphene. Such sensors exhibit a sensitivity of 0.015%/RH% with a very fast time response with a low thermal dependency and high long-term stability [1]. Another example is the manufacturing of laser-induced graphene (LIG) electrodes on polyimide substrates for boisignal acquisition [2]. The deployed electrodes do not require ionic gel for their use. Once the conductive pattern is lasered induced on the substrate, only a snap connector is placed on the terminal to allow the connectivity with standard biosignal's wires so they can be used with any biosignal acquisition system. They have shown excellent performance for electrocardiogram (ECG), electromyogram (EMG) and electrooculogram (EOG) [3]. Our group has also implemented a small reconfigurable platform capable of detecting these 3 types of signals by just modifying the software. Another research line that we cover is energy harvesting devices and energy storage elements. In this area, we combine LIG with MOFs to increase their performance [4]. In particular, we have already demonstrated that the functionalization of LIG with a copper-based MOFs enhances the performance of supercapacitors up to six times compared to LIG-only electrodes.

This contribution will give an overview of the advances made in the field of responsible electronics devices, including their integration in final systems that serve to prove the potential of the developed technologies.

Organic Mixed Ionic-Electronic Conductors for Low-Power Electronics *Simone Fabiano; Linköping University, Sweden*

Organic mixed ionic-electronic conductors (OMIECs) are versatile materials widely used in fields such as bioelectronics, optoelectronics, and energy storage due to their unique ability to transport both ionic and electronic charges efficiently. This sets them apart from other organic semiconductors and enables innovative signal transduction approaches. OMIECs are commonly employed in organic electrochemical transistors (OECTs), where ion-modulated doping and dedoping lead to significant changes in channel conductance, resulting in low operating voltage, high transconductance, and compatibility with biological systems. In this presentation, we will provide an overview of our efforts to create OMIECs that can be processed using environmentally friendly solvents, such as alcohol or water. We will explore the application of these formulations in the fabrication of energy harvesting devices and ultra-low-power complementary electronic circuits. Additionally, we will discuss the utilization of screen and 3D printing techniques for high-throughput screening of new materials and device concepts, demonstrating their effectiveness in developing energy-efficient bio-inspired organic electrochemical devices and circuits. This advancement holds the potential to significantly contribute to the widespread adoption and sustainable integration of organic electronics in various commercial applications.

Flexible Hybrid Nanogenerator Integrated with Codoped Barium Titanate/Zinc Oxide for Enhancement Energy Harvesting Applications *Vartika Khandelwal; Central University of Haryana, India*

This study focuses on a cost-efficient and adaptable approach for synthesizing a Flexible Hybrid Nanogenerator (FHNG). The composite, which comprises lead-free piezoelectric $Ba_{0.92}Ca_{0.08}Zr_{0.10}Ti_{0.90}O_3$ *(BCZT) and Zinc Oxide (ZnO), was synthesized through the reflux method. Fabrication of the FHNG involved incorporating BCZT/ZnO as a* *reinforcement within the polydimethylsiloxane (PDMS) matrix using a dispersion method. X-Ray Diffraction (XRD) analysis unveiled the presence of tetragonal and rhombohedral phases of BCZT, as well as the hexagonal phase of ZnO, and also confirmed the successful synthesis of the nanocomposite (BCZT/ZnO) at room temperature. A comprehensive exploration of dielectric, ferroelectric, and optical properties ensued. The notable increase in dielectric constant at lower frequencies was attributed to the space charge polarization phenomenon. Remnant polarization (Pr) achieved 0.326 μC/cm^2 on the application of a 160 kV/cm electric field. The peak open-circuit voltage (V_{OC}) and short-circuit current (I_{SC}) of FHNG were scrutinized on various mechanical stresses from 10 Pa to 450 Pa, exhibiting maximum $V_{OC} \approx 10.2$ V and $I_{SC} \approx 30$ mA. This technology, exemplifying practicality and adaptability, lays the foundation for prospective applications in flexible electronics, encompassing wearable devices, electronic skin, the Internet of Things (IoT) network, and environmental monitoring systems.*

EN09.11.03

Developing Scalable and Sustainable Organic Solar Cells *Sophie Koh[1], Jasmine Jan[1], Carla Benato Milsted[1], Julia Campbell[1], Aniruddh Khanwale[1], Julie Wang[1], Jakob Gunderson[1], Do-Kyoung Lee[2], Chenhui Zhu[2], Carolin M. Sutter-Fella[2] and Ana Claudia Arias[1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States*

Organic photovoltaics (OPVs) have emerged as a promising technology for renewable energy generation due to their potential for flexible form factors and scalable fabrication. Emerging photovoltaic research tends to prioritize device efficiency over scalability, focusing on spin-coated small-area devices, often relying on halogenated solvents such as chloroform or chlorobenzene to dissolve blends of organic semiconductors. These halogenated solvents are toxic to both the environment and human health. In this work, we demonstrate OPVs with layers deposited with blade-coating, a scalable and less wasteful method. In addition, active layers are processed with anisole as an eco-friendly alternative solvent. For blade-coating layers, we optimized blade speed to demonstrate that printed interlayers can achieve comparable performance to spun interlayers in OPVs. The printed-interlayer devices show efficiency of 3.7% as compared to the 3.3% efficiency obtained for spun devices. The material loading in anisole-based active ink formulation is optimized to achieve equivalent solution viscosity and absorbance as obtained with chlorinated solvents. In situ absorbance characterization of film drying and 2D GIWAXS measurements are used to confirm improved film morphology when increasing material loading and employing thermal annealing, resulting in increased performance. These results indicate the potential for scalable fabrication with sustainable materials without compromising OPV performance.

EN09.11.04

Wrinkled Parylene Coating for Implantable Strain Sensor Encapsulation *Xinghao Huang, Liheng Yang, Riley Jacobsen, Hao Xu, Max Wu and Hangbo Zhao; University of Southern California, United States*

Implantable strain sensors integrated on organ surfaces can monitor organ deformations, such as the filling and emptying of the bladder and the motility of the stomach, thereby providing important information about their functional states. A major challenge lies in achieving a large strain range while ensuring long-term stability inside the body fluid environment. Commonly used materials to achieve large stretchability, such as soft elastomers, have relatively high water permeability, which can lead to degradation of sensing performance and pose safety risks. The biocompatibility requirements present additional material challenges to stretchable encapsulation for long-term use. In this work, we present a wrinkled parylene coating for the encapsulation of stretchable strain sensors, which are made of silicone elastomer and spray-coated carbon nanotubes in a parallel-plate capacitor configuration. Conformal deposition of a parylene thin film on a pre-stretched, elastomer-based strain sensor followed by the release of the prestrain creates wrinkles in the parylene coating. This wrinkled parylene coating provides over 50% mechanical stretchability and biocompatible encapsulation. The coating can also increase the *gauge factor of the strain sensors from 1 to 2 by suppressing the Poisson's effect of the elastomer-based sensor. We investigate the influences of the coating thickness on the sensor performance, and demonstrate the long-term stability of these encapsulated strain sensors through cyclic stretching with thermally accelerated aging inside saline. The fabrication simplicity and biocompatibility of this wrinkled parylene encapsulation make it potentially useful for other stretchable, implantable devices.*

EN09.11.05

Zinc-Air Batteries as Oxygen Soil Sensors *Philothei Sahinidis[1], Carol Baumbauer[2] and Ana Claudia Arias[1]; [1]University of California, Berkeley, United States; [2]Boise State University, United States*

Oxygen in soil plays a critical role in facilitating plant physiological processes and regulating emissions of greenhouse gasses, like methane and nitrous oxide. Consequently, there is a growing need for high temporal and spatial resolution data on soil oxygen levels between 0% and 21%. However, traditional optical oxygen sensors rely on external power supplies, while conventional galvanic oxygen sensors use expensive precious metals, limiting their widespread deployment in soil. Here, we introduce a low-cost and scalable alternative by demonstrating stencil-printed zinc-air batteries as soil oxygen sensors. We explore hydrophilic and hydrophobic binders in carbon-based oxygen catalyst and zinc anode inks and develop a polypropylene packaging system to protect the sensors from fluctuations in soil moisture. We compare amperometric and potentiometric characterization of the devices as oxygen sensors and examine their sensitivity, stability, and lifetimes across temperatures between 12-30 °C and oxygen levels between 0-21%. This affordable oxygen sensing technique marks an important step towards the development of zinc-air batteries as alternative systems for measuring oxygen levels in soil, enabling the collection of high resolution environmental data.

EN09.11.06

Blade Coated Polyvinylidene Fluoride-Carbon Black Composites for Printed Solid Contact Ion Selective Electrodes *Lucas Lahann, Yuting Cai and Ana Claudia Arias; University of California, Berkeley, United States*

Solid contact ion-selective electrodes (SC-ISEs) have a high potential to enable continuous ion sensing in health and environmental applications due to their low readout power and complexity requirements. Despite this, their usage in distributed sensor nodes remains practically limited by the need for periodic recalibration. To address this challenge carbon nanomaterials have been effectively utilized in SC-ISEs to reduce calibration drift due to their high effective surface area, intrinsic hydrophobicity to resist interfacial water layer formation and electrochemical inertness. To translate these advancements to scalable sensor nodes, the processibility of these materials for high throughput solid contact fabrication across a range of device geometries needs to be considered. In this work, we have optimized an ink based on carbon black nanoparticles (CB) and polyvinylidene fluoride binder (PVDF) with desirable properties for blade coating at roll-to-roll compatible coating speed. This approach also gives control of solid contact geometry using a polyimide stencil during the coating process. The cured films have good flexibility and adhesion to PET substrates. By varying the blade height and speed this approach allows for control over the thickness and area of the resultant solid contact film in a single blade coating step, improving processibility over previous multilayer drop casting techniques. We find that by increasing the loading of carbon black, a maximum water contact angle of 154.7° ± 4.3° is achieved, which supports the superhydrophobic nature of the solid contact. SC-ISEs selective to nitrate utilizing these solid contacts exhibited expected Nernstian sensitivity (>50 mV/Decade) and selectivity coefficients that match previously published empirical values. The porous PDVF-CB solid contact forms a maximum specific electrical double-layer capacitance of 2.54 ± 0.21 F/g after drop casting the ion-selective membrane and resists water layer formation during extended ion sensing. Further, to eliminate the need for drop-casting of the ion-selective membrane, we demonstrate a modified ink composition to enable a simplified single-step blade-coated electrode for SC-ISEs. We *use this approach to increase the electrode sizing and achieve flexible SC-ISEs with >1 mF electrode capacitances as a step towards long-term, calibration-free sensing.*

EN09.11.07

Hydrogel Coated Ion Sensor Array for Continuous Nitrogen Monitoring in Variable Soil Conditions *Yuting Cai, Lucas Lahann and Ana Claudia Arias; University of California, Berkeley, United States*

Continuous monitoring of critical soil nutrients, such as nitrate and ammonium, could play an important role in agricultural data-driven fertilizer application improving nitrogen use efficiency and reducing pollution. The ion potentiometric sensor with an ion-selective electrode (ISE) is a widely accepted standard method in water analysis. Therefore, many researchers aim to utilize potentiometric sensors to detect various ion concentrations in soil moisture due to their low cost and high selectivity. However, a potentiometric sensor requires a water environment to function. The varying moisture content in different soil types (sand, clay, silt, peat, chalk, and loam) and the occurrence of freezing conditions in winter make the applicability of existing sensors challenging. To achieve this, we demonstrate an ISE hydrogel sensor with uniform and ultra-thin (around 5 μm) hydrogel coatings by in-situ polymerization onto the protection silicon rubber outer layer applied to the potentiometric sensor. The well-designed ISE hydrogel sensor inherits traditional ISE sensors' wide sensing range (0.01mM-100 mM), high sensitivity (~32.5 mV/dec), and stability (drifting < 0.5 mV/h), effectively measuring ion concentration in soil with moisture content as low as 5%, which is inaccessible to traditional ISE sensors even at 20%. Additionally, we design printed heaters to thaw frozen soil during winter, enabling the measurement of ion concentration. And the printed thermometer can effectively monitor soil temperature and control the operation of the heater. Based on that, the viability of continuous ion sensing at a wide range of expected soil temperatures with closed-loop heating is improved. This expands the application space for low-cost electrochemical ion sensors by proving that environmental factors can mitigated with careful materials and system design.

EN09.11.08

Tin Selenide p-n Thin Film Thermoelectric Elements Produced by Vacuum Thermal Evaporation and Thermal Processing *Fabiola De Bray Sanchez, M.T. Santhamma Nair and P.Karunakaran Nair; Universidad Nacional Autónoma de México, Mexico*

Interest in tin selenide (SnSe) with notable thermoelectric parameters and their suitability for developing wearable thermoelectric devices calls for their thin film thermoelectric elements to ensure lightweight non-toxic scalable products. However, the production of thin films by easily scalable vacuum techniques face the challenge of establishing the deposition conditions to avoid mixed phase SnSe-$SnSe_2$–Sn_2Se_3 content in the films with uncertain p – and n – type electrical conductivities, thereby lacking commercial viability for the products. The condition for the deposition of SnS thin films of 200 nm in thickness and orthorhombic (ORT) structure by vacuum thermal condition on glass substrates were established for transition to flexible substrates: substrate temperature 350 °C and deposition rate 3 nm/min. The p-type electrical conductivity the SnS-ORT film of 0.1 Ω^{-1} cm^{-1} was increased tenfold when heated at 280 °C for 30 min under nitrogen at 20 torr with trace amount of Se-vapor, but when heated in nitrogen enriched with more Se, the thin film partially converted to SnS-ORT with $SnSe_2$ with n-type conductivity of 1 Ω^{-1} cm^{-1}. The Seebeck coefficient of the films are: + 0.4 mV K^{-1} for p-SnSe-ORT and – 0.4 mV K^{-1} for the n-SnSe-ORT-$SnSe_2$ film. Thus, p-n thermoelectric devices may be built from these thin films with a coefficient of 0.6 mV K^{-1} per couple. Because the elements were stabilized at 280 °C, they are stable in room temperature range operation, as required for wearable devices.

EN09.11.09

Bidirectional Rotating Direct-Current Triboelectric Nanogenerator with Self-Adjusting Structure for

Mechanical Rectification Mechanism and Energy Harvesting from Reciprocating Motion *Joonmin Chae, Donghan Lee, Sumin Cho, Jong Woo Kim and Dongwhi Choi; Kyung Hee University, Korea (the Republic of)*

Triboelectric nanogenerators (TENGs) have garnered significant attention in the field of innovative energy-harvesting technologies. Recent studies have concentrated on direct current (DC) TENGs to provide a stable DC output for electronic devices. However, conventional DC TENGs face challenges in generating stable DC output from reciprocating motions due to their traditional operating mechanisms. To overcome this issue, we introduce a bidirectional rotating DC TENG (BiR-TENG) that can produce DC outputs regardless of the rotation direction, even from reciprocating movements. The distinctive design of the BiR-TENG allows for the mechanical rectification of the alternating current (AC) output into a DC output dependent on the rotation direction. Moreover, it can transform this directional DC output into a unidirectional DC output by adjusting the configurations based on the rotation direction. This design strategy and subsequent optimizations lead to an effective unidirectional DC output. We demonstrated the practical applications of the BiR-TENG by harnessing the reciprocating motions of swinging doors and ocean waves. These examples illustrate the versatility and efficiency of the BiR-TENG design for energy harvesting from reciprocating motions, highlighting the potential of DC outputs as a reliable power source for electronic devices. This study emphasizes the BiR-TENG's potential as an innovative solution for stable DC energy harvesting in various applications, paving the way for more efficient and adaptable energy solutions.

