Topological insulators have been studied to make high-efficiency thermoelectric devices, but microscopic thermoelectric properties of topological edge states remain to be explored at room temperature. Here, we report on the thermoelectric properties of the topologically protected helical edge states in twisted bilayer graphene. The boundaries of the Bernal stacked domain in twisted bilayer graphene show variation in thermoelectricity depending on the location of the Fermi level and topologically protected helical edge states when the Fermi level is controlled by back-gate voltage. Our results not only deepen our understanding of twisted bilayer graphene's unique electric and thermoelectric properties but also provide research way of high-performance thermoelectric devices.

Mechanical Manipulation of Moiré Ferroelectric Domain Structures in Twisted Bilayer WSe$_2$ *Sang Hwa Park[1], Nicolas Leconte[2], Fengping Li[2], Ayoung Yuk[1], Daesung Park[1], Hyobin Yoo[1], Jeil Jung[2] and Sang Mo Yang[1]; [1]Sogang University, Korea (the Democratic People's Republic of); [2]University of Seoul, Korea (the Democratic People's Republic of)*

Two-dimensional (2D) materials with vertical ferroelectric and piezoelectric properties are highly promising for future ultrathin electronic devices. In this viewpoint, moiré superlattices in van der Waals heterostructure with alternating vertical-polarization have attracted considerable attention in the communities of 2D materials and electronic devices. Bilayer of transition metal dichalcogenide (TMD, MX_2 structure where M: transition metal and X: chalcogen) stacked with a small angle gives birth to a micro-to-nano scale of moiré superlattices with two types of ferroelectric domains, so-called MX and XM domains. This new type of ferroelectric domains changes its polar structures by interlayer lateral sliding, which is a novel polarization switching mechanism distinct from conventional ferroelectrics.

Here, we present an ongoing study about the mechanical manipulation of ferroelectric domain structures (particularly, nodes where domain walls meet) performed by atomic force microscopy (AFM). Normal load of electrically-grounded AFM tip and its subsequent motion can guide to the top layer slips relative to the bottom layer, resulting in ripple-motion-like rearrangement in ferroelectric domains. Interestingly, this mechanical manipulation enabled the movement of the nodes or even break-up of them in the region where four domains meet (hereinafter referred to as “4-domain region”). However, such manipuation of nodes was not possible in the region where six domains meet (6-domain region). Theoretically, the 6-domain region has higher energy barrier for the node slip, leading to huge energy penalty compared to that of 4- domain’s. In accordance to both calculation and experimental results, we suggest the existence of these topologically protected and unprotected nodes in moiré bilayer heterostructures. Understanding the planar-nodes in moiré ferroelectric domains can be a major step to manipulate the switches made of a bistate topological dislocations. This work on dislocations opens up a new venue for the nanoscale control of ferroelectric domains and resultant topological structures in twisted TMD bilayer via non-electrical ways.

NM05.12.03

Enhanced Electrochemical Behavior Through Transformation of Solid-Solution MXenes into Complex Oxides

Timofey Averianov, Marcelo A. Andrade and Ekaterina Pomerantseva; Drexel University, United States

In this work, we will present the MXene-to-oxide transformation mechanism using $(V_{2-y}Nb_y)CT_x$ solid-solution MXenes. We will describe how the structure can be controlled through tuning of synthetic parameters and highlight the unique physical and electrochemical properties to the oxide derivatives in non-aqueous Li-ion batteries. Using two-dimensional MXenes for transition metal oxide synthesis is attractive due to their diverse compositions and nanoscale morphology, which can be leveraged to produce complex nanostructures. Incorporating multiple transition metals in solid-solution MXenes can lead to complex oxide derivatives with intergrown components that form tight heterointerfaces, improving their energy storage properties.

The formation of MXene-derived oxides produced in this work involved a three-step process, starting from the synthesis of the single-metal and solid-solution $(Nb_yV_{2-y})AlC$ MAX phases (y = 0.00, 0.25, 0.50, 0.75, 1.00, 1.25, 1.50, 1.75, 2.00). The $(Nb_yV_{2-y})CT_x$ MXenes were then obtained using a mixed-acid HF/HCl etchant. As the Nb/V ratio approached 1, MAX phase X-ray diffraction (XRD) features in the MXene XRD patterns gradually diminished and disappeared, indicating improved purity of the MXene compositions similar to $Nb_{1.00}V_{1.00}CT_x$. This better conversion from MAX to MXene for these compositions (y = 0.75, 1.00, 1.25) may be driven by the formation of defects in the MAX phase crystal lattice caused by lattice mismatch of V and Nb atoms in the M layers, which can allow for better etchant access to remove the A layer. The $(Nb_yV_{2-y})CT_x$ MXenes were then transformed into oxides *using hydrogen-peroxide-initiated dissolution followed by hydrothermal treatment process. XRD patterns of the V_2CT_x- and vanadium-rich (y = 0.25, 0.50) $(Nb_yV_{2-y})CT_x$-derived oxides show the formation of bilayered vanadium oxide ($V_2O_5\bullet nH_2O$, BVO), while the patterns of Nb_2CT_x- and niobium-rich (y = 1.75, 1.50) $(Nb_yV_{2-y})CT_x$-derived oxides showed nanostructured amorphous niobium oxide (nANO) formation. For solid-solution $(Nb_yV_{2-y})CT_x$ MXene derivatives with a Nb/V ratio close to 1 (y = 0.75, 1.00, 1.25), a mixture of BVO and nANO features indicated the formation of composite structures. Scanning electron microscopy of the $Nb_{1.00}V_{1.00}CT_x$-derived oxide revealed nANO particles embedded in the BVO matrix, forming tight heterointerfaces between the two materials. Electrochemical cycling of the $(Nb_yV_{2-y})CT_x$-derived oxides in non-aqueous Li-ion cells was conducted in a 1.0 – 4.0 V vs. Li/Li^+ potential window to encompass the electrochemically active regions for BVO and nANO. The V_2CT_x-derived oxide showed redox processes typical for BVO electrodes, while the Nb_2CT_x-derived oxide exhibited typical pseudocapacitive behavior for niobium oxides. The solid-solution MXene-derived oxides primarily showed composite-like behavior with some notable exceptions. The vanadium-rich $Nb_{0.25}V_{1.75}CT_x$-derived oxide exhibited a discharge capacity of 297 mAh g^{-1}, along with new redox behavior distinct from BVO and nANO, likely due to substitutional doping of Nb in the BVO structure. The $Nb_{1.00}V_{1.00}CT_x$-derived oxide achieved a discharge capacity of 298 mAh g^{-1}, with an additional pseudocapacitive response attributed to the heterointerfacial growth between the BVO and nANO particles. Heterointerfacial effects were also observed during extended cycling, where the $V_{1.00}Nb_{1.00}CT_x$-derived oxide exhibited three times the capacity retention of a 1:1 physical mixture of V_2CT_x-derived and Nb_2CT_x-derived oxides. These results demonstrate that transforming solid-solution MXene into oxide derivatives enables the design of unique two-dimensional layered materials that leverage doping and heterointerfacial growth. These derivatives can lead to novel functionalities in energy storage, which cannot be achieved through traditional composite fabrication.*

NM05.12.04

Influence of Chemical Interface Within Ferroelectric Dielectric Heterostructure on the Emergence of Negative Capacitance

SeungYong Byun[1,2], Seungheon Choi[1,2] and Cheolseong Hwang[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Department of Materials Science and Engineering and Inter-University Semiconductor Research Center, Korea (the Republic of)

Despite the number of reports that confirmed the possible integration of negative capacitance field effect transistor (NCFET)[1], exploring direct evidence of NC within gate oxide thin film is often limited, which could be due to the highly imprinted state of the ferroelectric layer within the ferroelectric-dielectric (FE-DE) heterostructure. Usable capacitance enhancement can be achieved only after applying a field larger than imprint (internal) bias, which hinders the exact evaluation of the coercive field (or the onset of ferroelectric negative capacitance). Meanwhile, the development of the hafnia-based ferroelectric thin films paved a new way for examining the NC effect, which can be readily fabricated by the atomic layer deposition (ALD) process[2]. Moreover, using a similar ALD process, FE-DE heterostructure can be readily fabricated by selecting robust DE thin film such as amorphous Al_2O_3. However, the ALD-Al_2O_3 films are often over-oxidized, rendering the FE layer in the FE-DE structure strongly imprinted toward the DE layer[3].

This study investigates the effect of the FE-DE interface on the ferroelectric imprint state and, ultimately, the overall performance of the negative capacitance within devices. Domain-based NC model[4] was used for quantitative performance evaluation, with the modified FE-DE interface condition to incorporate the FE layer imprint and domain propagation phenomena simultaneously. The interface between the 8nm-ferroelectric $(Hf_{0.5},Zr_{0.5})O_2$ (HZO) and 4nm-Al_2O_3 films was first investigated, which was also analyzed by the intrinsic NC theory elsewhere[3]. Using intrinsic NC theory, the S-shaped ferroelectric P-E relation was pre-determined, and data points were shifted to meet the coercive voltage of the curve. In contrast, the domain-based model describes ferroelectric behavior with a numerical dynamic equation, which does not require pre-determined parameters. The initial attempt to fit the data with the original domain-based NC model was unsuccessful because experimentally *obtained data showed a large coercive field up to ~2.6 MV/cm. However, when adopting modified boundary conditions with the negatively charged interface, the model showed improved fitting results, including reasonable coercive field (~1.5 MV/cm) and spontaneous polarization ($2P_s = 25$) at the measured voltage range. The model also showed that the charge density at the FE-DE interface can be as high as ~30% of ferroelectric polarization. Furthermore, other material stacks with FE-8nm-HZO/IL/amorphous DE-(Al- and N-doped) HfO_2 film, where the IL means the interface layer, were fabricated. The IL includes Al_2O_3, SiO_2, and MgO films. The amorphous HfO_2 film in direct contact with HZO was also investigated. The HfO_2 film was doped with Al and N to prevent layer crystallization. As a result, MgO IL showed the best capacitance enhancement. These findings can give insights into the appropriate material selection when fabricating NC-related systems.*

Density Functional Theory Study of CDW Structure in $TiSe_2$ *Seungrok Mun and Heung sik kim; Kangwon National University, Korea (the Republic of)*

1T-$TiSe_2$ is a well-studied TMDC (Transition Metal Dichalcogenide) material known for exhibiting a CDW (Charge Density Wave) at 165K. Despite extensive research, it is not clear whether this material is a semimetal or a semiconductor. Additionally, a second CDW transition at 165K has been identified. Here, we perform first-principles electronic structure calculations to investigate potential CDW patterns in 1T-$TiSe_2$ and their impact on electronic structures. When considering a 2x2x1 supercell, only a single type of CDW pattern is observed, as reported in previous theoretical studies. However, in the case of a 2x2x2 supercell, we found four different types of CDW orders, which are almost degenerate in energy. Furthermore, we utilized the band unfolding technique to compare the band structures of the four CDW phases with angle-resolved photoemission data and discussed the effects of spin-orbit coupling on the band structures. Additionally, we computed lattice-induced free energies to determine the presence of potential thermal phase transitions.

NM05.12.06

Heterolayered Anion-Mixed Salt-Inclusion Structures *Anna Berseneva[1,2] and Hanno z. Loye[1]; [1]University of South Carolina, United States; [2]National Renewable Energy Laboratoru, United States*

Mixed-anion materials are on the frontier of modern research since they present an additional tool to control electronic and structural properties as a function of the anion. In fact, those materials have demonstrated outstanding potential for applications that include batteries, superconductivity, thermoelectrics, electronics, and magnetism. Heterolayered anion-mixed (HAM) structures consist of two or more alternating sheets, usually built from different anions, e.g., combinations of halide-oxide, chalcogenide-oxide, halide-chalcogenide slabs, and etc.

The functional anion separation present in HAM materials can be boosted even further if the HAM structure contains both a covalent and an ionic building block, i.e., a salt inclusion, then it becomes heterolayered anion-mixed salt-inclusion (HAMSI) material. Up to date, nearly 40 HAMSI are known that represent less than 10 crystal structure families. Understanding the formation of those materials and expanding their number and functionality is of interest to material science and the solid-state community. Specifically, the first half of the talk will focus on the synthesis and classification of known chalcogenide containing HAMSI phases based on their topology, dimensionality, and crystal chemistry. This is the first step to understanding how to design HAMSI with enhanced properties. In the second half, a new family of HAMSI $[Na_2Cl]GaQ_2$ (Q = S and Se) containing $[Na_2Cl]^+$ salt-inclusion layers alternating with $[GaQ_2]^-$ sheets obtained through flux crystal growth will be discussed. Novel functionality of heterolayered materials, i. e., radioactive species sorption, will be uncovered as well as we will demonstrate how to use anion-mixed composition advantage to tune the photoluminescence profile of Mn-dopped $[Na_2Cl]GaS_2$ single crystals.

Creating Optically Anisotropic Layers Through Chromophore Alignment Using The Langmuir-Blodgett Technique *Maximilian Hupfer, Sarah Jasmin Finkelmeyer and Martin Presselt; Leibniz Institute of Photonic Technology, Germany*

The organization of molecules at the air-water interface is driven by their amphiphilicity, while the supramolecular structure of such layers depends on intermolecular interactions.[1] The latter can be quite strong, e.g., for π-electron systems, so that they may outweigh amphiphilicity as structure-determining driving force.[2] We present a structural motif featuring a linear dye where the entire chromophore serves as the hydrophilic moiety, enabling uniform alignment at the air-water interface.[3] We demonstrate how the orientations of chromophores in Langmuir and Langmuir-Blodgett layers can be determined using angle- and polarization-resolved UV-vis transmission and emission spectroscopy. This approach offers insights into the design of optically anisotropic films with tailored properties.[3,4]

NM05.12.08

Engineering Strong Electron-Phonon Coupling with Nanoscale Interfaces of Gold and Silver *Shreya Kumbhakar; Indian Institute of Technology Bangalore, India*

Interaction between the electrons and phonons determines some of the most fundamental properties of solids, including superconductivity, thermal and thermoelectric transport, polaronic effects, and electrical resistance in a metal at high temperatures. In good metals, particularly noble metals such as gold (Au), silver (Ag) or copper (Cu), the coupling of electrons and phonons is rather weak [1], and the electron-phonon coupling constant (λ) is small. The corresponding electron-phonon scattering rate $\tau^{-1}_{el\text{-}ph} = 2\pi k_B T/h$ provides an excellent quantitative description of the metallic resistivity when the temperature (T) exceeds the Debye temperature (Θ_D). The regime of however, *remained experimentally inaccessible so far, raising questions on possible universal Planckian bound on scattering rate [2], polaronic deformation, or indeed, even the stability of a metallic state itself [3]. In this work [6], we have demonstrated a novel nanostructuring strategy of Au via the formation of a hybrid with embedded ultra-small Ag nanoparticles (of radius~1-2 nm) [4] that allowed us to achieve an effective as large as* $\lambda \approx 20$*, which is almost ten times larger than that known for any solid. Using a combination of electrical transport and point contact spectroscopy, we observed (1) a systematic increase in by nearly two orders of magnitude with increasing density of Ag nanostructures, (2) robust metallic transport over the entire experimental range of T (6- 300 K) and* λ*, and (3) scaling of* τ^{-1}_{el-ph} *with for all devices for* $T>\Theta_D$ *. Intriguingly, with increasing* λ*, th resistivity approached the Mott-Ioffe Regel limit and the T-dependence of resistivity was found to become progressively sublinear. The resistivity saturation indicates a bad metal behavior emerging at large* λ *values. We attribute this enhancement of* λ *to the Coulomb interactions of electrons to the charge accumulated at the interfaces of Au and Ag. The effect of the nanoscale interfaces is also manifested in an unconventional positive magnetoresistance that is emerging from long-range unscreened Coulomb interactions. Our experiment outlines a new route to engineer the fundamental electronic interactions in a solid with embedded crystalline nanoscale interfaces.*

Novel One-Dimensional Lepidocrocite Titanium-Oxide Nanofilaments—Synthesis, Characterization and Superior Dye Adsorption Properties

Mohamed Ibrahim, Gregory Schwenk, Hussein Badr, Adam D. Walter and Michel W. Barsoum; Drexel University, United States

This study introduces a novel class of one-dimensional lepidocrocite titanium-oxide-based nanofilaments (1DLs), synthesized through a cost-effective and scalable solution-precipitation technique conducted under ambient conditions. The synthesis involves reacting titanium-based precursor powders, specifically TiB, TiC, Ti_5Si_3*, or TiN, with quaternary ammonium hydroxide solutions, such as tetraethylammonium hydroxide (TEAH), tetrapropylammonium hydroxide (TPAH), and tetrabutylammonium hydroxide (TBAH), at 80°C over 3-4 days. X-ray diffraction, density functional theory, and transmission electron microscopy analyses revealed that the building blocks are 1D nanofilaments with cross-sectional dimensions of approximately* 5×7 $\AA^2$*. These nanofilaments stack along the [020] direction and grow along the [100] direction. They can form pseudo-2D structures when filtered or non-agglomerating semi-spherical and porous mesoporous particles (PMPs) upon washing and drying. The bandgap (BG) of these nanofilaments is high, ranging from 3.8 to 3.9 eV, due to size confinement. The pronounced adsorption capability of these nanofilaments was demonstrated by their ability to absorb and degrade organic dyes. For instance, in the case of Rhodamine 6G, TEA-1DL achieved up to a 65% reduction after 30 minutes in the dark, surpassing the performance of any existing* TiO_2 *materials.*

NM05.12.10

Vapor Phase Polymerization of Thieno[3,4-b]thiophene-Tosylate and Its Application for Dynamic Structural Coloration

Mohammad Shaad Ansari, Stefano Rossi and Magnus P. Jonsson; Linköping University, Sweden

Reversible redox switching of conducting polymers modulates their electrochemical and electronic properties, such as polymer conformation, doping level, conductivity, and color. In turn, such electrochemical tuning are beneficial attributes to be applied for energy storage devices, displays, sensors, and much more. For certain *conducting polymers, vapor phase polymerization (VPP) has shown particularly useful to form highly conductive and solvent free smooth homogenous thin films on any substrate. Herein, we demonstrate for the first time VPP deposition of the conducting polymer thieno[3,4-b]thiophene-Tosylate (pT34bT-Tos), leading to record high electrical conductivity of around 700 S cm^{-1} at room temperature for this polymer. As observed high electrical conductivity could be achieved by systematic optimization of deposition conditions such as polymerization time, temperature, and oxidant concentration. Extinction spectra of resulting pT34bT:Tos thin films shows metallic absorption in their oxidized state, manifested as a wide near-IR absorption band extending beyond 2000 nm. We further show that the pT34bT thin films can be used for electrochemical switching as well as UV-patterned structural coloration applications. Electrochemical reduction reveals a neutral low bandgap peak around 1000 nm, making the pT34bT comparably transparent also in its neutral state compared to common conducting polymers. We further show that the VPP process is compatible with UV patterning to spatially control polymer conductivity and thickness, as used to create structurally colored images using the polymer as cavity spacer layer. Finally, we demonstrate dynamic electrochemical tuning of the structural colors by the application of different electrochemical potentials.*

NM05.12.11

Deciphering the Stability of Two-Dimensional III-V Semiconductors—Building Blocks and Their Versatile Assembly *Yuan Yan and Zhe Liu; The University of Melbourne, Australia*

*Two-dimensionalization unlocks the incredible potential of materials to exhibit unique and superior physical properties. Extending two-dimensionalization to non-layered crystalline materials presents both challenges and excitement. In this study, we employ high-throughput DFT calculation and machine learning to unveil a universal rule for creating stable two-dimensional counterparts of traditional high-performance III-V semiconductors: the versatile assembly of building blocks. The building blocks, comprising tetrahedrons, triangles, and distorted triangles, originate from the orbital hybridization and electron transfers, adhering to the Electron Counting Rule. By selecting and arranging various building blocks in different configurations, akin to assembling with LEGO, we successfully introduce a range of two-dimensional structures. These structures demonstrated superior energetic stability compared to theoretically predicted and experimentally synthesized counterparts. The tetrahedron building blocks contribute the most to stabilization, followed by triangular ones, as confirmed by linear regression analysis. The enhanced stability in these two-dimensional structures significantly reduces phonon scattering of carriers, leading to exceptional electronic properties. For instance, newly predicted two-dimensional GaSb exhibits remarkable hole mobility, approximately ~10^8 cm^2 V^{-1} s^{-1}, which surpasses the reported values for graphene (2 * 10^5 cm^2 V^{-1} s^{-1}) and MoS_2 (200 cm^2 V^{-1} s^{-1}). Our findings not only pave the way for expanding non-layered material systems into two-dimensional materials but also highlight the potential of two-dimensional confinement for these traditional materials.*

NM05.12.12

Investigation of $Zn_xCd_{1-x}O$ Thermoelectric Properties and Devices *Luke Miller and Gary Pennington; American University, United States*

Recent experiments indicate ultrahigh thermoelectric properties [1] and high optical conductivity [2] in ZnO-CdO thin films. This novel alloy has many potential applications to waste heat TE devices and photovoltaic systems, as well as being inexpensive to produce, nontoxic, and earth abundant [3]. To further investigate this phenomenon, We report COMSOL [4] based simulations of thermoelectric devices employing cubic ZnxCd1-xO alloys. The band structure of the alloys is found using semi-empirical techniques which agree with experiment data. The band structure and phonon spectra are used to model the lattice and electron thermal conductivity under the relaxation time approximation. To develop the specific thermoelectric properties for the alloys needed as input in the

COMSOL device simulations, the BoltztraP2 [5] simulation package is employed. Our work demonstrates how the content of Zn and Cd in these alloys affects the thermoelectric performance at the device level.

Guided Growth of 1D van der Waals Nanowires on 2D vdW Flakes for Enhanced Optoelectronic Functionalities *Maayan Persky, Shahar Bialer, Noya R. Itzhak, Katya Rechav, Olga Brontvein and Ernesto Joselevich; Weizmann Institute of Science, Israel*

1D van der Waals (vdW) materials, characterized by their chain-like structures connected by weak vdW forces, have emerged as promising candidates for various applications owing to their inherent anisotropic nature and intrinsic 1D dimensionality[1]*. Kind of these materails are Sb_2S_3 and Sb_2Se_3 which are semiconductors with promising potential for optoelectronics devices*[2–4]*. These materials unique properties, combined with our group's expertise in guided growth*[5]*, allowed us to fabricate well-aligned Sb_2Se_3 and Sb_2S_3 nanowires using a custom chemical vapor deposition (CVD) system. We used ReS_2 and $ReSe_2$ flakes, which are 2D vdW materials with optoelectronic functionalities*[6,7]*, as substrates for the nanowire growth.*
Scanning electron microscopy (SEM) confirmed the nanowire morphology and orientation on the substrates. Energy-dispersive X-ray spectroscopy (EDS) validated their chemical composition. Focused Ion Beam (FIB) is being used to prepare cross-sectional lamellae for HR-TEM analysis, which elucidate the epitaxial relationships and growth plane orientation. Following this, a photodetector was fabricated to characterize the optoelectronic properties.
The success in growing Sb_2Se_3 and Sb_2S_3 nanowires on ReSe2 and ReS2 flakes suggests promising avenues for exploring mixed-dimensional heterostructures. By understanding how these 1D vdW nanowires interact with 2D vdW flakes, we can tailor their properties to create next-generation optoelectronic devices with functionalities beyond imagination.

Deterministic Dislocation Control in Sliding Ferroelectrics *Youngki Yeo[1], Takashi Taniguchi[2], Kenji Watanabe[2] and Moshe Ben Shalom[1]; [1]Tel Aviv University, Israel; [2]National Institute for Materials Science, Japan*

Parallel stacking of van der Waals (vdW) materials breaks centrosymmetry in the lattice and induces charge transfer between the top and bottom layers. Marginal angle differences between these layers dictate the formation of Moire patterns giving rise to alternating polarization domains and dislocations. However, the rigid nature of Moire angles constrains the formation and positioning of dislocations. To address these limitations, we introduce a novel device concept minimizing the formation energy of dislocations. Dislocation can be added and removed by electric fields and exhibiting hysteresis behaviors. Furthermore, we have successfully demonstrated the capability to manipulate the Moire twist angle within our devices. These findings not only offer a practical method for controlling polarization and Moire twist-related phenomena in vdW materials but also suggest exciting prospects for the development of advanced electronic devices.

9:15 AM NM05.13.03
Manipulation of Topological Magnetism in 2D Magnets *Jinbo Pan, Peixuan Li, Xudan Zhang and Shixuan Du; Chinese Academy of Sciences, China*

Magnetic skyrmions, characterized by a particle-like magnetic whirl with non-trivial topology, have attracted considerable attentions due to their intriguing fundamental physics, and promising applications in advanced spintronics, e.g., the state-of-the-art racetrack memory. A key aspect of their role in racetrack memory involves the efficient control of the creation, motion, and delete of skyrmions.
Firstly, I will present the realization of nonvolatile and multistate control of topological magnetism in monolayer CrI_3 by constructing multiferroic heterojunctions with quadruple-well ferroelectric (FE) materials. The $Pt_2Sn_2Te_6/CrI_3$ heterojunction exhibits multiple magnetic phases upon modulating FE polarization states of FE layers and interlayer sliding. These magnetic phases include Bloch-type skyrmions and ferromagnetism, as well as a newly discovered topological magnetic structure. We reveal that the Dzyaloshinskii−Moriya interaction (DMI) induced by interfacial coupling plays a crucial role in magnetic skyrmion manipulation, which aligns with the Fert−Levy mechanism.
Then, we will present our strategy to eliminate Skyrmion Hall Effect (SkHE) of ferromagnetic skyrmion by introducing nonmagnetic elements at the interface of ferromagnetic bilayer to break the symmetry of the monolayer. The broken symmetry generates reversal in-plane DMI in each layer and provide possibility to achieve a zero topological charge number of the system, which is an indication of eliminating SkHE. Using this strategy, we identify ten topological magnetic structures in Sr (Ba) intercalated bilayer VSe_2 exhibiting zero topological charge number and free of SkHE.

9:30 AM NM05.13.04
Abnormal Nonlinear Hall Effect in Few-Layer Weyl Semimetals *Haotian Jiang[1], Tairan Xi[1], Jiangxu Li[2], Yangchen He[1], Yulu Mao[1], Daniel A. Rhodes[1], Yang Zhang[2], Jun Xiao[1] and Ying Wang[1]; [1]University of Wisconsin-Madison,*

United States; [2]The University of Tennessee, Knoxville, United States

Type II Weyl semimetal possesses exotic electronic properties arising from its unique topological structure near the Weyl nodes. The nonlinear Hall effect (NLH) is one of the most intriguing phenomena in these materials which originated from the crystal inversion symmetry breaking. In NLH, the transverse Hall-like double-frequency voltage can be generated without the presence of any magnetic field and this unique electronic property is determined by quantum geometry, which is known as Berry curvature. In this presentation, we will show an abnormal nonlinear Hall behavior in a layered Type II Weyl semimetal $TaIrTe_4$. From the temperature-dependent NLH measurement, we find that the nonlinear response is greatly enhanced above 2 orders below a critical temperature. We will also show angle-dependent NLH measurements and second harmonic generation (SHG) results to reveal the mechanism of enhancing the NLH effect and how it is related to quantum geometry. A theoretical model is also established to explain the abnormal NLH effect.

Formation and Characterization of Heterostructures with Moiré Patterns Through Deposition and Sintering of Bimetallic Gold-Platinum Group Metal Nanoparticles on MoS_2 *Alexandre Foucher and Frances M. Ross; Massachusetts Institute of Technology, United States*

Transition metal dichalcogenides (TMDs), such as MoS_2 2D films, can be combined with a layer of metals to form heterostructures with unique electronic, plasmonic, and optical properties. This class of heterostructures is rapidly expanding, with a constant push to design innovative combinations and understand the structure-property correlations. In this work, we designed heterostructures of MoS_2/Au-platinum group metals (PGMs) by deposition and sintering of free-standing bimetallic nanoparticles on MoS_2 2D films. We developed a process to remove carbon contamination on the sample thermally, then found that the sintering of nanoparticles forms flat bimetallic islands on the surface of MoS_2. The size and composition of the bimetallic nanoparticles was tuned to control the morphology of the resulting islands formed after sintering. Gold and PGMs (Ru, Rh, or Ir) remained segregated, and the metals formed moiré patterns showing the crystallinity and orientation relationship between the metals and MoS_2, after annealing at high temperatures. We used in situ gas-heating aberration-corrected advanced transmission electron microscopy to understand the formation, stability, and properties of these heterostructures. We also showed complex interfaces between phases (Au, PGMs, and MoS_2) that could be beneficial for precise tuning of physical properties. This work outlines a possible pathway to form heterostructures that combine MoS_2 with metallic islands to expand the range of available combinations through unique interface engineering.

Emergent Quantum Phenomena in Crystalline Multilayer Graphene *Long Ju[1], Zhengguang Lu[1], Tonghang Han[1], Yuxuan Yao[1], Liang Fu[1], Jixiang Yang[1], Junseok Seo[1] and Fan Zhang[2]; [1]Massachusetts Institute of Technology, United States; [2]The University of Texas at Dallas, United States*

Condensed matter physics has witnessed emergent quantum phenomena driven by electron correlation and topology. Such phenomena have been mostly observed in conventional crystalline materials where flat electronic bands are available. In recent years, moiré superlattices built upon two-dimensional (2D) materials emerged as a new platform to engineer and study electron correlation and topology. In this talk, I will introduce a family of synthetic quantum materials, based on crystalline multilayer graphene, as a new platform to engineer and study emergent phenomena driven by many-body interactions. This system hosts flat-bands in highly ordered conventional crystalline materials and dresses them with proximity effects enabled by rich structures in 2D van der

Waals heterostructures. As a result, a rich spectrum of emergent phenomena including correlated insulators, spin/valley-polarized metals, integer and fractional quantum anomalous Hall effects, as well as superconductivities have been observed in our experiments. I will also discuss the implications of these observations for topological quantum computation.

On-Chip Multi-Degree-of-Freedom Control of Two-Dimensional Quantum and Nonlinear Materials *Yuan Cao; University of California, Berkeley, United States*

Two-dimensional materials (2DM) and their heterostructures offer tunable electrical and optical properties, primarily modifiable through electrostatic gating and twisting. While electrostatic gating is a well-established method for manipulating 2DM, achieving real-time control over interfacial properties remains a frontier in exploring 2DM physics and advanced quantum device technology. Current methods, often reliant on scanning microscopes, are limited their application scope, lacking the accessibility and scalability of electrostatic gating at the device level. In this work, we introduce an on-chip platform for 2DM with in situ adjustable interfacial properties, employing a microelectromechanical system (MEMS). This platform comprises compact and cost-effective devices capable of precise voltage-controlled manipulation of 2DM, including approaching, twisting, and pressurizing actions. We demonstrate this technology by creating synthetic topological singularities, such as half-skyrmions or merons, in the nonlinear optical susceptibility of twisted hexagonal boron nitride (h-BN). A key application of this technology is the development of integrated light sources with real-time and wide-range tunable polarization. Additionally, we envision a quantum analog capable of generating entangled photon pairs with adjustable entanglement properties. Our work extends the capabilities of existing technologies in manipulating low-dimensional quantum materials and paves the way for novel hybrid 2D-3D devices, with promising implications in condensed-matter physics, quantum optics, and related fields.

11:30 AM *NM05.13.08
Engineering Flat Bands in Graphene-Based Materials *Shuyun Zhou; Tsinghua University, China*

Twisted bilayer graphene exhibits emergent correlated phenomena such as superconductivity, Mott insulat-ing state etc. The experimental electronic structure, in particular the evolution flat band near the Fermi energy, is critical for understanding the fundamental physics. In this talk, I will present our recent progress on the flat band electronic structure of various graphene-based materials using NanoARPES. In particular, by combining AFM which allows to determine the twist angle accurately with NanoARPES, we have succeeded in revealing the evolution of the flat band electronic structure across the magic angle and extracting the interlay tunneling parameters. Moreover, the remote bands also carry important information about the interlayer interaction. We also observe a switching of the spectral weight for the remote bands, highlighting the critical role of lattice relaxations [1]. I will also represent our progress on the electronic band structure of an asymmetrically-stacked twisted van der Waals heterostructure, where the flat band is further tunable by a bias voltage [2]. Flat bans in other graphene-based structures will also be discussed.

Moiré Engineering of Magnetoresistance in the Quantum-Critical Regime of Graphene Supermoiré Lattice

Junxiong Hu, Jiayu Chen, Yuntian Zheng, Reshmi Thottathil and Ariando Ariando; National University of Singapore, Singapore

*The Dirac plasma, an electron-hole (e-h) plasma of Dirac fermions at the charge-neutrality point of graphene, behaves as a hydrodynamic quantum critical fluid, similar to strongly correlated electrons in high-temperature superconductors [1-2]. However, the hydrodynamic transport of Dirac plasma through moiré potential is not well understood. In this talk, I present our investigation of the Dirac plasma in monolayer graphene encapsulated between two hBN crystals, where the strength of the moiré potential is controlled using our rotation alignment technique [3]. At zero magnetic field, the moiré potentials result in a slight temperature dependence, with resistivity saturating at ~1 kohm. This behaviour can be attributed to the onset of the quantum-critical regime, where the scattering is dominated by the Planckian frequency (~K_BT/h). When a magnetic field is applied, all moiré systems show a linear increase in resistivity with the magnetic field, but the magnitude varies significantly based on the moiré twist angels. In contrast, the magnetoresistance (MR) in non-encapsulated graphene/hBN moiré superlattice remains unchanged with different moiré twist angels. We developed a quantum effective medium theory (EMT) to show that in the hydrodynamic regime, moiré potentials dominate carrier density fluctuation, leading to modulation of the MR effect. While in the traditional diffusive regime, charge impurities dominate the carrier density fluctuation, masking the effect of the moiré potential on MR. Our work demonstrates a two-dimensional system based on the hydrodynamic regime of graphene supermoiré lattices, offering robust, stable, and highly sensitive magnetic field detection. This system shows promise for the next generation of 2D magnetic field sensor. This work is supported by the MOE Singapore Tier 1 (A-8001967-00-00), Tier 2 (MOE-T2EP50120-0015), the NRF-ISF Singapore joint program (NRF2020-NRF-ISF004-3518) and the A*STAR under its MTC Young Investigator Research Grant (YIRG) (Grant No. M23M7c0124).*

First-Principles Artificial Intelligence for Designing Moiré Materials *Yong Xu[1,2]; [1]Tsinghua University, China; [2]RIKEN, Japan*

First-principles methods based on density functional theory (DFT) have become indispensable in the study of physics, chemistry, materials science, and related fields, yet they are bottlenecked by the efficiency-accuracy dilemma. The integration of first-principles methods with artificial intelligence (AI) has the potential to revolutionize this field. In this talk, I will present the emerging interdisciplinary field of first-principles AI, which leverages cutting-edge AI techniques to address the key challenges of first-principles computation. I will introduce our recent work on developing the deep learning DFT Hamiltonian (DeepH) method and its applications in overcoming the bottleneck problems of first-principles calculations [1-12]. Moreover, I will demonstrate how to apply the DeepH method for designing advanced moiré materials with novel physical properties and provide an outlook on AI-driven materials discovery.

Epitaxy Growth of Self-Aligned Bi-Layered 2D TMDS Nanoribbons With Wafer-Scale Crystallinity *Kai Qi, Jui-Han Fu and Vincent Tung; The University of Tokyo, Japan*

Research in electronic nanomaterials has evolved remarkably over the decades. Traditionally dominated by studies of nanocrystals/fullerenes and nanowires/nanotubes, there is now a burgeoning interest in two-dimensional (2D) atomically thin films. Such materials present immense potential and practicality for unconventional soft electronics, i.e., foldable, bendable, and twistable to irregular surfaces. To this end, prevailing strategies typically hinge on transferring 2D thin films onto a pre-stretched elastomer substrate, tuning of material thickness, blending the 2D semiconductors with plasticizing agents, or the utilization of wavy or serpentine structures and patterning of elastomeric substrates of variable stiffness. While soft polymeric substrates often lead to polycrystalline or amorphous results due to their inherent limitations, crystalline substrates that are innately rigid offer the lattice alignment needed for epitaxy growth of single-crystal 2D materials. Thus, achieving direct epitaxy growth of single-crystal 2D materials on non-rigid substrates presents a dichotomy between desired electronic and mechanical properties. In this talk, we delve into the direct epitaxy growth of single crystalline 2D materials, particularly in their mono- and bilayer nanoribbon formats, on soft, insulating, or semiconducting substrates that are not only bendable but also twistable. This discovery significantly broadens the landscape of potential applications, enabling more robust and versatile electronic devices that can conform and adapt to varied form factors without compromising their performance. The synthesis techniques have also seen leaps and bounds in progression, leading to the creation of twisted heterostructures with unparalleled properties.

4:00 PM NM05.15.02

Transforming Graphene into High-Quality Large-Area 2D Mo_2C *Elif Okay[1], Eren Atli[1], Omer R. Caylan[2], Yury Gogotsi[3,4] and Goknur Cambaz Buke[1,1]; [1]TOBB University of Economics and Technology, Turkey; [2]Massachusetts Institute of Technology, United States; [3]Drexel University, United States; [4]A.J. Drexel Nanomaterials Institute, Drexel University, United States*

Transition metal carbides (TMCs) exhibit an exceptional combination of mechanical strength, electrical conductivity, chemical stability, and superior optical characteristics, rendering them highly appropriate for a wide range of applications. Molybdenum carbide (Mo_2C) holds significant promise for advanced electronics and quantum technologies due to its thickness-dependent superconductivity and excellent electrical properties, as well as its remarkable catalytic performance and chemical and thermal stability for other applications.

One of the most versatile methods for synthesizing high-quality 2D Mo_2C is chemical vapor deposition (CVD), which allows precise control over the morphology of the crystals. However, the use of hydrocarbon precursor in CVD results in the simultaneous formation of graphene, which affects the growth kinetics of Mo_2C, leading to the formation of graphene/Mo_2C heterostructures. While this one-step formation of heterostructures may be advantageous for certain applications, it may be undesirable for others where the presence of graphene is not desired. Therefore, post-synthesis removal of graphene using techniques such as reactive ion etching is necessary; this is also crucial for properly investigating the potential of Mo_2C.

In this study, we systematically explore the impact of graphene on the formation of 2D Mo_2C crystals through CVD by designing experiments with three different routes. Two of these processing routes, established in the literature, served as benchmarks for comparison with our novel approach. In our innovative method, we synthesized graphene prior to Mo_2C formation and halted methane flow at high temperatures. This strategy aimed to transform graphene into Mo_2C without needing an additional carbon source like CH_4, thereby preventing the formation of graphene/Mo_2C heterostructures. Raman spectroscopy was employed to characterize the presence of graphene, while atomic force microscopy and scanning electron microscopy were used to examine changes in crystal morphologies, highlighting the effectiveness of our approach. Scientific Research, grant numbers: FA9550-22-1-0358 and FA9550-18-1-7048.)

4:15 PM NM05.15.03

Polymorphs of the 2D Layered Semiconducting Gallium Monosulfide (GaS) and Antimony Trisulfide (Sb_2S_3)

Yael Gutierrez[1,2], Filippo Agresti[2], Dilson Juan[1], Stefano Dicorato[2], Maria Michela Giangregorio[2], Fernando Moreno[1], Javier Junquera[1], Pablo García-Fernández[1], Lidia Armelao[3,4] and Maria Losurdo[2]; [1]Universidad de Cantabria, Spain; [2]Consiglio Nazionale delle Ricerche, Italy; [3]Università degli Studi di Padova, Italy; [4]CNR DSCTM, Italy

Layered van der Waals (vdW) materials are garnering increasing attention due to their unique optical, electronic, and mechanical properties, paving the way for novel applications across various fields such as optoelectronics, photonics, and catalysis. Among these materials, layered post-transition metal chalcogenides (PTMCs) like gallium monosulfide (GaS) and antimony trisulfide (Sb_2S_3) are emerging as low-loss phase change materials (PCMs). GaS and Sb_2S_3 with optical band gap varying from 1.7 to 2.5 eV to 3.2 eV depending on its dimensionality and phase, fill the gap between semiconducting TMDs and two-dimensional insulators, enabling new optoelectronic devices. For GaS, the stable 2H phase is well-documented. We report on discovery of the rhombohedral 3R phase and on the successful growth of 3R GaS thin films using chemical vapor deposition (CVD) and present a comprehensive study of their structural, phononic, and electronic properties. Experimental techniques such as photoluminescence, Raman spectroscopy, and X-ray diffraction, combined with density functional theory (DFT) calculations. Unlike the indirect band gap of the 2H phase, the R-3m GaS exhibits a direct band gap of 2.55 eV, accompanied by near-blue light emission at room temperature.

Similarly, we report on the discovery of Type-I and Type-II spherulitic crystalline phases of Sb_2S_3, whose appearance is related to the crystallization temperature, with different stability and photonic properties. Guidelines to use one or the other phase in photonic devices will de provided.

4:30 PM NM05.15.04

Synthesis and Characterization of Amino-Functionalized Ti_3C_2 MXene with Extremely High Conductivity

Masaki Yamamoto, Mika Tagami and Keigo Suzuki; Murata Manufacturing Co., Ltd., Japan

MXenes are a family of 2D transition metal carbides, nitrides, and carbonitrides represented by the formula $M_{n+1}X_nT_x$, where M is an early transition metal, X is carbon and/or nitrogen, and T_x represents terminal groups. One of the main advantages of MXenes is that their surfaces are easy to modify, given the abundance of ligand-exchangeable terminal groups such as –OH. Altering the inherent surface functional groups through ligand exchange is a promising method for tuning the physical and chemical properties of MXene. For instance, introducing new functional groups onto the MXene surface via ligand substitution can enhance oxidation resistance, improve dispersibility in organic solvents, and modulate the material's work function.[1] Introducing amino groups on the MXene surface is also a notable modification, which provides many reactive sites for biomolecules, organic molecules, and polymers. Additionally, amino groups allow for modulating the generally negatively-charged surface potential of MXene. [2,3] There have been many reported methods for introducing amino groups onto the MXene surface, most of which involve silane coupling agents (SCAs). However, amino-functionalization using SCAs has significant drawbacks. The high reactivity of SCAs leads to reactions resulting in Ti-OH formation, but self-polymerization may also occur among the SCAs themselves, resulting in formation of polysiloxanes on the MXene surface that significantly reduce the high conductivity MXenes typically possess. Herein, we successfully achieved amino-functionalized MXenes using phosphonic acid as a ligand. The resultant material demonstrated a remarkably high conductivity of approximately 4,000 S/cm. Through various analyses, it has been revealed that dehydrating condensation occurs between Ti-OH on the MXene and P-OH in the phosphonic acid ligand, forming versatile Ti-O-P bonds on the final product. Beyond this, we will present other factors that are hypothesized to contribute to the improvement in conductivity seen for amino-functionalized

MXene.

Strain Engineering of MoS_2 by Tuning the Transfer Process for Improving Its Electrical Performance

Mitsuhiro Okada, Yuki Okigawa, Toshitaka Kubo and Takatoshi Yamada; National Institute of Advanced Industrial Science and Technology, Japan

Two-dimensional semiconductors, such as MoS_2, have garnered significant attention due to their potential as alternatives to silicon in electronic devices. In the case of MoS_2, reported experimental carrier mobility is an order of magnitude lower than expected, which hinders its future applications. Strain engineering is a common method in the semiconductor industry to enhance the carrier mobility of silicon and similar improvements have been expected for MoS_2: applying tensile strain into MoS_2 enhances its electron mobility. Therefore, strain engineering is a possible method to achieve future high-performance MoS_2-based electronic devices. One of the challenges in strain engineering of MoS_2 is achieving strained MoS_2 on rigid substrates, such as surface-oxidized silicon (SiO_2/Si): the surface inertness of MoS_2 makes it challenging to induce and maintain strain through lattice mismatch with the substrate. In this work, we report another approach of introducing strain into MoS_2 by tuning the wet transfer process. By optimizing vacuum annealing conditions during transfer process of CVD MoS_2, we successfully introduced approximately 0.5% tensile strain into CVD MoS_2, resulting in a 19-fold increase in carrier mobility. Our results show that controlling of the transfer process is an important way to achieve strain-engineered MoS_2 for future high-performance MoS_2-based devices.

MoS_2 flakes were synthesized on a SiO_2/Si substrate through CVD using MoO_2 and elemental S. For the growth, we added KBr as a growth promoter. Next, MoS_2 was transferred using PMMA-assisted wet-transfer method, with KOH solution as the etchant. After transferring the PMMA/MoS_2 stack onto another SiO_2/Si substrates, we annealed the samples at 50°C or 160°C under vacuum for 30 min to improve adhesion between the MoS_2 and SiO_2 (referred to as LTT and HTT MoS_2, respectively). Then, we measured the Raman mapping of these two samples to evaluate the strain and doping introduced by the transfer process. By plotting the relationship between the E' and A'_1 peak positions, the strain and carrier density of MoS_2 can be evaluated. The tensile strain in HTT MoS_2 increased approximately 0.5% from the LTT MoS_2. This strain remained after the PMMA removal process, indicating the successful transfer of strained MoS_2 onto a rigid substrate. By estimating the thermal expansion of MoS_2, SiO_2, and PMMA, we found that the strain in HTT MoS_2 could not be achieved by the thermal expansion of MoS_2 itself (~0.07%), while this value is almost same as the thermal expansion of PMMA (~0.8%). Thus, we speculated that HTT MoS_2 was expanded by the thermal expansion of PMMA, and the adhesion between MoS_2 and SiO_2 was improved. As a result, strained MoS_2 was successfully transferred onto SiO_2/Si. Note that the carrier density of HTT MoS_2 was 1.6 times higher than that of LTT MoS_2. This increase could be caused by carrier doping from the substrate due to improved adhesion between MoS_2 and SiO_2 during annealing at 160°C. Field-effect transistors were fabricated using photolithography, followed by thermal deposition of Ni and Au as contact metals. We measured the performance of over 30 devices fabricated by each process and found the average carrier mobilities of 0.48 and 9.1 $cm^2V^{-1}s^{-1}$ for LTT and HTT MoS_2, respectively. The increase in carrier mobility is attributed to both the tensile strain and the increased carrier density.

In summary, we successfully demonstrated that strain-engineered MoS_2 can be achieved onto SiO_2/Si by optimizing the transfer process. As a result, the carrier mobility of MoS_2 improved by 19 times. Our results suggest that the transfer process is one of the important parameters for tuning the electronic and optoelectronic *performance of MoS_2-based devices.*

8:00 AM NM05.16.01

Twisted Epitaxy of Gold Nanodiscs Grown in Twisted Bilayer Molybdenum Disulfide *Yi Cui, Robert Sinclair and Yi Cui; Stanford University, United States*

The concept of epitaxy is important in materials science for many technological applications, and it describes crystal growth on a single crystal substrate with crystallographic registry [1]. The recent development of two-dimensional (2D) van der Waals (vdW) materials has expanded the scope of epitaxy to vdW epitaxy [2], remote epitaxy [3], and confined epitaxy [4]. Thus far, all epitaxy research has been based on the framework of growing one crystal epitaxially onto or into one substrate. For example, previous studies of gold (Au) through vacuum deposition onto single crystal molybdenum disulfide (MoS_2) show that there is an epitaxial relationship between the FCC close packed Au planes ({111}) and the hexagonal MoS_2 planes ({001}) [5,6]. Here we expand the concept of epitaxy to a new regime of “twisted epitaxy” with the epilayer crystal growth between two MoS_2 substrates with varying mutual crystal orientations. Both substrates interact with intermediate Au nanoparticles in an appreciable way and influence its crystallographic orientation and registry, opening up opportunities of using the relative orientation of two substrates as a control parameter.

To demonstrate the concept of twisted epitaxy, we propose a method to synthesize 2D twisted epitaxial Au nanodiscs by depositing epitaxial Au nanoparticles onto exfoliated MoS_2, encapsulating them with a second layer of MoS_2 with varying orientation from 0° to 60° and then annealing at 500 °C for 2 hours in argon atmosphere. The orientation of the crystalline Au nanodiscs with respect to the MoS_2 lattice was studied by selected area electron diffraction (SAED) and Moire fringe image analysis using transmission electron microscopy (TEM) and it can be altered in a small but controllable fashion via the bilayer twist angle. Specifically, Au aligns mid-way between the orientation of the top and bottom MoS_2 when the twist angle of the bilayer is small ($< \sim 7^\circ$). For larger twist angles, Au aligns close to the bottom MoS_2, with a small misorientation varying approximately sinusoidally with the twist angle of the bilayer MoS_2 [[7]. These observations are consistent with the combined upper and lower interfacial energies of Au- MoS_2 calculated using Density Functional Theory [8]. In addition, 4D STEM analysis is used to study the strain variations ($< |\pm 1\%|$) in the Au nanodiscs associated with the twisted epitaxy. The discovery of twisted epitaxy therefore provides opportunities for tri-lattice heterostructure Moiré engineering and for structure-property investigation of 2D materials with advanced scanning transmission electron microscopy (STEM) [9].

Augmented Haloperoxidase Functionality in Defect-Modified Bi_2Te_3 Nanosheets for Combating Biofouling

Sagar S. Kulkarni and Surojit Chattopadhyay; National Yang Ming Chiao Tung University, Taiwan

Biofouling begins with the accumulation of microorganisms (microfouling) on surfaces in humid and marine environments, leading to the growth of plants and animals (macrofouling) and causing performance issues and economic losses. Current anti-biofouling treatments include surface modifications, bactericidal materials, and enzyme-based treatments. Next-generation solutions focus on eco-friendly methods like nanozymes with haloperoxidase (hPOD) activity, which use hydrogen peroxide (H_2O_2) to oxidize halogens (chloride ion and bromide ion) into hypohalous acids (HO-Z), inhibiting bacterial growth. Vanadium pentoxide (V_2O_5)[1] was the first hPOD nanozyme for marine anti-biofouling, followed by materials like cerium oxide (CeO_{2-x})[2] and cobalt-doped molybdenum sulfide (Co-MoS_2)[3]. Despite advancements, pristine nanomaterials exhibit limited hydrogen peroxide dismutase (hPOD) activity, leading to the adoption of heterografting, metal doping, and defect-mediated strategies to boost performance. Although some initial findings are promising, only a handful of nanozymes with inherent hPOD-like activity have been developed. Traditionally, transition metals have been recognized as the active catalytic centers in transition metal chalcogenides for nanozyme activity. However, the potential of non-transition metals as active catalytic centers for hPOD activity has not yet been explored. Bismuth-based non-transition metal chalcogenides, particularly bismuth telluride (Bi_2Te_3), show promise for their stability, catalytic activity, and cost-effectiveness. Defect engineering in Bi_2Te_3 can enhance its hPOD activity without relying on expensive noble metals. For instance, NaOH etching creates Te vacancies, leading to Bi^{3+} species that react with H_2O_2 and bromide ion to produce antimicrobial HO-Br and singlet oxygen ($^1O_2$). The defect-engineered d-Bi_2Te_3-250 nanozyme exhibits an 8-fold increase in hPOD activity compared to as-grown Bi_2Te_3. It shows significant antibacterial effects, reducing the viability of Staphylococcus aureus to 1% and Pseudomonas aeruginosa to 45%, and effectively inhibits P. aeruginosa biofilms, demonstrating up to 73% reduction in biofouling. This study highlights the potential of defect-engineered Bi_2Te_3 as a cost-effective, efficient alternative for anti-microfouling applications.

Low-Temperature Synthesis of Two-Dimensional Gallium Nitride via Liquid Metal Printing

Wei-Chih Chen[1], Wei-Jia Lin[2], Cheng-Chih Hsiang[1], Chang Hsun Huang[1], Kuan-Hung Chen[1] and Yi-Chia Chou[1]; [1]National Taiwan University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

With rapid technological advancements, the integration of third-generation semiconductor technology with two-

dimensional materials is revolutionizing society at an unprecedented rate. These materials, such as gallium nitride (GaN) and silicon carbide (SiC), show exceptional promise in electronics, energy conversion, and communication technologies[1]. Notably, advancements in third-generation semiconductor technology have significantly enhanced the performance and reliability of communication systems. Our research specifically focuses on synthesizing two-dimensional GaN. One notable challenge in the application of 2D GaN is the "Green gap" issue in light-emitting diodes (LEDs), which refers to the inefficiency in emitting light within the yellow-green range of the visible spectrum[2]. This inefficiency is primarily due to spontaneous and piezoelectric polarization effects in the wurtzite GaN structure, leading to the quantum confinement Stark effect and reduced emission efficiency[3]. In contrast, the zinc-blende GaN structure, due to its symmetric nature, lacks spontaneous polarization, making it a promising candidate to address the "Green gap" problem in LEDs. However, the growth of zinc-blende GaN is challenging because of its metastable nature, which makes it less stable compared to the wurtzite GaN structure. To address this, we employed the liquid metal printing technique to fabricate 2D gallium oxide (Ga_2O_3) films, which were subsequently nitridated to form a zinc-blende GaN structure. Liquid metal printing offers several advantages, including the ability to fabricate wafer-scale 2D metal oxide films that are only a few layers thick, simplicity of the process, and low production costs. These attributes make this method highly suitable for industrial applications and align with the ongoing trend of semiconductor device scaling. To validate our results, we utilized Raman spectroscopy, X-ray photoelectron spectroscopy, and atomic force microscopy to analyze the GaN structure under varying temperatures and durations during the transformation process, achieving an average film thickness at the nanoscale. Our goal was to determine the optimal parameters for the transformation to zinc-blende GaN. We discovered that 500°C is the minimum temperature at which successful transformation can occur. Based on this finding, we have decided to conduct further research at this temperature. Additionally, we examined the lattice structure of the samples using transmission electron microscopy (TEM).
Based on previous experiments, we used TEM and CL to observed that at a transform temperature of 800 degrees Celsius, the hexagonal crystals showed a reduction or appearance of defects as the time increased from 30 minutes to 90 minutes. In addition, further processes at 850 degrees Celsius and 900 degrees Celsius confirmed better stability of hexagonal structures at higher temperatures. Subsequently, we extended the reaction time, lowered the processing temperature, and conducted nitridation under vacuum conditions. We found GaN of different colors including blue, yellow, green, and brown under various experimental parameters. The transformation degree was assessed by the ratio of Ga-O to Ga-N in XPS, and the relationship between color and crystal structure was investigated using TEM, leading to the identification of zincblende GaN.

Synthesis of Mirror-Like, Large-Grained Graphite Films Using Ni-Mo Alloy Melts *Won Kyung Seong[1], Liyuan Zhang[1], Meihui Wang[1], Yongqiang Meng[1,2], Sun Hwa Lee[1] and Rodney S. Ruoff[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Graphite, known for its anisotropic physical properties, has widespread applications in thermal management, composites, and various other fields. Achieving high-quality artificial graphite crystals with large grain sizes and smooth textures has been a long-standing challenge. We report the synthesis of mirror-like, large-grained graphite *films with controllable dimensions, achieved by using flat Ni-Mo alloy melts as catalysts. In our method, after the formation of the graphite film, we deliberately evaporated a significant portion of Ni, producing a porous metallic substrate. This step weakens the substrate-graphite film interaction before cooling down to room temperature, resulting in graphite films with only a few nano kinks and a mirror-like appearance. The synthesized films are 100% AB-stacked with millimeter-sized grains, much larger than the multi-micron grain size of highly oriented pyrolytic graphite and rivaled in size only by a small percentage of natural graphite. The films demonstrate an electrical conductivity of 5.59 × 10^6 S/m at 4 K and 7.75 × 10^5 S/m at 300 K. Tensile testing of macroscale samples revealed an average Young's modulus of 969 ± 69 GPa and an average fracture strength of 1.29 ± 0.203 GPa, which are, to the best of our knowledge, the highest values reported for macroscale artificial graphite materials. Our method provides a promising approach for synthesizing high-quality graphite films with exceptional properties, opening up new avenues for their potential applications in various fields.*

Advanced Graphene Coatings on Copper, Copper Alloy and Silver—Low-Temperature Synthesis and Performance Analysis *Suyeon Son, Min Park, Hyunji Yun, Hosang Yoo, Jin-Woo Lee and Jongwoo Lee; HaesungDS, Korea (the Republic of)*

Rapidly evolved surface treatments, particularly those utilizing graphene, offer multifaceted benefits over conventional reactive metal substrates. These benefits include chemical stability, high electrical and thermal conductivity, and mechanical strength, which enable superior surface activations compared to existing methods such as chemical oxidation, electroplating, and plasma treatment for package substrates.

We demonstrated that graphene on a copper substrate plays an important role as an oxygen barrier and exhibits strong adhesion under accelerated stress test conditions at 85°C/85% RH. To further investigate the effects of different metal substrates—namely copper, copper alloy, and silver—on graphene growth and characteristics, we employed low-temperature plasma-enhanced chemical vapor deposition (PECVD). The analysis was conducted using Atomic Force Microscopy (AFM), Raman spectroscopy, and die shear tests between epoxy molding compounds and epoxy adhesive over the graphene surface.

Our findings show that low-temperature synthesized graphene forms multi-layer structures on each metal substrate, with growth characteristics dependent on surface conditions. The enhanced properties of graphene, such as its exceptional barrier capabilities and mechanical adhesion, were consistently observed across different substrates. This study not only demonstrates the viability of low-temperature PECVD for producing high-quality graphene films but also highlights the potential for integrating graphene into existing semiconductor and packaging processes.

We believe that the efforts described in this paper pave the way for the large-area production of graphene-coated substrates and roll-to-roll manufacturability. The scalability of this method and the improved material properties of graphene-coated substrates could significantly impact various industries, including electronics, energy storage, and flexible devices. Detailed low-temperature graphene synthesis and characterization on different metal substrates will be further discussed, providing insights into optimizing production techniques for commercial applications.

9:15 AM NM05.16.06

Doping vs Functionalization—Strategies for Enhancing the Sonophotocatalytic Degradation of Contaminants of Emerging Concern with 2D-Materials-Based Composites *Hugo Salazar[1], Amaia Zarandona[1], Eneko Sebastian[2], Jorge Saiz[1], Qi Zhang[1,3] and Senentxu Lanceros-Mendez[1,3]; [1]BCMaterials, Spain; [2]University of the Basque Country, Spain; [3]IKERBASQUE, Basque Foundation for Science, Spain*

The presence of contaminants of emerging concern (CECs) in wastewater poses significant risks to both human *health and ecosystem biodiversity due to their persistence, bioaccumulation, and potential to disrupt biological processes [1]. Consequently, there is an urgent need for advanced materials and technologies with enhanced properties to face these resilient contaminants.*

Bismuth sulfur iodide (BiSI) is a promising sonocatalyst due to its unique properties [2]. However, its narrow bandgap leads to rapid electron-hole recombination, hindering its effectiveness as a photocatalyst. To overcome this, doping and functionalization of BiSI with 2D materials may significantly enhance its catalytic performance by improving visible light absorption, increasing surface area, and promoting efficient electron-hole separation. Such improvements make 2D@BiSI composites highly effective for CECs degradation, offering sustainable and efficient solutions for water purification through combined sonophotocatalytic technologies [3].

In this study, we explored four different modification strategies of BiSI: (i) surface doping with silver (Ag) ions, improving visible light absorption; (ii) structural doping with oxygen to introduce sulfur vacancies and enhance carrier separation and transfer; (iii) functionalization with carbon nitride (C_3N_4), aiming to boost the photocatalytic activity; and (iv) functionalization with graphene oxide (GO), aiming to increase the surface area for contaminant adsorption.

All composites were fully characterized for their structural, physical-chemical, and optical properties, and applied to the degradation of carbamazepine (CBZ) through photocatalysis, sonocatalysis, and combined sonophotocatalysis. All modifications allowed to improve the degradation efficiencies. The combined sonophotocatalytic approach under ultrasound and visible light irradiation achieved degradation efficiencies higher than 90% for the modified Ag@BiSI, O-BiSI, C_3N_4@BiSI, and GO@BiSI catalysts. Remarkably, the 2D-based composites functionalized with C_3N_4 and GO achieved nearly complete degradation of CBZ, showing a synergistic effect in sonophotocatalysis with efficiency improvements of 145% and 157% for C_3N_4@BiSI and GO@BiSI, respectively. These achieved efficiencies were far superior to the sum of the efficiencies of each individual technique for both 2D-materials-based composites. Proposed degradation mechanisms highlight the impact of each modification on generating reactive oxygen species and specific degradation pathways.

These findings underscore the critical role of tailored modifications in significantly enhancing the sonophotocatalytic activity of BiSI-based catalysts. The integration of 2D materials, such as C_3N_4 and GO, not only allows for boosting the adsorption and photocatalytic capacity but also offers a sustainable and effective approach for the degradation of persistent contaminants in water. This study demonstrates the potential of advanced material design in developing robust and high-performance catalysts for environmental remediation, paving the way for more efficient solutions to address the challenges posed by contaminants of emerging concern.

Pioneering Advances in MXene Synthesis and Applications—Insights from Argonne MXene Innovations *Shiba P. Adhikari and Zachary D. Hood; Argonne National Laboratory, United States*

The rapidly expanding utility of MXenes in applications such as energy storage (Li-ion batteries, supercapacitors), catalysis, composites, and gas sensing underscores the necessity for enhanced efficiency, predictability, and reliability in their synthesis and processing. MXenes, characterized by their unique atomic structure of transition *metal carbides, nitrides, or carbonitrides, exhibit exceptional properties like high conductivity, mechanical flexibility, and surface reactivity, making them ideal for diverse applications. However, the intricate structure of MXenes presents significant challenges in achieving precise synthesis and processing. The "**Argonne MXene Innovations**" initiative represents a pioneering multidisciplinary approach aimed at addressing these complexities. By integrating advanced science and engineering capabilities—including supercomputing for materials design at the Argonne Leadership Computing Facility, high-resolution X-ray imaging at the Advanced Photon Source (APS), nanoscale insights from the Center for Nanoscale Materials (CNM), and synthesis expertise at the Materials Engineering Research Facility (MERF) - this initiative tackles the challenges of MXene synthesis and scale-up processes. This presentation will highlight specific subprograms within Argonne MXene Innovations - MXBat, MXCat, MXel, MXFab, MXMech, MXProtect, and MXSense - demonstrating their roles in refining energy storage, electrocatalysis, conductivity optimization, synthesis methodologies, mechanical reinforcement, surface protection, and sensing capacities of MXenes. In this presentation, We will showcase a detailed case study on aluminum-MXene composites developed under the MXel subprogram. This case study highlights collaborative achievements that drive the advancement of MXenes, emphasizing their unique structures with tunable nanoscale hierarchy, which significantly enhance composite performance. Specifically, the dispersion homogeneity of MXene-based materials with aluminum particles influences the mechanical properties of particle-reinforced metal matrix composites, improving conductivity, mechanical strength, and corrosion resistance. Furthermore, this case study demonstrates innovative approaches to optimizing the synthesis and processing of MXenes, ultimately improving their performance and broadening their application scope beyond conventional paradigms.*

Synthesis and Characterization of the 2D Layered Heterostructure Bismuth Triiodide—Graphene *Laura Fornaro, Camila Maidana, Heinkel Bentos Pereira, Ana Noguera and Alvaro Olivera; Universidad de la República, Uruguay*

Among the new emerging 2D materials, bismuth tri-iodide-graphene heterostructure has been reported both theoretical and experimentally, displaying intriguing properties. These findings suggest potential photovoltaic applications for BiI_3 layers and van der Waals superstructures. In this context, the present work reports the growth and characterization of the heterostructure BiI_3–graphene. The growth was performed in a chamber designed and built in our laboratory, through physical vapor deposition, by first nucleating BiI_3 on graphene-covered substrates pre-treated with UV/O_3, then allowing it to grow by non-classical attachment mechanisms followed by thermal annealing and post growth, up to three times (initial pressure 0.001-0.0001 Pa, sublimation temperature of BiI_3 for nucleation and post-growth 262±2°C, substrate temperature 40±1°C, thermal annealing at 150±1°C during 3600 s, post-growth (after annealing) from 120 to 600 s). The heterostructure was characterized by Bragg-Brentano X-Ray Diffraction (XRD), Grazing Incidence XRD (GIXRD), X-Ray reflectometry (XRR), High Resolution Transmission Electron Microscopy (HR-TEM), Energy Dispersive Spectroscopy (EDS), Selected Area Electron Diffraction (SAED), Fast Fourier Transform (FFT) analysis, High Resolution Scanning Electron Microscopy (HR-SEM), Atomic Force Microscopy (AFM), X-Ray Photoelectron Spectroscopy (XPS), Raman Spectroscopy and diffuse reflectance *spectroscopy with integrating sphere. TEM grids and ultra-flat silicon substrates, both covered with graphene, were used as substrates, according to the characterization needs. Results show that nucleation proceeds through a non-classical mechanism with metastable amorphous entities that later pass to crystalline forms about 4 nm in size, growing through non-classical mechanisms of "oriented attachment" and "amorphous addition". Entities are oriented with their c-axis perpendicular to the substrate. After the annealing and post-growth, structures obtained on substrates result in layers, with thicknesses in the range 7.6 to 35 nm, with roughness in the range 0.4 to 6 nm. The obtained heterostructures are uniform and aligned, without twisting (no Moire interference observed neither in HR-TEM images nor SAED diagrams). As the thickness decreases, the position of the (0 0 3) reflection peak in the diffraction pattern shifts to lower values and broadens, indicating an expansion of the cell along the c-axis. XRD and HR-TEM verify* BiI_3 *composition as well as the layer orientation with their c-axis perpendicular to the substrate. HR-TEM images of the structures show lattice planes with nearly perfect atomic arrangement, suggesting a single-crystalline nature, with a predominantly lattice spacing of 0.35 nm, which can be attributed to the (1 1 0) planes of* BiI_3 *hexagonal structure The FFT of the structure further confirms its single crystal nature and displays spots in a hexagonal symmetry, which can be indexed to the* BiI_3 *hexagonal structure along [0 0 l] zone axis. HR-SEM images verify the substrate continuous coverage, and AFM measurements confirm the roughness of the layers. XPS analysis gives peaks for Bi* $4f_{5/2}$ *(165.2 eV) and* $4f_{7/2}$ *(159.8 eV), I* $3d_{3/2}$ *(631.0 eV) and* $3d_{5/2}$ *(619.3 eV) which can be attributed to the characteristic signals from* I^- *and* Bi^{3+} *species, respectively, as far as the C-C from C* sp_2 *bond (284.7 eV), showing there are no chemical reactions between graphene and* BiI_3 *which then only interact through weak van der Waals interaction. Raman spectra show a peak around 115.2* cm^{-1}*, which represents out-plane Ag Raman mode. All these results agree with previously reported values for layers of this heterostructure. The obtained bandgap values, ranging from 1.55 to 1.62eV, closely align with theoretical predictions. The obtained results pose these structures as part of the 2D universe of other similar materials, such as TMDs-graphene, and open up exciting possibilities for new properties and applications.*

Intercalation Engineering of 2D vdW Magnet Properties *Eugene Park[1], Haihui Lan[1], Kate Reidy[1], Hanglong Wu[1], Paul Miller[1], Julian Klein[1], Zdenek Sofer[2], Prineha Narang[3] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Chemistry and Technology, Prague, Czechia; [3]University of California, Los Angeles, United States*

Van der Waals 2D magnetic materials have emerged as a novel platform that offers unique optoelectronic, magnetic, and quantum properties.[1] Such low-dimensional spin systems have vast potential in applications such as spintronics and nanoscale magnetic devices. Therefore, the ability to engineer the structure and defects with respect to magnetic, optical, and electronic properties is critical.

Here, we create a structural phase transformation on an A-type antiferromagnetic 2D magnet CrSBr via electron beam irradiation inside the transmission electron microscope (TEM).[2] This structural phase transformation reveals vdW gaps when imaged perpendicular to the original layers. Various transition metals are then deposited, followed by imaging, to study intercalation effects through the vdW gap. These experiments are carried out using an evaporator integrated with a TEM through an ultra high vacuum environment so that oxidation of the metals can be avoided. Density functional theory calculations quantify the electronic and magnetic ground state of the engineered 2D magnet. Lastly, in-situ heating during the intercalation process is carried out to study how temperature drives such processes. We believe that property tuning via intercalation at specific locations in a 2D magnet will offer opportunities to write magnetic/electronic textures for applications such as quantum simulators.

Chemical-Vapor-Deposition (CVD) Growth of Porous Two-Dimensional Polymer for Dielectric Applications in Microelectronics *Qiyi Fang[1], Jun Lou[2] and Yu Zhong[1]; [1]Cornell University, United States; [2]Rice University, United States*

Two dimensional polymers (2DPs) with designable structure and exciting physical and chemical properties, are increasing their interest for next generation technologies. In microelectronics area, the porous structures of 2DPs will lead to extra low dielectric constant (k<2), which can significantly decrease the interconnect crosstalk and reduce the resistance-capacitance (RC) delay. Distinct from other low-k dielectric, with process low thermal conductivity and low mechanical properties, benefit from the in-plane rigid covalent bonds and out of plane π-π stacking, 2DPs exhibit excellent mechanical and thermal properties, makes them promising low-k dielectric materials for next generation microelectronics. Here, we used CVD method to prepare a fluoride-rich 2DP (2DP-F) and measured its dielectric and mechanical properties. The CVD grown 2DP-F can confocally deposit on arbitrary substrates at low temperature and exhibited extra low-dielectric constant (~1.8) along with excellent Young's modulus (~18 GPa). We further integrated 2DP-F as dielectric interlayer in MoS2 field effect transistors. The inert surface of 2DP-F reduces the interfacial scattering between MoS2 and oxides, significantly increase the FET performance significantly. We also prepared hybrid 2DP-oxide structure based on vapor metal catalysts at low temperature (<200 C). These hybrid structures demonstrated a tunable dielectric constant across a broad range. Our results highlight the potential applications of 2DPs as both high-performance low-k and high-k dielectric materials for next-generation microelectronics.

Voltage Control of Magnetism in $Fe_{3-x}GeTe_2/In_2Se_3$ van der Waals Heterostructures *Jaeun Eom[1], Inhak Lee[1], Jung Yun Kee[1,2], Minhyun Cho[3], Jeongdae Seo[4], Hoyoung Suh[1], Hyung-Jin Choi[1], Yumin Sim[5], Shuzhang Chen[6,7], Hye Jung Chang[1], SeungHyub Baek[1], Cedomir Petrovic[6,7], Hyejin Ryu[1], Chaun Jang[1], Young Duck Kim[3], Chan-Ho Yang[4], Maeng-Je Seong[5], Jin Hong Lee[1], Se Young Park[2,2] and Jun Woo Choi[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of); [3]Kyung Hee University, Korea (the Republic of); [4]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [5]Chung-Ang University, Korea (the Republic of); [6]Brookhaven National Laboratory, United States; [7]Stony Brook University, The State University of New York, United States*

We investigate the electronic and magnetic properties of ferromagnetic/ferroelectric in $Fe_{3-x}GeTe_2/In_2Se_3$heterostructures. It is observed that gate voltages applied to the Fe_3xGeTe2/In2Se3 heterostructure device modulate the magnetic properties of Fe3-xGeTe2 with a significant decrease in the coercive field for both positive and negative voltages. Raman spectroscopy on the heterostructure device shows a voltage-dependent increase in the in-plane In_2Se_3 and $Fe_{3-x}GeTe_2$ lattice constants for both voltage polarities. Thus, the voltage-dependent decrease in the $Fe_{3-x}GeTe_2$ coercive field, regardless of the gate voltage polarity, can be attributed to the in-plane tensile strain. This is supported by density functional theory calculations showing tensile-strain-induced reduction of the magnetocrystalline anisotropy, which in turn decreases the coercive field. Our results demonstrate an effective method to realize low-power voltage-controlled vdW spintronic devices utilizing the magnetoelectric effect in van der Waals ferromagnetic/ferroelectric heterostructures.

2D MXene ($Ti_3C_2T_x$) Based Electrodes for the Hybrid Photo-Electro−Fenton Oxidation of Antibiotics *Durga Sankar Vavilapalli, Leiqiang Qin and Johanna Rosen; Linköping University, Sweden*

Wastewater containing recalcitrant and toxic pollutants are typically challenging to decontaminate in conventional wastewater facilities. Therefore, there is an urgent need for the development of powerful oxidation processes to ensure their green removal to preserve the water quality in the environment. An efficient and stable catalyst is essential for activating oxidants to produce reactive species for remediating water bodies contaminated by pollutants like antibiotics. In this work, an MXene-based electrode in the form of ferrocene (Fc) functionalized MXene (Fc-$Ti_3C_2T_x$) (cathode) and TiO_2 derived from MXene (anode) are used as electrodes for hybrid photo-electro-Fenton oxidation of antibiotic Tetracycline. The successful Fc functionalization of $Ti_3C_2T_x$ is confirmed by FTIR, XPS and UV-Vis spectrometry. In addition, a Ti_3C_2/TiO_2 Schottky junction electrode acts as a photoanode and enhances the photo charge carrier separation under UV-light illumination, which boosts the photo-electrocatalysis. The Fc-$Ti_3C_2T_x$ cathode acts as a stable Fe source for the Fenton reactions, and the hybrid oxidation process achieves a removal efficiency of over 90% for degrading antibiotic Tetracycline. The MXene-based electrodes are stable for five cycles with consistent degradation efficiency at different pH. The hybrid oxidation process can be adopted for the treatment of other persistent pollutants for environmental remediation.

11:30 AM NM05.16.13

Covalent Functionalization and Cross-Linking of 2H MoS2 and MXene *Shuwei Wu[1], Thiago Serafim Martin[1,2], Chengning Yao[1] and Felice Torrisi[1]; [1]Imperial College London, United Kingdom; [2]University of São Paulo State–UNESP, Brazil*

The hybridization of two-dimensional (2D) materials exhibits unique properties and opens up opportunities for new device designs and fabrication. Extensive efforts have been made to realize the stacking of different 2D material in a layer-by-layer fashion, forming van der Waals heterostructures[1]. To control the distance between flakes and construct 3D networks, the connection between different 2D material layers has also been achieved through covalent cross-linking. However, despite the well-developed synthetic strategies for carbon-based materials such as graphene, graphene oxide and carbon nanotube, covalent cross-linking remains underexplored for transition metal dichalcogenides (TMDs), especially for the semiconducting phases, such as 2H MoS2. This is due to the lack of dangling bonds on the TMD's basal planes, making them less reactive than their metallic counterparts and carbonaceous materials, and thus hindering the functionalization for further cross-linking steps. Functionalization of metallic MoS2 with organohalides and diazonium salts has been demonstrated [2,3], but a further annealing step is required in these processes to restore the semiconducting phase. While functionalization with organic thiols has been a widely accepted strategy for 2H MoS2, the nature of the interaction between the thiols and the MoS2 surface, whether physisorbed or covalently bonded, remains a subject of debate[4]. More recently, direct chemical functionalization of 2H MoS2 grown by chemical vapor deposition (CVD) has been reported, although this was limited to small-scale flakes on wafers.

In this study, we activated 2H MoS2 by introducing sulfur vacancies, which facilitated the grafting of aryl carboxylic groups using diazonium salts, resulting in a 13% surface coverage. The functionalized 2H MoS2 was then cross-linked with amino-decorated Ti3C2Tx MXene via a straightforward EDC/NHS reaction in aqueous media. The resulting 3D structure effectively prevents the restacking of these 2D materials and enhances the stability of MXene in aqueous environments by obstructing oxygen and water molecules through the cross-linked network.

This work introduces a novel strategy for the functionalization of semiconducting TMDs, enabling their use as building blocks for further cross-linking with zero-dimensional (0D), one-dimensional (1D), and two-dimensional (2D) materials, as well as biomolecules. The resulting hybrid materials hold promise for applications in sensors, energy storage and photodetectors.

The Impact of the Crystalline Carbide Phase on the Sulfurization of Ultrathin Tungsten Carbide Nanoplates

David Sanchez, Alexander J. Sredenschek, Jiayang Wang, Susan B. Sinnott and Mauricio Terrones; The Pennsylvania State University, United States

Recent efforts have been made to integrate layered (MXenes) or non-layered (ultrathin) transition metal carbides (TMCs) with layered transition metal dichalcogenides (TMDs) forming vertical or in-plane heterostructures [1, 2]. Pioneering work by Rothschild et al. implemented a hydrogen sulfide (H_2S) heat treatment process to synthesize core-shell non-layered tungsten monocarbide (WC), layered tungsten disulfide (WS_2) nanoparticles [3]. In this work, we will present a combined experimental-computational approach that highlights the synthesis and structural characteristics of crystalline, non-layered tungsten carbide [4, 5] and layered WS_2 heterostructures synthesized via a two-step high temperature sulfurization in H_2S. We have synthesized highly crystalline tungsten mono- and semi-carbide (WC, W_2C) nanoplates via a bottom-up liquid metal chemical vapor deposition (LMCVD) process. We found that a high temperature heat treatment in H_2S partially converted the tungsten carbide nanoplates into crystalline, multilayer WS_2. Through scanning/transmission electron microscopy (S/TEM) we surveyed the structural relationship between tungsten carbide and the converted WS_2 and identified two conversion modes corresponding to WS_2 on the edge and basal surfaces of tungsten carbide. On the basal surface, distinct moiré patterns were observed corresponding to epitaxial and twisted WS_2 layers. This combined experimental-computational demonstrates that the crystalline phase (WC or W_2C) of the non-layered ultrathin tungsten carbide is critical for converting to layered TMDs and forming novel TMC/TMD heterostructures.

Sulfurization of $NbTe_4$ Nanoparticles to Form $NbS_2/NbTe_4$ Heterostructures

Katherine Thompson, Alexander J. Sredenschek, Raymond Schaak and Mauricio Terrones; The Pennsylvania State University, United States

Niobium tetratelluride ($NbTe_4$) is a pseudo-one-dimensional (1D) material that exhibits fascinating electrical properties, and as a result it has been studied as a superconductor, charge density wave conductor, and phase change material. Traditionally, $NbTe_4$ has been synthesized through high temperature solid state reactions and thin film sputtering followed by thermal annealing, but we have demonstrated a low temperature solvothermal synthesis that results in nanocrystalline $NbTe_4$ particles through a diffusion-mediated formation pathway. Conversely, niobium disulfide (NbS_2) is a two-dimensional (2D) metallic material that has also been studied as a superconductor. Traditionally, it has been synthesized through chemical vapor deposition, solvothermally, and through high temperature solid state reactions. Here, we demonstrate a novel approach of synthesizing NbS_2 through the conversion of pseudo-1D $NbTe_4$ nanoparticles to 2D NbS_2. By heating the $NbTe_4$ below its melting point in an Ar and H_2S environment, the tellurium is removed and replaced by sulfur to partially or fully convert to NbS_2, while retaining the original rectangular morphology of the nanoparticles. Additionally, we probed heterostructure formation to better understand how the telluride to sulfide conversion is taking place. We utilized X-ray diffraction, scanning electron microscopy, transmission electron microscopy, and energy dispersive X-ray spectroscopy to determine the composition and heterostructure stoichiometry. This method demonstrates a facile way to synthesize rectangular particles of NbS_2 and $NbS_2/NbTe_4$ heterostructures. Our results could potentially be transferred to forming other nanoparticle-2D material heterostructures.

Characterization of Interfaces Between ZnO and Monolayer MoS_2 in the Epitaxially Prepared Heterostructure

Benjamin Derby[1], Gabriel Calderon Ortiz[2], Ahmed Towfiq[3], Yeonjoo Lee[1], Yeonhoo Kim[4], Jeongwon Park[5], Jinwoo Hwang[2], Michael T. Pettes[1], Kibum Kang[5] and Jinkyoung Yoo[1]; [1]Los Alamos National Laboratory, United States; [2]The Ohio State University, United States; [3]Pacific Northwest National Laboratory, United States; [4]Korea Research Institute of Standards and Science, Korea (the Republic of); [5]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Integration of incommensurate materials has become more important along advances in next-generation microelectronics and quantum information systems because the advances are based on novel functionalities which are not usually obtained by size and shape controls of a single material. Incorporation of two-dimensional semiconducting materials for ultimately thin transport channels in transistors is a representative example of integration of incommensurate materials. For the heterogeneous materials integration, stacking and growth of crystalline two-dimensional materials/conventional materials have been intensively studied.
Growth of crystalline materials on two-dimensional materials and vice versa is being considered as scalable and processing-compatible approach. However, the growth requires overcoming materials compatibility issue. Remote epitaxy based on lattice transparency across a two-dimensional material has been utilized as a solution to resolve the materials compatibility issue. As remote epitaxy research has been conducted in recent 7 years, understanding of interaction between the two-dimensional material and the overgrown layer has been expanded. The dominant mechanism of lattice transparency is being expanded by addition of other experimental observations, such as attenuative charge transfer. Most recent understanding of remote epitaxy mechanism implies that remote epitaxy is useful to control properties of the two-dimensional materials and the grown layers. Here, we present an example of interfacial phenomena induced by remote epitaxy. We prepared ZnO/monolayer MoS_2/ZnO heterostructure by remote epitaxy. The interface between ZnO and monolayer MoS2 was characterized by high-resolution scanning transmission electron microscopy, and four-dimensional scanning transmission electron microscopy. The atomic structure of the interface shows polarity inversion across the monolayer MoS_2. The inversion mechanism was explained by density functional theory calculation. Effects of the polarity inversion on microstructure and electronic properties were also investigated by cathodoluminescence microscopy.

Orientation Control of Layered Cobalt Oxides Thin Films *Tomohito Sudare[1], Ryo Nakayama[1], Kazunori Nishio[2] and Taro Hitosugi[1]; [1]The University of Tokyo, Japan; [2]Tokyo Institute of Technology, Japan*

Layered alkali cobalt oxides A_xCoO_2 (A: alkali metal) are promising candidates for thermoelectric applications, secondary batteries, and catalysts. Na_xCoO_2 exhibits a broad range of non-stoichiometric compositions with x varying from 0.5 to 1.0, and it is known to display four distinct crystal structures depending on the sodium content. Among these, γ-$Na_{0.5}CoO_2$ is a promising thermoelectric material, and the hydrated γ-$Na_{0.7}CoO_2$ demonstrates superconductivity. The physical properties of Na_xCoO_2 thin films are influenced by their crystallographic orientation. However, there are few systematic studies on the control of crystallographic orientation. In this study, we developed a novel synthetic route to obtain Na_xCoO_2 thin films by fabricating a stacked structure of sodium nitrate coating on a cobalt oxide thin film and subsequently heating it. The (001), (102), and (107) orientations of Na_xCoO_2 were successfully controlled by employing Al_2O_3(0001), $LaAlO_3$(100), and $MgAl_2O_4$(110) single crystal substrates, respectively. This presentation will discuss the detailed mechanism of film formation.

2:15 PM NM05.17.04

Novel dDesign of Epitaxial Quasi-2D Bi_2O_2(S, Se) *Li-Lun Chu[1], Li-Hui Tsao[1], Ming-Kuan Fan[1], Ching-Ming Su[2] and Ying-Hao Chu[1]; [1]National Tsing Hua University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan*

Since the discovery of graphene, the field of two-dimensional materials (2DMs) has emerged prominently and captivated researchers. This is primarily due to their exceptional characteristics, such as tunable bandgaps, distinctive planar structures, and high thermal and electrical conductivity. Moreover, these properties remain consistent even at atomic-scale thickness. Among the diverse range of 2DMs, bismuth oxychalcogenides (Bi_2O_2X, where X = S, Se, Te) have garnered significant attention in recent years due to their high electron mobility, air stability, and excellent photoelectric properties. Based on this foundation, bismuth oxychalcogenides are also considered candidates for the next generation of semiconductor materials. Therefore, precise control over the properties of these novel quasi-2D materials is crucial for practical applications. In this study, we aim to synthesize epitaxial thin films of Bi_2O_2(S, Se) with a compositional gradient of sulfur (S) and selenium (Se). Bi_2O_2S and Bi_2O_2Se exhibit strikingly similar structures, facilitating meticulous control over their blending ratios by tuning deposition proportions. This approach allows the modulation of electronic behaviors and crystal structures through variations in elemental composition. Our findings reveal that the lattice constants, band gaps, and electrical properties of the thin film exhibit nuanced shifts dependent on varying composition concentrations. Further, compared to the Bi_2O_2Se mobility of 148.7 cm^2/Vs, we have observed an increase in mobility to 191.1 cm^2/Vs in the Bi_2O_2(S, Se) compound. The outcome is expected to exhibit superior performance in electronic devices. With these efforts, this work not only establishes a pathway toward the development of novel designs for 2D materials but also holds the potential to significantly impact the field of materials science and engineering, opening new avenues for more applications in the future.

2:30 PM NM05.17.05

Unmasking the Hidden Doping Mechanisms in Misfit TMD Heterostructures—ARPES and Ab Initio Prediction of Incommensurate Electronic Structure Without Artificial Strain *Drake Niedzielski[1], Brendan D. Faeth[1], Berit H. Goodge[1,2], Mekhola Sinha[3], Tyrel McQueen[3,4,4], Lena F. Kourkoutis[1,1] and Tomás Arias[1]; [1]Cornell University, United States; [2]Max Planck Institute for Chemical Physics of Solids, Germany; [3]Johns Hopkins University, United States; [4]The Johns Hopkins University, United States*

Misfit heterostructures, such as $(LaSe)_{1.14}(NbSe_2)_2$, have been proposed as platforms for realizing heavily doped two-dimensional transition-metal-dichalcogenide (TMD) layers [1,2], which exhibit exotic quantum phases [2,3], *including Ising superconductivity [4]. Despite significant interest, the existence, extent, and nature of TMD doping in these materials has been a subject of contention [5], with many attributing the doping to an interlayer charge transfer. Although theoretical tools like density functional theory (DFT) are typically equipped to address these problems, the incommensurate nature of these misfit heterostructures hinders the use of conventional ab initio techniques. In this presentation, we extend Mismatched Interface Theory (MINT) [6] from single two-dimensional interfaces to three-dimensional layered heterostructures (MINT-Sandwich). This new approach allows us to perform ab initio studies on the misfits without introducing the artificial strain present in previous techniques.*

With our novel approach, we accurately predict the interlayer charge transfer in the misfit compound $(LaSe)_{1.14}(NbSe_2)_2$*. We further predict the incommensurate electronic structure, from which we extract the effective doping of the Fermi-level crossing bands. The excellent agreement between our ab initio predictions and angle-resolved photoemission spectroscopy (ARPES) measurements indicates that our novel MINT-Sandwich approach provides a highly accurate understanding of the electronic structure and the detailed charge transfer processes in this incommensurate material.*

Our results conclusively demonstrate, contrary to prior expectation, that the interlayer charge transfer and effective doping in $(LaSe)_{1.14}(NbSe_2)_2$ *differ by an order of magnitude. Through careful analysis of band hybridization and energy-resolved electron densities, we find that the formation of interlayer covalent bonds creates a net polarization between the layers, ultimately driving the observed effective doping. By interpreting this effective doping in terms of a polarized quantum capacitor model, we extend this insight towards the rational design of heavily doped heterostructures beyond the misfits. We then further discuss the use of our method in the calculation of electron-phonon linewidths and superconducting critical temperatures in incommensurate and twisted heterostructures.*

This work made use of the Platform for the Accelerated Realization, Analysis, and Discovery of Interface Materials (PARADIM), which is supported by the National Science Foundation under Cooperative Agreement No. DMR-2039380.