EN09.11.13

Development of Dielectric Inks for Printed Capacitive Pressure Sensors Through Surfactant-Aided Exfoliation of hBN Nanosheets *Meghana Jois and Anastasia Elias; University of Alberta, Canada*

With increase in development of specialized printable circuits and devices for wireless communication, dielectric materials with high dielectric constants and low losses at high frequencies are essential for additive manufacturing of flexible wearable devices. Hexagonal boron nitride (h-BN), an insulating analogue of graphene, is an excellent candidate due to its wide band gap and dielectric constant ranging from 2 to 4. This makes it ideal for applications such as gate dielectrics, capacitors, and passivation layers in a variety of sensor designs. However, there is a lack of research on the high-frequency dielectric properties of these materials. Additionally, stabilizing h-BN nanosheet dispersions for printing, while reducing the use of toxic solvents and excessive surfactants, is challenging. Current exfoliation techniques are often time-consuming and resource intensive. This study investigates a two-part, surfactant-assisted mechanochemical exfoliation method to obtain stable h-BN nanosheet dispersions quickly, using ball milling followed by probe sonication. Various concentrations (0 to 1 wt.%) of Triton X-100 were used to assist the exfoliation and stabilization. The yield of each mixture was quantified by thermogravimetric analysis (TGA), achieving a maximum yield of 18.4% with 1 wt.% surfactant. Colloidal stability was assessed using UV-VIS spectroscopy, with solutions remaining stable for up to 30 days. X-ray diffraction (XRD), scanning electron microscopy (SEM), and atomic force microscopy (AFM) were used to evaluate the quality and size of the nanosheets. Dielectric properties were measured using a vector network analyser (VNA) at microwave frequencies (2 – 18 GHz), with real permittivity ranging from 2.1 to 3.7 and low dielectric loss tangents from 0.012 to 0.014, depending on the surfactant concentration. The two-part exfoliation technique required less than half the processing time than some of the conventional exfoliation techniques and produced highly stable aqueous dispersions. The resulting h-BN nanosheets exhibited tuneable real permittivity and low dielectric loss, making them promise for dielectric ink formulations. Eco-friendly and biocompatible water-based inks were then formulated with polyethylene oxide (PEO) as the polymer binder. Filler and binder concentrations were optimized to achieve inks with suitable rheological properties for direct ink writing, a printing technique that uses viscous fluids as inks. Capacitors with the formulated h-BN ink as the dielectric layer and silver interdigitated electrodes were printed. Electrical properties such as dielectric constant, impedance, and capacitance were measured over a range of frequencies (KHz to GHz). The flexible planar capacitors had capacitance values ranging from 3-5 pF and *were tested as physical sensors for pressure sensing. These devices hold significant potential for a wide range of applications, particularly in the development of wearable sensors designed for comprehensive human health monitoring systems that provide real time data and insights.*

EN09.11.14

A Non-Invasive, Environmentally Stable and Reusable Wearable Sensor for On-Demand Sweat Cortisol Monitoring

Shingirirai Chakoma, Xiaochang Pei, Jerome Rajendran, Anita Ghandehari, Jorge Alfonso Tavares Negrete and Rahim Esfandyarpour; University of California, Irvine, United States

Stress significantly impacts our health, causing long-term effects like cardiovascular diseases and autoimmune disorders. This necessitates precise and objective stress assessment methods beyond traditional self-report questionnaires, often lacking reliability. Wearable technologies have been developed to measure physical stress indicators like electrocardiogram (ECG) and galvanic skin response (GSR) but they are nonspecific and susceptible to environmental factors. Current molecular biosensors, particularly those detecting cortisol, a key stress hormone, are based on aptamers, enzymes, and antibodies, they are environmentally unstable and non-reusable. To meet the demands for continuous and long-term stress monitoring, we developed an innovative wearable sensing system employing a molecularly imprinted polymer-radiofrequency (MIP-RF) mechanism for non-invasive, real-time cortisol detection in sweat. The wearable system is designed to be wireless, flexible, battery-free, reusable, and environmentally stable. It utilizes a 3D-nanomaterials printed inductance-capacitance (LC) resonator that converts cortisol levels into resonant frequency shifts with high sensitivity (~160kHz/log[μM]) within a physiological range of 0-1μM. Enhanced with Near-Field Communication (NFC) for seamless, battery-free operation and a 3D-printed microfluidic channel for on-demand sweat sampling, the device enables continuous cortisol monitoring throughout daily activities. This innovation represents a significant advancement in on-demand, non-laboratory health monitoring, leveraging wearable technology for precise molecular stress biomarker detection.

EN09.11.15

Novel Hydrocarbon Derived Carbon Nanomaterials for Wearable and Flexible Printed Micro-Supercapacitors

Ramu Banavath, Yufan Zhang, Sayyam Deshpande, Smita Dasari and Micah Green; Texas A&M University, United States

Carbon nanomaterials have emerged as a promising solution for advancing printed electronics, especially in applications such as micro-supercapacitors (MSCs). This study examines the significance and compatibility of a newly developed industrial carbon nanomaterial, derived from hydrocarbon streams via a scalable, catalyst-free process in a proprietary reactor. The resulting carbon nanomaterials exhibit a unique morphology, characterized by nanoscale building blocks forming micro-scale networks, which enhance the efficiency of printed flexible electronics. We utilized hydrocarbon-derived graphene nanoparticles (GNPs) as an electrode material for MSCs. These GNPs possess unique properties, including a networked structure, high electrical conductivity, and a large surface area, making them ideal for next-generation printed MSCs. The GNP-based printed MSCs operate efficiently without metal current collectors, indicating that the hydrocarbon-derived GNP-based printed electrodes have sufficient conductivity comparable to metal-based current collectors. The printed GNP-based MSCs demonstrated an excellent specific capacitance of 3.2 mF cm^{-2}, outperforming many graphene-based MSCs. Additionally, these MSCs exhibited outstanding cycling stability, retaining 97% of their capacity after 10,000 galvanostatic charge-discharge cycles, and superior capacitance retention of 91% at a bending angle of 180 degrees. These results indicate that the networked structure of hydrocarbon-derived GNPs maintains capacitance at various bending angles, confirming their high compatibility with flexible printed electronics. The integration of hydrocarbon-derived GNPs into printed electronics not only facilitates the development of lightweight, flexible, *and cost-effective devices but also opens the door to innovative applications in various technological fields.*

EN09.11.16

Zwitterionic Soy Sauce Based Gel Electrolyte for Edible Supercapacitors *Mete Batuhan Durukan, Deniz Keskin, Yigithan Tufan, Orcun Dincer, Melih O. Cicek, Bayram Yildiz, Simge Cinar Aygun, Batur Ercan and Husnu E. Unalan; Middle East Technical University, Turkey*

With the swift advancement of technology, the use and dependence on small and miniaturized electronics have grown substantially. Common power sources for wearable and implantable devices often contain potentially harmful materials, leading to significant environmental issues and waste that demand innovative and sustainable solutions, particularly in the Internet of Things era. In addition to new biodegradable and implantable devices, the emergence of edible and ingestible electronic devices offers a niche, sustainable solution. To make these devices viable, their energy sources must also be edible and ingestible. Here, zwitterionic and edible gel electrolytes are produced using hydroxyethyl cellulose and commercial soy sauce (shoyu) for superior ionic conductivity, providing a favorable environment for L929 proliferation [1]. These edible gels are combined with carbon electrodes to fabricate edible supercapacitor devices, resulting in an ideal double-layer capacitance with a maximum specific capacitance of 3.75 F g^{-1} and a capacitance retention of 86.5% after 10000 cycles. Fabricated edible supercapacitors can be flexed and even rolled smoothly. Gels showed a substantial resistance to drying and freezing due to the presence of the zwitterionic structure of soy proteins in soy sauce. Degradation studies using a simulated gastric fluid have also shown that all components of the edible supercapacitor can be digested within 40 min. Presenting an edible gel based on soy sauce with remarkable ionic performance offers a compelling alternative to traditional energy storage devices. This innovation paves the way for advancing state-of-the-art ingestible healthcare devices and environmentally sustainable electronics.

[1] An Edible Supercapacitor Based on Zwitterionic Soy Sauce Based Gel Electrolyte, M.B. Durukan, D. Keskin, Y. Tufan, O. Dincer, M. O. Cicek, B. Yildiz, S. Cinar Aygun, B. Ercan, H. E. Unalan, Advanced Functional Materials 34 (2024) 2307051.

EN09.11.17

Organic Thermoelectric Device Utilizing Charge Transfer Interface as the Charge Generation by Harvesting Thermal Energy *Mana Kameyama[1], Shun Kondo[1], Kentaro Imaoka[1], Yoko Shimoi[2], Fabrice Mathevet[3], Takashi Fujihara[4], Hiroshi Goto[4], Hajime Nakanotani[1,5], Masayuki Yahiro[2] and Chihaya Adachi[1,5]; [1]Kyushu University, Japan; [2]ISIT, Japan; [3]Sorbonne Université, France; [4]GCE Institute, Japan; [5]Kyushu university I2CNER, Japan*

Currently, environmental power generation technologies that convert not only sunlight but also heat, vibration, and other micro-energies around us into electric power have been attracting attention around the world. Thermoelectric devices using waste heat have been put to practical use, but their use is limited due to the problems of using the high cost of materials and the limited installation space required to form a temperature difference. In this study, we propose organic thermoelectric devices based on a new mechanism by utilizing the charge-transfer (CT) complexes that cause carrier separation with thermal energy as low as room temperature and the charge diffusion ability in organic thin films.
As CT forming materials, CuPc (Copper (II) phthalocyanine) and F_{16}CuPc (Copper (II) 1,2,3,4,8,9,10,11,15,16,17,18,22,23,24,25-hexadecafluoro-29H,31H-phthalocyanine) were used as a donor and an acceptor, respectively. In addition, C_{60} (fullerene) and BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) were inserted as the electron transport layers. In Device A, which utilizes CuPc (30 nm)/F_{16}CuPc (20 nm)/C_{60} (40 nm)/BCP (20 nm), we confirmed power generation with the value of V_{oc}=180 mV, J_{SC}=20 nA cm^{-2}, and P_{max}=0.9 $nWcm^{-2}$ in a completely dark environment at room temperature. Further, when the F_{16}CuPc film thickness was

changed from 100 nm to 200 nm (Device B), the power generation efficiency improved with increasing F_{16}CuPc film thickness. This can be ascribed to the improvement of diffusion force in the thicker F_{16}CuPc film, resulting in suppressed carrier recombination. When the C_{60} film thickness was changed from 40 nm to 20 nm (Device C), we observed the thinner C_{60} film leads to higher efficiency. Further, when the BCP film thickness was changed from 20 nm to 5 nm (Device D), the efficiency increased with decreasing BCP film thickness, while the devices without BCP showed lower efficiency. Based on these results, we fabricated an optimized CuPc (300 nm)/F_{16}CuPc (200 nm)/C_{60} (3 nm)/BCP (5 nm) device and obtained the value of V_{oc}=462 mV, J_{SC}=3.94 μA cm^{-2}, and P_{max}=394 $nWcm^{-2}$, demonstrating the proposed devices have high potential as a new power generation mechanism.

EN09.11.18

Origami Motion-Driven High Output Current Triboelectric Nanogenerator for Self-Powered Life-Jacket System *HanWook Ryu[1], Jinkee Hong[2], Sangmin Lee[1] and Myunghwan Song[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)*

Triboelectric nanogenerator (TENG) have proved their potential to convert mechanical energy to electricity. However, huge mass, volume and low current output remains a challenge. Therefore, in this work, we designed an Origami motion-driven High-output current Triboelectric Nanogenerator (OH-TENG) with low weight, high power density, and portability. Because of multiple charge accumulation at layer and electrostatic discharge mechanism using zig-zag folding and rotating origami structure design. The OH-TENG can generate high voltage and current output at 80V, 60V respectively, 15mA, 10mA high output current respectively, in contact, separation both case. The OH-TENG is optimized via quantitative voltage-current database and mechanical behavior analysis. This high output power can operate commercial LEDs and sensors enough. And, OH-TENG has elastic feature by using a polymer and fabric material. Using this feature, OH-TENG can expand the practical application, including thin thickness product. So, OH-TENG can applied to life jacket system's buoyancy material like 3.5cm ~ 6cm thickness. Our system designed for floating life jacket in ocean generating output power by using wave energy. A further study focuses on applied OH-TENG to life jackets buoyancy for floated in ocean. These findings suggest improving origami shape TENG's power and engineering design.

EN09.11.19

Engineering Flexible Triboelectric Laminates—Advanced Energy Harvesting and Sensing for Wearable Electronics and Smart Systems *Kaspars Malnieks, Andris Šutka, Artis Linarts and Linards Lapčinskis; Riga Technical University, Latvia*

Triboelectric generators (TEGs) are rapidly gaining attention as efficient small-scale converters of mechanical to electrical energy, with the capability to harness energy from a wide array of sources such as motion, ambient vibrations, noise, and even water droplets. Despite their promise, TEGs are often constrained by limitations in surface charge density and output power.
Recent advancements focus on overcoming these limitations through various innovative approaches. Enhancing triboelectric surface charge density has been achieved by optimizing material properties and molecular arrangements[1], leading to improved charge transfer capabilities. Surface functionalization techniques have been employed to chemically modify surfaces[2], thereby increasing charge retention and transfer efficiency. Additionally, controlling interfacial strain at the contact points between materials has been shown to significantly boost charge density[3]. Another key development involves exploiting volumetric dipoles, which arise from triboelectric and piezoelectric effects within the bulk of the material, contributing to higher energy output[4,5].
By integrating these approaches, it is possible to achieve substantial improvements in generator performance, with some systems reaching output levels of up to 50 W/m2 These advancements pave the way for more efficient energy harvesting and broaden the potential applications of triboelectric technology in

various fields, including wearable electronics and distributed sensing networks.

Resonant Dual-Narrowband Organic Photodetectors for Encrypted Optical Wireless Communication

Guodan Wei; Tsinghua-Berkeley Shenzhen Institute, United States

Organic photodetectors (OPDs) with narrowband response have gained significant attention for their exceptional spectral selectivity, making them ideal for applications in optical wireless communication (OWC), image sensing, biomedical diagnostics, and display technology. In this work, we present a filterless dual-narrowband OPD, responsivie in both the visible and near-infrared (NIR) regions, based on a unique organic Fabry-Pérot resonant cavity. The OPD exhibited remarkable selectivity at two distinct wavelengths: 485 nm in the visible spectrum and 910 nm in the NIR, with a full-width at half maximum (FWHM) of just 23 nm. It offers an impressive linear dynamic range (LDR) of 140 dB and an ultrafast response time of 440 ns. When integrated into an encrypted dual-channel OWC system, this device enables the secure transmission of a 600×600-pixel colored image with low bit-error rate (BER) of 9.17×10^{-5} at a data rate of 1.25 Mbps. The response time is the fastest for reported OPDs as the solution-processed method to data. The as-obtained OPD can work stably after immersing into water for 1000 hours and post-drying, and bending tests of 10000 cycles. Meanwhile, it's applied in imaging, health monitoring, and optical communication.The spectral tunability of the resonant peaks, extending into the shortwave infrared (SWIR) region, further demonstrates its versatility and potential for high-security, high-accuracy optical communication applications.

EN09.11.21

Biodegradable Self-Powered Biosensor for Histamine Detection Based on Triboelectric Nanogenerator

Heewon Song, Swati Panda and Hoe-joon Kim; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Scombroid food poisoning is a foodborne illness caused by the consumption of fish, such as tuna or mackerel, that has been improperly stored, allowing bacteria to break down proteins and produce high levels of histamine. This excess histamine causes symptoms like allergic reactions, such as flushing, hives, headache, and gastrointestinal discomfort. Traditional histamine detection methods include ELISA, HPLC, colorimetric assays, and biosensors, which help ensure food safety but can be time-consuming and labor-intensive. Since battery-free biosensors are crucial to detecting biological elements individually, many efforts have been made to utilize energy harvesting in biosensors. Moreover, due to many biosensors facing the limitation of recycling, it is considerable to utilize biodegradable materials as a substrate for a sustainable environment. Herein, we have demonstrated a self-powered biosensor to detect histamine by integrating the triboelectric nanogenerator (TENG) and a D-amino acid oxidase (DAO)-functionalized biosensor. The TENG comprises two triboelectric layers: biodegradable polycaprolactone (PCL) and wool fabric. The PCL TENG generates an output of 213 V, 640 nA, 70 μW power, and a stable voltage during 2000 seconds, respectively. DAO was functionalized in the PCL-based interdigital (IDT) patterned gold electrode using a simple self-assembled monolayer technique for the specific detection of histamine. Upon addition of histamine onto the sensor, it degrades the histamine, and the resistance of the TENG *decreases, leading to an increment in the current output. We have also demonstrated the specificity of the sensor by using various other biogenic amines such as l-tyrosine, tyramine, etc. The sensor indicated an excellent sensitivity of around R^2 =0.98. In addition, the biodegradable test of PCL has shown 9.4% degradability for up to 20 days. Thus, this study suggests a sustainable and fast method for screening histamine and a new paradigm for TENG-based biosensor platforms.*

Stretching-Dependent Charge Mobility Prediction Using Machine Learning in Single-Crystal Flexible Electronics *Xi Chen; Nanyang Technological University, Singapore*

High-performance molecular single crystal materials are seen as promising candidates for next-generation flexible electronics. Their electromechanical properties are crucial factors that will impact the performance of flexible electronic devices. Here, a method combining molecular dy-namics simulations, machine learning, and charge transport theory was developed to obtain the mechanical strain-charge mobility relationship for molecular single crystals. The simulation re-sults show that mechanical strains cause charge mobility anisotropy variation. Specifically, in pentacene crystal, stretching along the x-axis will enlarge the charge mobilities along all direc-tions in the xy-coordinate plane, while strain along the y-axis will reduce the charge mobilities. These results are due to the charge transport network change caused by the mechanical opera-tions. When the pentacene crystal is stretched along the x-axis, the inter-molecular distance de-creases, resulting the increase of electronic coupling which favors charge transport. When the pentacene crystal is stretched along the y-axis, however, the intermolecular distance increases instead. This further hinders effective charge transport. It was also found that dynamic disorder plays a crucial role in determining charge transport properties of molecular single crystals since static electronic coupling value gives wrong description of charge mobility anisotropy. Our find-ings provide microscale knowledge about the dependence of molecular arrangement and charge mobility anisotropy on external stretching in molecular single crystals, which can help to broad-en the application of molecular single crystal in flexible electronics.