Exploring Screw Dislocations in Layered Transition Metal Dichalcogenides *Ganchimeg Yunden[1], Anar Ganzorig[1], Jamiyanaa Dashdorj[2], Munkhsaikhan Gonchigsuren[1], Otgonbayar Dugerjav[1], Batdemberel Ganbat[1], Jargalan Sereenen[1], Gurbadam Erdene-Ochir[1], Zagarzusem Khurelbaatar[1], Ganbat Duvjir[3] and Battogtokh Jugdersuren[4]; [1]Mongolian University of Science and Technology, Mongolia; [2]Chatham University, United States; [3]University of Ulsan, Korea (the Republic of); [4]U.S. Naval Research Laboratory, United States*

When a screw dislocation occurs during the growth process, it generates three-dimensional continuous spiral steps in the van der Waals layered transition metal dichalcogenides (TMDs). Besides their two-dimensional monolayers, these dislocation-driven layered TMDs are also being explored as potential materials for nonlinear optics and quantum electronics. Understanding the growth kinetics of these materials is crucial for the development of lab-on-chip devices. In this study, we report the growth of layered WS_2*, one of the popular TMDs, driven by screw dislocations using the NaCl-promoted atmospheric pressure chemical vapor deposition technique on* SiO_2*/Si substrate. The growth process was systematically explored by varying the crystal growth temperature, nucleation time, catalyst concentration, and argon carrier gas flow rates. Atomic force microscopy images reveal crystallographic step edges with heights ranging from a single monolayer (~0.7 nm) to several layers (~3 nm) between surface terminations, observed in hexagonal and triangular shaped screw dislocation patterns. Sharp dominant Raman spectra were detected at 419* cm^{-1} *in the center of the patterns and at 349* cm^{-1} *near the edges. Powder x-ray diffraction shows the strongest peak at =14.40, corresponding to the (002) plane. We discuss the potential for controlling the formation of screw dislocations in TMDs.*

3:30 PM NM05.17.07

Chemically Tailored and Phase-Selective Growth of 2D Semiconductors via Hybrid Metal-Organic Chemical Vapor Deposition *Zhepeng Zhang[1,2], Lauren Hoang[1], Marisa Hocking[1,2], Zhenghan Peng[1,2], Jenny Hu[1], Mihir Pendharkar[1,2], Elijah D. Courtney[1,2], Gregory Zaborski Jr.[1], Pooja Reddy[1], Johnny Dollard[1], Marc A. Kastner[1,2,3], David Goldhaber-Gordon[1,2], Tony F. Heinz[1,2], Eric Pop[1] and Andrew J. Mannix[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Massachusetts Institute of Technology, United States*

Two-dimensional (2D) semiconducting transition-metal dichalcogenides (TMDCs) are a leading platform for excitonic physics and next-generation electronics, creating a strong demand to understand their growth, doping, heterostructures and polytypes. Despite significant progress in solid-source (SS-) and metal-organic chemical vapor deposition (MOCVD), further optimization is necessary to grow highly crystalline 2D TMDCs with controlled doping and heterostructures. Here, we report a hybrid MOCVD (Hy-MOCVD) growth method that combines liquid-phase metal precursor deposition and vapor-phase organo-chalcogen delivery to leverage the advantages of both MOCVD and SS-CVD.[1] Using our hybrid approach, we demonstrate WS_2 *growth with tunable morphologies – from separated single-crystal domains to continuous monolayer films – on a variety of substrates, including sapphire,* SiO_2*, and Au. These* WS_2 *films exhibit narrow neutral exciton photoluminescence linewidths down to 27 – 28 meV and mobility up to 34 – 36* $cm^2V^{-1}s^{-1}$ *at room-temperature. Through simple modifications to the liquid precursor composition, we demonstrate the growth of V-doped* WS_2*,* $Mo_xW_{1-x}S_2$ *alloys, and in-plane* WS_2*-*MoS_2 *heterostructures.*

Moreover, rhombohedral polytype (3R) TMDC multilayers exhibit non-centrosymmetric interlayer stacking, which yields intriguing properties such as ferroelectricity, a large second-order susceptibility coefficient $\chi^{(2)}$ *for nonlinear optics, valley coherence, and a bulk photovoltaic effect. However, phase-selective growth strategies for 3R TMDCs are still underdeveloped and are especially lacking for multilayer films which strongly exhibit the desired optoelectronic characteristics. We facilitate multilayer growth of* WS_2 *by introducing a confined space into the Hy-MOCVD process.[2] The confined-space Hy-MOCVD method preferentially grows 3R multilayer* WS_2 *films with thickness up to 130 nm. We confirm the 3R stacking structure via polarization-resolved second harmonic generation characterization and via the threefold symmetry revealed by anisotropic* H_2O_2 *etching. The multilayer 3R* WS_2 *shows a dendritic morphology which is indicative of diffusion-limited growth. Multilayer regions with large, stepped terraces enable layer-resolved evaluation of the optical properties of 3R-*WS_2 *via Raman, photoluminescence, and differential reflectance spectroscopy. These measurements confirm the interfacial quality and suggest ferroelectric modification of the exciton energies.*

Bottom-up Synthesis of Highly Chiral Two-Dimensional Transition Metal Dichalcogenides Nanostructures

Lorenzo Branzi, Lucy Fitzsimmons and Yurii K. Gun'ko; Trinity College Dublin, The University of Dublin, Ireland

*Chiral nanomaterials have recently stimulated large interest in the scientific community due their potential applications in several technologically relevant fields, such as: sensing, catalysis and photonics.[1–3] The development of novel synthetic procedures to induce chirality in inorganic nanostructures is a challenging task, which has garnered the interest of researchers worldwide. In particular, the use of chiral ligands to passivate the surface of plasmonic and excitonic nanocrystals has shown to be an efficient technique to introduce chirality, giving rise to a plethora of inorganic nanostructures with unique chiroptical properties.[2] Assemblies of small nanoparticles into chiral structures have been successfully proven to expand the chirality of the single monomeric unit into a collective behaviour.[2] More complex nanostructure growth in the presence of a chiral ligand as a directing agent shows complex morphologies, hierarchical chirality and superior chiroptical properties.[4–6]
Two dimensional transition metal dichalcogenides (TMDCs) nanostructures have recently become of large research interest due to their potential broad range of applications spanning from photonics,[7] to energy storage.[8] Previous studies from our group reported the first observation of chiroptical properties in MoS_2 produced via top-down exfoliation in the presence of a chiral inductor.[9] However, top-down processes such as liquid-phase exfoliation are affected by several drawbacks, including a large degree of heterogeneity in the materials produced as well as poor control of nanostructure morphology and relatively low chiroptical activity. Due to these intrinsic issues related to the synthetic procedure, the fine control of the optical and chiroptical properties, the understanding of the origin of the symmetry break, as well as applications of the nanomaterials are challenging. For these reasons, we are currently investigating other strategies to produce chiral two-dimensional TMDCs with higher control of the nanomaterials' morphology. In particular, our investigation covers the introduction of chirality in bottom-up colloidal two-dimensional TMDCs. Bottom-up syntheses are well-known procedures successfully applied to produce high-quality 2D TMDCs nanostructures with high control on morphology, crystallographic structure and chemical composition.[10] Our observations demonstrate the induction of chirality in MoS_2 nanocrystals prepared by bottom-up synthesis, using chiral ligands to control the breaking of the mirror symmetry during the material formation. This approach allow accessing to nanocrystals with complex and tunable morphology as well as superior chiroptical properties. Moreover, our study dedicate particular attention to the origin of chirality and the involvement of chiral coordination complexes in the formation of the chiral inorganic nanostructures. Thanks to the superior control on morphology accessible by bottom-up methods, this strategy allows for the production of high quality chiral nanostructures with potential application in a broad range of technologically relevant fields.*

Structural Properties of InSe Thin Films Grown on GaAs(111)B and Si(111) *Maria Hilse[1], Derrick Shao Heng Liu[1], Justin Rodriguez[1], Jennifer L. Gray[1], Jinyuan Yao[1], Shaoqing Ding[1], Andrew Lupini[2], Mo Li[3], Joshua Young[3], Ying Liu[1], Joan M. Redwing[1] and Roman Engel-Herbert[4]; [1]The Pennsylvania State University, United States; [2]Oak Ridge National Laboratory, United States; [3]New Jersey Institute of Technology, United States; [4]Paul-Drude-Instit für Festkörperelektronik, Germany*

Urgent societal and environmental needs have sparked searches for high-mobility 2D layered materials with sizeable bandgap and decent stability under ambient conditions for potential use in ultra-low power, ultra-high performance field effect transistors. With a reported carrier mobility exceeding 1000 cm^2/Vs at room temperature, small electron effective mass, flat electronic band dispersions, excellent optoelectronic properties, possible ferroelectric properties and a close-to-ideal solar spectrum matched bulk bandgap of 1.26 eV, InSe shows high potential for future use in electronics. Due to the van der Waals layered nature, and the many members of different polytypes and polymorphs in the InSe materials family, intriguing confinement phenomena and exotic electron-hole coupling mechanisms tunable by the number of single layers add to the potential wealth of properties in InSe. In the presented study, InSe thin films were grown by MBE on GaAs(111)B and Si(111). The presence of many InSe phases and polytypes required a systematic and careful mapping of the growth parameters to identify conditions for single-phase, single-polytype, and single-crystal growth. Through structural characterization in- and ex-situ using reflection high-energy electron and X-ray diffraction, growth conditions for solely gamma-phase, crystalline InSe films were found. Although the structural properties of the films presented nearly unchanged over a small window of growth conditions, the film morphology was seen to sensitively depend on the Se:In flux ratio. Raman spectroscopy confirmed the phase and polytype assignment deduced from large-area structural characterization. Microstructure analysis, however, revealed a high degree of structural defects in the films. Nano-scale domains of varying single layer stacking sequences, high-angle rotational domains as well as single layers of unusual bonding configuration resulting in a novel InSe polymorph were found in the films. The total number of defects and the general locations of the new polymorph varied in films across GaAs and Si. The highest structural homogeneity was found for InSe films grown on Si.
Density functional theory calculations for a representative selection of the experimentally observed defects confirmed that most defects, including the novel polymorph have formation energies at or below the thermal budget of the MBE synthesis process. Although the bandgaps of all InSe polytypes and polymorphs possess comparable values, large differences were found in their relative offsets. Due to the random distribution of polytypes and polymorphs in the film, our study suggests a high degree of electronic disorder in these films. Electrical transport showed a variable-range hopping-like behavior supporting the hypothesis of electronic disorder.

Combinatorial Sputtering of 2D Layered ScTaN2 Thin Films *Baptiste Julien, Sage Bauers and Andriy Zakutayev; National Renewable Energy Laboratory, United States*

Ternary nitrides, composed of two metal cations and a nitrogen anion, exhibit unique electronic and thermal properties that make them suitable for a wide range of applications, including ceramic coatings, semiconductors,

permanent magnets, spintronics, topological materials, and superconductors. Among these, ABN_2 *nitrides, where A and B are metals, form layered structures analogous to layered oxides and are promising candidates for thermoelectric materials due to their two-dimensional electronic characteristics induced by the inherent nanolaminate character [1]. Despite their potential, the thin film synthesis of ternary layered nitrides, such as* $ScTaN_2$*, remains challenging due to the tendency of physical vapor deposition techniques to produce cation-disordered metastable phases [2].*
In this study, we investigate the Sc-Ta-N system, specifically focusing on $ScTaN_2$*, which has already been synthesized in bulk but never as a thin film. We employ a high-throughput combinatorial sputtering approach to create composition-graded libraries of* $Sc_xTa_{1-x}N$*, followed by rapid thermal annealing (RTA) to induce the transition from cation-disordered to ordered layered phases. Our results demonstrate that an annealing temperature of 1200°C is necessary to initiate the nucleation of the desired layered structure (s.g. P63/mmc). We further explore the stability of these layered motifs under off-stoichiometric conditions, highlighting unexpected stabilization of the layered phase for Ta-rich compounds, and revealing the formation of the layered nitride* Ta_5N_6 *(s.g. P63/mcm), structurally analogous to* $ScTaN_2$*. The tie line between the two compounds and the ability of Ta to accommodate multiple coordination environment shows that it is possible to gradually substitute Sc by Ta in the octahedral layers, inducing site-specific disorder, and keeping the inherent layered structure symmetry.*
X-ray diffraction, including synchrotron grazing-incidence wide angle scattering (GIWAXS), is utilized to characterize the crystal structures and identify various phases. Complementary oxidation state characterizations and crystal field analyses provide insights into the stabilization mechanisms of Sc-Ta-N layered compounds. Our findings contribute to the understanding of kinetic pathways for synthesizing new layered ternary nitrides by controlling cation ordering and therefore tuning properties, advancing their potential for energy harvesting applications.

Open Channel Metal Particle Superlattices *Chad A. Mirkin; Northwestern University, United States*

Although tremendous advances have been made in preparing porous crystals from molecular precursors, there are no general ways of designing and making topologically diverse porous colloidal crystals over the 10-1000 nm length scale. Control over porosity in this size range would enable the tailoring of molecular absorption and storage, separation, chemical sensing, catalytic and optical properties of such materials. Here, a universal approach for synthesizing metallic open channel superlattices with 10 to 1000 nm pores from DNA-modified hollow colloidal nanoparticles (NPs) is reported. By tuning hollow NP geometry and DNA design, one can adjust crystal pore geometry (pore size and shape) and channel topology (the way in which pores are interconnected). The assembly of hollow NPs is driven by edge-to-edge rather than face-to-face DNA-DNA interactions. Two new design rules describing this assembly regime emerge from these studies and are then used to synthesize 12 open channel superlattices with control over crystal symmetry, channel geometry and topology. The open channels can be selectively occupied by guests of the appropriate size and that are modified with complementary DNA (e.g., Au NPs).

Complex Biomimetic Materials with Nonrandom Disorder *Nicholas A. Kotov; University of Michigan, United States*

High-performance resource-conscious composites represent the critical bottleneck in nearly many modern technologies. Following the blueprints from Nature, these uniquely capable materials always contain a superposition of order and disorder that can also be cumulatively described as material's complexity. Performance and complexity are inherently intertwined because repeatable structural patterns at different scales must be synergistically integrated to obtain tunable combinations of application-specific properties. While being nonrandom, the structural patterns with large degree of stochasticity make it difficult to describe these complex materials using methodologies developed for crystals, quasicrystals, and glasses.
Recently we showed that structural patterns of high-performance nanocomposites can be accurately described, purposefully designed, and scalably reproduced using graph theory (GT), which is equally applicable to biological tissues and their technological replicas. Graphs, i.e. sets of nodes and edges, are able to capture both ordered and disordered components of high-performance composites. GT descriptors can quantify the structural pattern with both short- and long-range regularities. The fundamental significance of GT models as 'chemical formulas' of nanostructures and their practical utility in the materials design will be demonstrated by cartilage-like composites based on aramid nanofibers (ANFs, ***Fig. 1C,D****) for Zn ion batteries, Li-S batteries, and supercapacitors. The graph-property relations will be demonstrated based on ANF composites, nanoparticle gels, layered nanocomposites, and hierarchically organized hedgehog particles. The designed materials include ion-conducting, chiroptical and catalytic nanocomposites with unique combinations of toughness, solvent dispersibility, polarization rotation,*

temperature resilience and chemical activity.

Nanoscale Materials with Programmable and Reconfigurable States

Oleg Gang; Columbia University/Brookhaven National Laboratory, United States

The diverse emerging nanotechnological applications, from photonics to biomaterials and from computing to sensing, require the integration of functional nanocomponents into complex engineered architectures. While top-down fabrication methods are limited in creating 3D nanostructures, self-assembly typically does not provide flexibility and designability for creating targeted architectures. The talk will discuss our advances in DNA-programmable self-assembly for realizing designed finite-size and large-scale nano-architectures from diverse inorganic and biomolecular nanocomponents with a pre-defined organization at different scales in 2D and 3D. We developed a bottom-up fabrication strategy for programming and assembly of designed periodic and hierarchical organizations and established guiding principles to enhance their fidelity based on information-efficient encoding. The advances in creating reconfigurable systems with defined structural states and coupling reconfiguration processes at different scales will be demonstrated. The development of advanced characterization methods for revealing the 3D organization of nanoscale materials will also be discussed in the context of the presented self-assembly by-design approaches.

SESSION NM06.02: Customized Nanoparticles and Colloidal Assembly

Moving Beyond "Black Box" DNA Aptamer Screening Approaches Using Barcoded Libraries

Valeria T. Milam, Mary Catherine Adams and Steven Ochoa; Georgia Institute of Technology, United States

Single-stranded DNA ligands called aptamers are self-folded, single-stranded oligonucleotide sequences that act as a probe or ligand for a particular non-nucleotide target. While the nature of aptamer-target binding is largely unexplored, aptamers are often considered to be promising substitutes for antibodies which are more expensive and susceptible to irreversible denaturation. To find suitable aptamer candidates for our protein targets we developed a competition-based screening platform called CompELS or "Competition-Enhanced Ligand Screening" to circumvent complications arising from the conventional, yet laborious evolutionary aptamer screening approach called SELEX or "Systematic Evolution of Ligands by EXponential enrichment." To gain insight into the CompELS selection process itself, libraries were barcoded to mark the cycle number a particular aptamer candidate was selected. Following the completion of CompELS, the screening library, target-bound "winners" as *well as nonbinding "losers" were evaluated using high throughput, next generation sequencing (NGS) analysis. Data analysis indicates a majority of the screening library emerge as losers, but the winners are numerous and surprisingly diverse in their sequence composition. Moreover, competition appears to play a role in selection since relatively smaller percentages of barcoded winners ultimately survive the first few selection rounds. Finally, the lack of overlap of winners with the screening library suggests that the barcoded sequence data itself is likely incomplete with many sequences lost either during sequence recovery steps or during multi-step, chip-based sequencing analysis. Thus, while NGS serves as an exciting tool for aptamer candidate analysis and future library design efforts, the possibility of an information gap – even in big data sets – is likely overlooked in many aptamer screening studies. Ongoing work includes additional one-pot competition experiments to rank aptamers as effective ligands and to characterize binding affinities of select winners.*

2:00 PM NM06.02.02

Periodic Reentrance Phase Transitions in DNA Origami Superlattices *Daniel C. Redeker[1], Zohar A. Arnon[1], Tobias Dwyer[2], Daniel McKeen[1], Dayoung G. Lee[1], Timothy Moore[2], Sharon C. Glotzer[2] and Oleg Gang[1,3]; [1]Columbia University, United States; [2]University of Michigan–Ann Arbor, United States; [3]Brookhaven National Laboratory, United States*

Self-assembly of DNA origami polyhedral frames allows for the facile fabrication of designed ordered 3D nanomaterials. These DNA frames behave as patchy particles where short DNA extending from the vertices mediate directional inter-frame interactions. Frames with complementary DNA interactions assemble into superlattices with vertex-geometry dependent crystal phases. We discovered that linker mediated inter-frame interactions can change the coordination of DNA origami frames for the given frame geometry, effectively modifying frame valence. When frames are co-assembled with the complementary DNA linkers, crystalline superlattices of different phases are formed depending on the inter-frame coordination, as dictated by the linker motif. The combination of the frame geometry and linker molecular design dictate the resulting crystal structure. We show linker-mediated frames undergo a periodic reenterance phase transition with increasing linker length. The phenomenon was observed for frames with different geometry and exhibiting transitions between different phases, and the phase diagrams were mapped out. We provide a mechanistic understanding of the observed effect through a combination of experimental results from small-angle x-ray scattering and scanning electron microscopy, and computational simulation.

2:15 PM NM06.02.03

Acidification-Induced Structural Evolution Within Ionizable Lipid Nanoparticles Correlates with mRNA Transfection in Macrophages *Haitao Yu, Joshua Iscaro, Brendan Dyett, Calum Drummond, Steven Bozinovski and Jiali Zhai; RMIT University, Australia*

Lipid nanoparticles (LNPs) represent a revolutionary technology for mRNA delivery, offering potential in preventing and treating various diseases, including those addressed by the COVID-19 vaccines. Our recent research involves the development and characterization of LNP formulations using ionizable amino-lipids, including ALC-0315 and SM-102 from COVID-19 vaccines, along with innovative structure-forming helper lipids like monoolein and phytantriol. Using high-throughput small-angle X-ray scattering (SAXS) in Australian Synchrotron, we observed acidification-induced structural transitions in these ionizable LNPs from inverse micellar to hexagonal and cubic phases, within a pH range of 7 to 4, mimicking the endosomal environment. These transitions significantly enhanced the transfection efficiency in macrophages, with SM-102-based LNPs performing better due to their ability to form cubic structures at lower pH conditions.

Additionally, we explored how the components, such as cholesterol, stabilizers, and mRNA cargos, modulate *these phase transitions and mRNA transfection. Notably, the cholesterol-enriched formulations contributed to nanostructure transitions and protein corona variations, enhancing transfection efficiency in both immortalized alveolar and primary macrophage cell lines. Our ex vivo studies confirmed the capacity of these LNPs in reprogramming macrophages, highlighting their potential for cell-based therapies in lung diseases.*

Our findings elucidate the connection between LNP structural evolution and mRNA transfection efficiency, providing valuable insights for the design of next-generation LNP systems for therapeutic applications. This research underscores the importance of mesophase behavior in optimizing LNP formulations for targeted gene delivery and advancing the field of mRNA therapeutics.

Structure and Behavior of Fluorescent Core-Shell Silica Nanoparticles *Ulrich Wiesner; Cornell University, United States*

The synthesis and characterization of nanoparticles for the sustainable development of highly functional nanomaterials for applications ranging from bioimaging to nanomedicine has been the center of enormous efforts in the scientific community. Despite progress substantial challenges remain. This includes quantitative assessment of particle structural and compositional heterogeneities, in particular for nanoparticles obtained from batch reactions, as well as the development of synthesis approaches scalable to reaction volumes addressing industrial needs. In this talk a class of ultrasmall fluorescent core-shell nanoparticles are discussed comprising a fluorescent dye-encapsulating silica core and poly(ethylene glycol) shell. After describing batch synthesis methodologies in water as solvent toward ultrasmall particles sizes (hydrodynamic diameters below 7 nm) and high degrees of control over surface functionalization, new inorganic-organic hybrid nanoparticle characterization techniques are being introduced. This includes high-performance liquid chromatography (HPLC) and its coupling with gel permeation chromatography (GPC) to quantitatively assess hitherto inaccessible details of their structure, composition, and associated heterogeneities. In all cases experimental results are compared with computer simulations to fundamentally understand the origin of observed behavior and properties. At the end, a few highlights are presented of applications of these nanoparticles in the medical field of oncology.

3:30 PM *NM06.02.05
Flexicles—Cellular Assemblies of Colloidal Particles with Emergent Robotic Function *Sharon C. Glotzer,*

Sophie Y. Lee and Philipp W. Schoenhofer; University of Michigan, United States

The growing ability to design and synthesize patchy and self-propelled particles of arbitrary shape creates the potential for realizing active complex particle assemblies with emergent behavior that mimics biological systems such as unicellular organisms. In this talk, we propose the "flexicle" – a deformable cellular superstructure composed of self-propelled particles encapsulated by a flexible membrane. Using molecular dynamics simulations, we investigate the collective behavior of many-flexicle systems, demonstrating how shape deformability of individual flexicles gives rise to a diversity of motility-induced phase separation phenomena and the spontaneous flow of flexicles, reminiscent of cellular migration. We also show how individual flexicle "robots" are able to navigate through a series of different complex geometries. Our findings demonstrate a new, experimentally realizable, bio-inspired class of complex particle system capable of novel behavior and function.

4:00 PM NM06.02.06

Novel Concept of Electroconductive Scaffolds for Cardiac Tissue Engineering *Maksym Pogorielov[1,2], Kateryna Diedkova[1,2], Yevheniia Husak[3,2], Viktoriia Korniienko[1], Veronika Zahorodna[4], Oleksiy Gogotsi[4,2], Iryna Roslyk[4], Ivan Baginskiy[4,2], Una Riekstina[1] and Wojciech Simka[3]; [1]University of Latvia, Latvia; [2]Sumy State University, Ukraine; [3]Silesian University of Technology, Poland; [4]Materials Research Centre, Ukraine*

Despite advancements in cardiovascular disease treatments, such as pharmacological interventions and surgical techniques, tissue engineering offers significant potential to improve the rehabilitation and treatment of myocardial damage. Modern strategies, including both cell-based and acellular therapies integrated with tissue engineering, promise the development of three-dimensional, biomimetic, conductive scaffolds for heart tissue repair. However, the combination of electrical stimulation with these materials and their progression to clinical trials remains limited. Transition metal carbides, nitrides, and carbonitrides (MXenes), first introduced in 2011, have emerged as a rapidly expanding class of 2D materials. Due to their excellent electroconductive properties, MXenes are considered promising candidates for regenerative applications, including cancer treatment, tissue engineering, and targeted drug delivery. MXenes exhibit high biocompatibility and in vivo safety, meeting essential tissue engineering criteria. Our previous studies have shown that PCL-MXene electrospun fibers offer favorable conductivity and host responses, though challenges remain with PCL fiber pretreatments using acids or alkalis. To address these limitations, we applied oxygen plasma treatment to electrospun PCL membranes, followed by multilayer MXene integration, conducting comprehensive structural, functional, and biological assessments for cardiac tissue engineering applications.

In this study, we present a new technique for depositing $Ti_3C_2T_x$ *MXenes onto hydrophobic PCL electrospun membranes using oxygen plasma treatment. This method has significantly enhanced the fibers' size and pore structure while drastically lowering the membrane's contact angle, allowing for deep MXene impregnation. Importantly, this new deposition process does not alter the chemical characteristics of the PCL membrane and is not anticipated to introduce toxicity during degradation. The PCL-MXene composite membranes produced exhibit electroconductive properties essential for cardiac tissue regeneration, with no substantial differences observed between different MXene layers. Moreover, plasma-treated PCL-MXene membranes introduce hydrophilic groups (O- and OH-), reducing the contact angle and promoting cell attachment. All membrane types demonstrated excellent biocompatibility, evidenced by cell symplast formation on day 7 after seeding. Integrating MXenes into biodegradable PCL scaffolds presents a promising route to impart electroconductivity and enhance cellular response in tissue-engineered cardiac patches. These innovative patches could provide mechanical support to damaged cardiac tissue while facilitating electrical signal transmission, replicating the native tissue's electroconductive properties. Given the lack of variability in conductivity and cell proliferation among membranes, a single MXene deposition process is sufficient for creating cardiac tissue scaffolds. The remarkable electrical conductivity of PCL-MXene membranes, coupled with the positive biological outcomes presented in this study,* *has the potential to drive significant advancements in the field of cardiac tissue engineering. After further investigation into scaffold-cell interactions and electrical stimulation, this technique may be suitable for clinical use in not only cardiac regeneration but also neural and muscular tissue engineering applications.*

4:15 PM NM06.02.07

Artificial "Axons" from Optoelectronic Silicon for Studying the Role of Electrical Activity in Oligodendrocytes Governed Myelination

Menahem Y. Rotenberg and Liubov Akselrod; Technion–Israel Institute of Technology, Israel

Myelin is a protective lipid that encircles nerve cells that significantly increases action potential's propagation speed and efficiency. Myelin degeneration degrades neuronal function and is associated in many neurodegenerative diseases such as multiple sclerosis. In the central nervous system, myelination is governed by oligodendrocytes, and although electrical activity plays a major role in this process, the underlying mechanism is not well understood. Myelination was found to be promoted in electrically active nerve, while neuron-independent intracellular calcium transients within the OLs themselves were also found to affect this process. Interestingly, this question has been thus far approached by imaging spontaneous calcium transients and correlating them to myelination outcomes. However, electrically modulating the myelinating axons during this process may add another layer and help develop bioelectrical protocols to enhance and induce myelination.

The gold standard myelination in vitro model is using neurons and OLs co-cultures, however, these co-cultures are difficult to control as neurons have their own activity adding biological "noise" into the system. Thus, neuron free myelination models using nano- and micro-fibers that mimic axonal morphology were developed. However, although this reductionist approach allows robust and high throughout tool for studding different component of the myelination process, they lack the ability to induce local electrical activity.

In this study, we developed new bioinspired artificial "axons" (AAs) from silicon mesh designed to imitate neuronal morphology. We then used our previously reported approach for developing in situ porosity-based optoelectronic heterojunction to make these AAs photo-responsive. We hypothesized that by optically inducing electrical activity in AAs interfacing OLs, we will be able to study how electrical activity governs myelination.

We used silicon on insulator wafers with 4 mm thick device layer, and a silicon mesh was fabricated using photolithography and RIE. The mesh was comprised of 4 mm thick ribbons, mimicking axons, and 30 mm round nodes, mimicking somas. Then, hydrofluoric acid (HF) was used to remove the SiO2 under the device, exposing 70 mm long ribbons with a 4 mm square cross-section. The 4 min HF exposure was long enough to remove the oxide bellow the "axons", while leaving some oxide bellow the larger "somas" so that the device remains in place. We then used a combination of anisotropic KOH etching and isotropic stain etching (HF and HNO3) to round the corners of the square to achieve an axon like morphology of long ribbon with round cross-sections and nanoporous rough surface. Moreover, the nanoporous surface modulated the band structure of the silicon-electrolyte interface to generate a highly responsive optoelectronic "axon". Then, another HF etching was performed to remove the device from the handle layer and the device was transferred to a 3D collagen gel. Transferring it to the collagen gel served two purposes, the cells were allowed to grow in a 3D microenvironment, and silicon AA were the only photo-responsive material (no handle) so that the electrical activity comes from the AA alone, which mimics neurons in the native developing brain. Then, OLs were isolated from neonatal rat brains and cultured on the devices. We then applied optical stimulation of the device, and showed how optical stimulation enhanced the formation of myelin on the AA as compared to non-stimulated controls.

Overall, the new bioinspired AA we propose here allows the investigation of the role of electrical activity in the myelination process. This is done by enabling local electrical modulation that is originated from the AA itself, and not from an external stimulating electrode. This also lays the ground to induce local modulation of specific "axons" or even different location of the "axons" and study the resulting myelination outcome.

SESSION NM06.03: Hybrid Organic and Inorganic Composites
Session Chairs: Alon Gorodetsky and Andrea Merg
Tuesday Morning, December 3, 2024
Hynes, Level 1, Room 103

8:00 AM NM06.03.01
Flexible $Ti_3C_2T_x$ MXene-Cellulose Nanofiber Membranes—Structural and Optical Functioning *Valeriia Poliukhova[1], Justin Brackenridge[1], Botyo Dimitrov[1], Laura Mae Killingsworth[1], Jisoo Jeon[1], Mykhailo Yelipashev[1], Iryna Roslyk[2], James Fitzpatrick[2], Yury Gogotsi[2] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Drexel University, United States*

Controlled organization of $Ti_3C_2T_x$ MXene within polymer networks is crucial for harnessing its full potential as a versatile 2D material across a broad spectrum of applications. Cellulose nanofibers (CNFs), extracted from natural plant sources, are biodegradable and characterized by a high aspect ratio, providing a large interface area for interaction with MXene flakes. In this study we investigate the fundamental properties and interactions between cellulose nanofibers (CNFs) and $Ti_3C_2T_x$ MXene flakes, focusing on a unique CNF-dominant mixture with distribution of MXene flakes in flexible free-standing membranes obtained via vacuum assisted filtration. Unlike conventional MXene-CNF composites, which emphasize MXene's predominance for enhanced conductivity and mechanical strength, this research reverses the typical ratio, exploring the impact of MXene flake organization within a nanofiber matrix allowing to observe unique optical properties and photonic behavior of the membranes. These flexible and strong membranes demonstrate layered structure, high optical transparency up to 85% with a volume fraction of MXene flakes < 1%. Our study reveals that the $Ti_3C_2T_x$/CNFs composite membranes, with a thickness of 3-4 microns exhibit unique color variations for flakes under bright field reflection mode from the multiple scattering events within the disordered structure of the $Ti_3C_2T_x$ flakes in the cellulose matrix. This work's discovery expands our understanding of $Ti_3C_2T_x$/CNFs composites, illustrating their potential for advanced photonic applications.

8:15 AM NM06.03.02
Roughness and Nanoscale Wetting of Plant Surfaces Using Atomic Force Microscopy—Rose Petals, Olive and Lettuce Leaves *Jaime Colchero[1], Lisa Almonte[1,2], Pranav Sudersan[1], Victoria Fernadez[3] and Giovanni Saenz-Arce[1,4]; [1]Universidad de Murcia, Spain; [2]Universidad de Alicante, Spain; [3]Universidad Politécnica de Madrid, Spain; [4]Universidad Nacional, Costa Rica*

A precise understanding of the structure-function relation of many bio-inspired interfaces is still an open issue, in particular for the case of wetting. This understanding of wetting goes well beyond biological interest, since also in Material Science two characteristic wetting behaviors have the names where the effect is observed in Nature: the Lotus and the Rose Petal effect. While macroscopic wetting behavior has been extensively studied, nano-scale wetting studies have been limited due to their challenging nature. Here, we demonstrate that non-contact Dynamic Atomic Force Microscopy (nc-DAFM) is a valuable tool for characterizing the wetting of water on plant surfaces at the nano-scale. In humid conditions tip-sample interaction is caused by the spontaneous condensation of liquid water necks when the AFM tip is close to the surface [1], resulting in an attractive capillary interaction that depends on the nano-scale contact angle of water with the surface. We use Atomic Force Microscopy (AFM) to simultaneously measure nanoscale topography and chemistry of different plant surfaces:

Rose Petals [2] well as Lettuce and Olive leaves [3]. We generally find two features linked to their peculiar wetting properties, namely: (i) very high surface roughness concentrated on the nanoscale which in some cases may show fractal-like behavior ($d_f \approx 2.4$), and (ii) an extreme nanoscale variability of the wetting properties[2]. While high roughness is generally accepted to be the origin of peculiar wetting (super-hydrophobicity) the role of nanoscale chemical variability is generally discussed much less; most probably because -up to now- this variability could not be "seen" due to lack of experimental techniques.
From a more theoretical point of view, we propose to model the combination of topographic and chemical variability with a single nanoscale wetting parameter $w(x,y)=\cos(\phi_{chem})/\cos(\phi_{nano})$ where $\cos(\phi_{chem})$ is essentially the (chemical) contribution to wettability of a (flat) surface of a material, and $1/\cos(\phi_{nano})$ is the (local) increase of (nanoscale) surface area due to tilting (=roughness) of the surface normal. From our data, we conclude that biological surface may have a very complex morphology and an extreme variability of nanoscale wetting properties. The combined effect of roughness and chemical (nanoscale) wetting properties can induce a high effective nanoscale contact angle, which may explain the surprising wetting properties of many plant surfaces.
Finally, we believe the use of Atomic Force Microscopy (AFM) to simultaneously measure nanoscale topography and chemistry of different plant surfaces is a very powerful tool to study plant surfaces and their chemical variability on the nanoscale; therefore this work may thus trigger new research on wetting and bio-inspired functional surfaces.

8:30 AM *NM06.03.03
Photonic Bioderived Materials with Discrete Helical Organization *Vladimir Tsukruk; Georgia Institute of Technology, United States*

Local and global chirality control is essential for many prospective technologies, including lightweight tough materials, photonics, optical sensors, pharmaceutics, and electronics [1]. Natural polymers, such as polysaccharides and plant-derived nanocelluloses in particular, self-organize into hierarchical structures, enabling mechanical robustness, bright iridescent color and emission, and polarized light reflection. This set of biomimetic functionalities is engendered by individual components such as high-aspect ratio cellulose nanocrystals (CNCs) that naturally assemble into a left-handed helical pitch [2].
Here, we discuss how optically active films with pre-programmed handedness (left or right) can be constructed via layer-by-layer shear-induced 3D printing with clockwise and counter-clockwise twisted printing vectors [3]. The resulting thin films are transparent yet exhibit pre-determined mirror symmetrical optical activity dominated by linear and circular birefringence, enabling distinction of absorbed and emitted circularly polarized light (CPL) with different handedness. The resulting films possess complex light polarization behavior due to step-like changes in linear birefringence within each deposited layer and give rise to pre-programmed circular birefringence, not seen in conventional self-assembled films. Furthermore, intercalating an organic dye into the printed structures induces circularly polarized luminescence while preserving high transmittance and handedness. Furthermore, twisted CNC films with dual CPL and near-infra-red range (NIR) reflectance properties are demonstrated [4]. It is demonstrated that by manipulation of the process parameters of the discrete twisted helical organization– twisting angle and anisotropic block thickness – distinct CD patterns and transmittance could be achieved. We further show that the produced films could be treated as optical twisted metamaterials swinging between two extremes – a 1D photonic crystal aka Bragg stacks from anisotropic blocks and a conventional continuous chiral nematic phases. These twisted chiroptical metamaterials with tunable circular polarization, reflection, absorption, and

emission can be explored for optical filters, photonic coatings, chiral sensors, and optical encryption as well for achieving tailored photonic bio-skin and exoskeletons for visual camouflaging.

Sepiolite Nanofibers Decorated with Zn Single Sites—A Sustainable Filler for Mechanically Robust, Self-Healing and Recyclable Ionomeric Elastomer Composites *Massimiliano D'Arienzo[1], Paolo Valagussa[1], Marianella Hernandez Santana[2], Sofia Faina[1], Marta Colombo[1], Roberto Scotti[1], Barbara Di Credico[1], Silvia Mostoni[1] and Roberto Nisticò[1]; [1]University of Milano-Bicocca, Italy; [2]Instituto de Ciencia y Tecnología de Polímeros, Spain*

In light of the persistent challenges associated with the recycling of certain polymers, particularly elastomers, the imperative to align them with the circular economy paradigm has become fundamental, given their crucial role in diverse applications. One potential pathway to achieve this objective is to imbue the materials with self-healing properties.

Inspired by the energy dissipation and the spontaneous regeneration of sacrificial bonds in nature, several research efforts have been devoted to the incorporation of labile bonds into synthetic and natural rubbers for imparting both mechanical strength and self-repairing ability. However, significant issues arise considering the discrepancy between outstanding mechanical properties usually required for rubber-based products, which entails rigid and stable covalently bonded molecular network, and self-healing, which instead implies polymer chains mobility.

In this context, ionomers represent promising materials combining the processability of thermoplastics with the elasticity of rubber. The ionic interactions occurring in ionomers usually entail electrostatic interactions between anions, such as carboxylates and sulfonates, and cations from Group 1A, Group 2A, or from transitional metals. These ionic interactions produce thermoreversible physical cross-links (i.e. aggregates or ionic clusters), which exert a remarkable influence on the mechanical and physical properties of the polymer and underpins the self-healing behaviour.

Specifically, the possibility of generating reversible ionic dynamic interactions in rubbery matrices by ZnO introduction has been recently reported in the literature as a suitable and versatile strategy. It was demonstrated that, at a molecular scale, the Zn^{2+} cations of the oxide can form ionic interaction with the carboxylic groups of carboxylated nitrile rubber (XNBR) capable of thermoreversible association. However, the extended use of ZnO together with leaching phenomena occurring during the production and life cycle of rubber products, especially tires, raise potential environmental risks, as ecotoxicity toward aquatic organisms.

Moreover, despite all the endeavors, achieving good repairability and maintaining satisfactory mechanical performances in crosslinked elastomeric networks still remain major challenges.

Pushed by all these issues, the present work proposes the preparation and the exploitation of a novel multifunctional filler based on sepiolite nanofibers (Sep) decorated at the surface with Zn(II) single sites, able to enhance the reinforcement and to deliver thermally activated self-healing properties to carboxylated nitrile rubber (XNBR) composites, simultaneously.

In detail, naturally available sepiolite was functionalized by an amino-substituted silane (3-aminopropyl-triethoxysilane, APTES), which provided the coordination through the amino groups of single Zn(II) centers onto the

oxide surface. The structural, surface, and morphological features of the functionalized Sep fibers were extensively inspected by spectroscopic, morphological and thermogravimetric analyses.
The Sep@APTES-Zn filler was then included in XNBR to produce composites in which the formation of thermally reversible ionic crosslinks between the Zn^{2+} *cations and the carboxylate pendant groups of the polymer offers a route to rubber recovery after damage. Indeed, XNBR/*Al_2O_3*@APTES-Zn composites display excellent mechanical properties, remarkable self-repairability and pronounced recyclability, maintaining comparable tensile strength and elongation at break even after reprocessing. Finally, the structural stability of Zn(II) single sites during the curing, the processing and in the final materials provides a turning point toward the elimination of zinc leaching phenomena.*
These results may open new avenues to design and fabricate high-performance and sustainable rubber products with extended lifetime, with paramount fallouts for automotive and rubber components industries.

9:15 AM NM06.03.05
Bioinspired Surfaces and Templated Patterning for Tunable Wetting and Sensing *Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States*

Bioinspired examples in nature have been used to design and control wetting behavior. Superhydrophobic, superoleophobic, and omniphobic surfaces have many applications. It is a question of how robust they are against fouling. Different separation and membrane filtration methods can exploit this phenomenon by cleaning up emulsions or enriching proteins. Applications in coatings are vital for non-fouling and anti-corrosion properties. We have demonstrated in several ways that superhydrophobic surfaces - a play with the Cassie-Baxter and Wenzel wetting approaches can be prepared to have high-performance properties. Templating, polymer brushes, electropolymerization, and 3D printing affords superhydrophobic and superoleophilic properties. The following examples are described in this talk: 1) Super switchable bio-inspired lotus leaf surfaces with polymer brushes, 2) 3D printed and stereolithographic featured mapping of hierarchical non-wettable surfaces, and 3) nano colloidal assembly of compositional surface and enzyme-receptor inspired thin films These films have many qualities and applications in anti-corrosion, anti-bacterial, separations, filtrations, anti-icing and electrochromic properties. There is a path towards predicting these properties and optimized fabrication and characterization with AI/ML approaches.

Build-up Surfaces Without Template for Anti-Wetting Properties *Frederic Guittard, Thierry Darmanin and Sonia Amigoni; Université Côte d'Azur, France*

Inspired by various natural surfaces such as gecko foot or rose petal [1], the control of surface hydrophobicity and water adhesion is fundamental for various practical applications such as water-harvesting systems. Vertically aligned nanotubes are particularly interesting for their high surface-area-to-volume ratio and tunable porosity giving unique wetting properties [2]. The soft-template electropolymerization can lead easily and rapidly to controllable nanotubes. In water, hydrogen and oxygen gas bubbles can be generated during electropolymerization leading to porous structures [3]. In organic solvent, we demonstrated that in the presence of water, micelles are present in solution prior electropolymerization acting as soft-template for the polymer growth [4]. For forming nanotubes, it is necessary to favor the polymer growth in one direction (1-D). This is possible with monomers favoring p-stacking interactions [5] while the polymerization speed should not be also too fast. Very recently, we investigated molecules based on the triphenylamine core differing by the fashion of the thiophene or carbazole arms attachment (Figure 1). The geometry and electronic structures of monomers were studied computationally by DFT method at the B3LYP/6-31G(d) level of theory. The optimized geometries of the monomers are shown in Figure 1. The molecules are not flat because steric hindrances result in some distortion between the *conjugated units. Impressive results were obtained especially with carbazole in para-position.*

10:30 AM *NM06.03.07
Nanoarchitected Biological and Bio-Inspired Composites—Mitigation of Catastrophic Damage *David Kisailus; University of California, Irvine, United States*

There is an increasing need for the development of multifunctional lightweight materials with high strength and toughness. Natural systems have evolved efficient strategies, exemplified in the biological tissues of numerous animal and plant species, to synthesize and construct composites from a limited selection of available starting materials that often exhibit exceptional mechanical properties that are similar, and frequently superior to, mechanical properties exhibited by many engineering materials. These biological systems have accomplished this feat by establishing controlled synthesis and hierarchical assembly of nano- to micro-scaled building blocks. This controlled synthesis and assembly require organic that is used to transport mineral precursors to organic scaffolds, which not only precisely guide the formation and phase development of minerals, but also significantly improve the mechanical performance of otherwise brittle materials.

In this work, we investigate organisms that have taken advantage of hundreds of millions of years of evolutionary changes to derive ceramic-polymer based biological structures, which are not only strong and tough, but also demonstrate additional functionalities such as wear resistance, self-healing, self-cooling, etc. All of this is controlled by underlying organic scaffolding that dictates the spatial and temporal deposition of mineral. We discuss the nucleation, growth and subsequent phase transformations of architected materials found in one system demonstrating extreme wear resistance. We also discuss a regio-specific architected structure that includes multiple convergent design features that synergistically impart exceptional damage mitigation under extreme strained conditions.

From the investigation of synthesis-structure-property relationships in these extreme performance organisms, we are now developing and fabricating multifunctional engineering materials that leverage the design features from Nature. Thus, inspired by the exquisite control of these biomineralized structures, we utilize organic templates to carefully orchestrate the synthesis of nanostructured materials. By modulating ratios of precursor and organic, as well as controlling other synthetic variables, we can tune morphologies which are subsequently implemented into engineered structures and subjected to mechanical testing. The results of these tests validate observations in the *biological structures, demonstrating significant protection against impact and offer potential use in multifunctional applications.*

11:00 AM *NM06.03.08

Preparation of Structured Biomimetic Composite Materials Through Magnetic Control of Sol-Gel Phase Transitions *Marco Lattuada; University of Fribourg, Swaziland*

Nanocomposites are an important class of materials with unique properties resulting from combining the matrix and the dispersed phase. Being able to control the structure of the disperse phase is paramount to maintaining the final properties of the material. Here, we present a new strategy for the preparation of bioinspired composite materials by using magnetic colloids to control the structure of a silica gel phase by magnetically manipulating the sol-gel phase transition. The gel phase was then used as a skeleton to prepare a polymer-inorganic hybrid material. Magnetic colloids were added to the silica sol precursor solution, and a magnetic field was applied during the sol−gel transition. A static field led to a fiber-like structure, with silica fibers aligned in the direction of a field. Conversely, when exposed to a rotating magnetic field, magnetic colloids organized in layers parallel to the plane of rotation of the field and template the growing silica phase, resulting in layered anisotropic silica reminiscent of the inorganic structure of nacre. The final nanocomposite materials were created by filling the porous structure with a monomer, which led to an elastomer upon polymerization. Compression tests of the structured composite show that their mechanical properties far exceed those of nonstructured composite materials with an identical chemical composition. Furthermore, more complex silica structures have been obtained by creating a structured silica gel, impregnating it with a second sol solution containing magnetic colloids, and applying a magnetic field in a different direction. In this case, silica gels with a fiber structure connected by perpendicular rods connecting them, or layered silica gels with rods perpendicular to the layer and connecting them were obtained, eventually leading to even stronger composite materials with defined anisotropy and with a complex architecture could be prepared. These structures remind us of the complex architecture of bones, shells, and other biological materials.