Plant Bioelectronics for Decoding and Stimulating Plant Signalling *Eleni Stavrinidou; Linköping University, Sweden*

The climate change and growing population call for plants with increased tolerance to biotic and abiotic stress and for plants with higher productivity. In my talk I will present our recent advancements on interfacing bioelectronic tools with model plant systems with the aim to overcome limitations of conventional methods used in plant science but also to enable new possibilities for plant interface. Electrical signals in plants are mediators of long-distance signalling and correlate with plant movements and responses to stress. These signals are studied with single surface electrodes that cannot resolve signal propagation and integration, thus impeding their decoding and *link to function. We developed conformable multielectrode arrays based on organic electronics for large-scale and high-resolution plant electrophysiology. This technology enabled us to performed precise spatiotemporal mapping of the action potential in Venus flytrap, a model system for fast electrical signalling, and to reveal key properties of the AP. Currently we are extending the application of this technology to other plant species with the aim to contribute to the mechanistic understanding of long-distance responses in plants particularly related to environmental stress. Apart from monitoring electrical signals we also used electric field to stimulate plants. We developed a bioelectronic platform that stimulates the growth of plants in hydroponics culture. We demonstrated that Barley, one of the most important crops, grows well within the bioelectronic platform and when stimulated, the biomass increased by 50%. Our work opens the pathway for enhancing plant growth in hydroponics using materials science and bioelectronics that may result in more sustainable food production.*

8:45 AM *EN09.12.03

3D Printing of Self-Healing Metal for Resilient, Eco-Friendly Flexible Electronics *Benjamin C. Tee; National University of Singapore, Singapore*

Metallic materials are essential for all electronic circuits. On-demand, rapid designing and realization of 3D printed metal structures could open new applications for wireless devices, especially in flexible electronics. Coupled with self-healing, such metal structures could be used in resilient, eco-friendly circuits to be manufactured. Current direct ink writing uses composite inks with generally low electrical conductivity. Many 3D printing processes also require support materials for generating 3D structures. In my talk, I will present a new 3D printing process that uses only tensional forces without pressure to extrude a low melting point metal such as Field's metal. Our approach can enable printing of various free-standing 3D structures without any post-treatments to enhance conductivity. Our printed Field's metal structures can reach electrical conductivities of 2×10^4 *S* cm^{-1}*. We demonstrate wireless devices that can monitor vital signs and 3D metamaterials for electromagnetic-wave manipulation. The devices can easily be self-healed and repaired when mechanical damage occurs, opening new possibilities to design electronics for sustainable and recyclable usage.*

9:15 AM EN09.12.04

Aerosol-Jet Printed, Molecularly Imprinted Polymer-Based Wearable Sensors for Lactate and Glucose Monitoring in Human Sweat *Diandian Zhang, Sohini Kar-Narayan and Thiyagarajan Natarajan; University of Cambridge, United Kingdom*

Molecularly Imprinted Polymer (MIP) materials can perform as chemical recognition elements for targeted biomarker detection. These materials are employed in small wearable devices to analyze biofluids, such as human sweat, and extract useful bioinformation, contributing significantly to disease diagnosis and healthcare monitoring applications [1], [2].

In this work, a selective lactate MIP sensor was developed. The sensor prototype consists of a polydimethylsiloxane (PDMS) microfluidic channel for the biofluids control and a MIP-modified electrode substrate for lactate sensing. The initial electrode substrate is aerosol-jet printed using the carbon nanotubes ink as the first layer, providing the deposition sites, while a metallic layer, such as silver and gold, is printed on top, functioning as the detecting probes [3], [4]. The electrodes are designed as interdigitated electrodes to form a capacitor for electrical signal detection. The selective MIP layer is polymerized using aniline with target analyte, lactate acid, and crosslinkers such as 3- or 4-Aminophenylboronic acid (3-APBA/4-APBA). The advantage of the MIP polymerized APBA over simple polyaniline chains is that it shows a response to glucose due to its reaction with boronic acid, while retaining sensitivity to lactate [5], [6]. The relationship between the conductivity, MIP polymerization efficiency, sensitivity, and accuracy was evaluated using Cyclic Voltammetry (CV), Differential

Pulse Voltammetry (DPV), and particularly, Electrochemical Impedance Spectroscopy (EIS). The impedance frequency sweeping results demonstrate significant differential features of lactate, glucose, and other interfering analytes, showcasing the sensor's sensitivity and specificity.

Anti-Pressing and Punch-Free Interconnects for Stretchable Multi-Layer Hybrid Electronics *Lixun Chen and Xiaodong Chen; Nanyang Technological University, Singapore*

Long-term wearable flexible electronic devices are crucial for health monitoring. These devices must excel in fit, breathability, anti-interference capabilities, and maintaining daily life quality. However, during prolonged signal monitoring, the hybrid interface of flexible electronics often generates significant noise due to pressure, friction, and stretching, which disrupts signal acquisition. In this study, we address this challenge by employing liquid metal as the connection for the hybrid interface. Liquid metal's insensitivity to pressure and its stable connectivity under stretching and friction make it an ideal choice. Our device, subjected to 1000 cycles of 200 kPa pressure, exhibited a minimal resistance change rate of just 3.7%. Importantly, the device does not produce noise signals that interfere with target signal acquisition during compression and friction post-wearing. This advancement has been successfully applied in long-term foot pressure detection and sedentary monitoring for diabetic patients.

9:45 AM EN09.12.06
Flexible Bonding Method for Creating Flexible Electronics System with a Plasma Activation *Masahito Takakuwa[1,2], Daishi Inoue[2], Lulu Sun[2], Daisuke Hashizume[2], Kenjiro Fukuda[2], Takao Someya[1,2] and Tomoyuki Yokota[1]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan*

On-skin devices are a critical technology for realizing next-generation advancements like the Internet of Things (IoT) and Digital Twins. To achieve this, researchers are focusing on developing high-performance, long-term stability, and flexible electronics that can conform to skin topography and movement. Common approaches to achieve this flexibility include utilizing organic materials and minimizing device thickness. Beyond performance enhancement, achieving robust and flexible bonding is crucial for the development of practical on-skin devices. Traditional bonding methods for flexible electronics include the use of adhesive layers and direct metal bonding.

However, the bonding method of simultaneously achieving flexibility and robustness is very difficult because of material characteristics differences at interconnection. Adhesive bonding offers superior mechanical strength due to its full surface, bonding both the metal electrode and the polymer substrate. This full-coverage approach compromises flexibility at the connection owing to the increased thickness. Conversely, direct metal bonding methods preserve flexibility at the connection by eliminating additional thickness. This method suffers from inconsistent mechanical robustness due to variations in the bonding area caused by fluctuations in the ratio of electrode to substrate material at the interconnection. (Conventional direct bonding methods were limited to either metal or polymer bonding.)

In this work, we developed a multipurpose direct bonding method for Au direct bonding and Parylene polymer direct bonding. This method exhibited metallic bonding or polymer fusion bonding under ambient air through plasma surface modification, water plasticizer effect and low-temperature heating. Therefore, by using this method as a bonding method for flexible electronics, we achieved ultra-flexible bonding of flexible electronics with the entire surface including the substrate area and the electrode area. A water vapor plasma treatment was applied to a sample in which 100 nm of gold was deposited on a 2-micron-thick parylene substrate. Next, the surface-modified surfaces were brought into contact with each other in the air. In this state, a water droplet of less than 5 μL was injected into the interface of the parylene substrate, which had been hydrophilized by plasma treatment. The sample was then heated in an oven at 85°C for 4 hours. When the cross-section of the bonded sample was observed, the interface of the gold electrode area disappeared, and a strong metallic bond was formed. The interface of the parylene substrate area showed the highest electron density, and crystallization or aggregation of polymer chains occurred. Thin film specimens with different wiring widths were created and bonded using the conventional gold direct bonding method, and our developed bonding and tensile tests were performed. As a result, the gold direct bonding method could not bond parylene substrates, so the bonding strength decreased to about 10% of the original when the width of the gold wiring was narrowed. On the other hand, our method could bond not only gold electrodes but also parylene polymer substrates, so the bonding strength remained constant even when the electrode width was changed. Moreover, Performance fluctuated by only 3% even after 10,000 bending cycles. The bonded area maintained a minimum bending radius below 0.5 mm due to the lack of an additional adhesive layer.

By using a new versatile direct bonding method using water vapor plasma and the water plasticizer effect, we have succeeded in flexible and robust bonding whole interconnection surface without adhesives. It can be applied to fabricate the multifunctional integrated flexible electronics.

Hydrogen and Electron as Anion and Their Effect on Materials Properties *Hideo Hosono[1,2]; [1]Tokyo Institute of Technology, Japan; [2]National Institute for Materials Science, Japan*

Ionic compounds consist of cations and anions. In conventional materials, an element with low electronegativity forms an anion such as oxygen and halogen. However, recent studies have revealed that hydrogen and electron as an anion are often present in the stable solid compounds, i.e., hydride and electride. Since hydrogen is the most common impurity and the ionic radius of H^- is similar to O^{2-} and F^-. Thus H^- often occupies the oxygen/fluorine sites but their occurrence is disregarded because of very small X-ray scattering factor.
This talk focuses on the presence of critical role of hydride and electron anion in complex solids and their effects on materials properties listed below;

a.Hydrogen as electron donor
b.Hydride as fast ion conducting species
c.Role of H^- in IBSCs and Nickelate superconductors
d. Electrides and their applications.

Synthesis and Dynamics of Stable, Highly-Dispersed Precious Metal Model Catalysts *Zdenek Dohnalek; Pacific Northwest National Laboratory, United States*

Surface science studies provide a unique platform for studies of atomically precise materials, focusing on their *structure, stability, and activity. These well-defined systems, often homotopic, are essential for validating theoretical methods and uncovering structure-activity relationships in more complex catalytic environments. The studies presented here demonstrate approaches for stabilizing highly dispersed late transition metals, both as single atoms and nanoclusters. High-resolution imaging, spectroscopic characterization, reactivity measurements, and density functional calculations were employed to gain mechanistic insights into their structure, thermally induced evolution, and activation in chemical environments. Specifically, the temperature and coverage-dependent formation and stability of monodispersed* $PdTe_x$ *nanoclusters on* $WTe_2(001)$ *and mixed Rh-*$Fe_3O_4(001)$ *surfaces will be discussed. On* $WTe_2(001)$*, Pd clusters are shown to not interact with surface defects but rather react with intercalated Te. Upon annealing, stable monodispersed* $PdTe_x$ *clusters form due to registry with the underlying* $WTe_2(001)$*. For Rh-*$Fe_3O_4(001)$ *system, the stability of undercoordinated Rh adatoms is compared with that of Rh atoms embedded in the surface layer. Further, formic acid is used to probe the activity of such single Rh atoms. Formate and hydroxyl intermediates are shown to destabilize in-surface Rh, transiently converting it to highly active Rh adatoms that revert back to in-surface Rh when the reaction cycle is complete. These studies provide mechanistic insight into model catalytic systems, which is essential for understanding complex high-surface-area catalysts.*

11:30 AM EN10.01.03

In Situ Observation of Hydrogen Interactions with Highly Strained Ni Twin Boundaries *Hyoju Park[1], Kelly White[2], Bertan Ozdogru[3], Ozgur Capraz[4], Kelsey A. Stoerzinger[2], Peter V. Sushko[1] and Dongsheng Li[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Minnesota, United States; [3]National Renewable Energy Laboratory, United States; [4]University of Maryland, Baltimore County, United States*

Transitioning from catalysis based on platinum group elements (PGE) to earth-abundant metal catalysts is crucial for sustainable large-scale hydrogen production. Due to its abundance, low price, and ability to promote hydrogenation reactions, nickel has been considered as a promising substitute for PGE catalysts, especially with enhanced catalytic activity achieved by tailored nanostructures such as grain size, defects, and strain. Among many defective structures, twin boundaries (TBs) have been noted to boost the hydrogen evolution reaction. However, the understanding of the kinetics of hydrogen incorporation and the formation of Ni hydride phases is limited due to the lack of direct microscopic evidence of hydrogen interaction with highly twinned areas and quantification of the effect of these interactions on the local structure.
We employed in-situ environmental transmission electron microscopy to directly observe the interaction of highly strained nickel films with hydrogen, along with the resultant structural changes and strain redistribution. These films contain high densities of TBs and their intersections. The distribution of pre-existing strain around highly twinned Ni was examined, and the evolution of defective structures around the Ni TBs due to the volumetric expansion associated with the formation of hydrides was studied under a hydrogen gas environment. Subsequently, the structural change of highly twinned Ni area by the absorption and desorption of hydrogen was explored repeatedly over time. Density functional theory calculations elucidate the influence of the kinetics of hydrogen incorporation and the formation of hydride phases in highly strained multi-twinned areas, which is responsible for the enhanced catalytic activity. This work illuminates the role of defects in the formation of hydrides and the consequent effects of hydrogen absorption on the Ni nanostructure, providing insight into the design of PGE alternatives.

11:45 AM EN10.01.04

Strain-Controlled Galvanic Synthesis of Platinum Icosahedral Nanoframes and Their Enhanced Catalytic Activity Toward Oxygen Reduction *Siyu Zhou and Younan Xia; Georgia Institute of Technology, United States*

The unique strain distribution on the surface of a Pd icosahedral nanocrystal is leveraged to control the sites for *oxidation and reduction involved in a galvanic replacement reaction. Specifically, Pd is oxidized and dissolved from the center of each {111} facet due to its tensile strain, while the Pt(II) precursor adsorbs onto the vertices and edges featuring a compressive strain, followed by surface reduction and conformal deposition of the Pt atoms. Once initiated, the {111} facets become more vulnerable to oxidation and dissolution as the vertices and edges are protected by the deposited Pt atoms. The site-selected galvanic reaction naturally results in the formation of Pt icosahedral nanoframes covered by compressively-strained {111} facets, which show enhanced catalytic activity and durability toward oxygen reduction relative to commercial Pt/C.*

SESSION EN10.02: Critical Materials for Energy Conversion and Catalysis II
Session Chairs: Zdenek Dohnalek and Peter Sushko
Monday Afternoon, December 2, 2024

1:30 PM *EN10.02.01
Steering the Selectivity of Single Atom Electrocatalysts—Static vs Pulsed CO_2RR Beatriz Roldán Cuenya; *Max Planck Society, Germany*

The re-utilization of CO_2 via its electrocatalytic reduction (CO_2RR) into value-added chemicals and fuels is a promising avenue to minimize the impact of existing technologies on the climate change. This requires the development of low cost, efficient, selective and durable electrocatalysts based of their rational understanding. Moreover, it should be considered that even morphologically and chemically well-defined pre-catalysts are susceptible to drastic modifications under operation, especially when the reaction conditions themselves change dynamically.

This talk will address the transformations that Metal-N-C catalysts (M=Cu, Ni, Co, Fe, Sn, Zn) experience during static and pulsed CO_2RR using operando quick X-ray absorption spectroscopy (XAS) and Raman spectroscopy, combined with machine learning based data analysis. In particular, I will illustrate the astonishing behavior displayed by Cu-N-C catalysts during CO_2RR, featuring reversible transformations from single atom sites towards Cu nanoparticles. The latter reflects the intricate interplay between the relative strengths of metal-metal atomic interactions, metal-adsorbate and metal-support interactions. The switchable nature of these Cu species that can be achieved by applying different potential pulses holds the key for the on-demand control of the distribution of the CO_2RR products and thus, a wide-spread adoption of this process.

Moreover, I will discuss the structural evolution and intermediate states of Ni and Co single atoms during static CO_2RR. In particular, I will unveil the nature of the ligands forming and present under CO_2RR at singly dispersed Ni and Co sites in Ni-N-C and Co-N-C catalysts, which are currently drawing great attention for their high performances in the CO formation. This will be achieved by a synergistic combination of conventional XAS, high energy resolution fluorescence detected X-ray absorption near edge structure (HERFD-XANES) spectroscopy, and X-ray emission spectroscopy (XES) coupled with unsupervised and supervised machine learning methodologies and density functional theory.

Overall, my lecture will feature the importance of operando characterization of electrocatalysts in order to unveil structure/composition-reactivity correlations during CO_2RR and ultimately optimize their electrocatalytic performance.

2:00 PM EN10.02.02

Work in Tandem—CO_2 Hydrogenation over NiPd/C_3N_4 *Nijita Mathew; JNCASR, India*

The utilization of anthropogenic CO_2 as a chemical feedstock to produce value-added chemicals like formic acid has garnered significant attention. Formic acid is emerging as a cleaner alternative fuel due to its nontoxicity, nonflammability, and its H_2 storage capacity of up to 4.4 wt%[1]. However, the high bond energy of CO_2 (806 kJ mol^{-1}) imparts significant thermal stability, resulting in low reactivity. Therefore, there is a critical need to develop an efficient catalyst that can produce formic acid with a high turnover number.

Our research addresses this need by developing a novel catalyst composed of Ni[2] and Pd supported on C_3N_4. This catalyst system leverages the synergistic interaction between the metal components and the support to selectively convert CO_2 to formate. Our catalyst achieves a remarkable turnover number of 2432 over 24 hours, significantly outperforming conventional Pd-based catalysts[3,4].

Furthermore, we have demonstrated from TPD and in operando FTIR studies that the basic sites on C3N4 facilitate CO_2 adsorption, effectively bringing it closer to the catalytically active metal sites. The cooperative effect between Ni and Pd at the active sites enhances the conversion efficiency of CO_2 to formate. This study underscores the critical role of metal-support synergy and the importance of N-doped supports in advancing CO_2 hydrogenation technologies.

Production of High-Quality Biogas Using Recycled Trimetallic Nanoparticles from Electronic Waste *Rania S. Ahmed; The American University in Cairo, Egypt*

A plethora of nanoparticles (NPs) significantly enhanced the biogas production from organic waste anaerobic digestion upon their optimized addition to the reactors. In this study, trimetallic Sn–Mn–Fe.NPs, recovered from waste-printed circuit boards, were used to enhance the quality and productivity of the anaerobic digestion (AD) of cow manure as an organic substrate. This study aims to make the biogas production process more efficient and economically sustainable, taking into account the environmentally friendly nature of the AD process. The obtained nanoparticles were characterized using scanning electron microscopy (SEM), high-resolution transmission electron microscopy (HRTEM), and X-ray diffraction (XRD) techniques. Various concentrations (20, 50, and 100 mg/L) of the trimetallic Sn–Mn–Fe NPs were added to the biogas reactors, which were made of 1000-ml autoclave glass bottles to host the animal waste during the AD process. The pressure of the biogas produced was monitored daily for 45 days as retention time, and the volume of the produced biogas was calculated at a constant temperature (15 °C) and pressure (1.013 bar). Generally, NP-based reactors showed superiority in biogas *production over blank reactors. Also, among the different concentrations, the best biogas-producing digester (RC2200) revealed the highest performance with a 113.6% enhancement in biogas production. In addition, it showed a significant increase of 231.2% in methane production.*

2:30 PM EN10.02.05

Untapped Potential of Scrap Brass Alloy—A New Frontier in the Use of Brass-Based Photocathodes for Stable and Durable Photoelectrochemical Water Splitting *Rahma G. Leil and Nageh K. Allam; The American University in Cairo, Egypt*

Photoelectrochemical (PEC) water splitting is a promising way to produce green hydrogen. However, one of the bottlenecks in realizing scalable green hydrogen production systems is the inability to identify and fabricate earth abundant, stable, and durable photocathodes. The main challenges with the reported photocathodes so far are their instability in aqueous solutions and the use of precious unabundant materials. To this end, the use of scrap materials to fabricate highly stable photocathodes would solve the two main challenges. Herein, scrap brass alloys with different zinc contents were used to fabricate photocathodes for photoelectrochemical green hydrogen production. The scrap brass alloy with 5% Zn showed enhancement in the photocurrent density of -0.26 *mA cm*$^{-2}$ *at 0.62 V vs. reversible hydrogen electrode (RHE), high long-term stability up to four hours under continuous illumination, high charge carrier density of* 6.2×10^{21} *cm*$^{-3}$ *and less total resistance than the other brass samples. Through electrochemical impedance spectroscopy (EIS), the presence of surface states was verified. The 95Cu–5Zn sample showed an amount of evolved hydrogen of 0.2658 µmole after one hour of continuous illumination (area = 0.5 cm*^{2}*), while the 100Cu sample only showed 3.965 nmole after 20 minutes of continuous illumination before being completely reduced to copper. Density functional theory (DFT) calculations were used to study the optical and electronic properties of the best-performing sample. This work is the first to systematically and fundamentally study scrap brass as a promising material for a more stable and durable PEC water splitting.*

Uncovering the Structure-Property Relationships in Epitaxial Pd Metal and PdO Thin Films *Yingge Du; Pacific Northwest National Laboratory, United States*

Palladium and other platinum group elements are highly valued for their exceptional physical and catalytic properties, playing pivotal roles in processes such as hydrogenation, carbon monoxide oxidation, and automotive emission control. The study of epitaxial thin films of palladium (Pd) and palladium oxide (PdO) holds significant promise for advancing our understanding of their structure-property relationships and optimizing their catalytic performance. In this talk, I will present our recent effort in the molecular beam epitaxy growth of Pd and PdO thin films, focusing on how controlled defect introduction, phase boundary engineering, and crystallographic orientation can influence their catalytic activities. Through a combination of advanced characterization techniques and theoretical modeling, we investigate the intricate interplay between structural defects and phase transitions in determining the electronic and catalytic properties of these films. We show that the extended defects and deformations associated with them directly affect hydrogen absorption, desorption, and the formation of hydrides upon hydrogen exposure. Further work along this direction will provide the physical principles for the design of PGE materials with tailored catalytic functions.

3:45 PM EN10.02.07

Crystal Reconstruction of PdO Film Caused by Oxygen Vacancy Generation Through Vacuum Annealing *Min-Ju Choi[1], Mark Bowden[1], Hua Zhou[2], Peter V. Sushko[1] and Yingge Du[1]; [1]Pacific Northwest National Laboratory,* *United States; [2]Argonne National Laboratory, United States*

The oxides of platinum group metals are of significant interest for sustainable energy, electronic, and spintronic applications.[1-3] Among them, palladium oxide (PdO) has been widely studied as a catalyst in powder form and a Dirac semimetal in thin film form.[4,5] Epitaxial growth provides a systematic apprach to modify their structure, phase, and strain state. However, synthesizing phase pure PdO thin films by molecular beam epitaxy (MBE) remains challenging due to its low vapor pressure and oxidation potential.[6] In this study, we show that tetragonal structured PdO thin films grown on MgO (001) substrates using oxygen plasma-assistant MBE often result in mixed (100)- and (001)-orientation. Our ab initio calculations reveal interfacial structures and stabilities of the PdO/MgO interfaces for both (100)- and (001)-orientations of the PdO films. We demonstrate that crystal structure reconstruction in PdO films occurs through the accumulation of oxygen vacancies indcued by post-annealing in vacuum resulting in a single crstalline film in the metastable configuration stablized by the interfacial interactions. This study suggests that vacuum annealing is a promising post-processing strategy for synthesizing single crystalline thin films and enhances our understanding of the role of oxygen vacacies in structural reconstruction.

Revealing Evolution of Cobalt Oxide Thermochemical Materials During Thermal Redox Cycles via Operando Synchrotron X-Ray Nano-Tomography and Spectroscopic Imaging

Yuxiang Peng[1], Chirag Saharan[1], Lyu Zhou[2], Cheng-Chu Chung[1], Mingyuan Ge[3], Xianghui Xiao[3], Youyang Zhao[4], Katherine L. Jungjohann[4], John Mangum[4], Shuang Cui[2] and Yu-chen K. Chen-Wiegart[1,3]; [1]Stony Brook University, The State University of New York, United States; [2]The University of Texas at Dallas, United States; [3]Brookhaven National Laboratory, United States; [4]National Renewable Energy Laboratory, United States

Thermal energy storage (TES) is crucial for enhancing energy efficiency, integrating renewable energy sources, and supporting sustainable energy systems. Among all thermal energy storage materials, thermochemical material (TCM), particularly Co_3O_4, is one of the most promising due to its high reaction enthalpy, fast reaction kinetics, and lower cost. However, in long-term applications, the energy efficiency of Co_3O_4 decreases due to degradation. The detailed degradation mechanism remains unclear, in part because the correlation between its morphological, structural and chemical evolution is not fully understood. In this work, the chemical and three-dimensional (3D) morphological evolution of Co_3O_4 at the micro and nanoscale during thermal reduction and oxidation cycles between 800 to 900 °C in air were studied using in situ synchrotron transmission X-ray microscopy (TXM), transmission electron microscopy (TEM) and thermal analysis techniques. Results indicate that the conversion rate of Co_3O_4/CoO was faster in nanoparticles compared to microparticles, especially during the reverse oxidation reaction. By further comparing different structural and morphological evolutions between microparticles and nanoparticles, the conversion kinetics is related to the morphological characters such as specific surface area, edge gradient, and the formation of porous structures within particles. These findings provide insights into the *distinct thermochemical behaviors of Co_3O_4 particles of different scales, which is essential for their applications in TES systems.*

4:15 PM EN10.02.09

Regeneration of Ni-Aluminate Spinel Catalysts for Dry Reforming of Methane— Insights from Exsolution-Dissolution Dynamics and In Situ STXM/Ptychography Analysis *Dong Hyun Kim[1,2], Bonjun Ku[1], Alexander Ditter[2], David Shapiro[2], Karen Bustillo[2], Young Sang Yu[3] and Kyubock Lee[1]; [1]Chungnam National University, Korea (the Republic of); [2]Lawrence Berkeley National Laboratory, United States; [3]Chungbuk National University, Korea (the Republic of)*

Dry reforming of methane (DRM) is a process that converts CO_2 and CH_4 into synthesis gas (CO and H_2) in a 1:1 ratio, which can potentially be used to produce value-added hydrocarbons. Although Ni-based catalysts are primarily used for DRM reactions, the commercialization of DRM has not been realized due to the lack of stability of these catalysts. Rapid deactivation of the catalyst is primarily caused by carbon deposition on the catalyst surface and sintering of supported Ni metal clusters/particles. Recent interest in DRM catalysts and processes has been concentrated on overcoming these issues in both research and industry. Despite optimization efforts that can reduce coke formation to some extent, completely suppressing coke formation is extremely difficult, and overcoming catalyst deactivation remains a significant challenge. We have recently developed exsolution-based Ni-aluminate spinel (AB_2O_4) catalysts with high surface areas and well-defined mesoporous structures. The exsolution phenomenon offers three distinct advantages for heterogeneous catalysts: (1) During the reduction process, active metal cations diffuse from the parent oxide and exsolve as metal nanoparticles. These active metal species are uniformly distributed on the parent oxide surface and gradually grow, significantly enhancing catalytic activity. (2) The active metal species are anchored on the parent oxide, effectively inducing strong metal-support interactions (SMSI), which provide resistance to coke formation and sintering. (3) The exsolved active metal species possess reversible properties, allowing them to be re-dissolved and re-exsolved from the host oxide, which can be utilized in the catalyst regeneration process. Our study has experimentally demonstrated that the size of the exsolved active metal nanoparticles and the porous structure of the catalysts remain unchanged after several exsolution-dissolution cycles at high temperatures. This indicates not only the feasibility of sustained DRM reactions but also the potential to minimize catalyst performance loss during regeneration steps. Furthermore, to gain an in-depth understanding of the 'exsolution-dissolution' phenomena in spinel-based catalysts, we have introduced in-situ TEM and in-situ STXM/ptychography analytical techniques. By tracking and monitoring the oxidation states and morphology of active metals under various temperature conditions at in-situ, we have proposed the most suitable conditions for the 'exsolution-dissolution' process. Especially, in-situ STXM/ptychography experiments, which directly observe the oxidation state changes of active metals and coke decomposition during exsolution-dissolution, are expected to provide comprehensive insight into our spinel-based catalysts along with various catalyst characterization results. These findings will lay the foundation for a significant leap forward toward the commercialization of DRM processes.

4:30 PM EN10.02.10

Reaction-Diffusion Coupling Enables Efficient Recovery of Critical Materials from Permanent Magnet and Battery Feedstocks *Elias Nakouzi, Qingpu Wang, Yucheng Fu, Pravalika Butreddy, Andrew Ritchhart, Erin Miller, Duo Song, Zhijie Xu, Jaehun Chun and Maria Sushko; Pacific Northwest National Laboratory, United States*

Coupling ion transport, nucleation, and growth offers a new paradigm for efficiently and selectively separating critical elements from liquid feedstocks. Inspired by the classic Liesegang experiment, this approach selectively and sequentially extracts competing metal ions according to a delicate interplay between their diffusion and precipitation kinetics. We present a proof-of-concept for recovering pure neodymium from recycled permanent *magnets and pure manganese from battery electrodes. Our overarching vision is to achieve the energy- and atom-efficient separation of rare earth elements, transition metals, and other critical elements from unconventional domestic feedstocks using non-thermal, reactive separations without costly membranes, ligands, toxic solvents, or other specialty chemicals.*

Modelling the Uptake and Transport of Lanthanide Ions Through MoS_2 and Other Membranes *George C. Schatz; Northwestern University, United States*

This talk will present recent computational studies of the Schatz group in collaboration with the Chong Liu and her group at the University of Chicago concerning the uptake and transport of lanthanides ions through membranes that consist of stacked layers of MoS_2 that have been functionalized with acetate. These calculations have primarily been studied with molecular dynamics using 12-6-4 empirical potentials and with by applying pressure to accelerate the transport, but some properties have also involved calculations using electronic structure calculations (VASP). Many new phenomena have been revealed in studies of ion transport, including volcano shaped profiles of lanthanide mixtures for transport in MoS_2 that reflect the competing effects of ion dehydration/rehydration as the ions enter/exit the channel and binding of the ions to acetate or to the channel walls during transport. We also find membrane pinning effects that enable improved separation in some cases.

9:00 AM EN10.03.02
Stimuli-Enabled Lanthanide Separations *Ilja Popovs; Oak Ridge National Laboratory, United States*

Lanthanide separation is an immensely difficult problem due to these elements' extreme chemical and physical similarity in the +3 oxidation state in aqueous environments and the relatively small differences in their ionic radii. Our research demonstrates that by using a highly functional ligand platform, lanthanide ions can be selectively separated under appropriate stimuli. The highly reversible response observed suggests that this approach could be a viable solution for lanthanide separation.

9:15 AM EN10.03.03
Modeling Separation of Lanthanides via Heterogeneous Ligand Binding *Kevin Leung and Anastasia G. Ilgen; Sandia National Laboratories, United States*

Individual lanthanide elements have physical/electronic/magnetic properties that make each useful for specific applications. Several of the lanthanides cations (Ln(III)) naturally occur together in the same ores. They are notoriously difficult to separate from each other due to their "chemical similarity." Predicting the Ln(III) differential binding energies (DDE) or free energies DDG) at different binding sites will help design of materials with lanthanide selectivity. We apply ab initio molecular dynamics (AIMD) simulations and Density Functional Theory (DFT) to calculate DDG for Ln(III) coordinated to ligands in water and embedded in metal-organic frameworks (MOFs), and DDE for Ln(III) bonded to silica surfaces. Perturbative AIMD simulations of water-inundated simulation cells are *applied to examine the selectivity of ligands towards adjacent Ln(III) in the periodic table. Static DFT calculations with a full Ln(III) first coordination shell, while less rigorous, show that all ligands examined with net negative charges are more selective towards the heavier lanthanides than a charge-neutral coordination shell made up of water molecules. Amine groups are predicted to be poor ligands for lanthanide-binding. We also address cooperative ion binding, i.e., using different ligands in concert to enhance lanthanide selectivity.*

Surface X-Ray Studies of Rare Earth Group Ion Transport Pathway on Functionalized Bilayer-Single-Channel MoS_2 *Maoyu Wang and Hua Zhou; Argonne National Laboratory, United States*

Rare earth elements (REEs) have been identified as critical elements with short-term supply risks. They are essential in modern technologies and devices such as permanent magnets, optical fiber, and medical imaging agents. REEs exhibit very similar chemical properties but varied electronic properties, and their application requires high purity of every single element. Therefore, achieving effective and efficient separation among REEs from one another has been the challenge since their discovery and this task is especially critical now to enable recycling to secure the REs supply. Currently, the solvent extraction used in industrial productions induces negative impact on the environment due to drawback of energy and chemical intensiveness.

Based on the two important properties of REs: ionic radius (decreasing with atomic number) and Lewis acidity (increasing with atomic number), we use 2D materials (e.g., cysteine molecule functionalized MoS2 membrane) that can modulate the dehydration, transport, and hydration of REEs. Concentration gradient is the only driving force here that does not need extra energy or hazardous chemicals. To achieve selective transport of REs by rational design, a better understanding of the binding and conduction of REs ions through the 2D channels is required. Hence, we used both single layer and bilayer-single-channel MoS2 with functionalized surface as model systems. By combining surface X-ray diffraction (crystal truncation rod) and gracing incidence X-ray absorption spectra, we could provide a precise local coordination configuration. This allows us to create an accurate molecular-level structural model for the electronic structure computation and modeling, which would be better to reconstruct the ion transport pathway and realize the selectivity control among REEs. Our results indicate that functionalized groups not only increase the interlayer space of MoS2 but also interact with rare earth elements (REEs), altering the dehydration process. After functionalization, different REEs insertion further expand the single-channel interlayer space to varying degrees to achieve dehydration. Additionally, bilayer single-channel MoS2 exerts a constraining force similar to that of bulk membrane systems, unlike single-layer MoS2. However, a single layer provides a simpler model system for understanding fundamental molecular interactions. The outcomes will have immediate impact to enabling new energy efficient separation methods, especially transport-based separation technologies (membrane separation), to be applied to REs extraction, separation, and recycling.

What Lanthanide Biochemistry Can Teach Us About Sustainable Rare Earth Separations *Joseph A. Cotruvo; The Pennsylvania State University, United States*

Biology's utilization of certain lanthanides (predominantly La, Ce, Pr, and Nd) to catalyze specific enzymatic reactions requires selective mechanisms of uptake into the cell and trafficking within it. Understanding how these systems function and how they select for certain lanthanides over others has the potential to reveal the principles by which biology separates lanthanides, which can inform the development of more efficient traditional and non-traditional (e.g., biomolecular) separation schemes for these essential technology metals. Intracellular protein-based chelators play a critical role – perhaps the most critical role – in distinguishing light rare earths from heavier rare earths. In this talk, I will describe my group's discovery of several lanthanide-binding proteins involved in this process – including the archetypal biological lanthanide chelators, the lanmodulins. The focus will be on the insights that the biochemical and structural characterization of these systems have yielded into the coordination chemistry underlying biological recognition of lanthanides. Finally, I will illustrate how the principles illustrated by these natural systems can be harnessed (and improved) for highly selective, scalable protein-based recovery and separations of rare earths.

10:45 AM EN10.03.06

Opportunities for Cerium Valorization in the Rare Earth Supply Chain *Alfred Amon and Scott McCall; Lawrence Livermore National Laboratory, United States*

Rare earth (RE) elements are co-located in ore deposits and must be treated together during the difficult extraction and separation. Cerium is the majority element in most deposits (> 50 %), and the growing need for Nd, Pr and the heavy lanthanides in permanent magnets and other energy transition technologies results in costly stockpiling of cerium oxide which has low demand. Finding new high-value applications for cerium metal or compounds is therefore a sought-after goal to improve the profitability of rare earth mining and processing.

This contribution will highlight the use of cerium in aluminum alloys and the preparation of Ce-based permanent magnets as two emerging technologies for high-value products that have potential to stabilize the fluctuating rare earth market and also substitute critical materials.

The development of aluminum-cerium alloys over the last decade has produced a range of new alloys with superior strength at high temperatures compared to conventional alloys. Despite their excellent properties and the abundance of cheap cerium oxide from rare earth mining, Al-Ce alloys have remained niche for specialty applications. The reduction of cerium oxide to the Ce metal for use in alloying is a major cost factor for the final alloy product and currently no domestic production of Ce metal exists. Our collaboration has developed an alternative process to directly reduce cerium oxide during aluminum alloying [1] *which drastically reduces the energy requirements and therefore the cost and market entry barrier for Al-Ce alloys.*

Permanent magnets based on the $REFe_{12}N$ *phase are promising alternatives to the established Nd-Fe-B and Sm-Co materials as they have lower rare earth content, and their superior performance has been demonstrated in powders and thin films. The need for stabilizing additives and their narrow processing window have obstructed the preparation of bulk magnets by conventional methods. Here, we will present the potential of advanced processing methods such as laser powder bed fusion and spark plasma sintering for the consolidation of Ce-Fe-N based permanent magnet powders.*

Both technologies, the preparation of Al-Ce alloys by directly reducing cerium oxide and the development of bulk Ce-Fe-N magnets using advanced consolidation methods, lead to high value products of the underutilized rare earth element cerium and would support the nascent rare earth industry as well as provide technologies for the pending green energy transition.