The More Exercise, the Better—Bone-Inspired Microporous Composites Enhancing Both Load-Bearing and Energy-Dissipation Capabilities Under Cyclic Loading *Sung Hoon Kang; Johns Hopkins University, United States*

Similar to the aging process of our body, materials suffer progressive degradation of their properties over time under repetitive loading that limits the performance and the lifetime of parts. This results in significant costs associated with inspection, maintenance, and downtime. Moreover, materials used in various applications, from soft robotics to spacecraft, require specific performance combinations such as stiffness and dissipation. However, improving one aspect of a material's performance often sacrifices performance in other properties, commonly referred to as performance tradeoffs, limiting the feasibility of creating materials with optimal performance profiles. To address these challenges, we report a liquid-infused microporous composite that dynamically enhances both load-bearing and energy-dissipation capabilities under cyclic loading and shows a reprogrammable self-folding behavior based on the spatial distribution of mechanical loading. For example, the *modulus and the energy dissipation of the material increased by 3,600% and 3,000%, respectively, after 12 million loading cycles. To understand the correlation between microstructure, change, and material performance, we utilized a sub-micrometer resolution computed tomography for in-situ characterizations of the material during loading and unloading. This remarkable behavior is achieved in a bone-inspired process by inducing mineralization from an infused liquid electrolyte upon mechanical loading. Furthermore, similar to bone, which changes its bone mineral density distribution based on the applied loading, the material can be (re)programmed to generate various shapes by self-folding based on the spatial distribution of mechanical loading. We anticipate that our findings provide stepping stones toward unprecedented opportunities in multiple fields, including soft robotics, vehicles, infrastructure, and tissue engineering/medical devices, and can contribute to changing the paradigm of material selection with improved resilience and sustainability.*

SESSION NM06.04: Multifunctional Composite Materials and Surfaces
Session Chairs: Maksym Pogorielov and Tiffany Walsh
Tuesday Afternoon, December 3, 2024
Hynes, Level 1, Room 103

1:30 PM *NM06.04.01
***Nano- to Micro-Scale Communication in Biomimetic, Chemically Active Posts** Moslem Moradi, Oleg Shklyaev and Anna C. Balazs; University of Pittsburgh, United States*

The rich, collective dynamics exhibited by biological cilia has prompted researchers to probe cooperative behavior in synthetic analogues, i.e., arrays of closely spaced, stimuli-responsive gel posts that are tethered to the surface of a fluid-filled chamber. For these dense arrays, cooperative behavior is facilitated not only by action of external stimuli, but also by the close proximity, which enables physical contact between the neighboring posts. There has, however, been little attention paid to cilia-like arrays in the opposite limit, where the tethered posts lie relatively far apart and do not rely on external fields for their actuation. Such studies are key to designing biomimetic synthetic systems that can spontaneously transmit long-range signals to distant components and thereby achieve greater control over the entire system. We model arrays of well-separated elastic posts in solution that are solely responsive to dissolved chemical reactants. A few of these posts are coated with a catalyst and thus, are chemically active; the remaining non-coated posts are passive. Through theory and simulation, we find that chemical reactions occurring at the immersed, active posts generates a surprising variety of long-range, cooperative interactions in a sparse array, including stable and unstable behavior; damped and highly damped oscillations; and non-reciprocal self-oscillations. Designing self-oscillating chemical systems, which convert constant input into oscillating output, remains a significant challenge. Oscillatory behavior is, however, vital to achieving self-regulation in synthetic materials; oscillating systems are constrained to operate within a certain parameter range and thereby maintain normal operating conditions.
The dynamic versatility and self-regulation found in these systems allow, for example, one non-oscillating active post to initiate synchronized oscillations between two passive ones. Furthermore, one active oscillating post and two passive ones can communicate to synchronize the oscillations among all three. We also find that a single array with two chemically different active posts can simultaneously produce and sustain different modes of motion in the array. Moreover, with different catalyst coatings, one can address and actuate individual posts by selectively adding the appropriate reagent to trigger the specific reaction. For this system, the combination of chemistry, hydrodynamics and fluid-structures causes the array to propagate a distinct message; each post to interpret the message; and the system to respond with a specific mode of organized, collective behavior. This level

of autonomous, remote control is relatively rare in synthetic systems, particularly as this system operates without external electronics or power sources. Eliciting the system's dynamics only requires the addition of chemical reactants.

The behavior of these chemically active posts is driven by solutal buoyancy, which arises as the catalytic reactions at the active posts transform reactants into products. If the volumes occupied by the reaction products are different from those of the initial reactants, then the solution will encompass local gradients, which generate forces that act on the confined fluid, the posts and walls of the chamber. The chemically generated flow in turn performs mechanical work as it actuates and deforms the compliant pillars. The flowing fluid continues to advect the dissolved chemicals to the active posts and through the above cascade of interlocking events sustains this chemo-mechanical coupling.

Bioinspired Multifunctional Composites—Processing, Mechanics and Functionalities *Tommaso Magrini[1,2]; [1]Technische Universiteit Eindhoven, Netherlands; [2]California Institute of Technology, United States*

Progress in lightweight composites design and manufacturing is paramount for the growth of an energy-efficient aircraft and transportation sector. However, designing composites with high strength and high fracture toughness remains an open challenge due to the trade-off between these properties in most synthetic materials. Replicating the hierarchical internal architecture of mollusk shells, I developed a novel class of strong and tough composites, reinforced across multiple length scales, from the nm- to the mm- scale. This new material platform allows to unveil the mechanisms responsible for high crack growth resistance in hierarchical architectures, and to address the timescale at which each mechanism activates during damage. Using in situ controlled mechanics and fracture testing, in combination with optical and electron microscopy, I visualize and study the mechanisms of fracture propagation. Furthermore, introducing stress-sensing functionalities in the organic phase of the composites, I use simple optical readouts, like color changes, to quantify the role of the matrix during composite fracture, and to preemptively detect the fracture trajectory during loading. In my presentation, I will highlight how multifunctional bioinspired composites can combine high mechanical performance and novel functionalities, and how these provide new insights into the interplay of multiscale toughening mechanisms, offering guidelines for the design and manufacturing of superior hierarchical composites.

2:15 PM NM06.04.03

Bioinspired Self-Healing Metal Oxide Coatings—A Novel Vapor Phase Approach for Enhanced Durability in Transparent Conductive Materials *Oksana Yurkevich[1] and Mato Knez[1,2]; [1]CIC nanoGUNE, Spain; [2]Ikerbasque, Spain*

In nature, biological systems have evolved remarkable self-healing capabilities that allow them to repair damage and maintain functionality over time. Inspired by these natural processes, the field of materials science has been increasingly focused on developing synthetic materials with similar self-healing properties. This research is particularly important in view of functional coatings, where maintaining integrity and performance over extended periods is essential for various applications.
We have developed a fundamentally new approach for creating self-healing metal oxide coatings on polymers,

drawing inspiration from biological repair mechanisms. This class of materials is of special interest as very few successful strategies to self-repair semiconductors have been demonstrated by now. Our method addresses a significant challenge: the longevity and durability of functional coatings, particularly those used in flexible electronic devices and other applications subject to mechanical stress.

The core of our approach involves the growth of well-dispersed metal oxide nanoparticles (NPs) within polymer matrices from the vapor phase. These hybrid systems are designed to facilitate the controlled diffusion and aggregation of the nanoparticles in response to damage, mimicking the way biological systems mobilize resources to heal wounds.

We focused primarily on ZnO and In_2O_3*, materials that are fundamental components of transparent conductive oxides (TCOs). These TCOs are crucial in various technologies, including touch screens, solar cells, and smart windows. The self-healing process we've developed is triggered when the coating is exposed to air following damage. This exposure initiates a sequence of events driven by an entropic penalty within the metal oxide/polymer hybrid system. This entropic force causes the metal oxide nanoparticles to migrate towards damaged sites and microcracks, effectively sealing them and restoring the coating's integrity.*

To test the efficacy of our system, we artificially induced defects in the coatings and observed their behavior upon exposure to air. The results showed that the damaged areas became sealed through the migration and aggregation of the nanoparticles. This self-healing capability has significant implications for the longevity of coatings, particularly in applications where mechanical bending is common.

One of the most promising aspects of our research is its potential to address a common issue in flexible electronics: the formation of cracks due to repeated bending. Our methodology demonstrates that these cracks can recover to a certain degree, which could significantly extend the lifespan of devices incorporating these materials. However, the implications of this work extend beyond just TCOs. The principles we've uncovered could potentially be applied to a wide range of functional coatings, opening up new possibilities in fields such as protective coatings, smart materials, and adaptive surfaces.

Our work represents a significant step forward in the development of bioinspired materials. By harnessing principles observed in nature and applying them to synthetic systems, we've created a novel class of self-healing coatings that could revolutionize the durability and functionality of various technologies.

In conclusion, our bioinspired approach to creating self-healing metal oxide coatings represents a significant advancement in materials science. By bridging the gap between biological self-repair mechanisms and synthetic materials, we've created new avenues for the development of more durable and adaptive functional coatings. This research not only enhances our understanding of self-healing processes in hybrid materials but also paves the way for the next generation of smart, resilient materials that could transform various technological fields.

2:30 PM *NM06.04.04

Functionalisation of Soil Minerals with Organic and Biomolecules—Insights from Computational Modelling

Natalia Martsinovich; The University of Sheffield, United Kingdom

Binding of naturally occurring organic molecules on oxide mineral surfaces is a key process in soil chemistry, since sorption enables protection of these organic molecules from microbial degradation in soil. To understand the nature and strength of sorption of organic molecules on soil minerals, we investigated the binding of small organic molecules and larger polysaccharide biomolecules (typical building blocks of soil organic carbon) on a-Al_2O_3*, a common soil mineral which is known to strongly bind organic matter. Our study aimed to determine the types of organic functional groups and biomolecules that display strong mineral-biomolecule binding and thus can be used to functionalise mineral surfaces [1,2].*

Calculations of adsorption on the a-Al_2O_3 *(0001) clean and hydroxylated surface were carried out using density functional theory (DFT) with empirical dispersion correction. A number of organic functional groups were identified, such as carboxylic acid, amine and amide, which adsorb on the a-*Al_2O_3 *(0001) surface strongly and are* *likely to bind to this mineral surface under ambient conditions. Hydrogen bonding was found to play a key role in adsorption of organic molecules; the clean a-Al_2O_3 surface was found to favour dissociation of adsorbed molecules, while molecular (non-dissociative) adsorption was preferred on the hydroxylated surface. Informed by these insights into the adsorption of small molecules, we modelled adsorption of biomolecules - fragments of naturally occurring polysaccharides: cellulose, chitin, chitosan and pectin, on the hydroxylated a-Al_2O_3 (0001) surface. These biopolymers were able to adopt a large variety of adsorption configurations; their strength of adsorption was controlled by the flexibility of the adsorbates' conformations and the number of interfacial hydrogen bonds. Cellulose, pectin and chitosan could adsorb particularly strongly, and therefore are likely to be stable in the soil environment and can be proposed as good candidates for functionalising mineral surfaces.*

3:00 PM BREAK

3:30 PM *NM06.04.05
***A Peptide Toolkit for Precision Assembly of Helical Nanoparticle Superstructures** Nathaniel Rosi; University of Pittsburgh, United States*

Nanoparticles are a class structural and functional building blocks for the construction of new materials. The properties of these materials depend on the size, shape, and composition of the constituent nanoparticles as well as their 3-D organization within the material. We have introduced and developed peptide-based molecular methods to direct and adjust the structure and properties of helical nanoparticle superstructures. This presentation will describe how and why subtle atomic-level modifications of the peptide constructs can lead to significant structural changes to the helical superstructures, and it will highlight how we can deliberately tune peptide sequence to fine tune structure and properties. In addition, methods for controlling the length and structural stability of the helices will be detailed.

4:00 PM NM06.04.06
***Super-Strong and Super-Tough Aramid Nanofiber Film** Jiongke Jin, Xunen Wu and Yingying Zhang; Tsinghua University, China*

Aramid, as a high-performance mechanical fiber, has played a crucial role in structural materials, equipment light weighting, and personal protection fields. In recent years, it has shown broad prospects in emerging areas such as energy storage, sensing, and soft materials. Its excellent properties stem from rigid polymer chains, high crystallinity, and extensive non-covalent interactions. However, limited by its non-melting and insoluble nature, the processing methods and material forms of aramid are restricted. In this work, aramid nanofibers were prepared from top-down exfoliation as the matrix, with the same molecular composition as macroscopic aramid, to fabricate aramid nanofiber composite films. On one hand, the size and surface charge properties of nanofibers were controlled to achieve excellent microscale interface stress transfer when combined with large-sized graphene oxide sheets. DFT calculations show strong interactions between ANF and GO, resulting in an overall energy decrease of 6.39 eV. On the other hand, small-sized polyvinyl alcohol micelles were introduced to minimize inherent structural defects such as bubbles and cracks, thereby enhancing system density and microscale stress transfer efficiency. After optimization, the composite film obtained in this work exhibited significantly improved strength and toughness compared to pure aramid nanofiber films, reaching 599.0 MPa and 37.7 MJ m^{-3}, respectively, representing an increase of 491.0% and 1094.5%. In addition to mechanical properties, the aramid *nanofiber composite film also demonstrated excellent resistance to extreme temperatures and mechanical fatigue, maintaining good mechanical performance after 8 hours at 300°C and 10,000 cycles of 180° folding, further highlighting the superiority of the synergistic strategy.*

4:15 PM NM06.04.07

Design of Light-Triggered Bioinspired Starch-Based Nanocomposites *Sara Fernanda Orsini[1], Laura Cipolla[1], Simona Petroni[1], Sandra Dirè[2], Riccardo Ceccato[2], Emanuela Callone[2], Roberta Bongiovanni[3], Luisa Raimondo[1], Silvia Mostoni[1], Barbara Di Credico[1], Roberto Scotti[1], Roberto Nisticò[1] and Massimiliano D'Arienzo[1]; [1]University of Milano-Bicocca, Italy; [2]Università di Trento, Italy; [3]Politecnico di Torino, Italy*

Food waste represents a significance fraction of the whole waste production, and this study proposes an original synthetic strategy to valorize organic wastes in the development of a new packaging material, recyclable and able to ensure a longer shelf life to food. The idea is to manufacture transparent composites employing as raw materials starch and mineral fillers.

As widely reported, starch is an environmentally friendly alternative to the common petroleum-based plastics used in packaging and could be combined with silica and natural silicates to improve its mechanical properties. In fact, silicate-based nanoparticles (NPs) represent a powerful platform due to their high versatility connected to the possibility of easily modulating surface properties. This leads to specific and unique applications, such as the formulation of smart materials which have the ability to change their properties when exposed to external stimuli (pH, heat, light). Along this line, innovative key point of the project is the introduction of photoreversible cross-linking groups on both polymer and filler surfaces for the development of light-triggered biodegradable composites.

We here propose an innovative synthetic way to functionalize both yuca starch and silicate-based NPs with cinnamyl group (CINN) units, as natural and beneficial moieties capable of undergoing photoreversible dimerization through [2+2]-cycloaddition reaction. In detail, natural yuca starch was modified by a tailored etherification protocol that provides good flexibility to the two double bonds undergoing photodimerization. The functionalization of cinnamyl starch with three different degrees of substitution was assessed by NMR spectroscopy, revealing the generation of a covalent ether bond between the starch and the cinnamyl moieties. Furthermore, the photochemical properties of the systems were preliminarily verified by UV-Vis and NMR spectroscopy. Besides unveiling a competition between photodimerization and isomerization reactions, the results confirmed a partial but successful cross-linking reaction trough the [2+2]-cycloaddition of the double bond of the cinnamyl units.

Photo-responsive materials made of silica and sepiolite NPs bearing cinnamyl units, able to cross-linking with cinnamyl starch, were also developed. A new trialkoxysilane (CINN-APTES) covalently derived with cinnamic acid was firstly synthesized starting from 3-aminopropyltriethoxysilane (APTES). Upon structural assessment by NMR spectroscopy, the new molecule was exploited for functionalizing the surface of silica and sepiolite NPs. The covalent bond to the surface was confirmed by FTIR and solid-state NMR spectroscopy, whereas thermogravimetric and CHNS elemental analysis unveiled a functionalization degree much higher compared to that achieved by a conventional double-step post-grafting procedure. A proof of concept of the photoreversibility of the obtained fillers has been carried out.

Finally, filler and starch functionalized with cinnamyl groups were exploited for the preparation of light-triggered nanocomposites, whose photoreversible and mechanical features are currently under examination. Preliminary results envisage their potential application for smart packaging products.

4:30 PM *NM06.04.08

Peptoid-Controlled Synthesis and Assembly of Inorganic Nanocrystals *Chun-Long Chen[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States*

In nature, biominerals (e.g. bones and teeth) are excellent examples of hierarchical composite materials with nanocrystal synthesis and assembly controlled over multiple length scales by high information content biomacromolecules. Inspired by nature, many biomimetic approaches have been developed for the synthesis and assembly of inorganic nanocrystals. These approaches are attractive because they generate complex, functional materials under mild aqueous synthetic conditions.[1,2]

As one of the most advanced classes of sequence-defined peptide-mimetics, peptoids offer great opportunities for the design and synthesis of bioinspired hierarchical composite materials.[3,4,5] Due to the lack of backbone hydrogen bonding, peptoid-peptoid and peptoid-surface interactions can be tuned solely by varying side-chain chemistry.[1,5] Recently, amphiphilic peptoids have been often used as programmable building blocks to generate various crystalline nanomaterials due to the well-controlled hydrophobic interactions.[1,3,6] In this presentation, two peptoid-based approaches will be discussed for the synthesis and assembly of inorganic nanocrystals. The first involves the design and synthesis of surfactant-like peptoids for controlling the formation and morphogenesis of inorganic nanocrystals. The second approach exploits the well-controlled hydrophobic interactions of self-assembling peptoids for controlling both synthesis and assembly of inorganic nanocrystals into hierarchical materials. A combination of in situ imaging (e.g. in situ TEM) and molecular simulations were used to elucidate the principles underlying peptoid-controlled composite materials synthesis.

SESSION NM06.05: Designer Biomolecular and Hybrid Materials
Session Chairs: Alon Gorodetsky and Frederic Guittard
Wednesday Morning, December 4, 2024
Hynes, Level 1, Room 103

8:00 AM NM06.05.01

Defective Quantum Dot Composite-Based Broad-Spectrum UV Blockers with Self-Cascaded In Situ O_2 Generating Potency and Superior Biocompatibility *Sayoni Sarkar and Ajit Kulkarni; Indian Institute of Technology Bombay, India*

Advancing the defect-mediated photophysics and surface chemistry-informed design of nanostructured active *ingredients by prioritizing affordability, safety, and multifunctionality is crucial for sun protection. Herein, β-cyclodextrin modified, oxygen vacancy (OV) engineered $CeO_{2(x)}/ZnO_{(1-x)}$ quantum dot composites (OV-QDs) are developed as multipronged active ingredients (AIs). Structure-property correlations employing HR-TEM, XPS, EPR, UV-Vis and PL spectroscopy unveiled long-lasting photostability (>5 h) and extension of the absorption spectra to UV and visible regime (250 nm–600 nm) via OV-driven band re-structuring and photogenerated charge separation. Unlike existing nano-inorganic AIs, these QD composites utilize OVs for a self-cascading antioxidant phenomenon, achieving 62.8% annihilation of toxic hydroxyl radicals. Intriguingly, investigations indicated that in-situ O_2 evolution from H_2O_2 scavenging, facilitated by the Ce^{3+}/Ce^{4+} redox switch, provides anti-photoaging and sunburn relief. OV-QDs exhibited synchronous oxidative stress inhibition and exceptional cell viability (≥90%) even under UV exposure. These fundamental rationales can assist in treating and preventing several ROS-induced diseases. Sequential experiments unravelled that incorporating an optimum composition of OV-QDs comprising 30 weight% of CeO_2 and 70 weight% of ZnO QDs significantly ameliorated overall photoprotection and ROS scavenging potency. These photochemically inert yet biosafe sunscreen AIs are promising candidates for formulating next-generation cosmetics.*

8:15 AM NM06.05.02

Folding and Self-Assembly of Nucleic Acid Nanostructures Mediated by Charged and Charge-Switching Peptides *Zhishang Li; Arizona State University, United States*

DNA and RNA nanotechnology provides a versatile toolkit for designing precise and sophisticated nanostructures for a wide range of applications in materials and biomedical sciences. Traditionally, the folding of DNA and RNA nanostructures requires non-physiological conditions, such as thermal annealing and high metal concentrations, which are necessary to overcome kinetic traps and to achieve the energetically favorable folded/assembled state. These conditions are not ideal for applications in biological environments. Here, we demonstrate that positively charged peptides could fold DNA and RNA structures efficiently under physiological conditions with high yield comparable to traditional thermal annealing protocol. This methodology is widely applicable to various constructs including DNA tiles, DNA origami, and single-stranded RNA origamis. Furthermore, the incorporation of functional peptides allowed for the design of customizable systems where the self-assembly is responsive to specific stimuli. For instance, modulating the peptide's positive charges through the addition of a phosphate group can produce peptides whose charges can be controlled by phosphatase. Based on these charge-switching peptides, we demonstrated the folding of DNA origami structures in response to phosphatase at physiological conditions. This research opens new avenues for the development of responsive, enzyme-controlled biological nanostructures holding significant promise in various biological applications.

8:30 AM *NM06.05.03

Engineering Bioinspired Polymers to Mimic Proteins *Alfredo Alexander-Katz; Massachusetts Institute of Technology, United States*

Single chain nanoparticles (SCNPs) are, as its name says, small globules composed typically of a single random heteropolymer (RHP) of 2 or more chemistries. The compactness of the globule can be attained by either crosslinking some of the groups, or by a thermodynamic transition to a collapsed state in the presence of some solvents. In the past two decades, there have been significant advances in controlling the properties of these SCNPs in order to convert such seemingly inert globules into chemical reactors. More recently, however, RHPs have been used in many other applications such as protein protectants, catalysis, membrane active polymers, as well as chaperon-like biomimetic polymers. Many of these properties were believed to be only possible with sequence-defined natural peptides, and it is of interest to understand how RHPs are able to achieve these functions. Here, we will present our work on how RHPs are arranged at the molecular level and highlight under *what conditions one expects these polymers to present some of the properties proteins display. In particular, we will put special attention to the thermodynamics of globule formation in the presence of multiple chemistries, and the effect of Flory interaction parameters between the different species. As will be shown, under some conditions, these globules are able to exhibit a key biological property called hydration frustration, where some hydrophilic groups are dehydrated and buried while some hydrophobic groups are exposed at the water interface of the globule. This frustrated state is the basis of protein function and we believe this property to be critical in the future development of single chain nanoparticle for biological or biomimetic applications. We will finalize with a perspective on how RHPs interact with proteins, and potential avenues for utilizing them for controlling certain biological processes.*

9:00 AM NM06.05.04

Bioinspired Raspberry-Colloid-Templating as a Modular Thermocatalytic Platform *Kang Rui Garrick Lim and Joanna Aizenberg; Harvard University, United States*

Nanoparticle-supported heterogeneous catalysts play a central role in the production of more than 90% of chemicals manufactured globally. The performance (activity, selectivity, and stability) of these catalysts is predicated on a variety of descriptors related to the nanoparticles, support material, and their interactions between them. Current preparative methods towards these catalysts often do not permit independent changes to these coupled factors, thereby hindering the understanding on the role of each individual descriptor on catalytic performance.

To unequivocally derive structure-property relationships, we draw bioinspiration from the morpho butterfly, in combination with our expertise in colloidal synthesis, assembly, and sol-gel chemistry, to devise a raspberry-colloid templating (RCT) strategy. The modular RCT platform enables independent combinatorial variations of the material's building blocks and their organization, thereby affording numerous degrees of freedom for optimizing the material's functional properties, from the nanoscale to the macroscale. Furthermore, the RCT method confers high thermomechanical stability by partially embedding nanoparticles within its support, while retaining high levels of reactant accessibility. Using the RCT strategy, we illustrate how collective nanoparticle properties, such as nanoparticle proximity and sptially disparate localization, can be independently controlled without concomitant changes to other catalytic descriptors that would otherwise confound catalytic analyses. We highlight the unique suitability of the modular RCT platform as a well-defined model catalyst platform to independently isolate and tune potential catalytic descriptors to unambiguously derive structure–property relationships that bridge surface science studies to technical catalysts.

9:15 AM NM06.05.05

Optical Control of Plasmonic Ferritin Based Quantum-Biological System *Chengjie Wang, Zhiming Wang and Arup Neogi; University of Electronic Science and Technology of China, China*

Ferritin protein is a self-assembled nanocage consisting of 24 subunits that have documented quantum dot material properties and can enable quantum mechanical electron transport over substantial distances. Ferritin is abundant in the dopamine neurons of the substantia nigra pars compacta and the norepinephrine neurons of the locus coeruleus. The distinct organization of neuron subgroups with extensive axon branches and synapses may have evolved to utilize electron transport mechanisms for coordinating conscious actions or other functions. Optically controlled charge transport in direct or indirect bandgap semiconducting ferritin protein quantum structures could enhance electron transfer mechanisms between neurons. This electron transport might be augmented by ferritin present in the intercellular fluid between neurons, alongside the creation of internal cell voltages and pressures.

In this work, apoferritin layers with a tunable bandgap tailored by the number of monolayers have been coupled to biocompatible Au nanoclusters or carbon quantum dots. The quantized states within the ferritin protein layer have absorption states above 4 eV, and its electron transport mechanism due to ultraviolet light excitation has never been studied before. The fluorescence properties of the ferritin protein with peak emission at 325 nm can be enhanced and modified by the inclusion of the Au nanocluster in and around the self-assembled protein nanocages. The emission lifetime of the protein is reduced from 1.5 microseconds to 4.14 ns due to the efficient charge transfer. Carbon quantum dots with emission in the UV wavelength can also enhance the fluorescence properties of the protein due to the Förster resonant energy transfer mechanism. Nondegenerate differential transmission spectroscopy has also been performed to study the light scattering mechanism in the apoferritin layers coupled to the Au nanoclusters. The differential absorption rate of the quantum states within the apoferritin layer is significantly enhanced due to coupling with the Au nanoclusters, and the carrier lifetime is observed to be 15 ps. The UV absorption peak is usually not efficiently observed in the absence of the Au nanoclusters. The efficient charge transfer facilitated by the Au-nanoclusters enables the observation of the higher energy states within the quantized protein layer.

The efficiency of the optically enhanced charge transport process within the Au-nanocluster coupled Ferritin layer has been verified using a solid-state device. A three-terminal device was fabricated using the Au-cluster coupled ferritin layer. The change in the electrical transport characteristics was measured using photocurrent spectroscopy. The photocurrent due to the Au nanoclusters is enhanced from a nano-amp scale to microampere scales due to UV light excitation. The electronic charge transfer can be controlled by the wavelength and photon density of the excitation source.
This novel apoferritin-based synthetic quantum biological protein cluster is an intrinsic semiconductor. The structural analysis supported by the optical and electrical properties of the clusters doped with Au nanocrystals suggests that it behaves like a doped semiconductor. The electron transport and photoelectric response performance can be enhanced by orders of magnitude. It provides a unique pathway to control and manipulate neural activity by modifying the excitation of the quantum states selected by optically tunable radiation.

9:30 AM *NM06.05.06
Silk Glycopolymers as Mucin-Mimetic Analogs *David L. Kaplan and Jugal Sahoo; Tufts University, United States*

Silk protein-based mucin mimics were prepared using selective chemistries, to generate a family of glycoproteins. The silk-based glycopolymers with different sugar types (GalNAc, GlcNAc, NeuNAc, GlcN, and GalN) and grafting densities were prepared and characterized, and then processed into formats suitable to explore microbial interactions. Such systems offer new tools to combat antimicrobial resistance, a range of pathogenic infections, and also insights into structure-function related to biopolymer designs and microbiome-related outcomes. Since mucins provide natural protection from virulent microorganisms in many tissues of the human body, options to employ these new families of mucin-analogs are being pursued. For example, the pathogen Streptococcus mutans and commensal Streptococcus sanguinis were exposed to the glycopolymers and the GalNAc-modified silk provided control of biofilm formation without affecting overall bacterial growth of either species; mimicking the virulence-neutralizing effects of native mucins while maintaining cytocompatibility when assessed with epithelial cells in intestinal tissue mimcs in vitro. Variables such as glycopolymer concentration, glycan types and density are assessed against specific pathogens. These silk-based biomaterials provide a new set of materials with which to potentially modulate infections, microbiomes and avoid bacterial resistance, which can potentially impact many areas of health management and consumer applications.

10:00 AM BREAK

10:30 AM *NM06.05.07

***Structure and Function of Bioinspired Nanomaterials** Abigail Knight; University of North Carolina at Chapel Hill, United States*

The remarkable functions of proteins, such as precise binding and efficient catalysis, are currently unmatched by synthetic macromolecules due to the complex hierarchical structures found in natural systems. To address this challenge, we have developed synthetic strategies to control these hierarchical structures and created high-throughput platforms to understand the fundamental design principles behind macromolecule conformation and function. By integrating experimental synthesis and computational strategies, we aim to advance the field of bioinspired materials and provide innovative solutions to global health and environmental challenges.

11:00 AM NM06.05.08

***Bioinspired Synthesis of Micelle-Templated Nanoparticles with Ultrathin Silica Layers for Enhanced Stability and Mass Transfer** Ae Sol Lee and Chang Sup Kim; Dongguk University, Korea (the Republic of)*

Bioinspired enzyme encapsulation technologies have gained attention for sustainable development due to their ability to protect enzymes from external stressors while imitating the cellular environment and structure. In this research, we developed a bioinspired method for synthesizing biocatalytic silica nanoparticles using silica-forming R5 peptide- and carbonic anhydrase (CA)-functionalized micelles as templates. Each CA and R5 peptide was covalently attached to the hydrophilic ends of triblock copolymer F127, modified with NHS-ester (F127-CA and F127-R5). F127-CA/R5 micelle@SiNPs were produced through R5 peptide-catalyzed silicification of F127-CA/R5 micelles in a two-phase system, allowing control over the silica layer thickness on the micelles. The micelles were formed by adjusting the molar ratio of F127-CA and F127-R5. The resulting F127-CA/R5 micelle@SiNPs showed uniform and monodisperse particles approximately 17 nm in size, indicating a silica layer around 3 nm thick compared to the F127-CA/R5 micelle. The silica nanoparticles exhibited K_M and k_{cat} values in CO_2 hydration activity almost identical to the free enzyme, with enhanced stability under conditions for CO_2 capture and sequestration, as well as good storage stability. These results indicate that the synthesized nanoparticles with a thin silica layer can protect enzymes from external environments while minimizing mass transfer limitations. Therefore, our approach could offer a new direction for enzyme-based green chemistry in practical applications, providing improved stability and mass transfer.

11:15 AM NM06.05.09

***Helical Polymerization on Chiral Nanoparticles and Composites** Ji-Young Kim[1], Wonji Lee[2], Emine Turali-Emre[3], Geunseon Park[3], Chung-Man Lim[3], Zhibei Qu[4], Brian Siemienczuk[1], Sangho Cha[2] and Nicholas A. Kotov[3]; [1]Rensselaer Polytechnic Institute, United States; [2]Kyonggi University, Korea (the Republic of); [3]University of Michigan–Ann Arbor, United States; [4]Fudan University, China*

Chiral materials constructed from chiral helical polymers (CHPs) are of significant interest due to their ability to mimic natural helical biomacromolecules such as DNA, proteins, and cells. This interest extends to chiral composites, exemplified by the chiral hierarchical structure of bone minerals, which exhibit unique mechanical properties and functionalities arising from their chiral organization. Inspired by these natural structures, the artificial synthesis of chiral polymers and their incorporation into composite materials has garnered considerable attention. However, conventional asymmetric catalysis faces challenges such as environmental concerns, catalyst deactivation, substrate scope limitations, and the need for high catalyst loading, often requiring harsh reaction conditions that can limit the practicality and scalability of the processes. We report the helical polymerization of achiral monomers using chiral ceramic nanoparticles (NPs) as asymmetric catalysts. Tungsten *oxide NPs, averaging approximately 1.6 nm, exhibit chirality in their metal oxide core, imparted by aspartic acid ligands via bio-to-nano chirality transfer. These NPs initiate the stereoregular polymerization of various monomers, with their chiral surfaces providing the necessary chiral bias for the helical conformation of the resulting polymers. Depending on the handedness of the NPs, the NP-polymer composites exhibit mirrored spectra in optical and vibrational circular dichroism. Density functional theory calculations support that the rotational direction of the helical polymers is determined by NP handedness. The NPs function as both initiators and cross-linkers, resulting in a more uniform NP distribution and enhanced mechanical properties compared to simple mixing composites. The NP-initiated composites demonstrate fascinating enantioselective mechanical properties, with the stiffness and hardness of composites driven by a mixture of L- and D-NPs up to an order of magnitude higher than those of homo-chirality composites. These NP-initiated chiral NP-polymer composites hold potential for applications requiring soft composites with unique chiroptical properties and strong mechanical performance.*

11:30 AM *NM06.05.10

Coiled Coil Peptide Tiles (CCPTs)—A New, Multivalent Peptide Macrocycle for Expanding the De Novo Coiled Coil Assembly Toolkit *Anthony Perez, Adekunle Adewole, Daphne Sihwa, Michael Colvin and Andrea Merg; University of California, Merced, United States*

As one of the most well-understood protein folds, coiled coils represent an attractive assembly directing motif for engineering modular and dynamic bionanomaterials. Here, we expand the coiled coil assembly "toolkit" through unveiling the design and synthesis of novel, multivalent peptide macrocycles (~100 amino acids) that comprise multiple orthogonal coiled coil peptide domains, which are separated by short, flexible linkers. These fully synthetic constructs, termed coiled coil peptide tiles (CCPTs), are assembled using a convergent synthetic strategy via native chemical ligation and Sortase A-mediated cyclization. Circular dichroism (CD) studies reveal the increased helical stability associated with cyclization and subsequent coiled coil formation along the tile edges. Size exclusion chromatography (SEC), analytical high-performance liquid chromatography (HPLC), and fluorescence spectroscopy provide comprehensive biophysical characterization of various CCPT complexes and confirm the orthogonal co-localization of designed peptides with their respective coiled coil partner domains within CCPTs. Moreover, we demonstrate the utility of molecular dynamic (MD) simulations, which provide complementary insights to experimental results, as a supporting method for understanding the structural dynamics of CCPTs and their complexes, and for guiding the design of future generations of CCPTs. Lastly, I will delve into our lab's current progress towards assembling CCPTs into predefined, oligomeric assemblies. We envision that CCPTs can serve as synthetically tractable constructs that mimic tertiary structural motifs (e.g., helix-turn-helix), and thus, have the potential to serve as highly modular, multivalent building blocks for unlocking the de novo design and assembly of fully synthetic protein-mimetic architectures with properties and function that extend beyond the scope observed in nature

SESSION NM06.06: Electroactive Proteins or Peptides and Applications

Wednesday Afternoon, December 4, 2024
Hynes, Level 1, Room 103

1:30 PM *NM06.06.01

Peptide-Based Context-Adaptive Supramolecular Networks *Rein V. Ulijn; CUNY Advanced Science Research Center, United States*

Peptides have tremendous potential as building blocks of designer materials with wide-ranging applications. These materials are stabilized by strongly directional hydrogen bonding patterns giving rise to one-, or two-dimensional assembly. It remains a challenge to mimic biology's context-adaptive and flexible structures. In this talk we introduce minimalistic di- and tripeptide sequences that form dynamic ensembles through incorporation of multivalent sidechain interactions that collectively self-optimize depending on their context. We explore the di- and tripeptide sequence spaces to establish design rules for formation of supramolecular dispersions. We demonstrate that these dispersions can display supramolecular recognition of small molecules, including sugars. Notably, we observed that these supramolecular dispersions undergo drying-induced liquid to solid phase separation involving interface stabilization and expansion, resulting in formation of films of stiff, and densely packed, porous peptide microparticles that can be instantaneously redispersed upon re-introduction of water. Air-drying of aqueous peptide dispersions in the presence of proteins or small molecule payloads results in spontaneous and efficient encapsulation, and retention of protein stability after redispersion. These supramolecular tripeptide dispersions therefore show promise for recognition, emulsification, encapsulation, and storage of biomacromolecules.

2:00 PM *NM06.06.02
Mechanisms of Proton Transport in Bio-Inspired Self-Assembled Peptide-Based Materials *Nurit Ashkenasy; Ben-Gurion University of the Negev, Israel*

Billions of years of natural evolution have yielded a variety of proteins involved in diverse biological processes. Leveraging the remarkable functions of these naturally evolved machinery presents significant potential for advancing present technologies. In line with this approach, our research group has employed de-novo-designed peptides to fabricate materials that facilitate proton transport. While efficient proton transport has been achieved, questions remain regarding the detailed mechanisms of these processes. In this talk, I will present our combined experimental and theoretical efforts to elucidate these proton transport mechanisms.
I will demonstrate the critical role of amino acid side chains in determining proton transport rates. These effects can be direct, involving amino acids that form hydrogen bond networks through which charge transport occurs, or indirectly, by influencing the self-assembly process, the resulting structures, and water adsorption. In particular, I will show that the confinement of protonating side chains into nanochannels is instrumental in achieving efficient proton transport. Additionally, I will demonstrate that charge transport can be influenced by counterions incorporated into the self-assembly solution, which determine the protonation state of peptide side chains and, consequently, influence proton transport.
Our studies uncover similarities between the mechanisms controlling charge transport in biological systems and their bio-inspired counterparts. Furthermore, we offer guiding principles for designing peptides that can act as robust building blocks for creating novel, high-performance, biocompatible, and environmentally friendly organic and hybrid electronic materials.

3:30 PM *NM06.06.03
Shape Shifting Proteins for Dynamic Biomaterials *Daniel L. Winter, Nelson Roberts and Dominic J. Glover; University of New South Wales, Australia*

The classic structure-function paradigm of proteins contends that a protein exhibits a single well-defined folded structure that gives rise to its biological function. However, proteins are dynamic molecules, with many proteins capable of undergoing changes in structure and interactions in response to specific environmental stimuli.

Harnessing the dynamic properties of proteins could enable the creation of nanostructured biomaterials that can be triggered to change shape and function. This presentation will highlight the engineering of modular protein subunits whose structure and interactions can be regulated by various inputs and their application in biomaterials. In the first example, protein switches were engineered that consist of helical domains whose interaction as coiled coils can be modulated by enzymatic inputs. Exposure of the switches to a specific kinase enzyme result in phosphorylation of the helical domains and altered charge interactions that either weaken or strengthen coiled coil formation, which is reversible by phosphatases that dephosphorylate the switch. The physical and kinetic constraints of these switches were explored using computational models that revealed intricate relationships between the binding kinetics, phosphorylation kinetics, and switch concentration that governs the sensitivity and reversibility of these protein switches. The second example will describe proteins that interconvert between different folded states in response to stimuli and how these dynamic properties can be harnessed to build protein switches. The application of dynamic protein switches was demonstrated by their incorporation into a variety of biomaterials to confer sensing and structural reconfiguration when a specific input is present.

4:00 PM NM06.06.04
Using Cell-Free Assembled Virus-Like Proteoliposome Complexes to Deliver Cargo Directly to Cellular Cytosol *Ekaterina Selivanovitch, Zhongmou Chao and Susan Daniel; Cornell University, United States*

Viruses present one of the most efficient mechanisms for intracellular cargo (i.e. viral genome) delivery in which interactions at the virus-host cell interface dictate the delivery pathway. For instance, enveloped viruses- those that are 'wrapped' in a lipid bilayer, deliver their genetic cargo by first interacting with extracellular receptors, triggering a reaction cascade that results in fusion of the virus- and host cell lipid membranes and cargo release into the cytosol. Harnessing the efficiency of this translocation mechanism would drastically improve cellular uptake of therapeutic and bioactive cargo. In this work, we propose that viral fusion machinery can be repurposed for delivering user-defined cargo to cells containing the appropriate receptors. Hemagglutinin (HA), which is a protein found on the surface of influenza viruses and is known to mediate the virus-cell fusion mechanisms, is one of the proteins explored for this goal, along with several other viral membrane proteins including NiV-F and Spike (SARS 2). To circumvent challenges associated with using infectious viruses or isolating/reconstituting membrane proteins, we use cell-free synthesis techniques to directly insert the proteins into our delivery vehicles of choice- liposomes. Not only do we show that we can successfully assemble folded and functional viral membrane proteins, we also show that our virus-proteoliposome complexes can deliver both genomic and intact proteins directly to the cell cytosol.

4:15 PM *NM06.06.05
Self-Organizing Peptides for Nanobioelectronics with 2D Materials *Yuhei Hayamizu; Tokyo Institute of Technology, Japan*

The physical properties of two-dimensional (2D) nanomaterials, such as graphene and 2D transition metal chalcogenides, have been extensively elucidated, revealing their potential for diverse applications. In the post-COVID era, the interface between biomolecules and 2D nanomaterials has gained significant attention due to their anticipated applications in biosensors. This presentation will explore recent advancements in controlling the biomolecule-nanomaterial interface on 2D surfaces using peptides that form ordered self-assembled structures. We focus on solid-binding peptides that form uniform monomolecular layers on 2D nanomaterial surfaces through self-organization [1-4]. The self-organization of these peptides is crucial as it allows for precise and consistent interface control, which is essential for the reliable performance of biosensors. These peptides can adapt their structure based on the electrochemical potential of the underlying 2D material [5] and modulate the electronic state of the 2D materials in response to changes in the solution's pH [6]. Additionally, the structure of the self-

assembled organization can be altered by incorporating organic solvents into the solution [7]. These peptides also function as electrochemical catalysts [8], broadening the scope of interface control.
A notable recent advancement is the development of graphene-based odor sensors using peptides that mimic the olfactory receptors of biological organisms. These sensors exhibit superior sensitivity and selectivity [9-11]. Specifically, a limonene-binding peptide was utilized as a bioprobe to detect the scent of lemon, successfully distinguishing the enantiomers of the limonene molecule with a remarkable 35-fold signal contrast. This significant signal contrast emphasizes the potential of these peptide-based sensors in achieving high sensitivity and specificity in odor detection. This presentation will detail these advancements and discuss the broader implications for controlling nanomaterial interfaces through self-organization of peptides.

Investigating Antimicrobial Behavior of Thymol/Zn Encapsulated Hierarchically Structured Zeolite and Thymol Release Kinetics *Melda Isler Binay[1], Didem Kart[2] and Burcu Akata Kurc[1]; [1]Middle East Technical University, Turkey; [2]Hacettepe University, Turkey*

A new bioactive material was proposed by encapsulating thymol molecules and Zn^{2+} cations within the post-modified intracrystalline voids of hierarchical zeolite X crystals. To enhance the accessibility of thymol molecules within zeolite X crystals, commercial zeolite samples underwent post-synthesis treatment involving consecutive aqueous KCl, NH_4Cl, and Na_2H_2EDTA solutions. The gas adsorption method utilized the encapsulation of both Zn^{2+} cation and thymol molecules into the resulting hierarchical zeolite X framework, which demonstrated improved antimicrobial activity. While sole thymol-encapsulated zeolite X exhibited no antimicrobial activity against S. aureus, Zn^{2+} encapsulated zeolite X (ZnX), thymol encapsulated post-treated zeolite X (HX-thy), and both Zn^{2+} and thymol encapsulated post-treated zeolite X (ZnHX-thy) displayed zone of inhibition values of 18.7 mm, 25.0 mm, and 37.5 mm, respectively. Adding Zn^{2+} and creating a hierarchical pore system in the zeolite X framework altered

the release profiles. The Higuchi kinetic release model has the highest R^2 value to describe the process of thymol release from X-thy, whereas the Elovich release model has the best fitting profile of thymol release kinetics from ZnX-thy, HX-thy, and ZnHX-thy. The resulting hierarchical material, incorporating Zn^{2+} exchange and thymol-loaded features, exhibited superior antimicrobial activity compared to its counterparts. This underscores the importance of integrating the post-treatment process, Zn^{2+} exchange, and thymol encapsulation within the zeolitic frameworks. Results indicate that thymol and Zn^{2+} containing hierarchical porous materials could be beneficial tools for obtaining enhanced antibacterial activity and stability with reduced degradation and volatility of thymol with longer protection against microbial attack due to the controlled release. These findings highlight an innovative approach to designing sustainable and green materials, utilizing modified porous networks that encapsulate natural antibacterial compounds with environmentally benign metal ions.

NM06.07.02

Synthesis and Characterization of Hydrochar from the Endocarp of Attalea Speciosa *Edson F. Batista and Margaret Dawson; Instituto Federal do Maranhão, Brazil*

Toxic waste produced from agro-industrial practices leads to aquatic contamination that causes ecosystem deterioration. Adsorption has been ranked among the most used methods to purify contaminants from wastewater, due to the advantages of many limitations of conventional approaches, such as inefficiency and complex purification processes. Activated carbon is widely used as an adsorbent, the production of which is not economically profitable with expensive, limited and non-renewable resources. In this sense, hydrochar based on babassu endocarp with high adsorption, high specific surface area and stable chemical properties is considered a cheap and accessible carbon-based material. The babassu coconut is made up mainly of four parts: epicarp, the fibrous outer part (11%); endocarp, inner part of hard wood (59%); mesocarp, a layer rich in starch, located between the epicarp and endocarp (23%); and almonds (7%) rich in oil with great commercial interest. The different compositions and properties of this biomass make this fruit a potential candidate for wastewater purification. Therefore, research has focused on the synthesis of economical adsorbents such as hydrochar with significant absorptive capacity from agricultural residues such as babassu coconut endocarp. Samples were synthesized using hydrothermal methodology from the biomass at 63 nm of the babassu endocarp with a fixed time of 180 min. and temperature variation between 248F until 464F, evaluating the yield and absorptive capacity of each sample. Furthermore, the presence of functional groups that increase the absorptive capacity of the hydrochar was confirmed by XRD and FT-IR analysis. This hydrochar is expected to generate significant impacts on society in terms of reusing this agricultural waste as a wastewater purifier promoting sustainability, contributing to the UN development goals (SDGs).

NM06.07.03

Unveiling Janus Particle-Bacteria Interactions Towards Nano-Antibiotics Development *Swagata Bhattacharyya[1], Danh Nguyen[2], Ying Li[2] and Yan Yu[1]; [1]Indiana University, United States; [2]University of Wisconsin–Madison, United States*

Multidrug-resistant bacteria pose a global threat to human health. To address this challenge, antibacterial nanoparticles (NPs) have been developed as a potential alternative to traditional antibiotics. These NPs can kill bacteria through mechanisms, such as DNA binding, generation of reactive oxygen species (ROS), and physical damage to bacterial cell wall, which are less likely to induce bacterial resistance compared to traditional antibiotics. However, due to the diverse nature of bacteria, there is a need to design antibacterial NPs that allow easy tuning of the NP surface chemistry for broad-spectrum antibiotic activity. In this study, we have successfully synthesized antimicrobial NPs by tuning the anisotropic surface chemistry. Specifically, we engineered anisotropic NPs with two distinct hemispheres, which are also known as Janus NPs. One side of the Janus NPs was coated *with a hydrophobic ligand and the other with a cationic/hydrophilic polycationic ligand. The amphiphilic Janus NPs exhibited superior antibacterial properties compared to NPs with uniform surface chemistry, demonstrating effectiveness against both Gram-negative and Gram-positive bacteria. We revealed that the antibacterial mechanisms of Janus NPs include both physical damage to the bacterial cell wall and the generation of ROS. Further, we made an interesting discovery that the Janus NPs preferentially damage the poles of Escherichia coli in a curvature-dependent mechanism. These findings collectively not only underscore the potential of Janus NPs as a new type of nano-antibiotics against multi-drug resistant bacteria but also elucidate physical interactions driving the NP antibacterial activities.*

NM06.07.04

Quantification of Cellular Forces on Electrospun PCL Nanofibers on PDMS, Silver-Pronged and Silver-Striped Glass Substrates *Jacob Bornstein, Isaac Macwan and Visar Ajeti; Fairfield University, United States*

The extracellular matrix (ECM) provides structural and biochemical support for cell adhesion, proliferation, and differentiation. Replicating ECM conditions is crucial for studying cell behavior and developing advanced biomaterials. Electrospinning is a widely used method for creating a nanofibrous ECM using an electric field to initiate jet formation, which elongates and solidifies the polymer solution. Polycaprolactone (PCL) was used as a synthetic polymer due to its biodegradable and biocompatible properties with cells. The core aim of this study is to quantify the cellular forces exerted by the Madin-Darby Canine Kidney (MDCK) epithelial cells on the porous electrospun PCL nanofibers on different substrates such as polydimethylsiloxane (PDMS) containing varying dimensions of microwells, a glass slide with conductive silver prongs, and glass slides with conductive silver strips as microelectrodes.

The PDMS substrate had dimensions of 34 mm by 20 mm with a height of 3 mm and varying patterns of surface cutouts to improve cell viability. The silver paste prongs consisted of two parallel posts, each 1.2 mm x 14 mm, connected by a perpendicular post with dimensions of 5 mm x 1.2 mm. The area between the parallel posts had dimensions of 5 mm x 14 mm. The silver paste strips consisted of two parallel strips, each 7.75 mm x 0.56 mm, separated by a 190 µm gap. The substrates were affixed to an aluminum foil collector sheet and secured using conductive double-sided tape. An electrospinning apparatus was set at the following specific parameters with a hybrid nozzle using a 15% w/v PCL polymer solution that was prepared by dissolving PCL in acetone: 17kV voltage, 15 cm distance from the nozzle tip to the collector plate, and a 1.5 mL/hour flow rate. The nanofibers were collected on the PDMS and silver paste substrates and examined under a scanning electron microscope for a detailed quantification and analysis. Following SEM, an analysis involving nanofiber deformation by the MDCK epithelial cells using inverted microscopy is underway to quantify the cellular forces. It is hypothesized that cells will exert varying degree of forces depending on PCL nanofiber alignment and the substrate's composition and topography, reflecting their suitability in mimicking the ECM. This research is expected to provide insights into the mechanical interactions between cells and PCL nanofibers on different substrates. The findings will contribute to the development of optimized biomaterials for tissue engineering and regenerative medicine by enhancing our understanding of substrate-specific cellular force dynamics. By quantifying cellular forces on these tailored nanofiber substrates, the study aims to advance the design of biomimetic materials that effectively replicate the ECM, promoting better cell culture systems and tissue engineering applications.

NM06.07.05

Designing Biomimetic Phosphate-Binding Materials for Environmental Clean Up *Andrew Cannon[1], Faten Hussein[2], Patrick Hogsed[1], Nathan Perry[1], Brooke Mayer[2] and Yaroslava G. Yingling[1]; [1]North Carolina State University, United States; [2]Marquette University, United States*

Biomimetic materials that are based on high-affinity phosphate-binding proteins (PBPs) have shown exceptional *selectivity and efficiency in phosphorus removal and recovery. Although immobilized PBPs hold significant promise for removing and recovering inorganic phosphate, there is a critical need to enhance the adsorption capacity of PBP-based materials. Here, we used the correlation between all-atom molecular dynamics simulations and experiments to determine the molecular mechanism responsible for specificity and affinity and to utilize this information in designing the new biomimetic absorbents. Experimentally, we demonstrated that PBP functionalized on inorganic nanoparticles have the potential to rapidly, spontaneously, selectively, and reversibly capture orthophosphate. Simulations determine the hinge-like and twisting motions of PBP domains during binding and identify protein residues that influence these phenomena, revealing that various amino acids contribute indirectly to binding. However, for the PBP/nanoparticle systems, the amino acid sequence must be shortened to increase the loading capacity. We use a machine learning approach to mutate and truncate the PBP sequence, aiming to create smaller, cost-effective proteins that retain their binding capabilities. Bioinformatics tools are then used to analyze these mutated sequences to ensure they form structures with phosphate binding sites. The most promising candidates are selected for further AMD simulations to confirm their orthophosphate binding affinity and compare to binding of phytic acid, sodium triphosphate, beta-glycerol phosphate, and sodium hexametaphosphate. Overall, our study reveals how individual amino acids of the PBP contribute directly and indirectly to the binding of orthophosphate, and demonstrates the viability of using PBPs immobilized on the surface of nanoparticles to capture and recover phosphates. Additionally, we've devised an approach combining machine-learning methods, bioinformatics tools, and all-atom molecular dynamics to develop new PBPs with shorter sequences that retain their binding capacity.*

NM06.07.06

Electrostatic Manipulation and Measurement of Liquid Transport Properties of Diatoms via In Situ Optical Microscope *Omer R. Caylan[1], Xuanjie Wang[1], Carlos D. Diaz[1], Jihoon Park[2], Joseph Flanagan[2], Kenneth Sandhage[2] and Lenan Zhang[1]; [1]Massachusetts Institute of Technology, United States; [2]Purdue University, United States*

Diatoms, a type of phytoplankton, inhabit diverse aquatic environments such as oceans, lakes, and rivers. These unicellular organisms are encased in complex, silica-based shells known as frustules. Diatom frustules are characterized by intricate, multi-level hierarchical pore patterns, with the smallest pores measuring just a few nanometers. Such sophisticated structures are beyond the capabilities of modern cleanroom fabrication techniques. Consequently, diatom frustules have garnered significant interest for various applications in nanotechnology and biotechnology, including drug delivery, wastewater treatment, and the development of bio and gas sensors.

To advance these applications, a deep understanding of the principles governing liquid transport within diatom frustules is crucial. However, studying liquid transport through the hierarchical pores of individual diatom frustules, which are only tens of micrometers in size, presents substantial challenges. To address these issues, we have developed a microfluidic test rig that incorporates high-resolution optical microscopy. This device can not only detect liquid propagation from multiple perspectives with high spatial resolution and frame rate but is also capable of lifting and placing diatoms at desired positions using an electrostatic manipulator. Using the diatom species Coscinodiscus Wailesii as a case study, we identified the key microscopic features influencing liquid transport in diatom frustules and, for the first time, determined critical liquid transport properties. Additionally, the electrostatic manipulation of these organisms can be achieved and is explained by theoretical calculations.

This research illuminates the fundamental mechanisms of manipulation and liquid transport in diatom frustules. The optical metrology-based test rig created for this study offers a versatile platform for various microfluidic analyses. This work was supported by the Air Force Office of Scientific Research under Award Number FA9550-23-1-0055.

NM06.07.07

Spatially Controlled Immunomodulation via Bioinspired Nanocarriers for Enhanced Cancer Therapy *Mi Hyeon Cho; Korea Basic Science Institute, Korea (the Republic of)*

This study presents a novel approach for cancer therapy using bioinspired nanocarriers for spatially controlled immune activation. Current strategies aim to convert the tumor microenvironment from immunosuppressive to immunostimulatory, inducing systemic antitumor immunity. While dendritic cell (DC) activation within the tumor is crucial for robust T cell responses, existing methods utilizing agonists often trigger severe side effects due to uncontrolled systemic immune stimulation.
We introduce a biocompatible nanocarrier platform conjugated with a TLR7/8 agonist. This platform, composed of iron (Fe) and carbohydrates, restricts immune activation to the tumor and its sentinel lymph nodes, achieving localized immunostimulation without compromising therapeutic efficacy. Localized delivery with this platform effectively activates DCs within the lymph nodes, promoting the proliferation of tumor-specific CD8+ T cells. Furthermore, the platform demonstrates synergistic therapeutic effects when combined with chemotherapy. These findings establish a foundation for localized tumor manipulation using bioinspired nanomedicine. This approach offers a promising strategy for developing safer and more effective cancer immunotherapies with spatially controlled immune activation.

NM06.07.08

Hollow and Plant-Like Copper Sulfide Nano- and Microstructures Grown from Colloidal Sulfur Seeds *Peter W. Dunne[1], Andrew S. Bathe[1], Teagan F. Sweet[1,2], Annie Regan[1], Matthew Priestley[1] and Rachel Bothwell[1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]University of Notre Dame, United States*

The formation of complex, biomimetic structures from ostensibly simple inorganic systems has been a source of fascination for centuries. This is exemplified by chemical gardens, in which non-equilibrium precipitation processes result in micro- and nanotubular morphologies driven by diffusion, osmosis, and convection effects.[1] The aesthetics of these systems were the major source of fascination in their early years, however they have seen a recent resurgence in interest, as the hollow structures obtained are envisaged as likely adsorbents, catalysts, sensors and fuel cell components.[2] Such biomimetic structures have also been identified as potential biomarkers for early life; however significant efforts must be made to ensure that potential abiotic origins excluded as routes to such biosignatures.[3]

Here we report on the synthesis of hollow, framboidal, and plant-like copper sulfide grown from colloidal sulfur seeds in a simple, and wholly inorganic process by reacting sulfur colloids with a copper salt solution a range of morphologies may be achieved. Varying copper to sulfur ratios allow hollow covellite (CuS) microspheres, complex framboidal-type morphologies, cracked microspheres, "germinating seeds", and copper sulfide tendrils to be obtained. It is posited that these varied and complex morphologies result from a nominally simple process — surface crystallisation inducing internal pressures — analogous to that observed in the freezing of water droplets.

Lubricated Surfaces with High-Density Polysiloxane Brushes *Toui Furukawa[1], Yoshihisa Fujii[2], Yukikazu Takeoka[1], Takahiro Seki[1] and Mitsuo Hara[3]; [1]Nagoya University, Japan; [2]Mie University, Japan; [3]Kagawa University,* *Japan*

The advanced coating technology known as SLIPS (Slippery Liquid-Infused Porous Surfaces) mimics the slippery surface of the pitcher plants. This technology uses a porous surface infused with liquid, creating a constantly lubricated and extremely slippery surface. However, conventional SLIPS has the disadvantage that the coating effect decreases due to evaporation of the lubricant, which is a major challenge for practical application. A promising solution to this problem is the use of polydimethylsiloxane (PDMS), a liquid at room temperature, grafted onto a substrate. This new type of lubricated surface involves chemical bonding of the liquid polymer to the substrate, preventing the evaporation issue seen with traditional SLIPS. This approach has been shown to maintain its slippery effect over time and demonstrates high efficiency in removing liquid droplets. While this technology has primarily focused on creating slippery surfaces for liquids, it has not been extensively studied for friction and wear between solid surfaces, also known as tribology. To address this gap, we explored the use of high-density polymer brushes. By grafting polymers densely onto a substrate, the polymers extend like brushes, resulting in low friction properties. This technique shows potential for applications involving friction and wear between solid surfaces.

Therefore, our aim was to prepare lubricated surfaces with excellent droplet removal and low friction by densely integrating PDMS onto substrates. Specifically, we prepared high-density PDMS brushes using a guanidine base as a catalyst for living ring-opening polymerization of siloxane monomers (D3), starting from hydroxyl groups on silicon substrate surfaces. This method yielded PDMS brushes with a graft density higher than 1.0 chains/nm^2.

The resulting samples exhibited excellent droplet removal properties for both water and hexadecane. Furthermore, they showed surfaces with approximately 90% less friction compared to untreated substrates. This suggests that the high-density grafting improved the load-bearing properties of the PDMS brushes.

In addition, we prepared samples with varying film thicknesses by adjusting the reaction time. Examination of the physical properties' dependence on film thickness revealed that thinner films exhibited higher droplet removal efficiency, while thicker films provided lower friction. These findings suggest that the viscosity of the polymer, influenced by film thickness, plays a crucial role in the droplet removal and low friction characteristics of PDMS brushes. Increased viscosity of the polymer with thicker films reduced brush mobility, thus decreasing droplet removal efficiency. Conversely, higher viscosity enhanced the load-carrying capacity of the PDMS brushes, facilitating the transition from boundary lubrication to mixed lubrication and resulting in lower friction.

This study contributes to the design of new lubricated surfaces capable of addressing friction and wear against solids, offering potential applications across various industries.

NM06.07.10

Micro- and Macro-Sized Mixed Conducting Hydrogels via 2-Photon Printing for Individual Cell Interaction and Stimulation

Mona M. Haemmerle, Ankit Mishra, Julian Winkler and Christine Selhuber-Unkel; Universität Heidelberg, Germany

The mixed transport of electrons and ions in polymeric systems gives rise to numerous applications, ranging from energy storage to bioelectronics[1]*. Conducting scaffolds composed of conducting polymers can enhance interactions with cells for biosensing and stimulation*[2]*. Interfacing tailored micro-sized conducting scaffolds with neuronal cells thus allows insights into electrical activity, signal transmission properties, and proliferation*[3]*. The conducting material in these scaffolds can be the base material itself or an additive that infers conducting properties to an insulator*[4,5]*.*

We employ 2-photon polymerization to generate interpenetrated hydrogel structures with sub-micron resolution.

The properties of acrylamide hydrogels can be tuned to maximize compatibility with cells[6]. Conductivity is achieved through in-situ oxidation and implementation of organic conducting polymers, such as polypyrrole and poly(3,4-ethylenedioxythiophene) (PEDOT). Additionally, electrospun conductive fiber templates are implemented into macro-sized hydrogels to infer electrical conductivity.

To validate our material, the formation of the conductive double network is characterized using conductivity measurements, FTIR analysis and SEM.

By tailoring conductive 3D hydrogel scaffolds, we will be able to optimize the way we interface with single cells, cell populations, or tissues. The generation of an interpenetrating network of organic polymers with mixed conductance behaviour within 3D printed hydrogel structures provides a first step towards enhancing interaction with living systems.

Integrating Bioinspired Experimental and Theoretical Methods for Assessing Neonicotinoid Exposure Risks in the Yangtze River Basin *Gedion T. Hailu; Tongji University, China*

Neonicotinoids, widely used insecticides, present significant concerns for environmental and human health. This study addresses the lack of comprehensive evaluation of their accumulation in surface water ecosystems and impacts on various human groups, using bioinspired and integrated methodologies inspired by emerging trends in nano- and micro-structured bioinspired materials. We evaluated neonicotinoid concentrations and their implications for human and aquatic health in the Yangtze River Basin (YRB), China. Employing Relative Potency Factor (RPF), Hazard Index (HI), Monte Carlo Simulation (MCS), and Species Sensitivity Distribution (SSD), we assessed exposure and risk from dermal contact and oral intake among four human demographic groups and aquatic organisms. Neonicotinoid concentrations ranged from 0.1 to 408.12 ng/L, indicating risks (10^{-3} to 10^{-1}) for humans and aquatic species. The Incremental Lifetime Cancer Risk (ILCR) for dermal contact and oral intake was moderate. Specifically, the Hazard Index (HI) for dermal exposure ranged from 1.49×10^{-2} to 0.125, while for accidental oral intake, it spanned from 2.69×10^{-2} to 0.14. These findings underscore the potential non-carcinogenic risks associated with neonicotinoid exposure. Ecological risk assessments revealed acute and chronic hazardous concentrations (HC5) for 5% of species at 946 ng/L and 338 ng/L, respectively. This study emphasizes the integration of bioinspired experimental and theoretical approaches aligned with emerging trends in nano- and micro-structured bioinspired materials, highlighting the urgent need for targeted interventions and policies to mitigate neonicotinoid exposure and its ecological threats in the YRB.

NM06.07.12

High-Precision Tattoo-Based Multiplexed Sensor for Real-Time Neurotransmitter and Electrolyte Ion Detection in Sweat *Nafize Ishtiaque Hossain, Atul Sharma and Sameer R. Sonkusale; Tufts University, United States*

Wearable biosensors are rapidly advancing, making health and wellness monitoring accessible without specialized tools or expertise. Non-invasive fluids such as sweat, and saliva offer significant advantages due to their ease of collection, safety, and the presence of key biomarkers similar to those found in blood [1]. This study presents the development of a tattoo-based multiplexed electrochemical sensor designed to quantify neurotransmitters (dopamine, DA), electrolytes (sodium and ammonium), and pH levels in sweat. The platform integrates with a portable and customizable electronic readout system with wireless capability. The sensor is *fabricated on tattoo paper with four working electrodes (WEs), a counter electrode (CE), and a reference electrode (RE), patterned in an origami design, which is then transferred to the skin. Conductive graphene ink forms the base electrode layer, while pseudo-reference electrodes are created by electrochemically depositing and chlorinating silver over the graphene. Polyvinyl chloride (PVC) insulation is applied to all electrodes except the WEs to prevent non-specific reactions. For dopamine detection, a nanocomposite of molybdenum disulfide (MoS_2) and nickel metal-organic framework (NiMOF), coated with Nafion, enables selective oxidation and amperometric detection of DA molecules amidst potential interferents. The sodium (Na^+) ion sensor employs an ionophore-based ion-selective electrode (ISE), and the pH sensor is developed through the electrodeposition of polyaniline (PANI) nanofibers. The ammonium sensor involves a multi-step process: electrodeposition of Prussian blue (PB) on the WE, drop-casting copper hexacyanoferrate (CuHCF) and applying an ISE layer. Changes in the Na^+, NH_4^+, and pH levels were measured using open circuit potential (OCV). Sensor data is collected after 15 minutes of exercise, continuously using a custom miniaturized readout circuit for the next 20 minutes. Testing with artificial sweat confirms high selectivity against common interferents, validating effectiveness in real sweat analysis [2,3]. The DA sensor demonstrates a sensitivity of 87.27 μA/log(DA). In contrast, the Na^+, NH_4^+, and pH sensors exhibit 55.25 mV/decade, 49.98 mV/decade, and -49.31 mV/pH for Na^+, NH_4^+, and pH, respectively, showing near-Nernstian behavior. The detection limits (LOD) for DA, Na^+, and NH_4^+ are 0.089 nM, 0.082 mM, and 8.66 μM, respectively. The developed epidermal multiplex tattoo-based biosensing platform offers considerable promise for the non-invasive monitoring of multiple biomarkers in practical settings, inspiring a new era of health monitoring. It can be readily expanded to monitor additional analytes. Future developments will focus on interfacing the sensor with energy harvesting platforms and employing machine learning techniques to analyze data and differentiate various exercise activities.*

Directionality of Anisotropic Wicking on Mesoporous Surfaces Obtained by Poisson Effect-Manipulated Crack Formation

Seong woo Jeon[1], Yunchan Lee[1,2], Min-Gi Jo[1] and Hyunsik Yoon[1]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]University of Pennsylvania, United States

Wicking is the rapid spreading of water through a combination of capillary wicking and evaporation when it comes into contact with a porous material. This phenomenon has practical applications in everyday life, such as in performance clothing that absorbs sweat and quickly evaporates it. In recent years, the study of directional wicking has led to breakthroughs in areas such as heat transfer, colorimetric devices, energy-harvesting devices, and microfluidics.

In this study, we present the wicking of anisotropic strips induced by mesoporous TiO2 colloidal films. Anisotropic strips are obtained by converting cracks in the micro-pyramidal array into anisotropic cracks. When an elastomer block with an array of micro-pyramids is stretched, the period of the force increases in the direction of stretching and decreases in the perpendicular direction due to the Poisson effect. This increases the difference in the angle of the pyramid edges between the part parallel to the stretching direction and the part perpendicular to it. Consequently, this angular difference induces anisotropic cracking by concentrating stresses at sharp notches. This suggests a method for fabricating mesoporous strips consisting of nanoparticles with TiO2 mesoporous microchannels, which have potential applications in various fields, including microfluidics, displays, colorimetry, *and photocatalytic microchannels.*

NM06.07.14

Lipid Membrane Formation on h-BN Modified by Self-Assembled Peptides *Soichiro Kato and Yuhei Hayamizu; Tokyo Institute of Technology, Japan*

Graphene and other two-dimensional (2D) nanomaterials have garnered significant attention as platforms for highly sensitive biosensors due to their exceptional electrical and physical properties [1]. The functionalization of graphene surfaces is pivotal in the development of effective biosensors. Transmembrane proteins perform their native functions within cell membranes, and by mimicking the cell membrane on a graphene surface, we can create innovative graphene biosensors incorporating transmembrane proteins. Indeed, several studies have demonstrated the formation of supported lipid bilayers (SLBs) on graphene at the solid-liquid interface [2]. However, the hydrophobic nature of graphene presents challenges in forming stable SLBs on its surface [3]. Therefore, it is crucial to modify the surface chemistry of graphene without compromising its electronic properties to enable the stable formation of uniform SLBs.

In this study, we developed a method to form stable supported lipid bilayers (SLBs) by modifying the surface of 2D nanomaterials with peptides. Certain peptides are known to self-assemble into monomolecular thick, uniform layers on the surfaces of 2D nanomaterials such as graphene and hexagonal boron nitride (h-BN) [4,5]. They are capable of modifying graphene biosensors as biomolecular scaffold [6-8]. Previous research has shown that peptides with dipeptide repeats of glycine (G) and alanine (A) exhibit ordered self-assembled structures on these 2D materials [9]. We utilized these peptides to enhance the surface modification of 2D materials, aiming to improve SLB formation.

In our experiments, we employed fluorescence microscopy to investigate SLB formation. h-BN, being optically transparent in the visible light range, is well-suited for fluorescence measurements, making it an ideal substrate for our studies. We aimed to determine whether peptide-modified h-BN supports SLB formation. Additionally, we used atomic force microscopy (AFM) to verify peptide self-assembly and SLB formation on h-BN.

To monitor SLB formation, we applied vesicle rupture and fusion methods on h-BN. Fluorescent-tagged lipids were used for fluorescence measurements. During the SLB formation process, the fluorescence intensity of lipids on peptide-modified h-BN significantly increased compared to unmodified h-BN, indicating that peptide surface modification facilitates SLB formation. AFM measurements showed that the height of the SLB on peptide-modified h-BN was approximately 5 nm, consistent with the typical thickness of a lipid bilayer, confirming SLB formation on the substrate.

In the future, it will be possible to design a variety of peptides with the capability to control interactions with SLBs, enabling the formation of cell membrane-like SLBs. These findings illuminate the potential for developing cell membrane-mimicking graphene biosensors using designed peptides.

Plasmonic Hydrogel Actuators for Octopus-Inspired Photo/Thermo-Responsive Smart Adhesive Patch

Jeeyoon Kim, Jeonghee Yeom, Yun Goo Ro, Geoseong Na, Woonggyu Jung and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Living organisms in nature exhibit remarkable adhesive properties, such as mussels, geckos, tree frosg, and octopuses, inspiring the development of novel adhesive systems for various applications such as skin attachable electronics, biomedical devices, and locomotion devices. Recently, octopus-inspired adhesives have gained attention owing to their ability to achieve high adhesion on various substrates. An octopus' suckers are sealed at the rim and function by reducing the pressure inside the cavity, thereby creating a pressure difference between the ambient environment and the inner cavity. In this study, we propose a smart adhesive patch that mimics the octopus adhesion mechanism, offering tunable adhesion in response to temperature and near-infrared (NIR) light. This dual responsivity is achieved by integrating plasmonic gold nanostars (GNSs) as NIR light-responsive photothermal materials and poly(N-isopropylacrylamide) (PNIPAM) hydrogels as thermo-responsive materials on a nanohole-patterned polydimethylsiloxane (PDMS) film, mimicking the suction cups of an octopus. The muscle-like, thermo-responsive PNIPAM hydrogel functions as a volumetric actuator to regulate the cavity pressure. At temperatures exceeding the lower critical solution temperature (LCST) of PNIPAM, the hydrogel layer contracts, enlarging the cavity volume and thus reducing the cavity pressure to achieve strong suction adhesion. The expelled water molecules during the process contribute to an increased adhesion effect. The smart adhesive patch demonstrates effective adhesion performance by controlling nanocavity pressure and leveraging both capillary-assisted and chemical adhesion mechanisms.

The smart adhesive patch shows strong adhesion forces up to 134 kPa at 45 °C and large on-off adhesion ratio (~63) through temperature control. During temperature elevation, the GNS adsorbed with the polymer enhances the responsiveness of PNIPAM hydrogel with a synergetic effect of strong mechanical stress and high thermal conductivity. GNS is characterized by a pronounced light absorption peak in the NIR light range and transforms light into heat using the localized surface plasmon resonance (LSPR) effect. The sharp tips of plasmonic GNS amplify localized electromagnetic fields more effectively than other nanoparticle shapes, resulting in a red-shifted LSPR band. The light absorption peak of GNS located in the NIR range effectively absorbs NIR light compared to gold nanospheres. The photothermally excited GNS increase the temperature under NIR light irradiation, resulting in a high adhesion force of 71 kPa at 85 mW cm^{-2}. The smart adhesive patch can be used on a variety of materials, including plastic, glass, metal, and organ, and it leaves minimal residue after operation due to the switchable adhesion properties, mitigating potential harm to delicate organs. We have further employed our smart adhesive patch to transfer an ultrathin Temperature Coefficient Resistance (TCR) sensor onto the organ of a living mouse. We utilized the smart adhesive patch as a transfer medium to successfully relocate a 3 µm-thick TCR sensor to a living mouse's liver for real-time temperature monitoring.

NM06.07.16

A Nano Method for Early Diagnosis of Alzheimer's Disease Using Amyloid-β(1-40) Biomarker

Ella Lee[1], Arthur McClelland[2] and Tingying (Helen) Zeng[3]; [1]Grant County High School, United States; [2]Harvard University, United States; [3]InnoBridge Institute, United States

Alzheimer's Disease (AD) is a growing issue in the United States of America with limited measures of early diagnosis. This complex neurodegenerative disorder is irreversible in terms of progression and damage to functionality. Biomarkers have great potential in early AD diagnosis as many of the damaging build-up of protein can be detected twenty years before clinical symptoms appear. There currently are multiple protein, peptide, and microRNA potential biomarkers to diagnose AD. However, a definitive approved biomarker is still necessary to help ameliorate AD. In our study, we investigate a new method with surface-enhanced Raman spectroscopy (SERS) to diagnose Alzheimer's Disease with Amyloid-β(1-40) peptides coated in silver nanoparticles. Our study aims to

advance the standard procedure of Aβ1-40 to combat the lack of certified reference material (CRM) in order to facilitate accurate and efficient diagnosis of AD. Aβ1-40 is a 40-amino-acid form of Aβ monomer that aggregates to a polymorphic state of oligomer or fibril. The 40-amino-acid form is composed of the amyloid precursor protein (APP). Aβ1-40 is a potential biomarker for its strong relation to extracellular amyloid plaques and abnormal accumulations in the brain. In the study, the silver-coated peptides will vary in concentration and be assessed via SERS. SERS is an optimized method for molecular specificity with high sensitivity and accuracy. By utilizing SERS and silver nanoparticles, the various concentrations of Aβ1-40 can be evaluated for their compatibility to diagnose AD. Our study proposes a new method with increased accuracy and efficiency in diagnosing AD.

NM06.07.17

Enhanced Properties of Artificial Nano Cells by Adjustment of Aspect Ratio *Yoojin Lee and Jinkee Hong; Yonsei University, Korea (the Republic of)*

The shape of nanoparticles is a crucial factor that can regulate their in vivo stability and therapeutic effect. Numerous studies have been conducted to create artificial antigen-presenting cells by controlling the shape of micro- and nanoparticles. These studies have consistently demonstrated that adjusting the shape can significantly enhance the in vivo stability and the effectiveness of T cell activation. For instance, certain shapes may facilitate longer circulation times in the bloodstream, better evasion from the immune system, and improved targeting of specific tissues or cells. The geometry of the nanoparticles can influence their cellular uptake, distribution, and interaction with biological systems, which in turn impacts their overall therapeutic efficacy.

Despite the growing attention to cell membrane camouflage technology, which involves coating nanoparticles with cell membranes to improve biocompatibility and evade immune detection, there is still limited knowledge about the differences in therapeutic effects due to the shape control of cell membrane-coated nanoparticles. Cell membrane coating has shown promise in enhancing the functional properties of nanoparticles, such as prolonging circulation time, reducing immunogenicity, and improving targeting capabilities. However, the interplay between the shape of these nanoparticles and the cell membrane coating in determining therapeutic outcomes has not been thoroughly investigated.

In this study, we sought to bridge this knowledge gap by comparing the therapeutic effects of antigen-presenting nanoparticles coated with cell membranes while systematically adjusting their aspect ratios. By varying the aspect ratio, we could examine how changes in shape influence the stability of the cell membrane coating and the subsequent therapeutic efficacy of the nanoparticles. Specifically, we aimed to understand whether certain shapes could enhance the robustness of the cell membrane coating, thereby improving the nanoparticles' ability to activate T cells and exert therapeutic effects.

We first synthesized nanoparticles with different aspect ratios and coated them with dendritic cell membranes to utilize their antigen-presenting capabilities. We then conducted a series of in vivo and in vitro experiments to assess the stability of the cell membrane coating over time, the activation of T cells, and the overall therapeutic outcomes in relevant disease models. Our analysis included evaluating parameters such as cell membrane coating stability, immune evasion, and targeting accuracy. Our findings indicate that the aspect ratio of cell membrane-coated nanoparticles plays a significant role in determining their therapeutic effectiveness. By demonstrating that aspect ratio adjustments can influence the stability and therapeutic effects of these nanoparticles, our research opens up new possibilities for the design and optimization of next-generation nanomedicines.

NM06.07.18

Novel Metallo-Chlorophyllin Complexes as Photodynamic Public Surfaces Disinfective Agents *David T. Leong; National University of Singapore, Singapore*

The recent pandemic has taught us the importance of public surfaces hygiene to stop the spread the infection. The initial demand for disinfection agents motivated us to seek out new and diverse agents. We were inspired by chlorophyll's ability to absorb visible light energy and convert it to chemical energy. Chlorophyll shares important features with chlorophyllin. We focussed on using chlorophyllin's porphyrin backbone as a framework for photodynamic activities that is based on visible light activation. The reasoning for visible light activation is because for most use cases, public surfaces' light environments are usually in the visible range. Replacing the central Mg2+ ion of Mg-chlorophyllin with Cu+/2+ ion or Fe2+/3+ ion, we found that these novel metallo-chlorophyllin complexes acquired photodynamic properties and produces reactive oxidative species. We next investigated the toxicity to E. Coli (bacteria) and found that these novel metallo-chlorophyllin complexes were able to kill bacteria with the induced photodynamic effects when there is light illumination and also through a chemical toxicity route. We also made nanoparticles of these complexes and found that the killing effect is enhanced. This study shows the potential of these novel metallo-chlorophyllin complexes to be applied as public surfaces disinfective agents.

NM06.07.19

Chemically Nanostructured Organogel Monoliths for Selective Infusion Templating *Yuanzhi Li, Abigail Plummer and Joerg G. Werner; Boston University, United States*

Organogels with spatially defined mesoscale distinction of chemical activity that guide and accelerate nanomaterial templating by chemical nanoconfinement are found ubiquitous in nature but inadequately studied in artificial systems. Herein, we introduce chemically nanostructured bulk organogels with two gyroidal three-dimensionally periodic network morphologies (alternating gyroid and double gyroid) as well as one- and two-dimensionally periodic structures from self-assembled block copolymer (BCP). Our rationally designed BCP bulk monoliths contain a single selectively crosslinked block and exhibit remarkable macroscopic and nanoscopic structural integrity upon swelling of up to 400 vol% and almost doubling of the nanoscale periodicity. These ordered organogels are a novel class of solvent-laden bulk materials with chemically distinct nano-environments on a periodic mesoscale lattice, which form a bio-inspired soft chemical template for structured functional materials. We demonstrate their use for selective infusion templating (SIT) with the nanoconfined synthesis of bulk monolithic polymer and functional inorganic materials of ordered gyroidal and mesoporous nanostructures. We believe that our bio-inspired nanostructured soft-gels applied to SIT will enable the fabrication of many traditionally hard-to-template materials as periodically nanostructured monolithic metamaterials due to the extensive tunability in their physico-chemical parameter space.

NM06.07.20

Macroscopic Hierarchical Self-Assembly Through Host-Guest Interaction *Dezhi Liu and Dong-Po Song; Tianjin University, China*

In living organisms, micrometer-scale structures are readily fabricated through self-assembly, yet artificially fabricating hierarchically ordered macroscopic structures via bottom-up methods remains a significant challenge. Here, we present a novel "molecular-recognition-driven block copolymer (BCP) self-assembly" strategy using an organized spontaneous emulsification (OSE) mechanism to generate macroscopic periodic porous structures. This approach achieves domain sizes an order of magnitude larger than those achieved with covalent BCPs. Furthermore, unprecedented domain sizes, ranging from 800 to 1800 nm, are precisely tunable by manipulating the conformation of supramolecular bottlebrush block copolymers (SBBCPs) and the curvature of water/oil (W/O) interfaces. This breakthrough opens a pathway for constructing macroscopic self-assembly systems, showing promising potential applications in radiative cooling, bioinspired camouflage, and advanced thermal management.

NM06.07.21

Bio-Mimetic Hierarchies for Universal Surface Enhancement and Applications in Water Treatment *Yifei Liu and Donglei (Emma) Fan; The University of Texas at Austin, United States*

Hierarchical superstructures, ubiquitously found in nature, offer enhanced efficiency in both substance reaction and mass transport owing to their unique multi-scale features. Inspired by these natural systems, this research reports a novel, general, and scalable electrochemical scheme for creating highly branched multilevel porous superstructures on various substrates. These structures exhibit cascading features from centimeters down to sub-100 nanometers, significantly increasing the surface area of substrates, such as foams, foils, and carbon cloth by two orders of magnitude—among the highest reported enhancements. The reported versatile and low-cost method, which can be applied to a range of substrates, enables energy-efficient flow-assisted water purification. The processed substrate successfully removes 99% of mercury within 0.5 hours at 540 rpm, meeting the safety standards for drinkable water set by the U.S. Environmental Protection Agency (EPA). Overall, this general, economical, and versatile scheme for imparting quasi-3D hierarchical structures to various surfaces could broadly impact energy and environmental remediation.

High Entropy Oxide as Interfacial Material for Toughened Textured Alumina *Zhuoran Ma and Hortense Le Ferrand; Nanyang Technological University, Singapore*

Textured alumina ceramics with brick-and-mortar microstructures exhibit sur prisingly high values of strength and toughness as compared to traditional ceramics. However, in full ceramic systems, pressure-assisted sintering restricts their shaping potential, and the study of interfacial materials is still insufficient. Here, we fabricate textured alumina exhibiting elevated indentation fracture toughness using a high entropy oxide (HEO) (MgAlSiTiZr)O as the mortar. The HEO undergoes a single-phase transformation at 1600 °C, resulting in a crystal lographic structure identical to that of ZrO_2. Our HEO mortar is tough and has a high wetting behavior to alumina platelets used in the green body, which pro motes densification via liquid phase sintering. Textured alumina ceramics with HEO mortar at concentrations varying from 0 to 90 wt% were fabricated using magnetically assisted slip casting and pressureless sintering through the tem plated grain growth process. A trade-off between density and grain anisotropy led to the highest mechanical properties. Textured alumina with 10 wt% HEO exhibited over 95% relative density, an elastic modulus of 244 ± 29 GPa, a flexural strength of 329 ± 27 MPa, and an indentation fracture toughness of 6.80 ± 0.65 MPa $m^{0.5}$, which is more than 1.9 times that of the usual polycrys talline alumina. Thanks to the mineral nature of HEO, the simplicity of the process, and the mechanical properties, the textured alumina with HEO mor tar can be produced in complex shapes and could find applications in stringent environments.

NM06.07.23

Molecular Dynamics Calculations of Thioflavin-T on Self-Assembled Peptides *Hiroki Maeda[1], Eiji Yamamoto[2] and Yuhei Hayamizu[1]; [1]Tokyo Institute of Technology, Japan; [2]Keio University, Japan*

Peptides have the remarkable ability to self-assemble into well-ordered structures on two-dimensional (2D) materials like graphene, making them promising candidates for biosensor applications due to their design flexibility and biocompatibility [1]. Recent studies have underscored the potential of graphene biosensors functionalized with peptides, mimicking olfactory receptors for odor-sensing applications [2,3]. Understanding the surface structure of self-assembled peptides on 2D material-based biosensors is vital for grasping their performance. Previous research [4] has shown that peptide self-assemblies form large domains exceeding 100 micrometers in diameter, yet the formation mechanism of these domains remains poorly understood. To date,

atomic force microscopy (AFM) has been the primary tool for precisely observing these peptide structures with high spatial resolution. However, AFM is not suitable for large-area measurements in a short time.
To address this limitation, we employ Thioflavin-T (ThT) fluorescent assays [5] to examine peptide self-assembly, which potentially allows us to obtain label-free fluorescent images with a wide field of view. We utilized peptides with dipeptide repeats of glycine and alanine, forming ordered monomolecular thick structures on 2D materials [4]. Hexagonal boron nitride (h-BN) surfaces served as substrates for peptide self-assembly and fluorescent microscopy. h-BN, an optically transparent member of 2D materials, is well-suited for fluorescent microscopy. ThT, known for its strong fluorescence when bound to β-sheet structures, is widely used in observing amyloid fibers associated with Alzheimer's disease. Given that the peptides in this study are expected to form β-sheet structures, we investigate the feasibility of using ThT for real-time observation of the macroscopic surface self-assembly process of peptides.
In our experiments, h-BN flakes were transferred onto glass slips, and peptide solution was applied to the surface. After a 1-hour incubation, AFM measurements revealed that peptides formed long-range ordered structures on h-BN. Upon introducing ThT into the solution, fluorescent microscopy detected strong fluorescence in regions with ordered peptide structures. The peptide domain size on the surface spanned tens of micrometers, surpassing the field of view of AFM measurements. The fluorescent measurement with ThT molecules enabled visualization of the macroscopic structures of peptides. Additionally, weak fluorescence was observed on the excess area of the h-BN surface, indicating the presence of peptide and/or ThT aggregates.
The ThT association with self-assembled peptides was further studied using molecular dynamics simulations. Initially, four peptides were placed on an graphene surface, and calculations showed stable β-sheet-like structures in an anti-parallel form. Upon adding ThT to the system, a ThT molecule was stably immobilized on the self-assembled peptides with a β-sheet conformation, corroborating the experimental results.
These findings highlight ThT's potential as a tool for assessing macroscopic peptide self-assembly over wide areas. Real-time monitoring of these processes under liquid conditions using fluorescence microscopy provides insights into the spatial uniformity of molecular thin films, critical for enhancing the activity of peptide-based bio-probes on graphene biosensors. This methodology paves the way for developing improved peptide biosensors with enhanced functionality and performance.

Exosome-Inspired Functionalized Calcium Phosphate Nano-Probes for Vaccine Application *Anshika Maheshwari, Rebecca Dookie, Meztlli Gaytán, Birgitta Henriques-Normark and Georgios Sotiriou; Karolinska Institutet, Sweden*

Subunit vaccines have emerged as a promising strategy in preventing infectious diseases, offering a safer alternative to conventional live attenuated or inactivated virus/bacterial vaccines. Additionally, their cost-effectiveness and ease of mass production give them a significant advantage over bacterial exosome-based vaccines. Nonetheless, challenges persist, such as limited immunogenicity and inadequate antigen stability within these formulations. To overcome these hurdles, nanoparticles (NPs) can serve as an effective delivery platform for vaccines. NPs exhibit the capacity to shield the antigen cargo, augment immunogenicity, and precisely deliver the cargo to the intended site [1].
Among the various NP delivery systems, calcium phosphate (CaP) NPs emerge as exceptionally promising candidates. Their biocompatibility and biodegradability render them well-tolerated by the body. Notably, CaP NPs

demonstrate potential as vaccine adjuvants, capable of provoking both cell-mediated and humoral immune responses [2]. Furthermore, multiple antigens can be conjugated to CaP NPs due to their high loading capacity for diverse proteins and peptides [3], positioning them as a favorable nanocarrier for protein-based vaccines.
CaP exists as a polymorph and a precise control of its composition, size and crystallinity is crucial for its translation for vaccine application. Therefore, we use flame spray pyrolysis, a single step and scalable aerosol synthesis technique which allows easy tuning of the mentioned NPs properties. We screened three different types of CaP NPs (named as S-CaP, M-CaP and L-CaP) varying in particle size and crystallinity to evaluate their immunomodulatory properties. Medium (M-CaP) and large (L-CaP) sized NPs were crystalline whereas the smallest NPs (S-CaP) exhibit amorphous nature. We achieved a high specific surface area of 232 m^2/g for the S-CaP. Upon loading ovalbumin (OVA), a model protein antigen, we achieved loading capacity values with S-CaP NPs reaching more than 400 µg/mg. Moreover, upon incubation with Proteinase K, OVA conjugated with the NPs resisted degradation until 3 hours compared to free OVA degrading within the 1st hour. Furthermore, all three sizes of CaP NPs enhanced the OVA uptake and processing by the DCs. We observed a significant upregulation of CD80 and CD86 expression on BMDCs in the case of the smallest CaP NPs (S CaP-OVA) conjugates, as compared to water and OVA alone thus indicating immunomodulation via DC activation.
S-CaP-OVA had the best immunogenic performance, so these amorphous particles were further studied with pneumococcal extracellular vesicle (referred as exosomes). The identified protective antigens, MalX and PrsA [4], from pneumococcal exosomes are decorated on these NPs and further tested in vitro and in vivo.