Work performed at LLNL under contract DE-AC52-07NA27344.

Green Circular Critical and Strategic Metal Recovery in a Laboratory Context *Elliott Menu[1], Teresa Cecchi[2,3] and Clara Santato[1]; [1]Polytechnique Montréal, Canada; [2]Istituto Italiano di Tecnologia, Italy; [3]Accademia delle Scienze, Italy*

Research with focus on sustainability has the potential to decrease the environmental impact of day-to-day activities, worldwide. Because of this, it should strive, itself, to be done more sustainably. For that, there needs to be a paradigm shift regarding research groups' vision of their waste, going from something to dispose of, to a potential source of new materials, prone for reuse. It is then interesting to study the case of "in laboratory" waste management of critical and strategic elements, because of their increasing demand and decreasing availability[1]. In our lab, this waste is present in the form of single-use Au electrodes patterned on SiO_2/Si substrate, making use of a Ti adhesion layer, microfabricated with e-beam evaporation.

These patterned substrates are used to study the electrical response of different (organic and inorganic) materials, with the objective to understand them for applications in sustainable electronics. Following the point made above, this calls for a more conscious management of the waste generated by these activities, from where the critical metals end up, to the different chemicals and techniques used to bring them there.

We adopted a hydrometallurgy protocol to recover Au from our patterned substrates in its metallic state. We used the mild oxidant hydrogen peroxide in a medium acidified with lactic acid, to dissolve base metals (Ti) for our "in lab" context [2]. The use of the aforementioned hydrometallurgy approach - that follows the principle of green chemistry - constitutes a sustainable chemical treatment that avoids gold oxidation, and subsequent reduction/precipitation [2][3]. Finally, the composition of the metal extracted has been studied with Energy-Dispersive X-ray Spectroscopy (EDS), to explore gold recovery to make new devices, thus mitigating the waste-flow of the laboratory's operation.

Electronic Waste Recycled Materials as Efficient Catalysts for Renewable Energy Technologies and Better Environmental Sustainability *Rania S. Ahmed; The American University in Cairo, Egypt*

Waste from electrical and electronic equipment exponentially increased due to the innovation and the ever-increasing demand for electronic products in our life. The quantities of electronic waste (e-waste) produced are expected to reach 44.4 million metric tons over the next five years. Consequently, the global market for electronics recycling is expected to reach $65.8 billion by 2026. However, electronic waste management in developing countries is not appropriately handled, as only 17.4% has been collected and recycled. The inadequate electronic waste treatment causes significant environmental and health issues and a systematic depletion of natural *resources in secondary material recycling and extracting valuable materials. Electronic waste contains numerous valuable materials that can be recovered and reused to create renewable energy technologies to overcome the shortage of raw materials and the adverse efects of using non-renewable energy resources. Several approaches were devoted to mitigate the impact of climate change. The cooperate social responsibilities supported integrating informal collection and recycling agencies into a well-structured management program. Moreover, the emission reductions resulting from recycling and proper management systems signifcantly impact climate change solutions. This emission reduction will create a channel in carbon market mechanisms by trading the CO2 emission reductions. This review provides an up-to-date overview and discussion of the diferent categories of electronic waste, the recycling methods, and the use of high recycled value-added (HAV) materials from various e-waste components in green renewable energy technologies.*

11:30 AM EN10.03.10
Maximizing Value from Municipal Solid Waste Incineration Ash—Electrochemical and Chemical Methods for Material Recovery *Duhan Zhang; Massachusetts Institute of Technology, United States*

In the United States, over 6.6 million tons of hazardous solid residue known as municipal solid waste incineration (MSWI) ash is generated annually by waste-to-energy (WTE) plants. These plants produce electricity and help reduce landfill volume. However, the ash produced is largely unused and typically disposed of in landfills at a cost. The economic viability of MSWI is further challenged by the decreasing price of renewable electricity. Despite this, MSWI ash holds significant potential for valuable element recovery, with an estimated value of $100-400 per ton.

We propose an innovative approach to recover valuable materials from MSWI ash using electrochemical and chemical processes. By harnessing electricity generated by WTE plants, our method electrolytically produces acid and base streams to facilitate material recovery and refinement. Our sequential process combines electrochemical extraction with chemical precipitation, enabling the successful recovery of elements such as copper, lead, zinc, magnesium, calcium, iron, and aluminum, along with a purified silica by-product. We have demonstrated the recovery of over 90% of the targeted elements with purities exceeding 90%. Our industry-scale techno-economic analysis indicates that this technology can extract the inherent mineral value from MSWI ash, resulting in net positive returns that far surpass the combined benefits of electricity sales and landfill cost savings.

Closed Loop Lithium Ion Battery Recycling Process *Yan Wang; Worcester Polytechnic Institute, United States*

Recycling spent lithium-ion batteries can play a significant role in alleviating the shortage of raw materials and environmental problems. However, recycled materials are usually deemed inferior to commercial materials in terms of electrochemical performance, preventing the industry from adopting recycled materials in their batteries. Here, we develop a closed loop lithium ion battery recycling process which can recover most of the battery materials and we also demonstrate that the recycled materials have a superior rate and cycle performance, verified by various industry-level tests. The recycled material outperforms commercially available equivalent, *providing a green and sustainable solution for spent lithium-ion batteries.*

2:00 PM EN10.04.02

Direct Extraction of Lithium from α-Spodumene via Electrochemical Leaching *Hanrui Zhang and Feifei Shi; The Pennsylvania State University, United States*

With the rapid growth in lithium consumption driven by the electric vehicle industry, the demand for lithium has surged significantly over the past decade. To ensure a stable supply chain, it is essential to explore alternative lithium extraction sources beyond traditional brine deposits. In this study, we developed an electrochemical method to directly leach lithium from natural α-phase spodumene without energy-intensive calcination. We found the H_2O_2 promoter can significantly lower the leaching potential by facilitating the electron transfer and altering the reaction path. During the leaching, the α-phase remains its original crystal structure with a lattice shrinkage. We also observed the intermediate product O_2^{2-} generated during the in-situ Raman test. To demonstrate scale-up capability, we designed a high-throughput current collector for suspended spodumene feedstock, achieving a leaching current of 18 mA and a leaching efficiency of 92.2%. Compared to the traditional leaching method, the techno-economic assessment shows the cost of electrochemical leaching can be reduced by 35.6%, with 75.3% less CO_2 emission. By minimizing environmental impact and reducing energy consumption, electrochemical leaching has the potential to transform traditional mining and recycling processes, thereby promoting more sustainable energy applications.

2:15 PM EN10.04.03

A Data-Driven Optimization of Materials Recovery in Battery Recycling Processes *Nima Emami[1], Luis A. Gomez-Moreno[2], Anna Klemettinen[2], Rodrigo Serna-Guerrero[2] and Milica Todorović[1]; [1]University of Turku, Finland; [2]Aalto University, Finland*

The electrification transition has increased the demand for raw materials for batteries, and superior recycling practices could allow us to retrieve more raw materials from battery waste. This study introduces a data-driven approach to optimizing battery recycling processes, explicitly targeting the recovery and purity of nickel-manganese-cobalt (NMC) and graphite during the mechanical separation stage. The main objective is to identify the sets of operational parameters of the recycling process that maximize the grade and recovery of the materials. We utilized HSCSim simulation software to generate an extensive dataset via the simulation of thousands of randomly generated operational scenarios. This dataset enabled advanced analytics to identify the optimal process conditions and parameters.

Our results show that precise adjustments in operational parameters, such as magnetic field strength, flotation cell residence time, and optimization of the flotation cell conditioner, can significantly boost the separation efficiency of NMC and graphite. We also showed that data analytics can help us iteratively optimize and improve the process design. The optimal process achieved simulated recovery rates of up to 79% for NMC and 91% for graphite, with purity levels of graphite surpassing 99%. The next step is to incorporate machine learning models in the workflow to optimize the process on the fly without human intervention. These advancements are crucial for strengthening the circular economy by increasing materials recovery and tackling the urgent requirement for sustainable and efficient battery recycling processes.

2:30 PM EN10.04.04

Boosting Lithium Extraction Process with Ion-Selective Solar Crystallizers Through Interfacial Evaporation

Jihun Choi and Sangmin Jeon; Pohang University of Science and Technology, Korea (the Republic of)

Bulk evaporation of brine is a sustainable method for extract minerals, particularly lithium, by utilizing selective crystallization based on ion solubility differences. However, this method requires a prolonged time period. In contrast, solar crystallizers, which use interfacial evaporation, can reduce processing time but lack adequate ion-selectivity due to insufficient re-dissolution and re-crystallization processes. This study presents a novel ion-selective solar crystallizer. The nature-inspired hierarchical water path, fabricated in an evaporative wind blade (EWB), facilitates water transport through centrifugal force induced by wind-driven rotation. The continuous supply of unsaturated solution promotes re-dissolution and re-crystallization of salts at the edges, leading to high ion-selectivity. Using the EWB to evaporate brine containing Na^+ and Li^+ ions, the ionic ratio of Na^+ to Li^+ increased from 31 in the initial solution to 651 in the crystallized salt, achieving an ion-selectivity of 20.8. This innovation can significantly improve the lithium extraction process from brine by selectively removing Na^+ and enriching LI^+ in solution.

2:45 PM EN10.04.05

Recycling of Fuel Cell/Electrolyzer Membrane Electrode Assemblies *Wenting Jin[1], Zeyi Yao[1], Karen SwiderLyons[2], Fan Yang[2], Zhenyu Liu[2] and Yan Wang[1]; [1]Worcester Polytechnic Institute, United States; [2]Plug Power Inc., United States*

Since platinum group metals are considered as the most efficient catalysts in proton exchange membrane fuel cells/Electrolyzers, the demands have constantly increased these years. Due to their limited reserves and irreplaceable role in the industry, recycling of the membrane electrode assemblies(MEA) are critical to achieve sustainable clean energy supplies. Different from conventional pyrogenic process, we developed a green method to selectively extract each precious metals from fuel cell/Electrolyzers MEAs with high efficiency and recycle florine-contained ionomers to reduce their detrimental influence to the environment.

Critical Material Insights and Innovations to Build Resilient Critical Materials Supply Chains *Jeremy S. Mehta; U.S. Department of Energy, United States*

The clean energy applications in which these critical minerals and materials are used—wind and solar power generation, grid storage, electric vehicle motors and batteries, vehicle lightweighting, power electronics, electrolyzers, fuel cells, LED lighting—are crucial for meeting U.S. climate goals. These goals include achieving 100 percent carbon pollution-free electricity by 2035 and a 100 percent clean energy economy with net-zero greenhouse gas emissions by 2050. Globally, CMM demand for clean energy technologies may quadruple by 2040 to meet climate goals.

The U.S. Department of Energy (DOE) has developed a broad CMM Strategy that build reliable, resilient, affordable, diverse, sustainable, and secure domestic critical mineral and materials supply chains to support the clean energy transition and decarbonization of the energy, manufacturing, and transportation economies while promoting safe, sustainable, economic, and environmentally just solutions to meet current and future needs.

The CMM Strategy consists of four core pillars: Diversify and Expand Supply, Develop Alternatives, Improve Materials and Manufacturing Efficiency, and Build the Circular Economy. These pillars are interconnected and, in some cases, their areas of focus overlap. For example, recycled materials help to diversify material supplies and

are also key to building a circular economy. To accelerate progress, DOE also conducts enabling activities: vital, crosscutting efforts that support all four pillars, such as criticality assessments and interweaving education and workforce development throughout the CMM portfolio.
DOE employs a material-by-material approach to research investments. These investments are informed by ongoing analysis including, but not limited to, criticality assessments and supply chain assessments as well as active stakeholder engagement and coordination with other federal agencies. Based on the results of such analyses, DOE developed a set of critical materials known as the "electric eighteen" that enables DOE to prioritize critical material investments. These investments strategically span across the entire supply chain, from mining and recovery to component manufacturing, and across the innovation pipeline from basic science to commercial deployment.
This presentation will highlight how DOE funded activities covering each of the four pillars of the CMM strategy yield material insights and innovations to build a resilient critical material supply chain.

Ion Exchange Pathways of Lithium and Sodium in Layered Oxides *Yu Han and Chong Liu; The University of Chicago, United States*

Ion exchange in layered materials is one type of special ion transport process, which involves ion insertion and ion extraction simultaneously. This type of bi-directional ion transport requires the rearrangement of interlayer ions and will induce the phase evolution of layered host structures. More importantly, ion exchange is a powerful method to access metastable materials with advanced functionalities for energy storage applications. However, the ion exchange reaction pathways in layered materials remain elusive. Here, using layered oxides as model materials, we tracked the real-time phase evolution during Li-Na ion exchange in layered oxides. An interesting pseudo-charging behavior has been observed. Combining with the chemical composition information, the ion exchange pathway of phase separation between Li-rich and Na-poor phases was revealed. Depending on the chemical potential of exchange ions in the solution side, we identified two different exchange routes, the surface reaction-limited route and the diffusion-limited route. The phase separation behavior accompanied by the charge transfer is general in both ion exchange routes. Both DFT calculation and experiments point to that the co-existence of Li-rich and Na-poor phases is governed by thermodynamics. Besides, we demonstrate that structural vacancy level and lithium preference are critical in determining the feasibility of ion exchange. Guided by this understanding, Na_yCoO_2 was converted from the parent Li_xCoO_2 for the first time and $Li_{0.94}CoO_2$ was converted from Na_yCoO_2 at 1-1000 Li-Na (molar ratio) with electrochemical assisted ion exchange. Our study opens new opportunities for ion exchange in predictive synthesis and separation applications.

Lithium-Ion Storage in Hybrid Bilayered Vanadium Oxide Electrodes with Large and Tunable Interlayer Distances *Xinle Zhang, Timofey Averianov and Ekaterina Pomerantseva; Drexel University, United States*

In this work, we demonstrate the hybrid bilayered vanadium oxide (BVO) electrode materials with large and tunable interlayer distances achieved through chemical preintercalation of decyltrimethylammonium (DTA^+) and cetyltrimethylammonium (CTA^+) cations. By varying the concentration of these linear organic cations during chemical preintercalation synthesis, we found that the interlayer distance of hybrid BVOs can be tuned from 11.1 Å to 35.6 Å, which is controlled by the amount of the linear organic cations and structural water confined in the interlayer regions. Thermogravimetric analysis (TGA) confirmed that the increased amounts of DTA^+ or CTA^+ bromide salt added in the chemical preintercalation synthesis led to a higher fraction of DTA^+ or CTA^+ cations confined in the interlayer regions, in agreement with the reduction of the vanadium oxidation state observed via X-ray photoelectron spectroscopy (XPS). We also observed that the bending and disordering of the vanadium oxide *bilayers intensified with the increase of alkylammonium cations concentration. Galvanostatic cycling of the hybrid $(DTA)_xV_2O_5$ and $(CTA)_xV_2O_5$ electrodes in non-aqueous lithium-ion cells showed that the specific capacities decrease as the interlayer regions expand, suggesting the confined linear organic cations might be densely packed in the interlayer regions and obstruct the intercalation and transport pathways of the electrochemically cycled ions. We confirmed this hypothesis by showing differences in Li^+ ions diffusion coefficients and charge transfer resistances in hybrid BVO electrodes evaluated by galvanostatic intermittent titration technique (GITT) and electrochemical impedance spectroscopy (EIS), respectively. Among the hybrid phases reported in this study, the CTA-preintercalated BVO with the smallest interlayer distance of 11.1 Å delivered the highest initial specific capacity of 274 mAh g^{-1}, which retained about 80% of its initial capacity after 50 cycles. We utilized atomic absorption spectroscopy (AAS) to reveal that a greater layer separation enhances hybrid BVO dissolution in the electrolyte, which leads to capacity decay in cycle life and rate capability tests. Our study sheds light on the rational structural design of hybrid layered electrode materials, which require both spacious interlayer regions and high stability in the electrolyte. This work emphasizes that the chemical composition of the interlayer region needs to be considered for structural engineering of layered material, and provides guidelines for the development of novel hybrid electrode materials for energy storage applications.*

An NMR Investigation of Structural Changes in Recycled and Upcycled NMC Cathodes Prepared via Different Synthetic Routes *Evelyna Wang[1], Sohyun Park[1], Matthew Nisbet[1], Cyrus Kirwa[2], Jaclyn Coyle[2], Hongpeng Gao[3], Maura Appleberry[3], Zheng Chen[3], Tao Wang[4], Sheng Dai[4], Tiffany Kinnibrugh[1], Tim Fister[1], John T. Vaughey[1] and Fulya Dogan[1]; [1]Argonne National Laboratory, United States; [2]National Renewable Energy Laboratory, United States; [3]University of California, San Diego, United States; [4]Oak Ridge National Laboratory, United States*

Recycling end of life lithium-ion battery (LiB) components is essential in developing a robust supply chain for these critical materials, particularly high-value cathodes such as $LiNi_xMn_yCo_zO_2$ (NMC). Recently, direct recycling methods have taken great attention as the cathode structure can be retained eliminating the need for resynthesis from the precursors. As such, various processes have been investigated to recycle as well as upcycle these NMC cathode materials, including ionothermal, hydothermal, solid-state, or redox methods. In conjunction with the recycling process development, detailed structural characterization is necessary in order to understand the mechanisms and effectiveness of various cathode recycling processes. Nuclear magnetic resonance (NMR) spectroscopy as well as high-resolution X-ray diffraction (XRD) were therefore used to characterize recycled and upcycled NMC cathodes. For our NMR methodology, we used ^6Li and ^7Li MAS (magic angle spinning) NMR to probe the lithium local ordering, structural changes and surface impurities that occur during each step in the various recycling and upcycling processes of cathode materials. During recycling and relithiation, we observe the reinsertion of Li into the NMC lattice and changes in cation ordering. During upcycling, where the goal is to increase the Ni content of NMC cathodes, we can observe the incorporation of Ni-rich phases into the bulk Li environment and possible nickel segregation. These studies allow us to understand the key structural changes during recycling, provide valuable information to modify recycling processes to reach targeted cathode composition and structure and correlation toward the performance of recycled materials in comparison to pristine cathodes.

Nanoparticle Catalysts for Fuel Cell Applications Prepared from Pt-Ion-Implanted Glassy Carbon Substrates

Tetsuya Kimata[1], Sho Kato[2], Tomohiro Kobayashi[3], Shunya Yamamoto[1], Tetsuya Yamaki[1] and Takayuki Terai[2]; [1]National Institutes for Quantum Science and Technology, Japan; [2]The University of Tokyo, Japan; [3]RIKEN, Japan

Proton exchange membrane fuel cells (PEMFCs) have a low environmental impact and are highly efficient as distributed power sources for automotive and residential applications. Platinum (Pt) nanoparticles on carbon materials have been used as electrocatalysts for oxygen reduction reactions, but the high cost of the Pt catalysts has hindered the commercialization of PEMFCs. To curb these costs, the Pt loading must be reduced, while improving the catalytic activity and durability of the Pt nanoparticles.
We have applied the ion implantation method to prepare Pt nanoparticles. This is because we have expected that the ion-induced phenomena during the implantation and the morphology of resulting nanoparticles would modify their catalytic properties. In this research, we prepared Pt nanoparticles on a glassy carbon (GC) substrate by Pt-ion implantation, electrochemical etching, and annealing, then we investigated how modifications of the carbon substrate surface by high-energy ion implantation and the resulting interface interactions enhance the durability of Pt nanoparticles.

A GC substrate was implanted with 100 keV Pt^+ at a fluence of $1.5×10^{16}$ ions/cm^2. The implants reached their maximum concentration at 38 nm in depth. The surface GC layer which is chemically stable was removed by the electrochemical etching in a sodium hydroxide, exposing the Pt-ion-implanted layer. Finally, the exposed Pt would aggregate through thermal treatment for 1 h at 400 °C in an N_2 atmosphere. The prepared Pt nanoparticle catalysts were investigated in terms of their morphology, chemical and catalytic properties.

The Pt nanoparticles with diameters ranging from a few nanometers to 10 nm were observed by the transmission electron microscope to be uniformly dispersed near the surface of the sample. The Pt nanoparticles demonstrated superior durability when compared to those prepared by the conventional magnetron sputtering method. It is considered to be attributable to the improvement of the electrochemical stability of the GC. The improved electrochemical stability, in turn, may be ascribed to the structural changes caused by the Pt-ion implantation, resulting in a defective structure of the GC substrate. The defective structure could promote the formation of Pt–C bonds, thereby enhancing durability of the Pt nanoparticles.

EN10.05.02

High Performance Multimetallic Nanoalloy Catalysts for Proton Exchange Membrane Fuel Cells

Dominic Caracciolo[1,2], Jin Luo[1,2], Guojun Shang[1], Megan Barber[1], Niko Vidakovic[1], Ylith Peck[1], Lorenzo Di Salvo[1], Gary Han[1], Jessica Tao[1], Zeqi Li[1], Zhipeng Wu[1] and Chuan-Jian Zhong[1]; [1]Binghamton University, The State University of New York, United States; [2]DomCat Technologies, United States

The ability to lower the loading of noble metals in the catalysts, critical materials for green energy conversion, while maintaining the high performance of proton exchange membrane fuel cells (PEMFCs) is essential for the mass commercialization of PEMFCs. We have been developing this ability by nanoengineering noble metal-based multimetallic nanoalloy catalysts through various synthetic and processing protocols. In this presentation, we will *describe recent findings of an investigation of the performance of catalysts derived from alloying platinum with non-noble transition metals for oxygen reduction reaction in PEMFC. Both oxygen and air were tested in the cathode of the PEMFC. The metal composition, loading, and phase structure of the nanoalloy catalysts and corresponding membrane electrode assemblies were systematically investigated in correlation with the PEMFC performance in terms of polarization and durability. Examples will be highlighted for those catalysts with ultralow loading of noble metals in achieving the M2FCT-targeted voltage (0.7 V at 1.0 A/cm^2) and insignificant reduction of the voltage over long-period operation under standard PEMFC testing conditions. Implications of the results for further refinements of the catalysts in PEMFC performance optimization will also be discussed.*

EN10.05.04

Compressively Strained and Interconnected Platinum Cones with Greatly Enhanced Activity and Durability Toward Oxygen Reduction *Siyu Zhou and Younan Xia; Georgia Institute of Technology, United States*

The synthesis of cone-shaped Pt nanoparticles featuring compressively-strained {111} facets by depositing Pt atoms on the vertices of Pd icosahedral nanocrystals, followed by selective removal of the Pd template via wet etching, is reported. By controlling the lateral dimensions down to ca. 3 nm, together with a thickness of ca. 2 nm, the Pt cones show greatly enhanced specific and mass activities toward oxygen reduction, with values being 2.8 and 6.4 times those of commercial Pt/C, respectively. Both the strain field and the observed activity trend are rationalized using density functional theory calculations. With the formation of ultrathin linkers among the Pt cones derived from the same Pd icosahedral seed, the interconnected Pt cones acquire stronger interactions with the carbon support, preventing them from detachment and aggregation during the catalytic reaction. Even after 20 000 cycles of accelerated durability test, the Pt cones still show a mass activity 5.3 times higher than the initial value of the Pt/C.

EN10.05.05

Pyroelectric Driven Energy Force in Cobalt Phthalocyanine/Graphene Catalyst Pair for Simultaneous Dual CO_2 Reduction and H_2 Evolution Reactions *Maryam Mokhtarifar and T. Alan Hatton; Massachusetts Institute of Technology, United States*

As the urgency of climate change grows, the need for efficient, eco-friendly energy sources like hydrogen (H_2) intensifies. Meanwhile, global carbon emissions exacerbate the greenhouse effect and global warming. Despite growing interest in CO_2 reduction reactions (CO_2RR) and H_2 production, challenges persist, including selectivity and high costs associated with electrochemical approaches, as well as low efficiency in photocatalytic methods. In this regard, the utilization of a huge available heat-waste energy source would be highly beneficial and could potentially be achieved using pyroelectric materials, certain structures that, surprisingly, can convert even a modest periodic temperature fluctuation into electrical energy. Here, we confronted this challenge by synergistically exploiting the pyroelectric and electrocatalytic properties of planar molecules (e.g. cobalt phthalocyanine (CoPc)). By demonstrating such a pyroelectric property of CoPc, we present an unprecedented opportunity for CO_2RR and water splitting (as a dual reaction) without the need for external electrical power, relying solely on thermal cycling. Our pyrocatalyst exhibits high CO productivity in the CO_2RR, with yield as high as 15 and H_2 evolution 25 within 12 few-second thermal cycles between 5–50 °C. This fantastic feature comes from an electric field induced due to the separation of charges within the pyrocatalyst with thermal cycling, resulting in a combination of asymmetry in CoPc cell volume expansion coupled with the reorientation and rotation of the CoPc molecule.

EN10.05.06

Synthesis of Core–Shell-Structured Nanoalloy Catalysts and Electrocatalytic Properties in Water-Splitting

Reaction *Seyed Danial Mousavi, Lorenzo Di Salvo, Dominic Caracciolo, Isaac Kolisch, Guojun Shang, Zeqi Li and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States*

The coupling of solar energy conversion to electricity, electrolytic water-splitting for hydrogen production, and the fuel cell conversion of hydrogen to water represent a clean energy pack for the future. A key challenge for electrolytic water-splitting is that the oxygen-evolution reaction (OER) is kinetically slow and requires an efficient electrocatalyst. Although noble metal-based catalysts like IrO_2 *or* RuO_2 *show good OER activity, their scarcity and high-cost limit their large-scale application. We have been developing nanostructured catalysts for various electrocatalytic reactions. In this presentation, we will describe recent results of our investigation of the synthesis of nickel-cobalt alloy decorated with platinum in a core-shell type of structure using wet-chemical and seeded-growth methods. Heat treatment of the as-prepared NiCo@Pt in a hydrogen atmosphere further engineering the phase and surface structures. For the OER in basic media, the NiCo@Pt catalysts are shown to exhibit enhanced electrocatalytic activity in comparison with Pt catalysts and show strong dependence on the amount of Pt. The NiCo@Pt catalysts were characterized using XRD, SEM, and TEM techniques, revealing correlation of the electrocatalytic activity with the catalyst's nanostructure.*

EN10.05.07

Catalytic Synergies by Alloying Noble Metals with Non-Noble Transition Metals in Binary and Ternay Catalysts

Merry N. Madiou, Connor Kanyuk, Julia Zottola, Shan Wang, Shiyao Shan, Dominic Caracciolo, Guojun Shang and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States

Platinum-group metals (PGMs) are a critical group of materials for energy and environmental reactions. PGMs have been the choice of catalysts for many emission control systems employed by the automotive industry to reduce the air pollution and meet the increasingly-stringent emission control standards. To address the materials challenge associated with the scarcity of PGMs, we have been developing catalysts by alloying noble metals with non-noble transition metals towards enhanced catalytic activities. In this presentation, recent results from investigations of the synthesis and processing of platinum-alloyed transition metal catalysts in both binary and ternary nanoalloy structures carbon monoxide (CO) oxidation will be discussed. The focus is to understand the catalytic synergies of alloying platinum with earth-abundant elements in terms of phase structures and catalytic activities. Techniques such as H_2 *Temperature Programmed Reduction (H2-TPR) and online Fourier Transform Infrared Spectroscopy (FTIR) are used to measure catalytic activity. The oxygenation of the nanoalloy catalysts is shown to depend on the binary or ternary composition, the synthesis method, and the oxygenation temperature. The catalytic activity for CO oxidation is shown to depend on the ternary composition, and the degree of oxygenation. The role of lattice/vacancy oxygen in the nanoalloys for enhancing the catalytic activity will also be discussed.*

EN10.05.08

Structural Design Giving Modulation of Photoactivity of Potassium-Sodium Niobate Ferroelectric—A Strategy Using Non-Isovalent Tungsten Doping

Silvania Lanfredi[1], Fabiano R. Praxedes[1], Marcos A. Nobre[2] and Juan M. Lale[3]; [1]University of São Paulo State–UNESP, Brazil; [2]São Paulo State University, Brazil; [3]Universidad Autónoma de Chile, Chile

Currently, dyes constitute 17-20% of all industrial waste, with 7×10^7 *tons of synthetic dyes manufactured annually worldwide [1]. Among them, azo dyes represent 70% of all dyes utilized in industry. These compounds possess high degradation energy because of their covalent bonds, representing a risk to the environment when disposed of with no control. Alternatively, semiconductors based on perovskite structure have emerged as a crucial class of catalysts in solar energy conversion capable of degrading recalcitrant pollutants [2]. In this context, alkali niobates* *have attracted growing interest in light harvesting [3] and energy field applications in recent years [4]. They are a traditional category of ceramics recognized for their piezoelectric and ferroelectric properties. Most of the properties of alkali niobates come from the morphotropic phase boundary [5] and the of centering of the B-site cation [6]. Recently, our research group has reported promising applications of* $K_{0.5}Na_{0.5}NbO_3$ *for pollutant degradation and water splitting [7] through light-driven processes. Conversely, we have noted that adding* W^{6+} *into the perovskite B-site of* $K_{0.5}Na_{0.5}NbO_3$ *enhances light absorption and significantly boosts the photoelectroactivity of the material. Nevertheless, the impact of* W^{6+} *on the photoactivity of* $K_{0.5}Na_{0.5}NbO_3$ *in pollutant degradation is still unexplored so far. Therefore, we have investigated a series of W-doped* $K_{0.5}Na_{0.5}NbO_3$ *obtained in spherical hollow particles by ultrasonic spray pyrolysis and applied them in the degradation of azo dye (Basic Blue 41) under UV radiation. The* $K_{0.5}Na_{0.5}NbO_3$*-based photocatalysts were characterized by transmission electron microscopy,* N_2 *adsorption/desorption isotherm, X-ray diffraction, and ultraviolet-visible spectroscopy. The analyses indicated that the ultrasonic spray pyrolysis technique produces crystalline nanostructured spherical hollow particles of W-doped* $K_{0.5}Na_{0.5}NbO_3$ *materials. The photocatalytic activity of W-doped* $K_{0.5}Na_{0.5}NbO_3$ *was evaluated by degrading 1 L of Basic Blue 41 solution (26 micromol/L) under neutral pH. The photocatalytic system treatment was maintained at a flow rate of 180 L/h with 400 mL of solution under UV radiation at 254 nm (7 W). The photocatalytic mass was maintained constant at 100 mg. The photoactivity of W-doped* $K_{0.5}Na_{0.5}NbO_3$ *materials showed a strict link to the structural property of the materials and the W/Nb ratio. The W-doped niobate-based perovskites have displayed the highest photocatalytic activity (*54.94×10^{-3} *mmol* m^{-2} min^{-1}*) compared to the* $K_{0.5}Na_{0.5}NbO_3$ *host structure (*17.49×10^{-3} *mmol* m^{-2} min^{-1}*). The photocatalytic mechanism by W-doped* $K_{0.5}Na_{0.5}NbO_3$ *was explored based on the reactive oxygen species, and a degradation mechanism for Basic Blue 41 was proposed by scavenger tests and analysis by mass spectrometry. Accordingly, structural polarization through the displacement of niobium from the center of the octahedron [*NbO_6*] leads to increased reactivity of the apical oxygens, favoring the formation of superoxide radicals. The photocatalytic kinetics performed by the materials indicated that the spherical particles act as microreactors. Finally, W-doped niobates obtained by USP present potential for scaling up photocatalytic processes about pollutant degradation.*

Pt/WO_3 Nano−Particles Dispersed PEDOT/PSS Hybrid Hydrogen Gas Sensor *Yutaro Futagami, Sota Takagi, Seiya Suzuki, Akane Samizo and Keishi Nishio; Tokyo University of Science, Japan*

Hydrogen gas sensor is of great demand for the safe use of the new generation energy source. To date, many types of hydrogen sensor have been proposed and developed. However, most of them including semiconductor and catalytic combustion hydrogen sensors require high−temperature such as above 200 °C for the operation. Moreover, hydrogen gas sensors should be flexible enough to be fabricated in any shapes, considering the application for leak detection in transport pipes and storage tanks with complex geometries. Here, we report a successful development of a noble hydrogen sensor with a flexibility and electrical and optical detection by combining a well−known conductive polymer, PEDOT:PSS, and a gasochromic material, Pt/WO_3*.*

Pt/WO_3 *nano−particles were synthesized by sol-gel process. The Pt/*WO_3 *nano−particles were dispersed in*

PEDOT/PSS aqueous dispersion. To obtain the hybrid thin film sensor, the aqueous dispersion was casted on a glass substrate using spin-coat technique. The hydrogen gas detecting ability of the thin film was evaluated by UV−Visible spectroscopy system as an optical property and digital multimeter as an electrical resistance combined with a H_2, O_2, and N_2 gas control system. The gases were exchanged in a certain interval between 100% H_2 gas and synthetic air (80% N_2 + 20% O_2). As a result, a decrease in transmittance and an increase in electrical resistance were detected under H_2 gas exposure. Under synthetic air, those were recovered to the initial state, indicating the response is reversible. We successfully fabricated a flexible gas sensor which can detect hydrogen by optical and electrical signals for the first time. The details of fabrication and measurements will be presented in our poster.

EN10.05.10

Prelithiation Enabled Recycling of Graphite from Pencils as Anode for Lithium-Ion Batteries *Barry Y. Wang[1], Jinzhao Fu[2] and Modi Jiang[3]; [1]Shrewsbury High School, United States; [2]Worcester Polytechnic Institute, United States; [3]Shanghai Jiao Tong University, China*

Graphite materials recovered from pencil waste (2B grades) were first tested as a possible anode source for Li-ion batteries, preliminary coin cell data indicated that the first cycle coulombic efficiency is quite low around 53% as compared to the control group (~90%), this is very likely due to significant parasitic reactions related to non-graphitic components presented in pencil graphite. To overcome this obstacle, prelithiation was applied to pencil graphite anode via lithium metal in a Swagelok cell, the resulting pencil graphite anode showed better cycle life than control in a full cell paired with $LiFePO_4$ cathode. These results implied that direct recycling of pencil graphite, combined with prelithiation treatment of the graphite anode could be a technically viable source for Li-ion batteries. This alternative graphite source may help address the critical battery materials shortage which is likely to hinder the growth of the EV battery industry.

EN10.05.11

Supercharged Sustainability—Reimagining Lithium-Ion Batteries and Palm Loofah Fibers Waste as Cost-Effective Approach to High-Performance Solid-State Supercapacitors *Yasmine I. Mesbah, Doha M. Sayed and Nageh K. Allam; The American University in Cairo, Egypt*

Green solid-state supercapacitors made of recycled materials are of paramount importance. Recently, the rising demand for energy storage systems and the growing concern over electronic and biomass waste have prompted significant research efforts toward sustainable and efficient recycling methods. Researchers have achieved a good potential to recover many materials used in supercapacitor applications. From electronic waste, graphene and metal oxides can be extracted from spent batteries while carbon and cellulose materials can be extracted from biomass waste like wood chips and sewage sludge. The use of recycled materials in supercapacitors is a developing field with promising potential. However, most of the current research tests the recycled materials as 3-electrode supercapacitor systems, not as a real supercapacitor device that would be used in the commercial sector. Even when the research tests the recycled materials as a 2-electrode supercapacitor system, it would use liquid electrolyte which causes leakage and affects the stability of the device.