This research is funded by the Swedish Foundation for Strategic Research (FFL18-0043, RMX18-0041) and European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (ERC Grant agreement n° 758705). Funding from Karolinska Institutet Faculty Board, Swedish Research Council (2018-05798 and 2021-02059) is kindly acknowledged.

Control of Bioprecipitated Ceramic Morphology and Thickness Through Nucleating Sequence Repetition

Joseph F. Mepham, Robert Stote, Erin Anderson, Emily St. George and Victoria Ayotte; Combat Capabilities Development Command Soldier Center, United States

Metal oxide-based ceramics have a multitude of applications in material engineering, from military vehicle coatings and textile finishes to nonstick cookware. Over the past decades, specialized bioceramic peptides have been used to adhere nano surface ceramics to textile and material substrates as an alternative to traditional adhesive/binder and microparticle systems. These bioceramic peptides bind to the material substrate on one terminal end and precipitate metal oxides with the other, creating a ceramic that is tethered to the base material surface with a single process. Typically, the engineering and production of ceramics for functional coatings uses hazardous materials, resulting in high costs, and requires adhesive for application of pre-formed particles that may change the physical properties of materials - especially textile hand, breathability, and flexibility. By using biosynthesis to fabricate bioceramic peptides, we are able to provide a new system that both binds and precipitates ceramic finishes using techniques that are cheap, fast, effective, and environmentally friendly. Bioceramic peptides contain a material binding region made up of 7 to15 amino acids that can be tailored to a variety of materials and metals. Binding sequences for chitin, cellulose, polyethylene, and nylon were fabricated, with ceramic nucleating sequences including alumina, zinc, titania, silver, and zirconia. Pichia pastoris is a popular *choice to use in biological production systems for its robust protein processing, folding, and modification abilities. One advantage of using P. pastoris as a biosynthesizer is that it allows bioceramic peptides to be produced with multiple nucleating sequences that cannot be made synthetically. Using the P. pastoris system, bioceramic peptide with up to 32 ceramic nucleating sites were synthesized. These peptides would allow for a thicker and more durable ceramic layer to precipitate compared to a single nucleating site produced through traditional synthesis.*

To produce the bioceramic peptides, amino acid sequences were translated to a DNA sequence and inserted into a P. pastoris plasmid. Plasmids were transformed using heat shock methods into cultured, competent Escherichia coli and P. pastoris cells. E. coli was used as a vector to replicate more plasmids while P. pastoris produced the peptide. SEM, XPS, and microscopy were used to analyze ceramic layers precipitated after binding the material substrates. After adjusting for concentration and purity, the bioceramic peptides were able to precipitate a uniform ceramic on multiple surfaces with thickness controlled by number of nucleating sites, with peptide length confirmed through gel electrophoresis.

The successful fabrication and application of these bioceramic peptides provides a new technique for precipitating surface transition metals onto materials, with potential to be a universal platform system that tailors peptides for a library of substrate materials and metal oxide ceramics. Applications such as water repellency, fire retardation, and cut/slash protection that use ceramic coatings or finishes will benefit from the lower cost, material flexibility, and environmentally friendly practices. Additionally, the combination of centralized peptide production and surface metal precipitation results in a streamlined process that can be completed in a single lab or easily transition to an industrial production line.

Tailoring the Hydrophobicity of Cross-Linked PDMS Films by a Combination of UV Ozone Treatment and Silanization

Anu M G and Rabibrata Mukherjee; Indian Institute of Technology Kharagpur, India

Hydrophobic polymeric thin films and coatings have received significant research attention due to their wide commercial and industrial applications, such as fabrication of self-cleaning surfaces, corrosion prevention, anti-microbial coatings and so on. Surface wettability is a fundamental property of any solid surface that arises out of a balance of its surface and interfacial tensions (Young's Equation) and is characterised by equilibrium water contact angle (θ_E) as well as dynamic wetting conditions such as contact angle hysteresis and sliding angle. For many applications involving hydrophobic surfaces, cross-linked PDMS (particularly Sylgard 184) films are widely used, due to various favorable properties like optical transparency, ease of patterning and moulding, gas permeation, thermal stability, biocompatibility, and so on.Traditionally, cross-linked polydimethylsiloxane (PDMS) surfaces exhibit weak hydrophobicity, which is characterized by $\theta_E \approx 105°$. In case it is exposed to UV ozone, then the surface becomes hydrophilic, which is followed by a slow and progressive hydrophobic recovery. On the other hand, silanization of the surface can lead to modulation of the surface property, depending on the nature of the functional group of the silane molecules. In this work, we demonstrate that by a combination of varying the UV Ozone exposure duration followed by silanization, it becomes possible to obtain surface wettability on demand. We also show that silanization after UVO exposure retards the rate of hydrophobic recovery. We also show that much faster modulation in the wetting property of the cross-linked PDMS surface is possible when it is exposed to oxygen plasma instead of UVO exposure. An oxidation/activation (UVO treatment/plasma treatment) step on the Sylgard 184 makes the surface with full of hydroxyl groups before the SAM formation. Silanization increases the hydrophobicity of the UVO-mediated PDMS surface with an oxide diffusion barrier layer.

Electrochemical Control of Microbial Biofilm Accumulation on Marine Infrastructures to Prevent Biofouling Without Generating Toxic Substances

Esraa M. Mohamed Farag and Nageh K. Allam; The American University in

Cairo, Egypt

Microbial biofilms are a major concern in industrial fouling, corrosion, and hygiene. In this study, we propose an electrochemical approach to effectively control microbial biofilm accumulation on marine infrastructures, specifically in seawater environments. Our method aims to prevent biofouling while avoiding the generation of toxic substances. To enhance the efficiency and versatility of the process, we introduce a novel carbon nanomaterial as the electrode material.
Marine bacteria were subjected to electrochemical treatment using conductive paint and a carbon nanomaterial-based electrode. By applying a potential of 1.2 V, the electrochemical treatment successfully killed the bacteria, significantly reducing biofilm formation. Subsequently, a potential of 0.6 V vs. Ag/AgCl was applied for 30 minutes, resulting in the desorption of the majority of bacterial cells from the electrode surface.
To proactively prevent bacterial cell accumulation and biofilm formation, we propose the application of alternating potentials. Applying an alternating potential of 1.2 V and -0.6 V vs. Ag/AgCl effectively controlled bacterial cell accumulation on the electrode. Importantly, this electrochemical control method does not generate chlorine or alter the pH of the surrounding seawater.
The applicability of this electrochemical control approach extends beyond seawater environments and can be successfully implemented in freshwater systems as well. Furthermore, the promising potential of this disinfection system extends to diverse applications, including its use in food and medical processes. Additionally, we explore the utilization of the proposed carbon nanomaterial-based electrode in battery technologies, highlighting its multifunctional properties.
This research contributes significant insights into the development of innovative strategies for combating biofouling and corrosion in marine infrastructures. The incorporation of a carbon nanomaterial as the electrode material enhances the electrochemical performance and efficiency of the control process. This nanomaterial exhibits exceptional electrochemical properties, facilitating improved bacterial cell killing and biofilm prevention.

NM06.07.28
Crystallization and Interaction of Histidine-Containing Tetrapeptides with Metal Ions *Yumie Nishiyama and Yuhei Hayamizu; Tokyo Institute of Technology, Japan*

Recent advancements in the study of supramolecular structures and crystals of peptides have been particularly significant at the intersection of nanotechnology and biotechnology. Diphenylalanine, composed of two phenylalanine residues, is known for its multiple self-assembling structures and functional properties, such as luminescence and piezoelectricity[1]. Building on this foundation, tetrapeptides inspired by diphenylalanine have demonstrated the ability to form dense hydrogen bond networks in crystals, promising the design of more functional peptide crystals with desirable properties[2].

Research has also been active in stabilizing structures and imparting new functions by adding metal ions to short peptides. For instance, metal ions are known to facilitate the fibrillization of amyloid peptides[3]. Additionally, artificial amyloid peptides containing histidine have formed nanowires with metal ions, exhibiting catalytic activity[4]. The imidazolium ring in histidine's side chain can coordinate with various metal ions, suggesting that peptides containing histidine could facilitate and functionalize peptide crystals if the design rules become clearer.

This study aims to design a new tetrapeptide containing histidine and examine its co-crystallization conditions with metal ions. To elucidate the intermolecular interactions between peptide molecules and metal ions, we utilized polarized Raman spectroscopy to investigate the peak shifts and anisotropy of vibrational modes in amino acids.

A tetrapeptide, HIIH, with histidine (H) at both termini was designed. Isoleucine (I), known for its hydrophobicity *and promotion of β-sheet formation, was included to stabilize the crystal structure through hydrophobic interactions. Copper chloride was selected as the metal salt due to the well-documented interactions between copper ions and histidine in nature. Crystallization was attempted for the peptide alone and with a 1:1 molar ratio of peptide to metal ions using the vapor diffusion method, commonly employed in protein crystallization. Crystals were observed using optical and polarized light microscopy, and changes in chemical bonding within the crystals were investigated using polarized micro-Raman spectroscopy.*

Crystals were obtained for both HIIH alone and HIIH mixed with copper ions. Both formed needle-like transparent crystals, with colorless crystals for the peptide alone and green crystals when mixed with copper ions. Raman spectra between 1550 cm^{-1} *and 1700 cm*$^{-1}$*, corresponding mainly to stretching modes of double bonds, showed significant changes when copper chloride was mixed with HIIH. The 1650-1700 cm*$^{-1}$ *region, known as the Amide I band, corresponds to the C=O stretching mode in peptide amide bonds[5]. The addition of copper ions resulted in a shift to lower wavenumbers without significant changes in polarization dependency, suggesting a shortening of intermolecular distances without altering the structure. In contrast, multiple peaks in the 1550-1650 cm*$^{-1}$ *range, corresponding to double bonds in the imidazolium ring, changed both in peak positions and polarization dependence[6]. This signature indicated that copper ions selectively influence the imidazolium rings in the peptide crystal. These findings provide insights into establishing design rules for tetrapeptides integrating with ions for peptide crystallization.*

Smart Window by Using Charged Nanoparticles Dispersed in the Pyramid Patterns

Hyeonwoo Park, Yonghyeon Lee and Hyunsik Yoon; Seoul National University of Science and Technology, Korea (the Republic of)

In modern society, energy issues are the most important issues, and according to a 2020 report by the International Energy Agency (IEA), energy used in buildings accounts for 35% of energy consumption used in industry. Accordingly, research and technology development aimed at reducing energy consumption are required. To solve this problem, a technology called smart windows is in the spotlight. A smart window refers to a window in which the transmittance can be adjusted according to light, temperature, and user preference. Electrical control methods are the most commercially available technologies among smart window driving methods, and typically include electrochromic (EC), suspended particle device (SPD), and polymer dispersion liquid crystal (PDLC).

These technologies are not only applicable to transparent display devices, but also have proven their commercialization potential. However, electrochromic (EC) has the disadvantages of high manufacturing cost and long time required for discoloration, and SPD has low manufacturing cost, but has a high driving voltage, which causes a problem of deteriorating durability due to condensation and deterioration. In addition, PDLC has a problem of a viewing angle without Haze due to a change in the refractive index of the liquid crystal in a transparent state. Technical research is needed to solve these problems.

Recently, display research using the transmittance change mechanism of cephalopods such as squid is being conducted. Squid has a pigment pocket in which pigment pigments are dispersed, and the size of the pigment *pocket is controlled with muscles to change transmittance. However, in the case of transparent display research based on the pigment bag of squid, there is a disadvantage that commercialization is difficult because it uses magnetic fields.*

In this study, in order to solve the above problems, a device was devised to control the transmittance by forming a pyramid pattern and dispersing charged nanoparticles within the pattern to move particles by electric force. The charged nanoparticle was used by dielectrophoresis. The irregular electric field required for the movement of charged nanoparticle by dielectrophoresis was used with a pyramid structure with an asymmetric structure. A method was introduced to control the light absorption area by dispersing charged nanoparticle in the micro pyramid pattern and applying an AC voltage to ITO-coated glass by dielectrophoresis. By making a pyramid pattern made of a polymer material having the same refractive index as that of charged nanoparticle, light was prevented from being refracted by the pyramid structure. In addition, it was verified whether ON/OFF switching is possible to check the behavior of charged nanoparticle in the pyramid pattern and measure the change in transmittance over time.

NM06.07.30

Design of Composite Polymer Brushes for Absorption of Contaminants from Water *Sergei Rigin, Jan Genzer and Yaroslava G. Yingling; North Carolina State University, United States*

Polymer brushes designed for environmental clean-up have emerged as a promising solution for addressing water contamination. Key design considerations include optimizing the brush density and thickness to maximize surface area and adsorption capacity, as well as the careful selection of functional groups and embedded absorbent materials tailored to target specific contaminants. The embedding of external adsorbent media (e.g., metal and metal oxide nanoparticles) within the brush is influenced by the configurations of both the brush and the particles, making the final structure prediction challenging. In this work, we employ coarse-grained molecular dynamics simulations with the MARTINI Force Field to explore the impact of grafting density and degree of polymerization on brush thickness and swelling dynamics, as well as the effects of ligands, particle size, and brush-particle interactions on diffusion within the brush. We systemize the conformational changes of dry polyethylene glycol (PEG) brushes and the resulting surface patterns, highlighting favorable chain lengths (within the range of 100-500 monomers) and grafting densities (up to 1 chain/nm^2) required for desired surface coverage. Furthermore, by controlling nanoparticle diffusion into hydrated brushes through tuning size, ligand length and density, and mimicking different ligand chemistries by adjusting the strength of polymer-ligand interactions, we establish suitable configurations for each of the three interaction regimes: repulsion, surface rolling, and mixing. These findings lay the foundation for a novel class of adsorptive materials designed to capture harmful pollutants from aqueous environments, thereby contributing to environmental sustainability.

NM06.07.31

Nanomolecularly-Induced Effects on the Synthesis and Properties of Inorganic/Organic Multilayer Nanolaminates *Collin Rowe[1], Mahima Sasikumar[1], Geetu Sharma[1], Henrik Pedersen[2], Arnaud Devos[3] and Ganpati Ramanath[1,2]; [1]Rensselaer Polytechnic Institute, United States; [2]Linköping University, Sweden; [3]Centre National de la Recherche Scientifique, France*

Molecular nanolayers (MNLs) at inorganic thin film interfaces are known to improve chemical stability, stimulate unexpected enhancements, and induce unusual mechanical responses, and electrical and thermal transport behaviors[1]. Stacking inorganic nanolayer/MNLs interfaces offers promise to access emergent properties, e.g., via superposition of MNL-induced interface effects[2]. Such hybrid multilayer nanolaminates mimic natural microlayered biocomposites such as nacre and bone, and provide a means to explore[3] and exploit *nanomolecularly tailored interface effects. Here, we describe the MNL-induced effects on the growth and properties of nanolaminates of metal-oxide/MNL[4] and metal-nitride/MNL multilayers. Nanolaminates with sharp interfaces were synthesized by sequential low-temperature atomic layer deposition (ALD) to preserve the integrity of the MNLs deposited by single-pulse molecular fluxes. Electron microscopy, X-ray diffraction, and ion beam and electron spectroscopy analyses show that MNLs alter the inorganic nanolayer growth rate, chemical composition, surface roughness, and phase stability. For example, organo-diphosphonate MNLs result in a twofold decrease in titania growth rate, and hydroquinone MNLs result in the conversion of aluminum nitride to aluminum oxide. Atomistic mechanisms underpinning these changes will be discussed relative to the impact of MNL backbone structure and terminal chemistry on film morphology, microstructure, and phase formation. Finally, unusual acoustic damping responses in the multilayer nanolaminates, revealed by femto-second pump-probe spectroscopy, will be described and correlated with the MNL interface chemistry and nanolayer periodicity. Harnessing such MNL-induced effects and understanding their correlations with enhanced/emergent properties is fundamental for designing high-interface-fraction hybrid nanolaminates for applications.*

Phytochemical-Based Oxytetracycline Nano-Formulation for the Management of Citrus Greening

Moitri Santra[1,2], Bryan Demosthene[2] and Ellen Kang[2]; [1]Oviedo High School, United States; [2]University of Central Florida, United States

Huanglongbing (HLB), also known as citrus greening, is a destructive bacterial disease affecting the phloem of citrus trees, leading to restricted nutrient flow and significant declines in fruit yield and quality. The economic impact has been profound, notably reducing Florida's citrus industry value from $9 billion to $2.9 billion within a decade. Traditional foliar applications of EPA-approved bacteriostatic agents, Oxytetracycline (OTC) and Streptomycin, have had limited success, primarily due to photodegradation. Current treatment strategies involve trunk injections of OTC, which cause trunk injury due to the acidic formulation (pH <2). This necessitates the development of a pH-neutral OTC formulation with UV-shielding properties to mitigate these adverse effects. This research focuses on creating a non-phytotoxic, pH-neutral OTC nano-formulation, which incorporates phytochemicals from a medicinal plant, Ocimum sanctum, to alleviate the effect of UV exposure on OTC. Existing methods of extracting Ocimum sanctum phytochemicals are limited to water, oil, and alcohol-based solvents, each releasing only solvent-compatible compounds. Instead, this study uses a novel high-temperature treatment method to extract a wider range of phytochemicals from Ocimum sanctum at once. Using Dynamic Light Scattering, the self-assembled nanoparticles' size and surface charge were characterized, revealing average particle sizes of 200 nm and a surface charge of -23 mV. UV-Visible and fluorescence spectroscopy confirmed interactions between OTC and the phytochemicals, with absorption spectra overlapping in the 300-400 nm range. Seed germination studies demonstrated that the neutral pH formulation alleviates OTC-induced phytotoxicity.

These results indicate that the phytochemical-based nano-formulation is a suitable OTC delivery system with potential to reduce trunk damage if administered through trunk injections. Fluorescence spectroscopy and solar exposure simulations were used to carry out photodegradation studies. The results show a 51% drop in fluorescence intensity and a peak shift of the traditional OTC formulation following exposure, compared to a 9% drop and the absence of a peak shift in the phytochemical-based treatment. Collectively, these findings show the promise of this nano-formulation for OTC trunk injections and foliar applications for future HLB management.

NM06.07.33

External Magnetic-Field Driven Delivery of Exosomes Modulates Immune and Metabolic Changes of Dystrophic Muscle

Valeria Secchi[1], Chiara Villa[2], Yvan Torrente[2] and Angelo Monguzzi[1]; [1]University of Milano-Bicocca, Italy; [2]Policlinico di Milano, Italy

Exosomes are nanosized extracellular vesicles which have been recently demonstrated as promising agents for tissue repair/regeneration by inducing and guiding appropriate immune responses in dystrophic pathologies. Unfortunately, the accurate manipulation of exosomes by controlling their biodistribution still poses significant challenges. Here we overcome this limitation by developing an externally controlled delivery system for primed ANXA1 myo-exosomes (Exomyo). Effective nanocarriers are realized by immobilizing the Exomyo onto ferromagnetic nanotubes (NT-MAG) [1] to achieve a controlled delivery and localization of Exomyo into skeletal muscles by an applied external magnetic field. Quantitative muscle-level analyses revealed that macrophages dominate the uptake of Exomyo from NT-MAG in vivo, to synergistically promote beneficial muscle responses in a murine animal model of Duchenne Muscular Dystrophy (DMD) thanks to the successful localization of therapeutic Exomyo upon systemic injection. These findings provide valuable insights into the development of exosome-based therapies for muscle diseases and in general highlight the formulation of effective functional nanocarriers aimed at optimizing exosome biodistribution. [2]

Machine Learning-Enhanced Point of Care SERS Detection of SARS-CoV2 Variants Using Handheld Raman Spectrometer

Sneha Senapati, Arvind Kaushik and J.P. Singh; Indian Institute of Technology Delhi, India

The rapid evolution of SARS-CoV-2 and its emerging variants necessitates advanced diagnostic techniques for effective pandemic management. On-field detection of disease-causing pathogens is one of the primary health concerns. This study introduces a Machine Learning (ML)-enhanced Surface-Enhanced Raman Scattering (SERS) methodology for the precise differentiation of distinct SARS-CoV-2 strains and sub-strains in clinical samples. Ag nanorods (AgNR) were fabricated using physical vapor deposition method glancing angle deposition (GLAD) were used as highly pristine SERS substrates. Characterization of AgNR substrates were performed using FESEM, AFM, HRTEM, EDX, XRD, UV-Vis and contact angle. Our research targets the detection of four different strains of SARS-CoV2: Wildtype, Kappa, Delta, and Omicron, including their respective sub-strains (BA.1, BA.2, BA.5 and XBB). Using pristine AgNR arrays and a handheld Raman spectrometer, discernible spectral variations were observed. Despite the clarity in isolated cultured strains of viruses, clinical validation using nasopharyngeal swabs from positive samples presented complexities due to spectral overlaps. By harnessing the unique molecular vibrational patterns elucidated by Raman spectroscopy, SERS offers heightened sensitivity. But problems came up because of the small differences in spectral patterns between closely related SARS-CoV-2 variants found in clinical samples. To address this, Machine learning (ML) algorithms were integrated to discern intricate patterns from SERS data, enhancing differentiation capabilities. Through the integration of gradient boost (GB) and support vector machine (SVM) models of ML within the SERS framework, our approach achieved an accuracy of 89% and

94% respectively in identifying targeted variants from nasal swabs of human patients. This integrated ML-SERS approach not only enhances detection efficacy but also offers cost-effective on-site detection capabilities and also disease prediction ability. The demonstrated precision underscores the methodology's potential in future variant identification and pandemic surveillance.

Designing Peptide Sequences as Scaffolds for Immobilising Electrochemically Active Cofactors *Marie Sugiyama[1], Ayhan Yurtsever[2], Wei Luo[1], Takeshi Fukuma[2] and Yuhei Hayamizu[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanazawa University, Japan*

There is a growing demand to establish biosensors for the rapid detection of trace substances via electrochemical signals. Despite their high selectivity, enzyme electrodes face challenges such as short lifetime and high cost. To address these issues, we propose the use of peptides, which are smaller, chemically stable and inexpensive biomolecules. In particular, short-chain peptides, which can self-assemble into fiber-like structures, have exhibited catalytic activity when complexed with cofactors in solution. These are histidine-rich peptides that stabilize the coenzyme with an imidazole group on the side chain, thereby enhancing its catalytic activity.

Our previous work succeeded to self-assemble the histidine-rich peptides on graphite surfaces to immobilize the cofactor hemins, which serve as effective electrocatalysts [1]. However, the complexity of the amino acid sequences used in the previous work has obscured the details of the self-assembled structures on graphite and the understanding of the importance of the peptide sequence on their catalytic activity.

In this study, we aim to elucidate the role of amino acids in the molecular scaffolding of the cofactors using simple sequences. We designed three types of peptides - $(YH)_4$, $(VH)_4$ and $(LH)_4$ - consisting of histidine paired with tyrosine, valine, and leucine, respectively. These peptides are composed of repeating units of two amino acids with histidine and another amino acid "X." They serve as useful tools to understand the role of the counter-amino acid X in their surface self-assembly and t in tuning the hydrophobicity of the surface [2]. These peptides were observed to form ordered hexagonal structures on graphite surfaces with monomolecular thickness, as revealed by atomic force microscopy (AFM). The addition of hemin resulted in dot-like structures on the peptide nanowires, indicating successful cofactor immobilization. Among the peptides tested, $(YH)_4$ exhibited the most efficient hemin immobilization and showed robust catalytic activity in electrochemical reactions, especially in the presence of H_2O_2.

Advanced molecular visualization techniques, including frequency-modulated AFM, provided molecular insights into the structural organization of these peptides on graphite electrodes. The hemins were shown to be aligned upwards along the rows of aligned peptides, with the peptides acting as templates to immobilize the hemins. Quantitative evaluation revealed that hemins are immobilized at a high surface density via self-assembling peptides. Strong hydrophobic interactions between peptide-peptides and between peptide and hemin contributed to the stability and efficiency of the molecular system. These results highlight the potential of simple peptide designs in the development of durable and low-cost catalytic interfaces for electrochemical applications, thereby extending the practical lifetime of enzyme electrodes and reducing costs.

Cell Capture and Culture Through Microtextured and Surface Treated Soft Polymers *Bert Vandereydt, Sean M. Parks, Laetitia Ceccoli, Domitille Avalle and Kripa K. Varanasi; Massachusetts Institute of Technology, United States*

The advancement of cell capture and culture technology is pivotal for progressing biological research and biomanufacturing. For example, the extraction and culture of primary cells from tissues - a procedure that has become increasingly useful with the advent of drug testing, regenerative medicine and personalized medicine. Tissue biopsies or surgical resections are the primary source of human cells for patient derived organoids (PDOs) and are gold-standards in cancer diagnosis, though they exhibit considerable pitfalls including: scarring and bleeding, discomfort and pain during and after the procedure, capture of epithelial cells which can overgrow desired cells in the PDOs.

Another area of interest concerns cell passaging: an often manual, time-intensive, and waste-producing process. In this process, cells are de-attached from the surface, usually using an enzymatic method like trypsin, diluted in media and plated onto new surfaces, either expanding or maintaining the cell culture. Trypsin and other enzymes like accutase are known to cause changes in the proteome of passaged cells, necessitate neutralization with inhibitors which adds steps and contamination risks, might affect the properties and the growth of primary cells on synthetic substrates during culture, and exhibit batch-to-batch variability affecting experimental consistency. The use of these enzymes also involves more steps, elapsed time and waste.

To combat these pitfalls, in this work, we develop a novel microtextured and surface-treated soft PDMS cell capture surface, designed to address these challenges by providing a more efficient, less invasive, and enzyme-free method of cell detachment and capture. By pressing the soft microstructured surface onto cell laden surfaces, cells are captured onto the surface. These can then be removed and re-cultured. Experimental results show an optimal pressure and surface design for maximizing viable cell capture. Through a combination of biomarkers, scanning electron microscopy (SEM) imaging, and in-situ live imaging, a surface chemistry mechanism of cell de-adhesion and capture is proposed. Finally, cells are successfully captured and cultured, showing the application of this technology.

NM06.07.37

Nano-Hypoxia and Aspirin Delivery via Liposome-Loaded Monocytes—Targeted Therapies *Seung Eun Yu; Yonsei University College of Medicine, Korea (the Republic of)*

This study introduces an advanced dual-therapy strategy that leverages nano-hypoxia-induced reprogramming and targeted aspirin delivery via liposome-loaded monocytes to enhance therapeutic efficacy for vascular regeneration and inflammation control. By employing liposomes encapsulated with a hypoxic-mimetic agent (CoCl2), in situ reprogramming of splenic CD11b+ cells into vasculogenic phenotypes is induced, promoting targeted angiogenesis and efficient tissue regeneration at inflamed sites. Concurrently, these reprogrammed monocytes serve as vectors for delivering aspirin-loaded liposomes directly to inflamed endothelial cells (ECs) and hepatocytes, capitalizing on the monocytes' inherent homing ability to inflamed tissues.
Advanced imaging techniques, including intravital multiphoton microscopy and 19F 2D/3D MRI, validate the effective targeting and functional reprogramming of monocytes. The combined approach not only facilitates site-specific anti-inflammatory and pro-angiogenic effects but also prolongs therapeutic action, as demonstrated in murine models of ischemic hindlimbs and fatty liver. The dual strategy ensures sustained release and superior therapeutic outcomes by minimizing systemic side effects compared to conventional methods.
Furthermore, the role of caveolin in mediating the intercellular handover of aspirin from monocytes to inflamed cells is elucidated, highlighting its increased expression in inflamed cells and its critical function in endocytosis. The therapeutic potential of this approach is evidenced by significant reductions in inflammatory markers, improved tissue repair, and prolonged anti-platelet effects, culminating in the effective rescue of atherosclerotic carotid arteries in mice.
Overall, the findings underscore a significant advancement in nanomedicine, providing a robust platform for

enhancing the precision and effectiveness of treatments for complex vascular and inflammatory diseases and suggesting a promising pathway for clinical translation.

NM06.07.38

Modulating Intrinsic Brittleness Impacts Damage Mechanisms in Bioinspired Lamellar Materials

Hajar Razi[1,2], Jozef Predan[3], Otmar Kolednik[4,5] and Peter Fratzl[6]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]University of Maribor, Slovenia; [4]Montanuniversität Leoben, Austria; [5]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria; [6]Max Planck Institute of Colloids and Interfaces, Germany

Bouligand or periodic lamellar structures are prevalent in nature and possess remarkable toughness properties. The intrinsic properties of their constituent materials, which can range from non-mineralized collagen-based fish scales to fully mineralized cortical bone, significantly affect their damage-resistant behavior. These hierarchical micro-structured materials serve as a valuable source of inspiration for the development of novel materials, particularly in the field of bio-inspired design. Despite the considerable attention given to replicating their intricate geometrical arrangements, the role of the constituent material itself remains relatively unexplored. Investigating how different base materials within complex arrangements, such as Bouligand patterns, could unlock new avenues for creating high-performance, damage-resistant materials. This understanding is crucial, especially in advanced manufacturing processes like additive manufacturing, where material choices are often limited yet must meet stringent performance demands.

Using computational modelling, we investigate the crack and damage behaviour in periodic-lamellar materials by systematically modulating the intrinsic toughness of their constituent materials. Our approach employs a phenomenological elastic-plastic finite element analysis (FEA) model to predict the progressive evolution of damage and failure. This is achieved by varying the parameter Γ, which represents the non-reversible fracture energy or crack growth resistance of the constituent material, while keeping other modelling parameters, such as elasticity and plasticity, constant. By isolating the influence of Γ, we can accurately study how material's intrinsic brittleness or toughness impacts overall fracture behaviour. The results reveal that fracture mechanisms in periodic-lamellar structures vary significantly with Γ. We demonstrate that the improvement in strength due to the hierarchical structuring is most pronounced for materials with smaller Γ values, i.e., more brittle constituents. Conversely, for less brittle materials, the structural arrangement has a minimal effect on improving their strength. This suggests that brittle materials, when patterned in Bouligand-like architectures, benefit more from the hierarchical structuring in terms of load-bearing capabilities, while tougher materials may not see as much of a performance boost from this arrangement.

Our analysis identifies three distinct fracture regimes based on the intrinsic fracture energies of the base material. In the lower range of Γ, a micro-cracking dominated regime is observed, where cracks bifurcate and propagate with minimal plastic dissipation at the softer regions of the structure. At medium values of Γ, we observe a unique mechanism driven by localized plasticity, where the strong layers are shielded by significant plastic dissipation occurring in the preceding softer regions. In this regime, the crack growth resistance plays a more pivotal role than the crack driving force. Interestingly, this medium Γ regime exhibits the most significant toughness improvements, as the balance between brittleness and plasticity seems optimal for resisting fracture. In contrast, at larger Γ values, the fracture behavior is dominated by the properties of the constituent material itself, and both the stiff and soft layers undergo significant plastic deformation and fracture.

These findings highlight the complex interplay between material properties and structural architecture, offering valuable insights for the design of bio-inspired tough materials. By strategically manipulating the intrinsic brittleness of base materials, it becomes possible to fine-tune the structural arrangements and optimize the fracture mechanisms, enabling the creation of materials with superior damage resistance and mechanical performance.

NM06.07.39

Novel Composite Nanoparticles of Saponin-Rich Yucca Extract and Chitosan— Characterization and Functionality *Guadalupe J. Góngora Chi[1], Jaime Lizardi-Mendoza[1], Yolanda L. López-Franco[1], Luis Quihui-Cota[2] and Marco Antonio López-Mata[3]; [1]Centro de Investigación en Alimentación y Desarrollo, Mexico; [2]Centro de Investigación en Alimentación y Desarrollo (CIAD A.C.), Mexico; [3]Universidad de Sonora, Mexico*

Biopolymers are natural resources with properties such as biocompatibility, biodegradability, and low toxicity. Recently, the importance of using compounds with these properties to develop biomaterials has been highlighted. Chitosan (Cs) is a biopolymer with structural properties used to create materials. Another natural compound is saponin-rich yucca extract (YE), which has been shown to possess emulsifying and antioxidant properties. This research holds the potential to harness these properties for the development of innovative biomaterials. The study aimed to prepare and characterize Cs and YE composite nanoparticles (NP-CsYE) and to evaluate their functionality during the preparation of Pickering emulsion (PE). These composite nanoparticles leverage the mechanical structure properties of Cs and the emulsifying capacity of YE. The NP-CsYE underwent physicochemical characterization, including FTIR, DLS, and AFM analysis. Pickering emulsions were prepared with NP-CsYE, and the emulsification index (EI) and micelle size were evaluated over time. Furthermore, two additional emulsions were included as controls: a PE control comprising solely chitosan nanoparticles and a traditional emulsion containing YE. The size and ζ- potential of the composite NP-CsYE obtained were 250 nm and +36 mV, respectively. FTIR and saponin quantification confirmed the formation of composite nanoparticles. Additionally, AFM morphology demonstrated that the nanoparticles are spherical in shape and non-aggregated. The formation of Pickering emulsions with NP-CsYE was demonstrated by EI, which exhibited sustained stability over time, with a value of 62% at the beginning and no significant differences over time. In contrast, differences over time were observed for emulsions prepared with YE and chitosan nanoparticles. When evaluating the stability of the PEs by measuring the micelle size, a more significant increase in size was observed for the emulsion with YE (90.7%), followed by PE with chitosan NPs (50.4%) compared to composite NPs (24.3%), demonstrated the slightest increase in size. The results indicate that the composite nanoparticles achieved PE formation and provided stability to the evaluated system on day 30, achieving better results when compared to controls. Combining both compounds resulted in enhanced functional properties, leading to a new biomaterial at the nanometer scale. This study provides a framework for applying these composite nanoparticles when forming Pickering emulsions as systems that can be used for chemical structural protection of bioactive substances.

NM06.07.40

Angle-Dependent Structural Color-Based CuO/ZnO Nanopatterns with Deep Learning Authentication *Mun Jeong Choi[1], Siyoung Lee[2] and Geon Hwee Kim[1]; [1]Chungbuk National University, Korea (the Republic of); [2]University of Pennsylvania, United States*

To prevent counterfeiting and piracy, various anti-counterfeiting technologies are used. In the past, labels such as holograms and watermarks have been used, but due to their high predictability, small electronic tags (RFID, QR code, etc.) or high-precision nanopatterns have been widely used in recent years. For these methods, complex processes such as MEMS, lithography, and high-precision writing are required to produce sophisticated patterns, which increases production costs and limits mass production. In this study, we propose a fabrication method for unpredictable nanopatterns through electrospinning, and independently depositing CuO and ZnO through a two-step solution process to provide patterns with high information density. We also demonstrate that the pattern has an excellent pattern discrimination accuracy of 97% through simple deep learning verification.

The fabrication process of nanopatterns is as follows: 1) fabrication of the base pattern by electrospinning, 2)

deposition of CuO & ZnO materials. First, a polymer solution containing palladium ions is collected vertically between parallel aluminum electrodes and transferred to the target substrate. The aligned transferred nanofibers are periodic diffraction grating structures of one-dimensional (1D) order, which can exhibit optical effects by showing separated colors that vary significantly with the angle with respect to the input light. Here, palladium is used as an active catalyst for copper deposition. The aligned nanofibers transferred to the substrate undergo solvent decomposition and fiber stabilization steps by heat treatment at 500 °C. Subsequently, Cu nanofibers are obtained by Cu electroless plating. A polymer solution containing nitrate ions is then transferred to the target substrate using similarly parallel electrodes. A heat treatment of 500 °C results in the formation of a seed layer for ZnO growth. During this process, thermal oxidation of the already prepared Cu NFs takes place under an open atmosphere. The raman spectrum shows bands of CuO centered at 302, 338, and 624 cm-1, copper(II) oxide has been formed. ZnO hydrothermal synthesis is then carried out at 80 °C to obtain the final CuO/ZnO composite nanopatterns. By adjusting the ZnO hydrothermal synthesis time, the ZnO particle size and the diameter of the NFs can be controlled, which enables the fabrication of different structural colors. The fabricated patterns are applied to a deep learning-based discrimination model, which has an excellent pattern discrimination accuracy of about 97%. It was compared with the binary pattern and ZnO pattern, and the CuO/ZnO composite pattern showed a high angle dependence based on the structural color, making it suitable as a strong anti-counterfeiting pattern.

In this study, we proposed a fabrication method for unclonable anti-counterfeiting patterns that can be discriminated without specialized optical devices. The nanopatterns with artificially aligned grating structures, which are non-replicable through a simple setting during electrospinning, become the base pattern for structural color induction. Then, CuO/ZnO composite nanopatterns with two materials deposited by solution process are obtained. At this time, the structural color can be controlled by adjusting the ZnO synthesis time, and the mixing of CuO with high absorption in the visible light region can improve the color saturation and angle dependence of the system by reducing the incoherent scattering of the grating structure, thus ensuring high information density. The discrimination algorithm based on deep neural network supervised learning achieves a high pattern identification accuracy of about 97% for an area of at least 80 (mm^2). It also proves that the pattern can be estimated with a probability of about 73.5% for untrained patterns, demonstrating that it is a practical anti-counterfeiting technology.

Exploring the Potential Effects of Biotemplation in Titanium Dioxide (TiO$_2$) Particles for Dye Sensitized Solar Cells

Wilnelia M. Barea, Lymari Fuentes-Claudio and Diego A. Valderrama; Universidad Ana G. Méndez, United States

In recent years, the world has witnessed a significant increase in the use of fossil fuels. This trend has raised concerns due to the environmental impact associated with the extraction and consumption of these fuels. As a result, there has been a global shift towards finding alternative energy sources that are sustainable and environmentally friendly. Among these, solar energy has stood out due to its abundance and potential to meet a significant portion of the world's energy needs. Solar technologies, such as photovoltaic (PV) systems, harness sunlight and convert it into electricity.

One promising alternative that has emerged within the realm of PV systems is the Dye Sensitized Solar Cells (DSSC). Since their invention in 1991, DSSCs have become one of the most researched photovoltaic systems because they present a cost-effective and greener alternative for energy production. Unlike traditional silicon-based solar cells, DSSCs use a photosensitizing dye to capture sunlight, initiating an electron transfer process that generates an electric current. This design enables DSSCs to operate efficiently even under low-light conditions, offering potential advantages in regions with less direct sunlight. In this type of system, titanium dioxide (TiO$_2$) is one of the most used semiconductor materials in DSSCs. This material is favored due to several key properties: it

has a large surface area, exhibits low toxicity, offers long-term chemical stability, and demonstrates excellent photoactivity.
This study focuses on the understanding of the effect of biotemplation on TiO_2 particles size and physicochemical properties, and its impact on the efficiency of the DSSCs. Biotemplation was achieved by using oregano brujo leaf biomass as part of the solgel method during the particle synthesis. In addition, the synthesis was performed using a ghost leaf prepared by decellularization and discoloration techniques to only retain the cellulose structure of the leaf. Resulting particles were characterized using spectroscopic experiments that include FT-Infrared (FTIR), diffused reflectance spectroscopy (DRS) and dynamic light scattering (DLS) to characterize the particles. In addition, dye adsorption measurements were performed using absorption and emission UV vis spectroscopy.

Preliminary results indicate that the biotemplation impacts TiO_2 band gap energy, particle size and chemical composition of the samples when compared to commercial anatase. Also, a difference in dye adsorption on the surface of the particle was observed.

NM06.07.42

X-Ray Absorption and Photoelectron Spectroscopy of Biotemplated Titanium Dioxide for Solar Energy Applications *Diego A. Valderrama[1], Louise Debefve[2], Antonio Torres Lopez[2] and Lymari Fuentes-Claudio[1]; [1]Universidad Ana G. Méndez, Puerto Rico; [2]Cornell University, United States*

Climate change is having profound and far-reaching impacts on our planet, including rising ocean levels, disrupted temperature patterns, and increasingly severe storms. These changes are largely driven by human reliance on fossil fuels for energy production, which leads to increased greenhouse gas emissions. To address this issue, researchers are actively exploring alternative energy sources that can mitigate the effects of climate change. Solar energy is one of the most promising options due to the abundance of the sun as a resource for producing energy. Clean solar energy is crucial in combating climate change and reducing dependence on fossil fuels.
Among the available solar technologies, dye-sensitized solar cells (DSSCs) are notable for their cost-effectiveness and lower environmental impact. DSSCs operate by using a semiconductor, typically titanium dioxide, to facilitate electron transport, but their efficiency remains limited by factors such as dye adsorption and light absorption capabilities. This project focuses on understanding how biotemplation affects the structure and physicochemical properties of the semiconductor titanium dioxide to improve light harvesting. Specifically, biotemplation with oregano leaves was used in the synthesis of titanium dioxide nanoparticles, aiming to control particle growth and porosity, thereby improving dye adsorption and light harvesting efficiency. A deeper understanding of the structural and property changes in titanium dioxide could lead to the development of better materials for solar cells.
In this study, X-ray Absorption Spectroscopy (XAS) was employed to assess the effect of biotemplation on the oxidation state, structure, and symmetry of titanium in biotemplated titanium dioxide nanoparticles. In addition to structural analysis, X-ray Photoelectron Spectroscopy (XPS) was performed to assess the surface chemistry of the biotemplated titanium dioxide. Preliminary results from these analyses reveal that biotemplation significantly alters the crystalline structure of the titanium dioxide particles obtained by this method and contributes to changes in the chemical composition of the samples.

Innovative Design Strategies for Developing Self-Assembling Hierarchical Porous Materials for Low-Carbon Applications

Kwan W. Tan; Nanyang Technological University, Singapore

Hierarchically porous structured materials with multifunctional properties and higher order dimensional complexities are highly desirable for various sustainable energy and environmental applications. This contribution explores our recent advancements in synthesizing hierarchical porous polymeric and inorganic structures for low-carbon applications, using commercial thermoplastic copolymers in directed self-assembly processes that operate under both thermodynamic equilibrium and far-from-equilibrium conditions. We have employed additive selection to precisely control the formation of mesoscale and macroscale structure order and porosity within the resulting hierarchical polymeric and inorganic carbon and oxide structures. Additionally, our use of solvent chemistry has accelerated the simultaneous polymerization of oligomeric modifying agents and the spinodal decomposition-induced phase separation, resulting in electrically conductive and mechanically flexible polymer and carbon porous structures. By coupling copolymer self-assembly with transient annealing, we have effectively regulated atomic and molecular diffusivities and supercooling kinetics, enabling the precise generation of well-defined nanostructures ranging from single atoms to nanoparticles, as well as thin films and bulk solids. These self-assembly-derived hierarchical porous materials are fundamentally and technologically vital for emerging low-carbon technologies, including carbon dioxide adsorbents, separation processes, energy storage, and water splitting.

9:15 AM NM06.08.02

3D Printed Cellulose Nanocrystals with Controlled Dual Chiroptical Properties and Infra-Red Reflectance

Botyo Dimitrov[1], Daria Bukharina[1], Ugo Michel Loic[1], Dhriti Nepal[2], Michael Mcconney[2], Timothy J. Bunning[2] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Air Force Research Laboratory, United States

Daylight management in buildings is increasingly important due to ongoing efforts to reduce energy consumption for heating and cooling. Current absorption-based technologies affect the visible spectrum, while near-infrared (NIR) reflecting materials, such as chiral nematic liquid crystals, often require crosslinking stabilization of synthetic mesogens, which can be undesirable in certain cases. In this work, we demonstrate development and manufacturing of a material with good visible transmittance that limits NIR interior irradiation, using abundant and renewable sources via an accessible method. Additionally, there is growing demand for materials with engineered circular dichroism for applications sensitive to circularly polarized light.

To address these needs, we produced twisted helical cellulose nanocrystal (CNC) films with dual chiroptical properties using a facile blade coating-based 3D printing method. With our top-down approach we assemble cellulose nanocrystals thin films of both handednesses. First, we assembled linearly oriented CNC monolayers via shear induced alignment. Then, engineered twisted Bouligand nanostructures were constructed via a sequential deposition technique by depositing each next layer in clockwise and counter-clockwise fashion by rotating the substrate at a fixed angle.

Material characterization was performed using atomic force microscopy, UV-Vis-NIR spectroscopy, ellipsometry, circular dichroism spectroscopy, and FDTD simulations. The films exhibited both left- and right-handed (LH, RH) chiroptical properties, unlike homochiral self-assembled CNC films. We demonstrate that by manipulation of the process parameters – rotation angle and layer thickness – distinct circular dichroism patterns and transmittance could be achieved. Furthermore, we show that the produced films could be treated as a hybrid between a 1D *photonic crystal and a chiral nematic film, exhibiting both IR reflectance and circular dichroism peaks, resulting in a material with dual chiroptical properties.*

The versatility of this desktop method also enabled the production of achiral films with NIR reflectance. These two cases demonstrate the potential of the top-down structuring of cellulose nanomaterials for chirality-sensitive photonic and energy management applications.