In this regard, this study aims to fabricate an asymmetric solid-state supercapacitor device using metals from battery waste (M-BW) and utilizing amorphous carbon recycled from agriculture waste (C-AW). Through simple and cost-effective recovery methods, the valuable metal oxides are extracted from spent lithium-ion batteries (LIBs) and purified hydro-metallurgically, ensuring their efficient reuse and reducing environmental impact. Furthermore, the potential of palm loofah is explored as a carbonaceous material for supercapacitor electrodes after its recovery using chemical and thermal activation.

The morphology and structure of both recycled materials (metal oxides and carbonaceous material) are characterized by different material characterization techniques like FESEM, HRTEM, XPS, etc. This carbon structure sandwiched with the recovered metal oxides and separated by KOH-PVA as a gel electrolyte, forms the basis for fabricating the solid-state supercapacitor device which exhibits excellent electrochemical performance. The device achieves a good specific capacitance (60 F g^{-1}) with high energy and power densities, and superior stability with up to 50,000 cycles of charges/discharges indicating its ability to efficiently store and deliver electrical energy. Moreover, the device retains its capacitance over multiple charge-discharge cycles with a retention rate of 100%. That proves the potential of using recycled materials in supercapacitor devices to promote sustainability, improve energy efficiency, reduce costs, and enhance performance. The fabricated M-BW//C-AW solid-state device achieves high performance and can compete with other counterpart devices fabricated from recycled materials and a wide range of newly synthesized ones.

EN10.05.12

Single Crystal Upcycling of Spent Polycrystalline NMC Cathode Active Materials *Ryan Andris, Hao Liu, Xiaofang Yang and Jared Liao; Princeton NuEnergy, United States*

Lithium-ion battery (LIB) recycling is a critical step within the renewable energy ecosystem. LIBs are necessary to store charge from clean energy sources such as wind and solar for use in homes, electric vehicles, and personal electronics. However, heavy metals such as nickel and cobalt that are required for modern battery chemistries are of limited supply, and their extraction and refining processes present additional safety and environmental concerns. LIB recycling can be used to isolate and regenerate the cathode active materials (CAMs) from spent batteries to create a circular LIB economy to reduce waste and greenhouse gas emissions. In addition, the chemistry and morphology of CAMs can be upgraded to better suit the energy density requirements of today's batteries. Ni-rich and single crystal CAMs offer increased charge storage capacity and improved long-term cycling performance, respectively, compared to the cathode chemistries found in spent LIBs that are ready for recycling. This work illustrates how Princeton NuEnergy can use direct recycling to upcycle spent CAMs to a single-crystal morphology and Ni-rich chemistry with comparable performance to their respective pristine materials.

Princeton NuEnergy (PNE), a U.S.-based innovative clean-tech company, initiated its pilot production in 2022 and manufacturing plant in 2024. PNE is revolutionizing the supply chain of critical materials through its patented technology for directly recycling and upcycling cathode materials from spent LIBs and manufacturing scraps. Utilizing an innovative low-temperature plasma-assisted process (LPAS™), PNE efficiently rejuvenates high-value cathode active materials, making them suitable for direct reintroduction into cell manufacturing. PNE's technology is set to significantly disrupt the battery market, representing a major leap forward in sustainable material recovery and recycling.

EN10.05.13

Efficient Solvent-Based Removal of Epoxy Resin Coatings from NdFeB Magnets for Improved Recycling *Anna M. Dickinson-Lomas, Mike Jenkins and Matthew Keith; University of Birmingham, United Kingdom*

Due to global warming, electrification of transport has become a prominent focus, since transport is responsible for around 25% of global carbon dioxide emissions. This contributes to increasing demand for Rare Earth Elements (REEs), because rare earth permanent magnets such as neodymium iron boron (NdFeB) are a key constituent of electric vehicle motors. These materials must be recycled to meet demand. NdFeB has poor corrosion resistance, so is often coated with protective crosslinked epoxy resin. Increased crosslinking density improves mechanical properties and chemical resistance, making it challenging to recycle. NdFeB magnets can be recycled via *hydrogen processing, but the epoxy coating can only be partially separated from the recycled magnet powder via sieving. Remaining carbon negatively impacts the processing and magnetic properties of the recycled magnet. Solvolysis is being explored as an alternative method of coating removal.*

This research focussed on NdFeB magnet samples from industrial motors. Characterisation via differential scanning calorimetry and infrared spectroscopy revealed that they were coated with an epoxy resin based on diglycidyl ether of bisphenol A (DGEBA) hardened with 4,4'-diaminodiphenyl sulfone (DDS). Solvolysis of this coating took place after 30 minutes in a pressure vessel with 10-30 ml of isopropanol, at temperatures of 200-350 °C. Using microscopy, ImageJ, and density values from literature, the mass of the epoxy coating was estimated to be 0.0484 g per sample. This value was used to quantify the extent of coating removal. This data was then subjected to kinetic analysis using the Arrhenius equation.

The coercivity of the remaining material after solvolysis increased by 1.1% while the remanence and maximum energy product decreased by 6.1% and 11.7% respectively. Despite this, the magnetic properties still fell within the acceptable range for functioning NdFeB magnets. Therefore, solvolysis could be considered as a technically viable step in the magnet recycling process.

EN10.05.14

Selective Liberation and Extraction of Energy-Critical Metals from Mafic and Ultramafic Ore Tailings with Carbon Mineralization

Alex Peng[1], Zolbo Garinchuluun[1], Raymond Farinato[1], D.R. Nagaraj[1] and Aaron Moment[2]; [1]Columbia University, United States; [2]University of California, Los Angeles, United States

Sustainable recovery of energy-critical metals such as Co, Ni, and Cu from mining waste tailings represents a major opportunity for supply of these metals. Though mafic and ultramafic ore is rich in Ca, Mg, and Fe silicates which make liberation via conventional methods difficult, this also provides a unique avenue to combine innovative extraction and separation technology with carbon mineralization of those elements for the future of sustainable mining. This poster presents a framework for the design of functionalized ligands for both targeting Mg and Ca, aiding in the liberation of metals from tailings and separating them for carbonation, as well as the separation of Co and Ni for high purity recovery after liberation. The effectiveness of the ligands was compared, for a collection of input ore, across particle size, mineralogy, and composition, using low-energy in-situ grinding to improve liberation to allow for less acid and base usage for greater sustainability. Oxalic acid, a compound of interest from a CO_2 utilization perspective, was used in this system to leach Mg and Ca, with Mg being leached into solution at comparable rates to the standard of sulfuric acid, while selectively precipitating out calcium oxalate. The resulting leachate was evaluated in downstream separation using ligand-assisted solvent extraction and electrowinning with a target of high recovery and purity of Ni and Co. Using ligands with tuned binding constants and pH windows, we can separate metals like Ni and Co while minimizing acid use and maintaining ligand recycling. After this, the remaining Mg-rich leachate was used to form magnesium carbonate from carbon dioxide under mild conditions. With this framework, we target the recovery of high purity value metals from mine tailings while also sequestering carbon.

EN10.05.15

Computational Investigation of Immobilized Molecular Extractants for Critical Mineral Recovery

Andrew Grorud, Julianne Oshiro and Aaron Moment; University of California, Los Angeles, United States

The transition from an energy landscape driven mainly by the combustion of fossil fuels to one driven by renewable resources will require improved extraction and separation techniques for the critical minerals that are essential to many clean energy applications. Molecular extractants provide a promising opportunity for developing efficient *and selective strategies for recovering critical elements from both ores and end-of-life materials through alteration of the steric and electronic properties of the molecule. However, despite these opportunities, implementation of molecular extractants for the recovery of critical elements suffers from the frequent need for large volumes of organic solvents in liquid–liquid extractions, representing an environmental hazard and generating significant waste. Immobilizing molecular extractants onto solid materials to create molecule–material hybrids would obviate the need for an organic solvent allowing extraction to proceed at the solid–liquid interface. An in-depth understanding of both the adsorption process of molecular extractants and the resultant effect on the geometric and electronic structure of the molecule towards critical element binding, as well as the influence of the substrate on the extraction process, are necessary for designing robust, efficient, and selective hybrid materials. Towards this end we have investigated computationally the adsorption properties of a series of aldoxime molecular extractants on a variety of substrates using density functional theory. The evaluation of appropriate computational methodologies for representing these systems using thorough benchmarking studies, including solvation effects and dispersion interactions, are described. Next, the thermodynamics and structures of aldoximes immobilized either through physisorption or chemisorption on carbon, silicon, and metal-based substrates were compared to identify strategies for developing materials with high-stability under extraction conditions at the solid–liquid interface. Furthermore, the thermodynamics of critical element extraction were evaluated for the immobilized molecules at the solid–liquid interface to evaluate the efficiency and selectivity of these hybrid materials. These values were compared against the same molecules under typical liquid–liquid extraction conditions to identify the benefits and shortcomings of the immobilization strategy. Finally, initial experimental efforts towards synthesizing and characterizing aldoxime–material hybrids and their performance for the extraction of critical elements are described.*

EN10.05.17

Energy-Mineral Nexus—Recycling Critical Minerals for Hydrogen Technology *Nikhil Komalla and Triveni Gangadari; The Pennsylvania State University, United States*

The energy transition is hindered by the complex energy-mineral nexus, where reliance on critical minerals presents significant challenges. Neodymium, a rare earth element, exemplifies the recycling difficulties that pose substantial obstacles to sustainability in renewable energy applications. The Department of Energy (DOE) has identified these minerals as critical to the clean energy transition, underscoring the urgent need for innovative solutions. This study focuses on critical minerals essential for hydrogen technology, examining the current state of recycling technologies and exploring alternative materials with higher recycling potential to enhance the sustainability and efficiency of hydrogen technologies.

EN10.05.18

Enhanced Fast-Charging Performance of Lithium-Ion Batteries Using Acid Etched Spherical Graphite *Keerti Rathi and Mohini Sain; University of Toronto, Canada*

This study explores the enhancement of fast-charging performance in lithium-ion batteries through the use of acid-etched spherical graphite as an anode material. Acid etching significantly improves the structural characteristics of spherical graphite, resulting in a highly porous network with increased surface area. Both acid-etched graphite (AEG) and KOH-etched graphite (KG) demonstrated specific capacities exceeding 300 mAh/g at 100 mA/g, surpassing those of pristine graphite. Notably, KG exhibited exceptional capacity retention at high current densities, maintaining 250 mAh/g at 1000 mA/g over long-term cycling. Additionally, spherical nano-graphite synthesized via electrochemical stripping showcased remarkable performance with a high rate capacity of 313 mAh/g at 0.1 A/g, fast-charge capability of 119 mAh/g at 4 A/g, and impressive cycling stability, retaining 83.6% capacity over 3000 cycles. The integration of these advanced graphite materials into NMC cathode-based full cells *significantly enhances the fast-charging capabilities and safety of lithium-ion batteries. These findings highlight the potential of acid-etched spherical graphite to accelerate charge times and improve overall battery performance, offering promising advancements for energy storage applications in consumer electronics and electric vehicles.*

EN10.05.19
Environmental Sustainability of Different Recycling Approaches for Perovskite Solar Cells *Juan P. Herrera, Jules Freeman, Achyuth Ravilla and Ilke Celik; Portland State University, United States*

Perovskite solar cells (PSCs) have emerged as a promising alternative in next-generation photovoltaic technologies. However, their sustainable end-of-life management remains a critical challenge. In this study, we conducted a life cycle assessment (LCA) to compare the environmental impacts of innovative recycling methods recently developed for managing PSC waste. Our primary focus was on the recycling phase of PSCs. To provide scalable information for mass production, we selected a functional unit of 1m2 of PSC for our LCA. After a rigorous literature review, we identified five recently developed approaches suitable for large-scale manufacturing. These approaches were further analyzed from an environmental sustainability perspective. For the LCA analyses, we employed the TRACI method (Tool for the Reduction and Assessment of Chemicals and Other Environmental Impacts). Our analysis revealed that a recycling method based on potassium iodide solution outperforms others by reducing environmental impacts across nine TRACI categories. This method demonstrates minimal impact, largely due to the low environmental burden associated with steam heat during iodine integration. <div>In contrast, recycling processes utilizing chemicals like chlorobenzene (CB), dimethylformamide (DMF), and ethyl acetate exhibit significantly higher environmental footprints. In addition, we analyzed five methods in terms of PSC component recovery, including coated glass, absorber, hole transport layer, and back contact. We compared these methods with the environmental impacts of producing the raw materials for these layers. Our analyses concluded that the recovery of coated glass and back contact materials exhibits better environmental performance compared to the production of raw materials. Furthermore, the environmental impacts of recovering these materials can be further reduced by reusing the solvent based on their solubility product values. Our findings offer critical insights into the feasibility of scaling up environmentally benign recycling processes, laying the groundwork for the sustainable industrialization of PSC technologies.
</div>

EN10.05.20
Electrowet Coalescer to Remove Entrained Aqueous from Organic *Tinoush Dinn; BASF Corporation, United States*

Aqueous entrapment in organic phase frequently occurs when the two phases are contacted in processing steps such as solvent extraction to extract critical minerals (e.g. Ni, Li, Co) or REE. Entrained aqueous in form of microdroplets remains in organic phase and are difficult to separate. The bulk organic phase is typically scrubbed with another aqueous, e.g. water, in multiple steps to reduce the entrained aqueous which generates wastewater and is not always efficient. The droplets carry impurities and undesired elements (e.g. Ca, Na, etc.) which end up in the stripping stages and final product inhibiting production of high purity material. Electrowet coalescer (EWC) is a novel technology which is being developed by BASF. It uses DC voltage field between polymer-coated electrodes to coalesce microdroplets into larger droplets, at least an order of magnitude larger, which can be easily separated by gravity. The poster presents the EWC principles and some of the experimental results.

Enhancing Rare Earth Element Separation with Neutral Organic Ligands *Santa Jansone Popova; Oak Ridge National Laboratory, United States*

The selective separation of rare earth elements (REEs)—including lanthanides, scandium, and yttrium—is challenging due to their similar chemical properties. Currently, the predominant method for REE separation is solvent extraction, which often involves hundreds of stages to achieve high-purity recovery of individual elements using acidic, phosphorous-based extractants. Existing libraries of organic compounds can differentiate between heavier and lighter lanthanides but fall short in selectively separating adjacent elements within the series. This presentation will detail the design of specialized ligands and the creation of tailored reactive environments aimed at achieving the precise level of specificity required for effective separation.

9:00 AM EN10.06.02

Environmentally Benign Recovery of Critical Minerals Using Mixture of Citric Acid and Sulfate Salt *Guangping Xu[1], Matthew Powell[1], Elisabeth R. Thomas[1], Yongliang Xiong[1], Yifeng Wang[1], Mark J. Rigali[1], Cindy X. Fan[1], Claire Larson[1], Dawn Wellman[2], Willem P. Duyvesteyn[3], Robert Wilson[4] and Kennth Dresang[4]; [1]Sandia National Laboratories, United States; [2]Rio Tinto, United States; [3]Extractive Metallurgy Consultancy LLC, United States; [4]South32, United States*

Decarbonization requires widespread deployment of key clean energy technologies over the coming decades to meet the world's climate goals. The demand for key critical minerals (CMs) in these technologies could grow over 450% by 2050. The U.S. currently relies heavily on import. Existing CM extraction processes are labor-intensive and take a devastating toll on the environment due to the generation of large volumes of waste streams. Assuring a secure, reliable, and sustainable domestic supply of CMs is essential to both national security and net-zero carbon goals by 2050. Its success depends upon enabling environmentally friendly extraction from unconventional and secondary domestic sources.

Citric acid and other organic acids have been used as chelating agents to leach metals from coal and coal ash [1]. Sulfate salt alone, such as magnesium sulfate, has been used as a leaching agent to recover metals from clay-based ion adsorption type rare earth element (REE) ores [2]. Magnesium sulfate salt alone can barely leach metals from non-ion adsorption type metal sources, such as, coal ash, sandstone ore deposits, mine and slag tailings, and shale. However, the mixture of citric acid and sulfate salt is shown to have a 50-100% extraction efficiency increase in removing REEs from coal ash originated from powder river basin, and an REE-bearing sandstone deposit, a Nevada lithium clay, and slag tailings when compared to using citric acid alone.

The citric-sulfate mixture leaching has several advantages: (1) the critical metal extraction efficiency increases by a factor of two or more; (2) the heat released (heat of dissociation) when sulfate salt dissolves in water increases the temperature of the resulting solution and increases the rate of critical metal extraction and reduces the required contact time between the leaching solution and the critical mineral source; (3) sulfate salt is an inexpensive additive; and (4) both citric acid and sulfate salt are food grade reagents and thus are environmentally friendly.

Electrokinetic Rare Earth Element Purification *Kyle P. McCarthy, Tylan Watkins and Laura C. Merrill; Sandia National Laboratories, United States*

Rare earth elements (REEs) are vital components in new and innovative electrical technologies and are in high demand worldwide. Primary mineral deposit sources of REEs are limited for most countries, leading to a large dependance on secondary recycled sources including magnets, LEDs, LCDs, cathode ray tubes, and phosphorous lamps amongst other industrial waste. Hydrometallurgical techniques are an effective route for REE recovery yet are limited by the difficult purification of REEs due to their similar physical and chemical properties. Currently, liquid-liquid extraction is required for significant REE recovery, but due to low single pass efficiencies and large hazardous waste production of hazardous waste, there is substantial need for new, greener, and more economic purification techniques. Large scale REE purification can be improved by low energy consumption, low waste generation, high REE selectivity, and high insensitivity to acidic leaching conditions in an economically feasible and environmentally friendly process. We describe here an electrokinetic based REE purification method using ionic polymer coated silica capillaries. This technique drives selective REE purification through electromigration of solvated REEs against an induced electroosmotic flow in an applied electric field. We show the viability of this process to individually isolate REEs and the potential for larger scale REE purification through an array of coated capillaries. This electrokinetic purification shows the potential for an environmentally friendlier and low energy technique for REE purification.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

9:30 AM EN10.06.04

Harnessing Mining Waste for Sustainable Steel and Rare Earth Element Production *Duhan Zhang; Massachusetts Institute of Technology, United States*

Rare earth elements (REEs) are essential for advanced energy and defense technologies. The U.S. has an estimated 13 million tons of REE ore reserves, but domestic production is limited to a single high-grade mine in Mountain Pass, CA. Although low-grade REE deposits are more plentiful, the scarcity of high-grade deposits in the U.S. presents a challenge. Additionally, REE-containing tailings accumulate, incurring significant economic and environmental costs, with the REE value in tailings such as red mud estimated at $796 per ton. Extracting REEs from these low-grade deposits and tailings is difficult because REEs are often locked within a mineral matrix, typically iron oxide, making mechanical or chemical separation challenging.

We propose a novel process to recover REEs from low-grade deposits and tailings. Our approach involves electro-metallurgically removing iron oxide, hydro-metallurgically extracting aluminum salt, and separating the REEs. This method not only yields refinable REE concentrates but also produces emissions-free iron metal and supplementary cementitious materials, contributing to the decarbonization of the steel and cement industries. By tackling the economic and environmental issues associated with low-grade REE deposits and mining tailings, our electrochemical process provides a sustainable solution for unlocking the potential of domestic rare earth resources. This strategy offers a pathway to utilize mining waste effectively, producing valuable materials while *supporting green technology and reducing environmental impact.*

Designing Materials and Systems for Permanent Magnets—State-of-the-Art, Challenges and Progress *Laura H. Lewis; Northeastern University, United States*

Permanent magnets are crucial for modern society and are essential in the global transition to clean energy. In addition to enabling electrical power generation and conversion, they are required for e-mobility, robots and drones, among other 21st-century aspirations. The 'gold-standard' of permanent magnets, the widely used $Nd_2Fe_{14}B$ *and* $SmCo_5$ *"supermagnets", are able to store significant energy by virtue of their elevated rare-earth content. The demand for rare-earth magnets is steadily increasing; the International Energy Agency suggests that Net Zero Emissions goals can only be met via achievement of a ten-fold increase in rare earth extraction by 2030.[1] However, it is not clear how this demand will be met, especially in light of present-day economic and societal issues surrounding rare-earth elements, including supply, sourcing and attendant geopolitical and environmental impacts.*

Rising to these challenges, there is a concerted global effort to develop new permanent magnet materials that use reduced concentrations of rare-earth elements, or even no rare-earth elements at all. This presentation will provide an overview of state-of-the-art permanent magnets and examine new approaches to augment the supply of these essential materials. These new approaches include materials development, recycling and revised design of systems incorporating permanent magnets.

Reduced-Co Heusler Compound Revealed Through High Throughput Synthesis and Magnetic Screening

Georgia Leigh[1], Elaf Anber[1], Brian L. DeCost[2], Emily Holcombe[1], Howie Joress[2], Jonathan Hollenbach[1], Jason R. Hattrick-Simpers[3], Olaf van't Erve[4], Bruce Ravel[5] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]National Institute of Standards and Technology, United States; [3]University of Toronto, Canada; [4]U.S. Naval Research Laboratory, United States; [5]Brookhaven National Laboratory, United States

Heusler alloys (HAs) have peaked interests for their unique magnetic functionalities and highly tunable structures. Cobalt-based HAs, in particular, are remarkable for their robust magnetic moments and high magnetic ordering temperatures. However, with a limited supply, production concentrated in geopolitically unstable regions, and other key supply risks, cobalt is considered a critical material. This criticality underscores the need to explore alternative compositions, incorporating more abundant elements without compromising magnetic performance. In this study, we demonstrate the utility of a high-throughput approach leveraging Magneto-Optical Kerr Effect (MOKE) and Extended X-ray Absorption Fine Structure (EXAFS) fingerprinting in combination with combinatorial synthesis to identify Co-lean compositions in a thin film Co-Cr-Al Heusler alloy system. By screening for magnetism-defining attributes, such as coordination chemistry and phase, we identify promising compositions. Subsequently, we conduct high fidelity analyses on selected alloys to investigate the relationship between magnetism, composition, chemical short-range order, and structure. In doing so, we highlight a method to identify Co-lean HAs, providing insights into their magnetic properties and potential role as sustainable alternatives.

Innovating the Recycling of Solar Panels with an Eco-Friendly Alkaline Leaching Process *Owen Wang[1,2] and Xiaotu Ma[2]; [1]Acton-Boxborough Regional High School, United States; [2]Worcester Polytechnic Institute, United States*

The surge in waste from solar panels and associated materials necessitates more effective recycling solutions. Current methods for recycling solar panels are often economically unfeasible due to the complexity of disassembly and the low value of recovered materials, leading to prohibitively high service fees. Many approaches to streamline disassembly and improve the quality of recovered materials rely on expensive, toxic, and intricate processes. To address these challenges, we present a novel green recycling technique based on a simple alkaline leaching process. This approach facilitates the efficient recycling and refinement of solar cells, producing high-purity SiO_2 (99.994%) with a notable recycling rate of 92.74% and generating hydrogen gas as a sustainable byproduct. Preliminary cost analysis suggests significant commercial viability and profitability for this method. Our technique provides a promising new direction for enhancing the sustainability and economic feasibility of renewable energy technologies.

11:15 AM EN10.06.08

Properties over Process—Understanding the Properties of Minerals and Waste for Their Utilization as Raw Materials *Selin Cansu Gölboylu[1,2], Pelin Pasabeyoglu[1,1], Suleyman Sener Akin[1] and Burcu Akata Kurc[1]; [1]Middle East Technical University, Turkey; [2]Kalyon PV Research and Development Center, Kalyon Günes Teknolojileri Üretim, Turkey*

In the current century, addressing energy demand and environmental issues has become crucial. The two prominent factors affecting the quality of the process depend on the type of raw material used for their further utilization and the energy demand for their conversion into useful materials. In that sense, obtaining synthetic materials in the chemical industry using waste and/or clay compounds as raw materials has been of great interest based on the similar chemical constituents the reactants and products possess. Accordingly, the properties of the reactant compounds become far more important for tailoring the final process that one wishes to accomplish.

In the current study, synthetic zeolite production routes based on using coal ash waste and clay minerals were discussed showcasing the importance of ingredients that these compounds have with a wide range of alterations depending on their local source and post-treatment strategies. Despite advancements in adopting renewable energy sources, coal continues to be the predominant energy supplier, contributing to 30% of the global energy demand. The majority of this waste (80% of the total) is disposed of in landfills. The impurities such as iron, calcium, and sulfates were shown to greatly influence the nucleation process of crystallization, which can be used as tools to control the crystal properties. Consequently, effective management of fly ash waste is imperative due to the severe threats it poses to ecosystems and soil pollution. For clay minerals, the calcination step of Kaolinite and halloysite, known for their pivotal roles in diverse industries, including ceramics, chemicals, and food production was shown to have a distinct role as a route of thermal process affecting their transformation into useful silica and alumina resources for their further utilization. In such cases, zeolite 13X started to form at a high temperature of ~940 °C via a transition state and partial formation of Al-Si-spinel (gamma-alumina type), resulting in a product mixture of zeolite 4A and zeolite 13X.

With an increasing demand for zeolites due to their existing and emerging applications in the field of catalysis, separation, carbon capture, and wastewater treatment, avoiding the usage of expensive chemicals as silica and alumina sources and toxic organic structure-directing agents, the production of such inorganic chemicals using fly ash and minerals offers excellent opportunities for cost reduction and mitigation of the impact on the environment. In the current study, it was also shown that the replacement of rotary kilns using fossil fuels for calcination with a *newly developed solar calcination process of clays and waste materials adds a further enhancement, particularly in the context of the growing demand for cleaner energy sources.*

11:30 AM EN10.06.09

Chemical Separation Through Thermomechanical Nanomolding *Michael O. Aderibigbe, Wiliiam Wang and Jan Schroers; Yale University, United States*

We introduce thermomechanical nanomolding (TMNM), a method that can separate an alloy by its constituents' diffusivities. Filling of the nanocavities which can be extrusion dies of nanoscale dimensions is based on atomic diffusion and the composition of the extruded or nanomolded material is a function of the relative diffusivities of the constituents and their nominal composition. Based on TMNM we developed separation methods for gold from gold containing aluminum alloys, which is challenging to separate with state-of-the-art methods.
We show, particularly through the use of silicon, which is either added to the alloy or used as a mold material, that highly enriched in gold material is separated into the nanocavities. We argue that proposed method is not limited to gold and aluminum separation but can be applied to a wide range of alloys that exhibit alloy constituents with different diffusivities of the constituents.

11:45 AM EN10.06.10

Sustainable Recovery of Critical Metals from E-Waste—Low Energy Wet Media Milling for Selective Extraction of Cu, Ni and Au from Printed Circuit Boards *Amanda Whai Shin Ooi[1], Danny Haonan Huang[1] and Aaron Moment[2,1]; [1]Columbia University, United States; [2]University of California, Los Angeles, United States*

Electronic waste (e-waste) management remains a persistent and escalating environmental challenge due to its growing volume and hazardous nature. E-waste contains critical metals such as Cu, Ni, and Au, which are of increasing importance and value. Traditional processes in e-waste treatment, such as high-energy shredding and pyrolysis, are highly energy-intensive, dilute the feedstock, and produce toxic gases. At the same time, the treatment and refining of Au often involve the use of aqua regia or cyanide, which also imposes environmental hazards on aquatic systems and human health. This study addresses these issues by investigating low-energy media milling and sequential chemical etching to directly recover Cu, Ni, and Au from printed circuit boards (PCBs). We provide a detailed characterization of the chemical and mechanical properties of the Au fingers on the PCBs, using techniques such as nanoindentation and focused ion beam etching to probe its layered structure. We then examined the effects of sulfuric acid and hydrogen peroxide concentration on the extent and selectivity of Cu and Ni recovery. We also explore the impact of in-situ wet grinding conditions and look at how using different milling materials (borosilicate, ceramic, zirconia) and shapes (spheres, rods, prisms) affect the kinetics of Cu and Ni leaching and Au delamination. Our findings demonstrate that this novel process achieves quantitative recovery of Au in its solid form, with concomitant selective extraction of Cu and Ni, offering an efficient approach to e-waste management that does not include high-temperature smelting or shredding.

Development of Hydride and Nitride Materials for Low Temperature Ammonia Synthesis *Masaaki Kitano; Tokyo Institute of Technology, Japan*

Catalytic ammonia synthesis is essential for production of synthetic fertilizers and various nitrogen containing chemicals. However, high temperature (400-500°C) and high pressure (10-30 MPa) are required for industrial ammonia synthesis (Haber-Bosch process) because the bond energy of N-N bonds is extremely large. Nowadays, small-scale and on-site processes for NH_3 *synthesis are in demand for green ammonia, in which ammonia should be produced from* H_2 *electrolyzed by renewable energy. To realize this process, it is required to develop a novel catalyst system that works effectively under low reaction temperatures. We have reported that electride and hydride materials promote the activity of transition metal catalysts significantly at low reaction temperatures, which demonstrates the essential role of hydride* (H^-) *ion in low-temperature ammonia synthesis. These materials have very low work function because of the formation of anionic electrons at anion vacancy sites. Recently, we have demonstrated that ammonia synthesis can be significantly promoted by using lattice anions as active sites for* N_2 *dissociation. In this case, nitride-based materials such as* $BaCeO_{3-x}N_yH_z$ *and LaN work as efficient catalyst supports for transition metal catalysts.*
In this presentation, first, background of catalytic ammonia synthesis is introduced. Then, novel inorganic materials with various anions such as e^-, H^-, *and* N^{3-} *will be demonstrated to function as efficient catalysts for ammonia synthesis. Finally, the role of the anion sites on the catalytic performance will be discussed.*

2:00 PM EN10.07.02
Semiconductor Nanowire-Supported Palladium Nanocatalysts *Marie Bermeo, Leonard Schilling, Daniel Strand and Maria Messing; Lund University, Sweden*

This work presents the innovative design, fabrication, and performance evaluation of aerosol palladium (Pd)-based catalysts supported by semiconductor gallium phosphide (GaP) nanowires (NWs), targeting their application in hydrogenation reactions, which are crucial in the industrial production of fine chemicals and pharmaceuticals.

Pd nanoparticles (NPs) are generated via spark ablation (Messing et al. 2010), a clean and versatile technique enabling the production of high-purity aerosols with controlled density, composition, morphology, and size. The support material plays a key role in maintaining the stability and catalytic performance of NPs, as well as facilitating their separation for reuse and minimizing NP loss. The use of semiconductors as supports has been investigated to enhance the catalytic activity of the well-established Pd catalyst (Hao et al. 2018; Liu et al. 2022).

GaP NWs, fabricated by metal-organic vapor phase epitaxy (MOVPE), offer a distinct advantage due to their high aspect ratio (length/diameter), providing a larger surface area to expose the Pd NPs, thereby increasing the number of active sites. The biocompatibility of GaP NWs (Franzén et al. 2021) further broadens their applications, making them appealing for potential synergy effects.

The fabrication of these nanocatalysts involves the generation of 10 nm Pd NPs with a particle density of 1000 $\#/\mu m^2$. *These Pd NPs are subsequently deposited along the tapered side walls of standing* 〈111〉 *GaP NWs supports by means of an electrostatic precipitator, as part of the spark discharge generator setup, ensuring a good NP-NW bond. The fabrication of the GaP NW support at 540 °C and 100 mbar, controlling the V/III ratio (phosphine to trimethylgallium), allows for precise tuning of the morphology and crystal structure (hexagonal wurtzite and/or cubic zinc blende with stacking faults).*

Electron microscopy confirmed the preservation of the morphology of both Pd NPs and GaP NWs after nanocatalyst fabrication, in addition to their well-defined crystallinity according to their fabrication parameters.

Wettability analysis revealed a correlation between nanocatalyst morphology, crystal structure, and surface energy, with surfaces ranging from hydrophilic to hydrophobic.

Catalytic performance was assessed through the partial hydrogenation of phenylacetylene to styrene, a valuable commodity in the polymer industry. These nanocatalysts present a promising alternative to the commercial Lindlar catalyst used in the hydrogenation of alkynes, consisting of Pd particles poisoned with lead and quinoline.

The results suggest catalytic performance predominantly linked to the surface energy of the NW support, which is dependent on its morphology and crystal structure. This study provides a controllable method for nanocatalyst fabrication, offering an advantage over typical wet chemical synthesis. The diverse behaviors of Pd-based nanocatalysts underscore the critical role of NW supports, contributing to a deeper understanding of key parameters that influence nanocatalyst functionality.

This work was supported by the LMK foundation for interdisciplinary research, Swedish Foundation for Strategic Research (Grant No. FFL18-0282) and the European Union's Horizon 2020 research and innovation program under the Marie Sklodowska-Curie grant agreement No. 945378. Part of the work was performed at Lund Nanolab, part of Myfab.

High-Throughput DFT Screening of ABO_{3-d} Perovskites for Hydrogen Storage

Zhen Jiang and Christopher Wolverton; Northwestern University, United States

Hydrogen is a promising optimal energy source due to its clean and versatile nature, enabling the decarbonization of various fields and contributing to a sustainable and low-carbon future. To utilize the hydrogen energy in many applications ranging from energy science to electronics, we aim to discover the host materials for excellent hydrogen capacity and conduction. Recently, all charge states of the H carrier: H^+ (proton), H^0 (atom), and H^- (hydride ion) have been experimentally reported in specific ABO_{3-d} perovskites,[1-2] which indicates the prospect of perovskite compounds in hydrogen energy and information science. However, it remains unclear that how the crystal, electronic structure, and chemical property of each element in ABO_{3-d} perovskites affect their performance in hydrogen incorporation and transport. To this end, we performed a comprehensive design of bulk channels in near-equilibrium perovskites by high-throughput density of functional theory (DFT) calculations. The perovskites were diversely screened with notable cations for A-sites (Ca, Sr, Ba) and B-sites (Co, Fe, Mn, Ti, and Zr) in a collection of phases (cubic, tetragonal, orthorhombic, and hexagonal). Our results showcased that the perovskites with active B-site cations (Co, Fe and Mn) can only uptake protons (H^+, rather than hydride H^-) in all configurations of stoichiometric and non-stoichiometric ABO_{3-d} configurations with minor effects from crystal phases. In comparison, the perovskites with d^0 cations (Ti and Zr) on B sites are inert to uptake protons (H^+) in their ground-state phases of pristine structures, however, the resulting hydride (H^-) will be easily observed in their non-stoichiometric configurations. Moreover, we also provided machine learning (ML) predictors for the solubility of O vacancies in the ABO_{3-d} Perovskites, which compiles the electronic effective mass as correlation term into ML predictors of single-site O vacancy reported in previous studies.[3-4] Finally, we also investigated the Grotthuss *mechanism of H transfer in our* ABO_{3-d} *perovskites to uncover the competitive effects of hopping and rotation motions towards the H conduction. Overall, we highlighted the importance of many metrics of the perovskites toward hydrogen uptake and conductivity from HT-DFT screening of our* ABO_{3-d} *candidates. The stable cubic-phase* $CaMnO_3$ *and* $BaTiO_{3-d}$ *configurations are the most promising parent models for* H^+ *and* H^- *host materials, respectively. Our ML-based solubility predictors for O deficient and kinetic understanding of H diffusion provide broader avenues to achieve precision-guided discovery of the next-generation materials for hydrogen storage.*