9:30 AM NM06.08.03

Multiaxial Superomniphobic Hyperbola Structures for Self-Cleaning Properties in Solar Cells *Mike Jason Koleczko[1], Jaekyoung Kim[2] and Hyunsik Yoon[1]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]University of Pennsylvania, United States*

By mimicking naturally occurring surfaces, researchers have successfully created superomniphobic surfaces even from intrinsically wetting materials. While structured surfaces like mushrooms or inverse trapezoids have exhibited superomniphobicity, generating a robust surface capable of repelling liquids from a lateral direction has remained a challenge. In this study, we leverage capillary forces for the facile manufacture of a robust surface with lateral repellency, featuring a hyperbola-star-grid structure inspired by the skin of a springtail insect. Our results demonstrate that this structure maintains its repellent functionality even when subjected to abrasion and lateral liquid exposure. Moreover, the surface encapsulates air when fully submerged in low surface energy liquids. Additionally, successful encapsulation of a 50 µm Si thin film solar cell enhances its flexibility and increases Power Conversion Efficiency through the light trapping principle, while imparting the self-cleaning properties to the cell.

9:45 AM NM06.08.04

Bioinspired and Sustainable Materials Concepts for Passive Daytime Cooling *Markus Retsch, Qimeng Song and Tobias Lauster; Universität Bayreuth, Germany*

Passive daytime cooling is an advanced technology that uses radiative cooling principles to remove heat from surfaces and release it into outer space. This is achieved without requiring external energy inputs. The process involves using materials with specific optical properties to reflect sunlight and emit thermal radiation within the atmospheric window (8-13 microns). As a result, it can cool objects below ambient temperatures, even when in direct sunlight. Passive daytime cooling is important because it has the potential to significantly reduce energy consumption for air conditioning, lower carbon emissions, and provide sustainable cooling solutions in various climates.
In this contribution we outline three concepts with a focus on sustainable or circular materials usage to realize scalable passive cooling materials.
Firstly, we take inspiration from nature, where passive cooling materials based on chitin are used by the silver Sahara ant to maintain comfortable temperatures. We will, therefore, outline the potential of chitosan and chitin as polymer matrix materials for passive cooling composites. We demonstrate the fundamental passive cooling properties of this ubiquitous, biogenic polymer as a thermal emitter.[1] Nevertheless, this approach still requires a metallic support structure to effectively scatter solar radiance.
Secondly, we outline how to repurpose post-consumer aluminium-plastic laminate (APL) waste, specifically from chip bags, into passive daytime cooling foils. APL waste poses significant recycling challenges due to its complex material composition. However, its mirror-like surface with high solar reflectance makes it well-suited for passive cooling applications. We have developed a flexible, low-cost cooling foil by coating APL waste with high-emissive polydimethylsiloxane (PDMS) or laminating pouch layer.[2, 3] This innovative approach demonstrates the potential of converting waste materials into valuable resources for sustainable cooling technologies.
Thirdly, we turn our focus to biocompatible, strongly scattering composite materials. Both the polymer and filler

material are ubiquitously available and food-grade. Their combination results in strong solar scattering and broadband thermal emission. This approach even empowers non-experts in remote areas to fabricate paint-like passive cooling formulations that can be applied to various surfaces.

Bioinspired Molecular Electrets—The “Anomalies” of Dipoles, Solvation and Charge Transfer *Valentine I. Vullev; University of California, Riverside, United States*

The importance of charge transfer (CT) and charge transport for sustaining life on Earth and for making our modern ways of living possible cannot be overstated (Phys. Chem. Chem. Phys. ***2020****, 22, 21583-21629). Concurrently, the ubiquitous nature of electric dipoles warrants deep understanding of how they affect CT. As electrostatic analogues of magnets, electrets present outstanding paradigms for exploring dipole effects on CT (Can. J. Chem.* ***2018****, 96, 843-858). Polypeptide α-helices are some of the best-known molecular electrets. These natural structures, however, do not efficiently mediate CT, which limits their utility. Therefore, we undertake the task for developing bioinspired molecular electrets based on synthetic amino acids that provide sites for charge-hopping and allow CT at ranges of several nanometers. Even a single electret amino-acid residue can rectify CT (Angew. Chem. Int. Ed.* ***2018****, 57, 12365-12369; J. Am. Chem. Soc.* ***2014****, 136, 12966-12973). The molecular macrodipoles and the CT properties of these bioinspired molecular electrets strongly depend on their structure and conformational flexibility. Sinergy between molecular-dynamics (MD) simulations and quantum-mechanical (QM) calculations provides insights into the structural properties of these macromolecules. The structures of the molecular electrets do not fluctuate much. Nevertheless, the macrodipoles of these conjugates show picosecond fluctuations with amplitudes amounting to a factor of two or three from the average values (J. Am. Chem. Soc.* ***2024****, 146, 5162-5172). The structural variations of the electret oligomers cannot account for the dipole fluctuations. The analysis, however, reveals that the solvent dynamics, inducing fast-oscillating Onsager reaction fields in the solvated cavities, is principally responsible for the huge dipole fluctuations. The impact of this discovery extends way beyond the realm of electrets and our explorations show that solvent-induced picosecond dipole fluctuations are a norm, rather than an exception, for solvated species and interfaces. Averaging these dipole fluctuations over 10-ps or 20-ps intervals drastically decreases their amplitudes. It indicates that they would have a minimum effect on nanosecond and sub-nanosecond CT. Nevertheless, these dipole fluctuations may have decisive effects on picosecond and sub-picosecond processes, such as ultrafast CT. These revelations about the dipole dynamics present unexplored paradigms for condensed-phase interfaces and electronic materials.*

11:00 AM NM06.08.06
Active Antifouling Methods—Remote Actuation Using Magnetic Nanoparticles *Irene Andreu, Payel Biswas,*

Mastoure Shirjandi and Ethan Marchetti; University of Rhode Island, United States

Bacterial biofilm growth on surfaces leads to occlusion, change of surface functionality and micro- and macroorganism proliferation. This process is commonly known as fouling, and can cause problems as varied as rise of costs for shipping of goods, food disease outbreaks and hospital-acquired urinary tract infections. To combat fouling, current techniques for removal of biofilms from surfaces typically involve scrubbing of surfaces and/or use of antibiotic agents. However, use of these techniques is limited by increasing costs, environmental concerns of the biocides, and the rise of antibiotic resistance.

Living organisms such as fish, mollusks and plants have natural mechanisms to reduce the growth of bacteria on their surfaces. Many of Nature's antifouling strategies are multi-pronged, combining for example hierarchical surface structures and active surface motion. Our work explores the possibility of using magnetic micro- and nanoparticles to achieve active antifouling and/or fouling release surfaces against diverse bacterial biofilms in the marine and biomedical environment. Magnetic particles can be used as actuators to achieve mechanical strains on surfaces, with the advantage that the activating magnetic fields can be applied without direct physical contact. Additionally, due to the aggregation experienced by freely-moving magnetic particles under magnetic fields, magnetic particles can also be used to pattern surfaces at the nano- and microscale. By combining magnetic particles and soft polymers, we can fabricate bioinspired antifouling/fouling release surfaces with potential applications in soft robotics.

11:15 AM NM06.08.07
Polydopamine/Zinc Oxide Nanoparticles Incorporated UV Protective Textile Material for Outdoor Sportswear

Rivindu R. Thanthilage[1] and Thusitha N. Etampawala[1,2]; [1]University of Sri Jayewardenepura, Sri Lanka; [2]Center for Nanocomposite Research, Faculty of Applied Sciences, University of Sri Jayewardenepura, Sri Lanka

Solar radiation is the main source of UV exposure for life on Earth. Solar radiation contains UV A, UV B, and UV C radiations. The ozone layer and gases in the upper atmosphere absorb high-energy UV radiation. Therefore, only UV A and a portion of UV B will reach the earth's surface. A small amount of UV B is required to synthesize Vitamin D. However, exposure to high doses of UV radiation can be detrimental to health. Personnel engaging in outdoor activities are vulnerable to high UV exposure. This can be mitigated by developing new and improved solar protective equipment including UV protective textiles. Although UV-protective summer clothing is already present, no proper attention has been directed towards developing UV-protective sportswear. In this research, a UV-protective textile material suitable for outdoor sportswear was developed by employing ZnO nanoparticles and mussel-inspired polydopamine (PDA) adhesive coating on a Nylon-Spandex textile substrate. ZnO nanoparticles are a well-established UV absorber while Nylon-Spandex is a widely used material in the production of sportswear. ZnO nanoparticles were synthesized in situ using the sol-gel method employing Zinc nitrate and Hexamine. Polydopamine functionalization was done through dip coating. Oxidative Polymerization of Dopamine hydrochloride in the presence of Tris buffer was employed in the synthesis of polydopamine which is an excellent adhesive that can bind with a myriad of surfaces. Hence it can bind with both the fabric as well as ZnO nanoparticles. Apart from being a powerful adhesive, polydopamine is also a strong UV absorber due to its eumelanin structure. Eumelanin is the brown-coloured pigment in the skin that absorbs UV radiation. Combining all these advantageous properties, an exceptional UV protective Nylon-Spandex textile material exhibiting UPF 472 was developed. Previous studies on polydopamine-coated substrates reported the development of either black or dark brown-coloured PDA-templated substrates. However, in this research, it was possible to overcome the drawback of obtaining predominantly black or dark brown coloured PDA-templated fabrics. This was achieved by varying the PDA coating duration. Increasing polydopamine coating durations resulted in progressively darker shades of fabric. This resulted from increased deposition of polydopamine. The presence of a higher amount of

UV-absorbing polydopamine resulted in better UV absorption. Thus, it was possible to develop PDA-templated textile materials in several shades while still providing 3-, 10-, and 15-times better UV protection than the unmodified fabric. As-produced UV-protective textile material exhibited a 53.6% higher breathability than the initial unmodified fabric. This was the result of a slight loosening of the weave during modification. The PDA/ZnO modified fabric shows good mechanical properties despite slight loosening of the weave. The polydopamine adhesive coating has significantly improved the wash fastness of the modified fabric. A PDA/ZnO modified fabric exhibiting UPF 331 was still able to provide UPF 127 even after 25 wash cycles. This indicates a 68% drop in UV protective ability after 25 wash cycles. However, this was much better than the 91% drop in UV protective ability after 25 wash cycles in the absence of polydopamine. This proves that the modified fabrics have a significant improvement in wash fastness with the use of polydopamine. As the PDA/ZnO modified fabrics show high UV protection and wash fastness, they fall into the textile category providing the highest level of UV protection (UPF 50+) even after 25 wash cycles.

Towards Power Autonomous Smart Environments Inspired by the Fly's Motion Detection *Canek Fuentes, Brian Jiang, Zhenming Yang, Shamik Datta, Huan T. Ngo, Tara Arjomandbigdeli and Shaghayegh Mesforush; Northeastern University, United States*

The temporal changes of light at the surface of an object reveal contextual information that can be used to develop smart environments. From revealing human presence and movement to an object's orientation and position in space, dynamic changes of illumination provide a way for humans to engineer environments that can interact with digital systems and augment their experience of the world. Vision-based approaches, using digital cameras and machine vision can enable such interactive environments, but cameras are distinct objects that require imaging optics, and large amounts of electrical and computing power to sustain their operation, and cannot be used in privacy-sensitive environments.

In nature, visual systems are one of the most energetically demanding in the brain. Despite this, natural visual systems are still orders of magnitude more energy efficient than digital ones. In flies, one key aspect of this efficiency is the ability to perform local computation through differential measurements in adjacent photoreceptors and the ability to adapt the photoreceptor sensitivity, reducing or increasing contrast, to compress visual information and save energy. Here, we are inspired by the following physiological feature which leads to reliable biological motion detection, which for a fly is essential for fast and robust navigation of complex environments. For artificial stimuli, e.g. a high-contrast target traveling in a specific direction, the fly's neural visual response is well explained by correlation-based detector models that rely on the multiplication of spatially adjacent and asymmetrically filtered signals. Remarkably, at the neuronal level, the direction of motion is codified in only four distinct directions.

In this talk, we will describe an autonomous sensor that mimics such biological motion detection by using differential networks of inorganic or organic photodiodes, which in the past we have referred to as computational photodetectors. Computational photodetectors can extract mid-level vision features by performing differential sensing at different positions of an object. Analog signals from the photodiode network are aggregated into a single channel, drastically reducing the power demands for data acquisition and in-sensor data processing. In turn, this enables computational photodetectors to sustain their operation by harvesting energy from the environment. Here we describe the principles of operation of such computational photodetectors and demonstrate energy-autonomous sensors that reliably detect proximity and direction of motion. In the area of assistive technologies, such proximity sensors can be mounted on eyeglasses or smart canes to aid the navigation of people with visual impairment. They can also be used to detect human presence in a room or behind a closed door. Such power-autonomous sensors advance the realization of resilient and privacy-preserving smart environments.

Reshaping Silk Proteins at the Micro- and Nanoscale for High Technology *Fiorenzo Omenetto; Tufts University, United States*

Water-based processing plays an essential role in high technology, especially in the realms of electronics, material sciences, and life sciences. Its significance lies in the development of high-quality, reliable devices, as well as in enhancing fabrication efficiency, safety, and sustainability. Particularly at the micro- and nanoscale, water serves as a unique enabler, bridging biological and technological systems. However, the high surface tension of water poses fundamental challenges, hindering wetting and complicating fabrication at the bio-nano interface.

In the field of nano and micro manufacturing, overcoming these challenges is critical for advancing the integration of biological and technological systems. The amphiphilic nature of the silk molecule, with its adaptive adsorption onto substrates with diverse surface energies, enhances intermolecular interactions between disparate materials. This capability is particularly relevant in nano and micro manufacturing, where precise control at the molecular level is crucial.

Incorporating water-based processing method into nano and micro manufacturing could significantly increase the utility of the field, providing a sustainable and efficient alternative to conventional methods. The potential applications span across various high-tech industries, promising advancements in device fabrication, material science innovations, and the seamless integration of biological and technological systems across multiple micro- and nanofabrication strategies.

2:00 PM NM06.09.02

A Self-Healing Multispectral Transparent Adhesive Peptide Glass *Gal Finkelstein[1,1], Zohar A. Arnon[1,2], Thangavel Vijayakanth[1], Or Messer[1], Orr S. Lusky[1], Avital Wagner[3], Galit Zilberman[1], Ruth Aizen[1], Lior Michaeli[4], Sigal Rencus-Lazar[1], Sharon Gilead[1,1], Sudha Shankar[1], Mariela Jorgelina Pavan[3], Dor Aaron Goldstein[1], Shira Kutchinsky[1,1], Tal Ellenbogen[1], Benjamin Palmer[3], Amir Goldbourt[1], Maxim Sokol[1] and Ehud Gazit[1,1]; [1]Tel Aviv University, Israel; [2]Columbia University, United States; [3]Ben-Gurion University of the Negev, Israel; [4]California Institute of Technology, United States*

Despite its disordered liquid-like structure, glass exhibits solid-like mechanical properties. The formation of glassy material occurs by vitrification, preventing crystallization and promoting an amorphous structure. Glass is fundamental in diverse fields of materials science, owing to its unique optical, chemical and mechanical properties as well as durability, versatility and environmental sustainability. However, engineering a glassy material without compromising its properties is challenging.

Here we report the discovery of a supramolecular amorphous glass formed by the spontaneous self-organization of the short aromatic tripeptide YYY initiated by non-covalent cross-linking with structural water. This system uniquely combines

often contradictory sets of properties; it is highly rigid yet can undergo complete self-healing at room temperature. Moreover, the supramolecular glass is an extremely strong adhesive yet it is transparent in a wide spectral range from visible to midinfrared.
This exceptional set of characteristics is observed in a simple bioorganic peptide glass composed of natural amino acids, presenting a multi-functional material that could be highly advantageous for various applications in science and engineering.

2:15 PM NM06.09.03

Multiapproach for Structural Colour Modulation in Electrodeposited Cellulose Nanocrystals Films *Alexandre Fonseca[1,2], Paul Grey[2], Elvira Fortunato[2], Rodrigo F. Martins[2], Luis Pereira[2,3] and Diana Gaspar[3,2]; [1]CENTI, Portugal; [2]Universidade Nova de Lisboa, Portugal; [3]AlmaScience, Portugal*

Cellulose Nanocrystals (CNCs) have a natural ability to self-organize into a chiral nematic liquid crystal phase with a helical arrangement. This characteristic can be preserved in dry CNC films, resulting in iridescent colors and interesting photonic properties. These properties include the selective reflection and transmission of right- and left-handed circular polarized light (RCPL and LCPL, respectively). CNCs naturally develop into a left-handed structure, which only reflects LCPL. Therefore, there is a need for structures capable of reflecting RCPL to access both polarization states.
This work demonstrates how the reflected wavelength of CNCs electrodeposited layers can be modulated across the entire visible light range through passive and dynamic stimulation. The photonic bandgap is modulated trough ions exchange and by the adsorption of humidity. In addition, multilayer electrodeposited CNCs structures with the ability to reflect in both left-handed circularly polarized light (LCPL) and right-handed circularly polarized light (RCPL) channels were studied using polypropylene tape as retardation plates. This method allows for a wide variety of colors in LCPL and RCPL to be obtained, depending on the number of layers and the initial photonic bandgap conditions of the CNCs films. Additionally, the birefringence is studied and predicted through reverse engineering in stress-induced birefringent tapes, particularly polypropylene. The results demonstrate the potential of CNCs multilayer structures to be applied in photonics, stereoscopic imaging, sensing, and information processing.

2:30 PM NM06.09.04

Protein Building Blocks from Intrinsically Disordered Proteins to Control Phase Separation *Thalyta Santiago[1,2], Brian Carrick[2], Melody Morris[2], Marisa M. Beppu[1] and Bradley Olsen[2]; [1]Universidade Estadual de Campinas, Brazil; [2]Massachusetts Institute of Technology, United States*

Intrinsically disordered proteins (IDPs) have the ability to undergo liquid-liquid phase separation (LLPS) in cells to form biomolecular coacervates that facilitate complex biological processes. The ability of an IDP to undergo LLPS is frequently associated with the presence of low-complexity regions, characterized by low amino acid diversity and often repetitive sequences. Motivated by this, possible consensus repeat sequences of IDPs were identified from the DisProt database by categorizing amino acids into four classes based on charge and hydrophilicity, generating a simplified protein representation. These simplified sequences were aligned at various repeat unit cassette lengths and compared using a one-hot encoding strategy, revealing consensus repeat units intrinsic to the protein sequence. These reduced motifs were then manually transcribed to base amino acids and expressed in E. coli. The ability to form phase separation complexes was confirmed via turbidimetry, demonstrating that the engineered proteins exhibited a similar coacervation behavior compared to the native protein. We propose that additional consensus repeat sequences can be identified and extracted to further develop a platform of engineered protein materials based on these systems.

10:30 AM *NM07.01.01
Understanding the Forces that Regulate Crystallization by Particle Attachment *Elias Nakouzi[1], Lili Liu[1], Sakshi Yadav Schmid[1], Dongsheng Li[1], Christopher J. Mundy[1,2], Gregory K. Schenter[1], Jaehun Chun[1,3] and James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]The City College of New York, United States*

Nanoparticles in solution can grow, aggregate, assemble, attach, or remain dispersed due to the interplay of energetics and dynamics. These phenomena have been exploited to create an impressive array of nanomaterials such as colloidal crystals, mesocrystals, highly branched nanowires, and adaptive materials that respond reversibly to external stimuli. When the nanoparticles fuse to create larger single crystals, they often become crystallographically coaligned before the point of contact in a process referred to as oriented attachment (OA). Traditional colloidal theories such as DLVO provides a traditional framework for evaluating the forces that underly the interactions and dynamics of nanoparticles but fail to capture key particle interactions due to the atomistic details of both the crystal structure and the interfacial solution structure that are part and parcel of the OA process. Moreover, despite the fact that attachment on any two identical facets would create an energetically *favorable product, OA is well known to occur preferentially on specific facets, implying that forces which oppose particle-particle approach may be as important as those the drive it. In particular, solvation barriers, which are intimately related to the structure of the underlying crystalline lattice, provide an obvious source of barriers to particle-particle contact but are not captured by DLVO theory. Here we explore the non-DLVO forces, both attractive and repulsive, that regulate the dynamics and outcomes of particle aggregation, coalignment and attachment. Using ZnO as a model system, we investigate the effect of dipole-dipole interactions on the long-range forces and torques that drive particle approach and alignment by combining by in situ TEM observations of ZnO nanoparticle OA events with Langevin dynamics simulations for solvents whose dielectric constants differ by an order of magnitude. We compare the magnitude of these forces to the electrostatic and van der Waals forces calculated using DLVO theory and show that they non-DLVO forces both dominate and provide a rationale for the discrepancies observed in the different solvents. We also investigate the short-range repulsive forces arising from the structuring of the solvent near the surface using 3D AFM. We find that the solvation force is stronger in water compared to ethanol and methanol, due to the stronger hydrogen bonding and denser packing of water molecules at the interface. To further understand the nature of the solvation force, we used 3D AFM to measure the repulsive hydration force between the AFM probe and mica for a series of monovalent and divalent electrolytes and low and high concentrations. The results exhibit a direct scaling between the work required to bring the tip to the surface and well-known proxies for the strength of the ion-water and ion-ion interactions. Our results highlight the importance of non-DLVO forces in a general framework for understanding and predicting particle aggregation and attachment and suggest a scheme for controlling the outcomes of particle aggregation and attachment by varying the solution conditions to tune the solvation forces.*

Crystalline and Amorphous Precursors to Aragonite but Not Calcite Biomineral Formation Pupa Gilbert[1,2];
[1]University of Wisconsin-Madison, United States; [2]Lawrence Berkeley National Laboratory, United States

Analyzing 200 million spectra with Myriad Mapping (MM) of nanoscale mineral phases we found expected and unexpected precursors on the surface of forming coral skeleton and nacre, but not on sea urchin spines. The expected phases, found on all biominerals (1-11), were amorphous calcium carbonate hydrated (ACCH_2O) and anhydrous (ACC). The unexpected crystalline precursors were calcium carbonate hemihydrate ($CaCO_3$-½H_2O, CCHH) and monohydrocalcite ($CaCO_3$-1H_2O, MHC)(12). CCHH, in particular, had been synthesized I the lab (13) and fully characterized, but had never been observed as a natural mineral of biomineral. The observation of crystalline precursors demonstrates that biomineralization pathways are more complex and diverse than previously understood, opening new avenues for the synthesis of self-assembled materials via multiple metastable precursor phases, amorphous and crystalline.

Chiral Plasmonic Superlattices Based for Biosensing *Tsz Him Chow[1] and Luis Liz-Marzán[1,2,3]; [1]CIC biomaGUNE, Spain; [2]Ikerbasque, Basque Foundation for Science, Spain; [3]Centro de Investigación Biomédica en Red, Bioingeniería, Biomateriales y Nanomedicina, Spain*

Surface plasmons are coherent and collective oscillations of conduction electrons along the surface of a metal. In plasmonic metal nanoparticles, these oscillations result in remarkable optical properties that can be finely tuned under appropriate conditions. Chiral plasmonic metal nanoparticles have recently demonstrated chiral electromagnetic field enhancement and strong interaction with chiral materials. In 2020, Liz-Marzán's group demonstrated the synthesis of chiral Au nanorods using chiral micelles formed from dissymmetric cosurfactants.[1] The sharp chiral surface wrinkles led to dissymmetry g-factors on Au nanorods as high as ~0.20.

Besides using circular dichroism spectroscopy and surface-enhanced Raman spectroscopy (SERS) independently for biosensing, surface-enhanced Raman optical activity (SEROA), combining SERS with Raman optical activity (ROA), makes use of highly polarizable chiral platforms that can discriminate enantiomers via SERS using equal amounts of left-hand and right-hand circularly polarized light. Chiral plasmonic metal nanostructures have recently demonstrated chiral electromagnetic field enhancement and strong interaction with chiral materials, which is highly beneficial in SEROA. The plasmonic and chiroptical properties of individual chiral nanoparticles can be optimized with different overall shapes and sizes as well as the synthetic methods. But for practical sensing and enhanced-spectroscopy applications, it requires assemblies of plasmonic nanoparticles to large electromagnetic field at hotspots, enabling extremely high sensitivity, even down to single molecule detection under certain conditions. However, there are no (or very few) studies of understanding the effects of the interparticle/lattice spacing and orientation of chiral superlattices based on individual chiral nanoparticles on their chiroptical response.

In this work, we explore self-assembled chiral plasmonic superlattices to optimize their plasmonic properties and chiroptical responses for biosensing. By utilizing templated-assisted self- assembly,[2] we can construct hierarchical chiral plasmonic arrays demonstrating precise numbers of nanoparticles in each lattice. We anticipate self-assembled chiral nanostructures with exceptional chemical and optical properties will provide versatile designs for highly efficient and reproducible SEROA-based platforms for chiral molecule detection. A diverse range of substrates with varied patterns, nanoscale architecture, and hotspot chirality morphology can be produced using advanced nanofabrication techniques.[3]

The Role of Surface Potential in Formation of Branched Cubic Pt Mesocrystals by Oriented Attachment *Yuna Bae[1], Eunmi Kim[2], Kristen A. Fichthorn[2], James J. De Yoreo[1,3] and Dongsheng Li[1]; [1]Pacific Northwest National*

Laboratory, United States; [2]The Pennsylvania State University, United States; [3]University of Washington, United States

Crystals grow through a variety of pathways, such as monomer-by-monomer addition or attachment of higher species, including amorphous or crystalline particles and ionic or molecular clusters. Oriented attachment (OA) is a common pathway of crystal growth in which primary nanoparticles become crystallographically aligned before they make contact. The process of particle approach and attachment is determined by the interplay between interparticle forces, including vdW attraction, repulsion associated with the liquid-solid interfacial structures at particle surfaces, steric hindrance due to ligand-ligand interactions, and electrostatic repulsion between like-charged particle surfaces. The latter depends strongly on the surface potential, which can be affected by changes in the solvent composition and pH as the system evolves through repeated attachment events that eliminate particle surface area. In this study, we explore the formation of branched cubic Pt mesocrystals via the oriented aggregation of nanoparticles, employing cryo TEM, liquid-phase TEM, and DFT calculations. We find that the mesocrystals form via aggregation of particles into a disorganized cluster and subsequent OA events. The nanoparticles in the cluster are initially spatially separated and become oriented before attachment. The inner particles in the cluster start attaching on (100) faces, forming a cube-shaped core. As time progresses, nanoparticle attachment switches to occurring on the (111) faces, causing branched rods to grow on the faces of the cubes. Combining measurements of facet-specific zeta potential as a function of total particle surface area with DFT calculations, we demonstrate that the direction of OA in this system is altered from [100] to [111] due to the competitive adsorption of chloride ions and formate on Pt surfaces, which evolves as the total Pt surface area decreases through the OA process, altering the resulting electrostatic forces. The insights gained from this work have the potential to enable predictive control over the morphology of crystals formed through OA processes in order to produce tailored materials' properties.

Nanoparticle-Derived Cholesteric Liquid Crystals Assembled Under Confinement Eugenia Kumacheva; *University of Toronto, Canada*

The organization of nanoparticles in constrained geometries is an area of fundamental and practical importance. Confinement of nanocolloids leads to new modes of packing, self-assembly, phase separation, and relaxation of colloidal liquids; however, it remains an under-explored area of research for colloidal liquid crystals.

This talk highlights the behavior of colloidal liquid crystals under spherical and cylindrical confinement. We show that geometrically constrained cholesteric liquid crystals formed by rod-shapes cellulose nanocrystals (CNCs) exhibit new self-assembly modes in the process that is governed by the elastic energy reduction. Well-defined topological defects of this liquid crystalline host govern the organization of polymer, metal, carbon and metal oxide nanoparticle guests.[1-4] The resulting hierarchical structures exhibit fluorescence, and plasmonic properties, as well as magnetic actuation. Furthermore, we demonstrate interactive morphogenesis between the cholesteric liquid crystal host and nanoparticle guests, which stems from the coupling of self-assembly modes of CNCs and

guest nanoparticles. These results advance our understanding of how the interplay of order, confinement and topological defects affects soft matter materials.

***Crystallization via Particle Oriented Attachments** Dongsheng Li; Pacific Northwest National Laboratory, United States*

Nanomaterial properties such as morphology, size, strain, defect, etc are tied to their structures at micro-, nano-, and atomic scales. Understanding the fundamental mechanisms of crystal growth, the formation of material structures, and the factors that control them enables us to design materials with tailored properties. We study mechanisms of crystal growth via particle attachments by integrating in-situ techniques, such as TEM and AFM, with theoretical simulations. Interactions between active species at liquid-solid establish conditions to control the assembly process. We study the crystal surface interactions as a function of viscosity, pH, electrolyte type, and concentration and the resulting structures and defects formed via particle aggregations. The findings of this work enable us to control crystal growth and the resulting structures and design materials with tailored properties.

2:30 PM NM07.02.03

***Mesoscale Multi-Shell Architectures with DNA-Programmable Nanoscale Organization** Dayoung G. Lee[1] and Oleg Gang[1,2]; [1], United States; [2]Brookhaven National Laboratory, United States*

DNA-based assembly approaches offer the creation of highly ordered and functional nanomaterials by leveraging the programmability of DNA sequences. This approach enables precise spatial control, allowing the assembly of complex structures through engineered bonds to program the placement of functional nanoparticles. However, to fully utilize these new materials for applications in optics, energy materials, and biomaterials, it is required to develop methods for controlling multiple scales, from nano- to meso- and macro-regimes.
To address this challenge, we have explored the creation of multi-shell DNA-based lattice architectures with both nanoscale and mesoscale organization. We developed an epitaxial growth strategy for fabricating multi-shell DNA superlattices by controlling DNA crystal growth via selective assembly of monomers. This approach leverages the designed binding capabilities of DNA scaffold, enabling precise formation and in-situ monitoring of shell growth. The developed methodology overcomes nucleation challenges, facilitating the creation of complex multi-shell DNA superlattices. We used the developed approach to control nanoparticle loading and release within the mesoscale structure and analyzed the kinetics of these processes. Our investigation demonstrates the effectiveness of multi-shell DNA superlattices as carriers for controlled release applications, offering promising avenues for enhanced stability and efficacy in drug delivery systems. Additionally, through the design of directional bonds of monomers and control of assembly processes, we further demonstrate that this strategy allows for the creation of intricate configurations such as Janus-like and dumbbell mesoscale architectures.

2:45 PM NM07.02.04

***Colloidal Structure and Interactions of Quantum Dots Characterized by Neutron and X-Ray Scattering** Eliza Price[1], Niamh Brown[1], Jimin Kwag[1], Lilin He[2] and William Tisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States*

The self-assembly and aggregation of colloidal particles such as quantum dots (QDs) are driven by complex interparticle interactions and dynamics. Experimentally studying these interactions is challenging due to the nanoscale and hybrid nature of QDs, which are composed of an inorganic core coated in an organic ligand shell. To address this gap, we performed complementary small-angle neutron scattering (SANS) and small-angle X-ray scattering (SAXS) measurements to investigate the colloidal ligand shell structure and interactions of PbS QDs and inform their self-assembly behavior.

We consider PbS QDs with core sizes between 4.8-7.4 nm, dispersed in toluene, hexane, and cyclohexane solvents. We probe the colloidal structure of both the inorganic core and organic ligand shell through SANS contrast matching experiments, where solvent deuteration is varied to resolve each component. After fitting appropriate models to the SANS data using Bayesian methods, we find a statistically significant correlation of the QD ligand shell thickness with core size. This correlation persists despite nearly identical passivation for all samples, confirmed by H^1*-NMR. We also find significant differences in the solvent penetration into the ligand shell for each of the solvents studied. To quantify the colloidal interactions of the PbS QDs, we extract the second virial coefficient from SAXS measurements of colloids with varying concentrations. We then study how the ensemble-scale properties of a QD colloid translate to self-assembly behavior by comparing our measurements to self-assembled films of PbS QDs.*

Our work leverages complementary SANS and SAXS measurements to study the colloidal structure and interactions of PbS QDs and inform their self-assembly behavior. In addition to thoroughly characterizing colloidal PbS QDs, we demonstrate the utility of these tools and analyses for studying structure-property relationships in other self-assembling colloidal systems of interest.

3:30 PM *NM07.02.05
Exploring Crystal Growth and Phase Transitions Through Self-Assembly Simulations *Julia Dshemuchadse; Cornell University, United States*

How can we make new materials and better understand how their underlying structures form? The direct observation of crystal growth and transitions remains supremely challenging, but gaining insight into these fundamental processes is central to our quest of creating materials in a rational and targeted way, connecting structure to functionality. We build self-assembly models designed for structural complexity and diversity, aiming at assembly robustness, and we study how they respond to perturbations on the particle and system levels. By using simple coarse-grained models, we gain systematic insights into the processes that lead to structural complexity, order/disorder phenomena, or magic-size effects. Our goal is to derive the essential principles that govern the formation of materials' structures and to use these insights to tailor crystallization pathways and create new functional materials. Our work promises to establish new pathways to materials design through simulations, which explicitly incorporate and explore phase transformation kinetics.

Mechanism of Hierarchical Plasmonic Biomaterials Engineered Through Peptide-Directed Self-Assembly
Lubna Amer, Maurice Retout, Zhicheng Jin, Sumathi Kakanar and Jesse V. Jokerst; University of California, San Diego, United States

Nanomaterials have garnered significant attention for their exceptional physical and chemical properties.

Plasmonic metallic nanoparticles, such as gold (AuNPs) and silver (AgNPs), are particularly fascinating because they exhibit a localized surface plasmon resonance (LSPR) band caused by electron oscillation in response to light. This LSPR band, and thus, their electronic and optical properties, can be tuned by altering the size, shape, and surface chemistry of the nanoparticles. In particular, AgNPs possess great scattering and a high molar absorption coefficient, and thus exhibit multiple colors within the visible range, making them invaluable in sensor applications. Hierarchical assembly of nanoparticles is an extension of this phenomena and offers properties and functionalities beyond those of individual nanoparticles such as increased surface area, improved signal amplification, and synergistic interactions that mimic biomolecules. However, self or directed assembly techniques often require complex redox chemistry, limiting widespread application.

In this study, we explore the hierarchical self-assembly of silver biomaterials using a peptide-directed approach to induce diffusion-limited aggregation. We use specific peptide sequences to control interparticle distance and morphology thereby avoiding complex syntheses to provide an accessible and tunable method for building fractal structures. We first synthesized ~20 nm nanospheres stabilized with bis(p-sulfonatophenyl)phenylphosphine dihydrate dipotassium (BSPP-AgNP) to be incubated with various short peptides (3 – 13 residues). Here, the peptides served as bridging motifs, facilitating the formation of fractal structures through noncovalent interactions with the charged surface. Peptides containing arginine, lysine, histidine, phenylalanine, and tryptophan were chosen, reflecting different interactions such as electrostatic, pi-pi stacking, and hydrophobic forces. We systematically investigated the impact of peptide sequence, concentration, and length on the biomaterials' morphology via TEM, DLS, and UV-Vis spectroscopy.

We determined that arginine-rich peptides were especially effective in promoting self-assembly because of the strong electrostatic interactions facilitated by the guanidine group, which can engage in multiple directional interactions with anionic counterparts. These peptides yielded well-defined fractal structures with high fractal dimensions at low concentrations (1 μM). Peptide concentration played a crucial role for all peptides; higher concentrations led to rapid aggregation and a loss of structural control, while lower concentrations failed to induce significant assembly. Optimal peptide concentrations ranged from 1 to 30 μM, balancing the interaction strength and assembly kinetics. Moreover, fractal dimension analysis indicated that monomeric peptides led to the highest fractal dimensions (~ 1.7), while longer peptide sequences resulted in denser aggregation and reduced fractal complexity. We also investigated C_{50} values, defined as the peptide concentration required to achieve 50% of the maximum assembly intensity. Arginine-based peptides demonstrated a C_{50} value two times lower than other sequences, reinforcing their superior ability to drive self-assembly. These structures also exhibited substantial colorimetric changes, confirming their potential for sensor applications.

Control experiments with citrate-AgNPs and BSPP-AuNPs showed no fractal assembly, highlighting BSPP's specificity on silver. S/TEM analysis revealed particles merging as a function of time or ligand concentration, confirming that AgNPs behave as soft particles that undergo spontaneous coalescence after modification of their surface properties with charge neutralization and desorption of ligands.

By leveraging the simplicity of peptide design, we present a scalable and tunable approach to building fractal biomaterials with applications in medical sensing and electronic devices.

Aggregation-Enabled Biomaterials for 3D Bioprinting Yu Shrike Zhang; *Harvard Medical School, United States*

Over the last decades, the fabrication of three-dimensional (3D) tissues has become commonplace. However, conventional 3D fabrication techniques are limited in their capacity to produce complex tissue constructs with the *required precision and controllability that is needed to replicate biologically relevant tissues. To this end, 3D bioprinting offers great versatility in the fabrication of biomimetic volumetric tissues that are structurally and functionally relevant. It enables precise control of the composition, spatial distribution, and architecture of bioprinted constructs facilitating the recapitulation of the delicate shapes and structures of target organs and tissues. This talk will discuss our recent efforts in developing advanced 3D bioprinting strategies with a correlation to those that are relying on aggregation and self-assembly. These platform technologies will likely provide new opportunities in constructing functional tissues to facilitate regeneration as well as microtissue models for promoting personalized medicine.*

Colloidal Chains Assembled from Nanoscale Micelles of Diblock Copolymers and Their Orientation for Linear Alignment of Fluorophores and Nanoparticles *Jaemin Kim, Kyunghyeon Lee, Sangyoon Kim and Byeong-Hyeok Sohn; Seoul National University, Korea (the Republic of)*

Colloidal particles in nano- or micro-scale can assemble into a variety of superstructures, which can deliver cooperative properties not observed in individual particles. Patches created on the particle exterior, which are chemically or physically different from the particle surface, are useful for effective bindings between colloidal particles. Thus, the patchy particles can be combined into structures like colloidal molecules and chains by utilizing directional bonding between the patches. In particular, colloidal chains exhibit anisotropic properties that can be intensified at the macroscopic scale by orientating the chains. In this presentation, we confirmed the step-growth mechanism in the self-assembly of patchy micelles of diblock copolymers and also functionalized the colloidal chains with fluorophores and nanoparticles. To elucidate the mechanism of assembling the micelles, we investigated well-separated colloidal chains with sufficient numbers using electron microscopy and evaluated the dimensional evolution of the chains. As the assembling process progressed, the chains appeared to become longer, confirmed by an increase in the number of longer chains in the size distribution, which follows the most probable distribution, a feature of the step-growth polymerization. Based on the mechanism, we were able to accelerate colloidal polymerization by increasing the initial concentration of patchy micelles and form cyclic chains by diluting the solution. In addition, the colloidal chains were coated differently by drop-casting and spin-coating. Then, the orientation and stretching of the chains were analyzed quantitatively by directly observing individual chains with an electron microscope. For drop-cast chains without external force, no specific orientation was observed. In contrast, the spin-coated chains subjected to centrifugal force were oriented in the radial direction. The spin-coated chains also exhibited stretched conformations compared to the drop-cast chains. We utilized these oriented and stretched chains as a template to align fluorophores and nanoparticles. By incorporating red-emitting fluorophores into the cores of patchy micelles forming colloidal chains, we observed the oriented chains showing red fluorescence. We also synthesized Au and Pt nanoparticles at the location of the oriented chains by loading the precursors into the micellar cores of the chains, followed by plasma treatment, which resulted in their linear alignment.

Multiscale Self-Assembly of Nanoparticles into 3-Dimensional Photocatalysts *Markus Niederberger; ETH Zürich, Switzerland*

Multiscale nanoparticle assembly is at the heart of efforts to integrate nanoparticles into macroscopic materials and devices [1]. The idea of arranging nanoparticles in a modular and defined way to larger entities is extremely appealing, because in such a way a nearly indefinite number of different architectures is accessible from a limited set of building blocks. Among the many geometries, 3-dimensional structures like aerogels are unique in the sense that the size-specific properties of the nanobuilding blocks are fully preserved in the macroscopic material [2]. With their extensive porosity and large surface areas aerogels are particularly attractive for applications in gas-phase photocatalysis. However, to exploit the full potential of aerogels in photocatalysis, not only the composition of the aerogels, but also their macroscopic shape and the choice of reactor must be carefully matched to ensure efficient gas flow through and light penetration into the aerogel [3][4].

In this presentation, a widely applicable strategy for the production of two-component aerogels with different geometries from colloidal dispersions of titanium dioxide and noble metal nanoparticles will be presented. Using the example of photocatalytic hydrogen production from methanol, it will be shown how these nanoparticle-based aerogels and the associated reactors can be improved step by step to significantly increase hydrogen production.

Heterogenous Aggregation and Assemblies via Thermal Modulation of DNA and Elastin-Like Polypeptide Nanosystems *Jundai Shen[1], Yifeng Cai[2], Oleg Gang[1,3] and Francois Baneyx[2]; [1]Columbia University, United States; [2]University of Washington, United States; [3]Brookhaven National Laboratory, United States*

DNA nanotechnology offers a sophisticated bottom-up approach to nanofabrication, overcoming the inherent limitations of conventional top-down methods. Due to its predictable chemical reactivity and structural regularity, DNA enables the engineering of a wide variety of nano-objects through sequence-dependent oligonucleotide binding. The functional integration of DNA with nanoparticles in diverse physicochemical forms has led to the creation of numerous composite nanomaterials that frequently exhibit novel or enhanced capabilities as a result of the synergistic interplay between the components.

A notable example of such nanomaterials is the biopolymer elastin-like polypeptide (ELP). Owing to its surface cysteine residues and solid-binding peptides (SBPs), the ELP protein (VPGVG)96-C can be employed in strategies to bind or mineralize nanomaterials, with its efficacy further enhanced through conjugation with various nanomaterials such as nanoparticles and nano-assembled structures. As a thermally responsive protein, ELP can bind to nano-objects and DNA nanostructures, facilitating the formation of higher-dimensional nanosystems that leverage temperature stimuli to initiate assembly formation.

This study investigates the morphologies of ELP-DNA conjugates, the interactions within AuNP particle hybrid shells, and the multidimensional assemblies mediated by DNA-ELP hybrid linker systems. This system exploits the intrinsic and distinct thermal behaviors of DNA and ELP across different temperature regimes, considering factors such as DNA/ELP sequence, ionic environment, and linker ratios. Our aim is to elucidate the behaviors and the *mechanisms of temperature-mediated assembly within DNA-ELP complexes and their associated systems, thereby providing valuable insights for the development of future dynamic and functional nanotechnological applications.*

9:00 AM NM07.03.03

Self-Assembly of Electroactive Small Molecule Crystallites in Polystyrene-Based Gate Dielectrics for Increased Threshold Voltage Shifts and Memristor Activity *Christopher R. Bond, Howard E. Katz and Daniel Reich; Johns Hopkins University, United States*

Charging of organic-field effect transistors (OFETs) provides insight into the charge trapping behavior of polymer dielectrics via shifts in the threshold voltage (V_{th}) that occur after charging and can confirm memristor activity in these devices. Top-contact bottom-gate pentacene OFETs were fabricated with single layer dielectrics comprising either polystyrene (PS), poly(4-methylstyrene) (P4MS), or poly(4-tert-butylstyrene) (P4TBS). The polystyrenes were blended with varying concentrations of two different small molecules known as dibenzotetrathiafulvalene (DBTTF) and 2,8-difluoro-5,11-bis(triethylsilylethynyl)anthradithiophene (diF-TES-ADT) to form self-assembled, small, separated crystallites contained throughout the polymer dielectric layer. The output and transfer characteristics of these devices were investigated and the shift in the threshold voltage of each device was measured after applying static charging of -70 V to source and drain electrodes for 5 minutes. Two-terminal measurements were conducted using multiple different gate biases in the range of -50 V to +50 V to investigate memristor behavior in the devices. The devices were subsequently analyzed via laser optical microscopy, x-ray diffraction (XRD), scanning electron microscopy (SEM), and energy-dispersive x-ray spectroscopy (EDS) to confirm the presence and persistence of the small molecule crystallites while further characterizing their structure and morphology. Threshold voltage shift data obtained from the transfer characteristics of each device show that inclusion of DBTTF crystallites in the dielectric layer substantially increases the threshold voltage shift observed in the two substituted polystyrene matrices. Threshold voltage shift increases as large as 330% are observed in OFETs with P4MS dielectric layers when DBTTF is included, while a maximum average threshold voltage shift of 49.1±2.2 V is observed in the OFET with P4TBS and 10wt% DBTTF. OFETs comprising PS, P4MS, and P4TBS with at least 7.5wt% of DBTTF added showed memristor activity with gate voltage range set to -50 V and +50 V, where shifts in current are reversible and reproducible while all other devices break down under similar conditions. This work demonstrates that including small, separated crystallites in polymer dielectrics enhances their charge storage ability and could be promising for creating nonbinary memory devices for data processing, such as memristors used in neuromorphic computing.

Controlling Macroscale Morphology in DNA-Based Assembly Using Acoustic Energy *Zohar A. Arnon[1] and Oleg Gang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States*

One of the main challenges of developing bottom-up designed materials is the issue of scaling their formation and shaping them into a desired morphology. A high degree of nanoscale control hinders the ability to form nanomaterials with predefined macroscale morphology. DNA nanotechnology allows accurate spatial control at the nanoscale which enables fabrication of intricate organizations; yet, structural arrangement at the macroscale remains a challenge. We developed an assembly approach driven by acoustic waves in order to control the morphology of DNA-assembled materials at the scales from tens of microns to millimeters, thus complementing a nanoscale assembly regime offered by DNA-guided methods. Specifically, we explored the use of standing surface acoustic waves (SSAW) to direct assembly and control morphology of DNA origami based crystal lattices. By controlling both acoustic forces and temperature, we investigated the assembly process at different scales by a combination of optical microscopy, small-angle x-ray scattering and electron microscopy techniques. We further studied the nucleation, crystal fusion and growth under different acoustic conditions. The developed approach *allows to form macroscale nanomaterials with prescribed morphology, as defined by the acoustic field, while their nanoscale organization is programmed by DNA. Our experimental observations are supported by a model that incorporates nucleation dynamics, diffusion-limited growth, and the effects of acoustic driving. The model provided valuable insights into the impact of acoustic waves on suppressed nucleation and crystal growth. Overall, our study demonstrates the potential of acoustic waves as a complementary method for controlling the morphology of DNA-assembled nanomaterials at the macroscale. This approach expands the scope of DNA nanotechnology and paves the way for the fabrication of nanomaterials with tailored properties and functionalities for a wide range of applications.*

9:30 AM *NM07.03.05

Fluorescent Peptide Probes for Living Cell Proteins Analysis *Xiaoding Lou; China University of Geosciences, China*

There are abundant proteins in living cells, which interact with each other to form a signal transduction network system. When diseases occur in the body, the protein will have obvious expression or function abnormalities. However, proteins change rapidly and vary in concentration within living cells, making accurate measurement difficult. The development of effective detection methods to achieve protein analysis in the complex environment of living cells is significant for the development of novel disease diagnosis and treatment methods. As the core tool of protein detection, fluorescently labeled antibody mainly relies on the recognition site of the variable region to bind to the protein specifically, and then output the signal by modifying the signal molecule on the antibody. However, protein analysis in living cells is difficult due to its structural characteristics.
Inspired by the structure of fluorescence-labeled antibody, we designed peptide sequences with the ability to cross the membrane barrier as a transmembrane module. The peptide sequence at the antibody recognition site was selected and reconstructed as the recognition module. Synthesis of signal molecules whose rotation restriction results in enhanced fluorescence acts as a signal output module. Developing an integrated peptide probe by covalently linking the three parts. 1) Establishing a new method for dynamically changing the interaction force between probes and cell membranes; 2) Proposing a new identification strategy of matching spatial configurations to increase Kon and induce covalent binding to decrease Koff; 3) Designing asymmetric fluorescent small molecule scaffolds, constructing a universal detection platform, to achieve localization and quantification of various proteins in living cells and tissue sample analysis.

Three-Dimensional Colloidal Nanocrystal Metamaterials *Cherie R. Kagan; University of Pennsylvania, United States*

Colloidal nanocrystals (NCs) have inorganic cores and organic or inorganic ligand shells. They are prized for their size- and shape-dependent properties and serve as building blocks of artificial materials and unconventional devices. Here, we describe NC-based, three-dimensional optical metamaterials constructed using imprinting techniques from single- and multiple-types of metal and metal oxide NCs. We focus on the chemical and thermal addressability of NCs, i.e., the ability to select, exchange, strip, or add atoms, ions, and molecules during or post-deposition, that is not accessible in bulk materials, and allows the control of metamaterial structure and properties. Through ligand engineering we tailor the dielectric function of metal NC assemblies through an insulator-to-metal transition.[1] By juxtaposing NC assemblies and bulk thin films to make bilayer heterostructures, we exploit ligand exchange to trigger folding of two- into three-dimensional structures,[2] which we use to achieve broadband[3–5] and reconfigurable 3D chiral optical metamaterials. These structures can also be released from the *surface to create and study active matter and its interface with microscale robotics.*[6]

Understanding The Evolution Mechanism of Structural-Activity Relationships at Nano Scale With ZEPTOOLS in-situ TEM holders *Xuanyu Chen and Xiaolong Zhang; Anhui Zeyou Technology Co., Ltd., China*

Transmission electron microscopy (TEM) is a crucial tool for analyzing the nanoscale structure-activity relationships of samples. In recent years, advancements in nanomanipulation and nano environment construction technologies have enabled scientists to build nano-laboratories in a plug-and-play manner within TEM. This allows researchers to utilize TEM's advanced structural characterization capabilities to observe the real-time evolution of sample structure-activity relationships. In this talk, we will present application cases that highlight two main types of in-situ solutions for TEM, as well as discuss their technological iterations and evolution. This presentation aims to provide researchers with new ideas for advancing their studies.

11:30 AM *NM07.03.08
Engineering and Direct Imaging of Nanoparticle Self-Assembly Pathways *Xingchen Ye; Indiana University, United States*

Functional materials built from nanoparticle assemblies are enabling new applications in energy conversion and storage, optoelectronics, nanomedicine, among others. Essential to the realization of materials-by-design is to elucidate synthetic pathways and understand the kinetics of structural transitions. The process of nanoparticle assembly, like a chemical reaction, typically traverses a complex free-energy landscape before reaching the final state. Fully understanding these pathways requires real-space, real-time characterization with meaningful spatiotemporal resolution, which is difficult with existing ex-situ characterization or scattering-based techniques. In this talk, I will discuss our recent advances on direct imaging of nanoparticle assembly using liquid-phase electron microscopy. The interaction potential between nanoparticles can be readily tuned by changing the solvent, which enabled observation and quantitative analysis of nonclassical assembly pathways of nanoparticle superstructures.

Building Conceptionally New Clusteroluminescent Materials via Clusterization of Nonemissive Molecules
Ben Zhong Tang; The Chinese University of Hong Kong, China

Luminescence, as a natural gift, plays an essential role in our colorful world. So far, it is believed that the development of highly efficient fluorophores relies on covalently electronic conjugation. The traditional photophysical mechanism based on through-bond conjugation seems to be perfect in explaining the luminescence of most conjugated molecules. However, some common materials without any aromatic conjugation, such as peptides, polysaccharides, and some artificial polymers, can emit visible and bright emission. Although this phenomenon has been observed for a long time, it has not attracted much attention as the underlying mechanisms were still unclear, and these materials were hard to utilize as luminescent materials due to their low efficiency. Recent works illustrate that the single-dispersed solutions of these (macro)molecules do not emit light under UV excitation, but their aggregates can emit bright visible light. This kind of unconventional emission is named "clusteroluminescence (CL)" and the luminogens with CL characteristics are termed "clusteroluminogens (CLgens)". Further experiments and theoretical calculations suggest that the through-space electronic interactions between the lone pairs of heteroatoms would form rigid cluster structures in the aggregate state, which ultimately emit light as a chromophore. Several approaches have been developed to manipulate the performance of CLgens with controllable CL. In terms of application, CLgens always show excellent biocompatibility, which may find applications as bioimaging or tracking probes. Meanwhile, as the inter- or intra-molecular distance is sensitive to mechanical force, smart mechanically responsive materials can be developed.

2:30 PM NM07.04.03
Coupling Surface Interactions with Colloidal Transport to Understand Antibiotic Delivery with Self-Assembled Lipid Nanocarriers *Brendan Dyett, Haitao Yu, Sampa Sarkar, Calum Drummond and Charlotte Conn; RMIT University, Australia*

Low discovery rates for new antibiotics, commercial disincentives to invest and inappropriate use of existing drugs has created a perfect storm of antimicrobial resistance (AMR). This 'silent pandemic' of AMR looms as an immense, global threat to human health. In tandem, many potential novel drug candidates are not progressed due *to elevated hydrophobicity which may result in poor intracellular internalization and undesirable serum protein binding. With a reducing arsenal of effective antibiotics, enabling technology platforms which improve the outcome of treatments, such as repurposing existing bioactive agents is a prospective option. Self-assembled lipid nanoparticles, such as cubosomes, have emerged as promising nanocarriers (NCs) capable of amplifying the therapeutic outcome.*

Here, the performance of several antibiotic classes encapsulated within the lipid-based cubosomes are examined. The findings demonstrate that encapsulation affords significant improvements in drug concentration:inhibition outcomes and assists in other therapeutic challenges associated with internalization, enzyme degradation and protein binding. Here we demonstrate the utilisation of surface sensitive techniques[1], particularly total internal reflection fluorescence microscopy to reveal dynamics in interactions and uptake of cubosomes. The rationale in optimized drug selection and nanocarrier choice is contextualized by surface interactions and multiscale transport modelling which agrees with experimental inhibition results[2]. We emphasize that currently sidelined compounds became active and revealed a significant increase in inhibition against the pathogenic gram-negative strain, Pseudomonas aeruginosa. The results demonstrate that lipid nanocarrier encapsulation may alleviate a range of challenges faced by antibiotic therapies and increase the range of antibiotics available to treat bacterial infections.

2:45 PM NM07.04.04
DNA Origami-Engineered Plasmonic Nanomaterials for Targeted Cancer Imaging *Lintong Wu, Swati Tanwar, Gagandeep Kaur, Siddhi Date, Linika Goel, Arnab Chatterjee, Patty McGuiggan and Ishan Barman; Johns Hopkins University, United States*

Surface-enhanced Raman scattering (SERS) has become a valuable technique in various biomedical detection and bioimaging applications. However, the practical application of SERS-based imaging strategies faces challenges due to the lack of a straightforward method to produce highly sensitive SERS-active nanomaterials efficiently and with high yield. To address this issue, we utilized the principles and properties of DNA origami to develop SERS-based plasmonically coupled nanomaterials for targeted cancer imaging, named SPECTRA. The multifunctional nature of the DNA origami technique allows us to precisely position two plasmonic nanorods with a controlled gap and attach cancer cell-targeting DNA aptamer sequences at specific locations. This nanoscale material with probing capability also incorporates a vibrational tag with a stretching frequency in the Raman window that is silent in cells, thereby providing a high signal-to-noise ratio indication of targeted cancer cells. By incorporating an aptamer sequence specific to aggressive DU145 human prostate cancer cells, we demonstrate the unique capability of SPECTRA for targeted imaging of DU145 cells. These findings underscore the scalability, cost-efficiency, and reproducibility of our fabrication approach for SERS-based nanomaterials, offering a versatile platform with wide-ranging applications in biomedical imaging and cancer biology.

Pressure-Induced Nanoparticle Assembly *Hongyou Fan; Sandia National Laboratories, United States*

Precise control of structural parameters through nanoscale engineering to improve optical and electronic properties of functional nanomaterials continuously remains an outstanding challenge. Previous work on nanoparticle synthesis and assembly has been conducted largely through solution chemistry at ambient pressure and relies on specific chemical or physical interactions such as van der Waals interactions, dipole-dipole interactions, chemical reactions, ligand-receptor interactions, etc. In this presentation, I will introduce a new pressure-induced assembly and fabrication method that uses mechanical compressive force applied to nanoparticles to induce structural phase transition and to consolidate new nanomaterials with precisely controlled structures and tunable properties. By manipulating nanoparticle coupling through external pressure, instead of through solution chemistry, a reversible change in their assemblies and properties can be achieved and demonstrated. In addition, over a certain threshold, the external pressure will force these nanoparticles into contact, thereby allowing the formation and consolidation of one- to three-dimensional nanostructures. Through pressure induced nanoparticle assembly, materials engineering and synthesis become remarkably flexible without relying on traditional crystallization process where atoms/ions are locked in a specific crystal structure. Therefore, morphology or architecture can be readily tuned to produce desirable properties for practical applications. (SAND2024-00611O)

Toward Controlling the Morphology in Nanocrystal Growth—Thermodynamic vs. Kinetic Shapes *Kristen A. Fichthorn; The Pennsylvania State University, United States*

Metal nanocrystals have the capability to revolutionize established technologies, such as catalysis, plasmonic, and electronic devices, sensing, and photovoltaics. Additionally, metal nanocrystals will figure prominently in upcoming technologies, such as photothermal desalination,triboelectric nanogenerators,electromagnetic interference shielding, and "smart" technologies, such as electrochromic and photochromic devices, fabrics and wearable devices, and e-skin. For most established applications, there is ample evidence that the efficacy of a nanocrystal is sensitive to its shape and fine details of its structure. Thus, there is significant impetus to be able to predict and characterize fine details of nanocrystal structure. Crystal growth begins with the nucleation of metal atoms from a (partially) reduced metal salt. It is often stated that the nuclei grow to seeds that determine the final nanocrystal shape, which presents a compelling case for understanding how seeds acquire their shape. How seeds grow to final, kinetic shapes is an enigma and the subject of this study.

We use parallel tempering molecular dynamics (MD) simulations, accelerated MD, and machine learning (ML) to quantify equilibrium and kinetic shapes of Ag and Cu nanocrystals as they grow and transition from equilibrium to kinetic shapes. We find equilibrium nanocrystal shapes can change significantly with temperature, indicating that the nanocrystal shape with the minimum potential energy (at zero K) is not necessarily the shape seen at a higher temperature in an experiment. Moreover, the preferred nanocrystal shapes at low temperatures change drastically with size. These qualitative features have significant ramifications for experiments: It can be vastly more important to understand the free energies of nanocrystals than potential energies. We find that small (sub-nanometer to single nanometer) nanocrystals assume an equilibrium distribution of shapes for experimental temperatures and deposition rates. As the nanocrystals grow beyond this size range, the rate to transform between shapes decreases and becomes slower than the rate at which species add to the nanocrystals and growth becomes a *kinetic phenomenon. We probe the growth of nanocrystals that evolve via both monomer addition and aggregation with other nanocrystals and find interesting differences between the two growth modes.*

The shapes of fcc metal nanoparticles are typically quantified in terms of perfect morphologies: octahedron, icosahedron (Ih), decahedron (Dh), etc., but such shapes only arise for certain "magic numbers" of atoms that give the crystal a perfect shape. Here, we analyze and quantify the generated nanoparticle morphologies using ML. We find a hierarchy of shape classes for these nanocrystals: two broad classes (amorphous and crystalline), five broad sub-classes, and 14-15 different fine-structured sub-sub-classes. Overall, these studies provide a promising framework for understanding how nanocrystals grow and how shapes might be classified for applications.

Revealing Two-Dimensional Self-Assembled Structures on Liquid Surfaces Using X-Ray Scattering Methods

Honghu Zhang and Benjamin M. Ocko; Brookhaven National Laboratory, United States

Liquid surfaces offer intrinsic two-dimensional (2D) confined spaces with angstroms-level surface roughness, ease of 2D motion, and convenient liquid transport of chemicals to the interfaces. These surfaces provide an ideal platform for the interfacial self-assembly of 2D soft materials, including biomolecules, surfactants, polymers, and nanoparticles (NPs). Interface-assembled 2D soft materials are flexible, free-standing, and potentially tunable in lateral spacing and thickness, exhibiting distinct electronic, optical, mechanical, and catalytic functions. In-situ approaches are essential to monitor and quantify the role of the liquid surfaces in the self-assembly process of 2D soft materials. The Open Platform Liquid Surfaces (OPLS) endstation at the Soft Matter Interfaces (SMI) beamline at National Synchrotron Light Source II is well-suited for probing molecular and nanoscale structures at vapor/liquid and liquid/liquid interfaces. At OPLS, we provide a suite of surface-sensitive X-ray techniques: X-ray reflectivity (XRR) for determining the surface-normal electron density profile, and grazing-incidence small-angle and wide-angle X-ray scattering (GISAXS/GIWAXS) for examining the lateral nanoscale/molecular structures. Here, we present investigations of interfacial structures in two self-assembly systems, i.e., fatty acids with two terminal methyl groups (19-methyleicosanoic acid, 19-MEA) and nanoparticles grafted with charged-end polyethylene glycol (PEG-NPs). Our in-situ results reveal that interfacial 19-MEA molecules self-assemble into 2D hexagonal lattices of nano-objects resembling squished hemispheres, with a lateral lattice constant that decreases with increasing surface pressures. For charged PEG-NPs, we observed the formation of distinct checkerboard square lattices across various pH levels and molar ratios of the constituents. Theoretical models to explain the self-assembly behaviors in these systems are being developed and will be discussed.

Understanding Colloidal Crystallization Through Simulation—Design and Assembly of Anisotropic Particles

Timothy C. Moore and Sharon C. Glotzer; University of Michigan, United States

Crystallization is a universal phenomenon. Despite its importance in wide-ranging technologies and natural processes, there is no single theoretical framework that accurately describes diverse crystallization phenomena. Colloidal crystallization is particularly rich, as the building blocks and the interactions between them span many length scales. The diversity in the shape and rigidity of colloidal buildings blocks further expands this design space and makes its exploration a daunting task. So, given the many potential transformative applications of self-assembled materials combined with their enormous design space, how do we make progress toward understanding self-assembly mechanisms? Researchers have used particle-based simulations to gain insight into such processes, and given the ever-increasing compute power available, simulations will play an increasingly important role in guiding the development of new self-assembled materials. In this talk, we present our recent *work on the development and simulation of particle-based models. In particular, we highlight the role and importance of anisotropy in both particle shape and interparticle interaction potentials (i.e., patchy particles). Through minimal models of several specific systems, we show how these two factors can be used to control the structure of particle assemblies. Our work demonstrates the utility of modeling for understanding assembly processes and designing new self-assembled materials.*

SESSION NM07.05: Poster Session: Building Advanced Materials via Aggregation and Self-Assembly
Session Chairs: Qian Chen, Sijie Chen, Bin Liu and Xin Zhang
Tuesday Afternoon, December 3, 2024

Redistribution-Induced Transverse Orientation in Cylinder-Forming Block Copolymer Films *Baopu Zhang, Mingchao Ma, Zehao Sun, Jaedong Jang and Caroline A. Ross; Massachusetts Institute of Technology, United States*

Block Copolymer (BCP) directed self-assembly is a promising pathway for fabricating highly ordered nanoscale patterns. We show that for cylinder-forming polystyrene-b-polydimethylsiloxane (PS-b-PDMS) BCPs (11 kg/mol-b-5 kg/mol, f_{DMS}=32.9%) self-assembled on substrates with trenches and mesas of 500 nm width, the PDMS cylinders of period =19 nm can orient in plane, transverse to the trench edge. The transverse orientation is often attributed to capillary flow, which involves polymer redistribution from the mesas to the trenches during annealing[1,2]. To better understand the redistribution process, we use atomic force microscopy to characterize the surface topography of the film after spin coating and solvent annealing with acetone for trenches of various depths. Assuming conservation of the BCP volume, we determine the BCP film thickness on the mesas and in the trenches as a function of trench depth and annealing time. We find that the ratio of film thickness on the mesas to that in the trenches for the as-spun film decreases as trench depth increases, being approximately 1:3 for a trench depth of 50 nm (3 L_0) and approximately 1:9 for a trench depth of 100 nm (6 L_0). This ratio also decreases with longer annealing time as more polymer flows from the mesas into the trenches, with the time for the BCP to flow off the mesa ranging from 5 minutes to less than 2 minutes.

The self-assembled BCP structure is characterized for a range of film thicknesses and trench geometries. Transverse cylinders are only observed in the case of 16 nm (L_0) deep trenches with an annealing time sufficient to allow redistribution of BCP from the mesas to the trenches. On further increasing the annealing time, the cylinders gradually align parallel to the trenches. In the case of deeper trenches, the transverse morphology does not occur regardless of annealing time. Therefore, we believe sufficient polymer on the mesas is critical for the transverse morphology, and a trench depth matching a monolayer thickness facilitates the appropriate polymer distribution. Further, the transverse orientation is metastable and eventually transitions to the parallel orientation. This work illustrates how the BCP self-assembled structure correlates with the redistribution process, where the initial and final state are determined by trench depth and annealing time. The ability to control cylinder orientation provides greater flexibility and capabilities in designing and fabricating nanoscale patterns through BCP directed self-assembly.

NM07.05.02

Synthesis and Morphology Control of Yttrium Oxide Sub-Micrometric Spheres Composed of Multiple Aggregated Nanoparticles *Danilo B. Janes[1,2], Raphael M. Garcia[1], Igor B. da Cruz[1], Tarcisio Perfecto[1] and Edson R. Leite[1,2]; [1]CNPEM-Brazilian Center for Research in Energy and Materials, Brazil; [2]UFSCar, Brazil*

In the world of advanced materials, yttrium oxide is regarded as a promising material for multiple applications such as lasers, sensors, catalysts, magnets and so on due to its high thermal, mechanical and chemical stability. As with any other ceramic material, its application relies heavily on the morphology and size distribution of its particles. Specifically, yttrium oxide sub-micrometric spheres allow for high packing densities, lowering significantly the temperature required for achieving high density ceramics through conventional sintering techniques. The application of yttrium oxide for scintillators requires transparent, highly dense ceramics, thus the synthesis of yttrium oxide sub-micrometric spheres is of high interest for such applications. A traditional method for the synthesis of these spheres is the urea homogenous precipitation method, which forms yttrium hydroxide carbonate precipitates. By heating the samples to temperatures of several hundred degrees Celsius, the precipitates are transformed into oxides. As such, the present study makes an in-depth investigation of the synthesis of yttrium oxide sub-micrometric spheres by the urea homogenous precipitation method. Through scanning electron microscopy (SEM), observations regarding the precipitation mechanism were made by visualizing the particles' growth over time during precipitation under different conditions. Transmission electron microscopy (TEM) and X-ray diffraction (XRD) revealed that the precipitated spheres are porous and composed of much smaller, aggregated amorphous nanoparticles. Analyzing the spheres' size distributions, the possibility of different precipitation and/or aggregation mechanisms taking part in the process was raised. Additionally, investigations of the heat treatment's temperature demonstrated that this step is crucial for the particles' final shape, altering both their morphology and size as the nanoparticles inside each sphere transform, grow and interact with each other, even in temperatures much below the traditional sintering temperatures. Under higher temperatures, the spheres start to interact with each other, losing their spherical conformation as they irreversibly transform into larger aggregates. However, under lower temperatures, sphericity is preserved, forming spherical particles with various degrees of porosity, which can be sintered into transparent ceramics or used in other applications such as a support for catalysts.

NM07.05.03

Innovative 3D Self-Assembly Using Polymer Cross-Link Gradients *Zihao Lin, Shehua C. Thor, Pengyang Li and Jeong-Hyun Cho; University of Minnesota Twin Cities, United States*

SU-8 photoresist has been utilized for decades for diverse applications including small scale patterning, microfluidic channels and MEMS. However, the intrinsic thermal stress generated during the post-baking process causes mechanical failures in the SU-8 film. Numerous literatures have been studied to minimize stress generation. Here, conversely, this intrinsic stress has been leveraged for the deformation of a SU-8 thin film in multi-directions including z-axis, which enables the creation of complex 3D micro architectures. To realize 3D structures, the SU-8 photoresist is intentionally exposed to an ultraviolet (UV) dose that is 25% lower than the recommended dose by SU-8 manufacturer. The low dose induces a cross-linked gradient along the exposure direction, generating stress gradient in the same direction. However, the structure remains flat even after removing a sacrificial layer underneath. This is because the elastic restoring force (stiffness) of a SU-8 layer, at room temperature, is larger than its bending stress generated from the stress gradient. Therefore, to reduce the stiffness and fully release the stress, the SU-8 (essentially a thermal epoxy) is heated in water. The softened SU-8 diminishes its stiffness, and the bending stress, induced by the cross-linked gradient, becomes adequate to overcome the elastic restoring force at around 70 ~ 80 degrees C, resulting in a lasting curvature shape with the directions preprogramed by the 2D patterns of the UV exposure. To support this new finding mechanism, *mechanical parameters, stiffnesses and stress gradient varied with temperature and dose, are characterized. Beyond simple curved architectures, with a careful intention on the dose control, complicated 3D structures like vertically aligned helix and tubes are also able to realize. Moreover, this photo-sensitive material property also enables a new way of patterning, such as pre-programming metals and 2D materials on it, and subsequently self-assemble together with the SU-8 itself. The proposed technique may promote further development of complex micro robotics, 3D sensors, and e-muscles.*

NM07.05.04

Examining the Fouling Resistance of Random Zwitterionic Amphiphilic Copolymers *Ryan O'Hara, Seda Atas, Hyunmin YI and Ayse Asatekin; Tufts University, United States*

Nanoscale amphiphilic surfaces combine both the benefits of hydrophobic self-cleaning materials and the enthalpic barrier that comes from hydrophilic surfaces. Amphiphilic block or hyperbranched copolymers that self-assemble into domains of 10-100 nm can prevent the adhesion of some marine microorganisms. However, these systems often do not entirely resist the adsorption of biomacromolecules such as proteins. Random zwitterionic amphiphilic copolymers (r-ZACs) have much smaller domain sizes and may be an effective alternative to these materials. Our group has shown that r-ZACs have the ability to self-assemble into domains of <1-2 nm and exhibit unmatched fouling resistance as membrane-selective layers. However, no intensive material studies have been performed on r-ZACs as coatings. To address this unmet need, we have synthesized a cohort of r-ZACs at varying compositions and chemical structures and analyzed their water uptake, tensile properties, water contact angle, and thermal properties. We examined their protein fouling resistance through quartz crystal microbalance with dissipation (QCM-D) monitoring of the coatings while in contact with various protein solutions and through measuring the adsorption of GFP-producing E.coli cells. Increasing the understanding of the link between non-specific protein adsorption and biofouling of random zwitterionic amphiphilic copolymers (r-ZACs) and their chemical structure and composition will allow for the development of the next generation of fouling-resistant copolymers.

NM07.05.05

Ion Separation Utilizing Crosslinkable Zwitterionic Amphiphilic Copolymeric Membranes *Ashleigh B. Herrera and Ayse Asatekin; Tufts University, United States*

There is a growing need for valuable mineral resources like lithium and heavy metals. While these resources exist in aqueous sources like wastewater and brines, they are difficult to extract and differentiate. Polymeric membranes provide a sustainable, cost-effective, and scalable method to recover these resources in ion form from these aqueous sources. However, current commercial membrane technology is inadequate in achieving this selectivity, especially while maintaining reliability and fouling resistance. Previous work in our group has investigated the self-assembly of zwitterion based polymers in fabricating fouling resistant, thin film composite membranes that can achieve exceptional anion separation coined crosslinkable zwitterionic amphiphilic copolymeric membranes (x-ZACS). These x-ZACs readily self-assemble into a network of nanochannels where the zwitterions line the pore walls. Previous work suggests the ion selectivity is driven by the selective interactions between the zwitterions lining these x-ZAC nanochannels and the ions traversing through the ~1nm confined, self-assembled nanochannels. To date, only one commercially available zwitterion chemistry has been investigated for ion selectivity. My current work expands on the anion selectivity achieved to synthesize x-ZAC membranes that focus on other zwitterionic repeat units. The goal is to create membranes with cation-cation selectivity for use in the recovery and selective extraction of lithium and valuable metal ions from brines and wastewater. To accomplish this, different zwitterionic chemistries have been synthesized to fabricate alternate x-ZAC membranes which were analyzed for selectivity between cations. Preliminary results show some selectivity differences *between zwitterion chemistries, with promise in cation selectivity with a commercially available zwitterion.This work suggests that pressure-driven membranes with well-selected x-ZAC chemistries and crosslink densities can separate similarly sized and charged ions which enables more scalable and energy-efficient recovery of metal and mineral resources.*

NM07.05.06

Synthesis of Fluorescent Boron, Nitrogen Co-Doped Carbon Nanodots for Detection of Nitrophenols *Sunil Kumar[1], Nurul Hassan[1], Ravi Pratap[1], Avanish S. Parmar[2] and Jayeeta Lahiri[1]; [1]Banaras Hindu University, India; [2]Indian Institute of Technology (BHU), India*

In this work, we have utilized fluorescent Boron and Nitrogen co-doped Carbon nanodots (BNCDs), for optical detection of nitrophenol isomers (p-NP, m-NP, o-NP) and 2,4,6 trinitrophenol (TNP) in water. We synthesized the BNCDs using one-step hydrothermal treatment of Trimethyl ammine borane (TMAB) at different temperatures (100°C, 150°C, 200°C) for different reaction times (4hrs, 8hrs, 12hrs & 16 hrs). The as-prepared BNCDs dispersion in water were characterized using microscopic and spectroscopic techniques. We observed that these BNCDs synthesized at 200°C displayed a broad fluorescence peak at 400 nm for 350 nm excitation wavelength. In the presence of nitrophenols, we observe strong quenching of the fluorescence of BNCDs with quenching efficiency TNP>p-NP>m-NP>o-NP. We also observed a red shift in fluorescence quenching with minimum shift detected for TNP. From the Sterm-Volmer plot, we determined the lowest level of detection as 21nM and 26nM for TNP and p-NP respectively. To improve the selectivity between TNP and p-NP, pH of BNCDs dispersion was varied.

NM07.05.07

Controlled Corrosion—Synthesizing Nickel Nanostructures via pH-Dependent Pitting *Ayron A. Lima[1], Duber M. Munar[1], Antonio A. Zuben[1], Richard Landers[1], Douglas S. Oliveira[2] and Monica A. Cotta[1]; [1]Universidade Estadual de Campinas, Brazil; [2]Universidade Federal do Paraná, Brazil*

Due to its physical and chemical properties, such as high corrosion resistance, excellent thermal and electrical conductivity, and good ductility, Nickel (Ni) is an interesting material for many applications. The fabrication of nickel nanostructures has attracted significant interest due to their potential applications in advanced fields such as catalysis, sensors, and electronic devices [1,2]. This study investigates a novel method for synthesizing nickel nanostructures via pitting corrosion on nickel thin (~60 nm) films deposited by e-beam evaporation. Our objective was to explore the slow corrosion of nickel induced by solutions containing deionized water, glycine and calcium chloride at different pH values. After 48 hours of contact between the solutions and the films, we observed pitting corrosion, with the pits exhibiting approximately circular shapes. Within these pits, nanostructures were formed, varying accordingly to the pH of the solution. At low pH values, very thin planar nanowires with a fractal aspect originated from the center of the pits. At high pH values, in addition to these structures, nanowire-like structures vertically projecting from the center of the pits were also observed. Scanning electron microscopy coupled with Energy dispersive spectroscopy revealed that the central nanostructures are composed of nickel, whereas the planar nanowires can not be resolved by this latter technique. Atomic force microscopy indicated that all pits, regardless of pH, have the same depth, approximately 60 nm, which coincides with the nickel thickness of the deposited nickel thin film. This suggests that the corrosion process occurs at local defects in the Ni film, followed by redeposition due to the radial gradient of dissolved Ni in the solution, particularly when the corrosion reaches the silicon substrate. COMSOL simulations confirmed this possibility, as the Ni removed from the surface flows towards the substrate for large enough pit areas. Additionally, X-ray photoelectron spectroscopy showed an increased presence of calcium on the surface as the solution pH increased, indicating that calcium acts as a corrosion inhibitor [3], as the average pit area decreases with increasing pH. These results suggest a potentially controllable process for synthesizing nickel nanostructures, although further studies are needed to confirm this *possibility and explore the applications of this new method.*

Effects of Ion Bombardment and Humidity on Polymer Films *Alessia Danagoulian[1], Grace Pettis[1,2], Jocelyn Zhang[1,3], Neil Baker[1], Eda Güney[4], Jalal Karimzadehkhoei[4], Weijing Chen[1], Jiaqi Tang[1], Henry Chuang[1], Benli Jiang[1], Anubhav Wadehra[1], Karl F. Ludwig[1] and Gozde O. Ince[4]; [1]Boston University, United States; [2]Oregon State University, United States; [3]Massachusetts Institute of Technology, United States; [4]Sabanci University, Turkey*

This study examines wrinkling behavior of Poly(4-Vinylpyridine) (4-VP), (Hydroxyethyl)methacrylate (HEMA), and 2,4,6,8-tetramethyl-2,4,6,8-tetravinylcyclotetrasiloxane (V4D4) polymer thin films bombarded with Ar+ ions. When held in a humid environment post bombardment, HEMA developed nanopatterning within a few hours, reaching hundreds of nanometers in height. Other samples exhibited nanopatterning as well, with V4D4 also developing holes on the surface. When held in a dry chamber instead, 4-VP and HEMA showed no signs of nanopatterning at all, while V4D4 showed slight wrinkles on its surface. To measure chemical structural changes in-situ, some of the experiments utilized an ion sputtering gun within an X-ray photoelectron spectroscopy (XPS) system. By studying bombardment results with in-situ XPS, combined with post facto characterization using atomic force microscopy (AFM), one can begin to understand the chemical and physical causes of wrinkle pattern formations.

This work was partly supported by NSF DMR-2117509.

NM07.05.09

Generating Organized Designs Within Block Copolymer Thin Films Through Precise Application of Controlled Thickness Gradients *Ho Jun Jin[1], Simon Kim[1], Jang Hwan Kim[2], Hyeong Min Jin[3] and Bong Hoon Kim[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Ajou University, Korea (the Republic of); [3]Chungnam National University, Korea (the Republic of)*

Self-assembly is the spontaneous formation of intricate micro/nanostructures by nanomaterials such as liquid crystals, peptides, and DNA driven by secondary forces among their molecular components. Block copolymers (BCPs) in thin films exemplify this process, allowing for precise control of diverse polymer properties at scales smaller than 100 nm. The nanopatterns generated by BCPs self-assembly hold promise for various applications, including bio/optical sensors, MEMS/lithography, and semiconductor devices.

However, practical applications of nanopatterns created by BCPs require exact control over the alignment of nanodomains, which is accomplished using diverse directed self-assembly (DSA) methods. These techniques, such as graphoepitaxy and chemoepitaxy, utilize top-down approaches to control the alignment and positioning of BCP nanopatterns. Despite advancements in manipulating BCPs structures, achieving non-defected and highly oriented nanopatterns often involves expensive, multi-step procedures and sophisticated equipment. A new method has been suggested to address this issue, focusing on the automatic alignment of lamellar structures in BCPs thin films with controlled thickness variations.

This method exploits the influence of geometric alignment, promoting extended alignment of lamellar structure *along a gradient in film thickness. However, ensuring uniform thickness across the film remains crucial for subsequent nanofabrication processes. To address these challenges, we have effectively showcased the generation of meticulously structured nanopatterns using BCPs with a consistent thickness across a wide area. This accomplishment was achieved by implementing a straightforward two-stage thermal annealing method to introduce a controlled thickness gradient in the BCPs thin films. This method employed an economical and uncomplicated thermal imprinting technique to establish a micro-scale thickness gradient, contrasting the expensive demands of traditional photolithography methods.*

The process of thermal annealing in two stages was meticulously planned. First, annealing at a lower temperature of 160°C facilitated the initial alignment of BCPs nanodomains along a gradient in film thickness, leveraging the geometric anchoring effect. Subsequently, a second annealing step at 250°C was applied to enhance lamellar nanopattern alignment further and ensure uniformity in film thickness. During this high-temperature annealing, the BCP thin films, exhibiting curvatures up to 350 nm, underwent spontaneous alignment and flattening via thermal reflow. The effectiveness of these processes was confirmed through detailed analysis using scanning electron microscopy (SEM) and grazing incident small-angle x-ray scattering (GISAXS). The second annealing step induced the flattening of the BCPs thin films, potentially creating shear stress in the direction of the thickness gradient. This effect contributed to enlarging the grain size of the lamellar nanodomains of BCPs initially aligned by the thickness gradient, thus establishing a highly ordered nanostructure across the thin film.

This novel approach to guiding BCPs self-assembly enables the formation of well-oriented vertical lamellar nanopatterns with consistent thickness, circumventing the need for intricate and expensive nanopatterning techniques that typically involve advanced micro/nanofabrication processes. Apart from creating the initial master mold, this method offers a straightforward and efficient strategy to achieve precise nanopatterning, presenting a cost-effective and accessible alternative for nanolithography.

Ordering in GO-CNT Hybrid Nanostructures via Polyelectrolyte Assisted Self-Assembly *Lokesh Soni, Kamendra P. Sharma and Ajay Singh Panwar; Indian Institute of Technology Bombay, India*

Self-assembly of nanoparticles offers creative pathways to organize individual components into a complex nanostructure with precise spatial arrangements. Anisotropic nanoparticles such as 2D-graphene/graphene oxide, and 1D-carbon nanotubes can be self-assembled, with the help of polyelectrolytes, in the formation of hybrid structures with enhanced electrical, thermal, and mechanical properties [1, 2]. The incorporation of polyelectrolytes facilitates the assembly process by leveraging electrostatic interactions, in the formation of spontaneous and well-defined architectures. We utilise Coarse-grained molecular dynamics simulations to study the pathways and governing parameters in self-assembled GO-CNT hybrid nanostructures. GO and CNTs are modified with Cationic (PEL(+)) and Anionic polyelectrolyte (PEL(-)) respectively, and mixed with different relative concentrations to form assemblies. These assemblies can be fine-tuned by adjusting parameters related to electrostatic interaction between particles, such as (a) charge density on the surface of GO sheets, and (b) strength of polyelectrolytes. We aim to optimise the adsorption of CNTs on GO sheets and maximise the ordering of CNTs in uniform arrangement. It was found that an increase in the concentration of anionic polyelectrolyte (PEL(-)) adsorbed CNT, was found to increase the number of CNT adsorbed at a given charge density of GO. Also, the mobility of PEL(+) on the GO surface by grafting the PDDA affected the arrangement of CNTs, showing the need for mobile polyelectrolytes in an ordered arrangement. This study will lead us to formulate highly ordered GO-CNT hybrids with astounding control over the ordering of CNTs between GO sheets, which could improve the functioning of hybrid nanostructure in various applications such as membrane, catalysis, and supercapacitors.

Effect of pH and Ionic Strength—Moringa Oleifera Protein Particles

Namrah Azmi and Jon Otto Fossum; *Norwegian University of Science and Technology, Norway*

Protein aggregation is a common phenomenon in food, significantly impacted by factors like particle size and shape. However, the exact mechanisms behind this process remain unclear. While protein aggregates can influence functional properties, food's inherent complexity further complicates aggregation behavior. Proteins naturally interact to form complex structures. However, these structures are vulnerable to stress, which can disrupt weak chemical bonds (non-covalent interactions) within the protein. This disruption can cause the protein to lose its secondary structure and clump together, forming aggregates[1]. While scientific studies on protein folding and aggregation often focus on isolated proteins, real food systems are far more complex. Instead of highly purified proteins, food contains a mixture of different proteins. This heterogeneity adds another layer of complexity to understanding how proteins aggregate[2].

An interesting perspective emerges when comparing protein aggregation in biological systems (often viewed as "self-assembling" from a molecular chemistry standpoint) to food processing (considered "induced assembly" due to various physico-chemical conditions and external factors)[3]. The interplay between these factors in food requires further investigation. Therefore, elucidating the formation mechanism of protein aggregates and the factors influencing it is crucial for optimizing food quality and safety.

The way proteins assemble in food is a delicate sway between two key factors: pH and ionic strength. Generally, a low concentration of charged molecules (ionic strength) favors the ordered formation of protein aggregates, while a high concentration leads to messy clumps (disordered precipitates). Similarly, a low pH (more acidic environment) often promotes the formation of stable protein aggregates[4]. This is because pH directly affects the electrical charge on protein molecules. Proteins have specific amino acids that can gain or lose charges depending on the surrounding pH. These changes influence how proteins interact with each other, impacting their final structure. pH and ionic strength can also influence the shape of the resulting aggregates. Studies by Amagliani & Schmitt (2017) have shown that different pH conditions can lead to diverse morphologies, ranging from neat spheres to flexible strands and even semi-rigid fibers[5].

We believe that by understanding how pH and ionic strength influence protein aggregation, we can gain better control over the structure and function of these aggregates in food systems. To achieve this, we're investigating the aggregation of Moringa Oleifera seed protein particles by manipulating pH and ionic strength as driving forces. We employ Dynamic Light Scattering and Laser Diffraction to monitor changes in protein particle size as these factors are varied. These size measurements are further confirmed by advanced techniques like Small Angle X-Ray Scattering (SAXS) and X-Ray Photon Correlation Spectroscopy (XPCS). Raman and FTIR spectroscopy confirm the presence of proteins in our extracts. While the iodine test assures the absence of starch, the potential presence of other carbohydrates alongside proteins necessitates further investigation. Future studies will also focus on tuning the physicochemical properties of these aggregates through pH adjustments. This approach holds promise for enhancing their emulsifying properties, which could be valuable in food product development.

A Simple Synthesis Towards Colloidal Particles with a Defined Size and Composition Gradient

Alexander Berger, Maximilian Theis, Henrike von Wedel, Tamino Rößler, Georg Papastavrou, Jürgen Senker and Markus Retsch; Universität Bayreuth, Germany

Colloidal particles are essential in numerous applications, necessitating precise control over their size and size distribution.[1] Seeded growth reactions are a well-established synthetic approach to achieve good structural control in combination with a wide choice of the material's composition. However, traditional batch synthesis methods typically produce discrete particle sizes,[2] which do not meet the requirements for tailored drug delivery system[3] or advanced optical devices such as photonic displays or sensors.[4] Therefore, innovative methods for producing colloidal particles with controlled and complex size distributions or compositions are in high demand. The controlled emulsion extraction process (CrEEP), introduced by Schöttle et al.,[5] represents a notable advancement. It enables the production of polymer nanoparticle dispersions with defined, gradual size distributions via time-resolved extraction during the synthesis. In our study, we present significant improvements to this technique, enhancing both its reliability and versatility. Our refinements include achieving more complex size distributions by selectively omitting specific size ranges. Additionally, we demonstrate the ability to vary the monomer feed composition, resulting in a gradual change in both particle size and glass transition temperature. Moreover, the CrEEP method is not limited to polymer particle synthesis. It can be adapted to sol-gel processes, such as the established silica Stöber synthesis.[6] This adaption, referred to as the controlled extraction Stöber process (CrESP), yields a similar size gradient, thereby expanding the applicability of this innovative technique. By improving and extending CrEEP and CrESP, we provide versatile tools for producing colloidal particles with tailored properties.

Indoor CO_2 Direct Air Capture with Self-Assembled Nanofiber Architectures via Electrospinning

Younghun Kim[1,2], Jeong Rae Kim[2], Gunhee Lee[1], Bangwoo Han[1], Jungho Hwang[2] and Dae Hoon Park[1]; [1]Korea Institute of Machinery & Materials, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

The intensifying effects of climate change have underscored the urgency of developing alternative and sustainable technologies to achieve carbon neutrality. Various strategies for carbon dioxide (CO_2) capture, conversion, and the preparation of relevant materials have been addressed through individually-tailored approaches. Hence, there is

an urgent need for a flexible process to ensure optimal methods and materials, facilitating a convenient and swiftly implementable approach to reduce CO_2 emissions. In particular, indoor CO_2 direct air capture (iCO_2-DAC) represents a significant application of carbon capture technology. A diverse array of materials possessing distinct properties for CO_2 capture have been explored, such as amine-based adsorbent, carbon based porous materials, zeolites, and metal-organic frameworks, among others.

Therefore, this study aimed to develop polyethylenimine (PEI) and poly-methyl-methacrylate (PMMA) carbon nanofiber as effective CO_2 adsorbents using porous materials fabricated via electrospinning. This self-assembled process was designed to expedite their practical deployment, leveraging adsorption's notable benefits for CO_2 capture, including simplicity of operation, broad applicability, cost-effectiveness, and stable performance in indoor environments where CO_2 concentrations typically range from 1000 to 3000 ppm, occasionally peaking at 6000 ppm.

Utilizing electrospinning and commercially available materials like PEI for CO_2 chemisorption and PMMA as a base for porous carbon nanofibers, a composite self-assembled nanofibrous structure (PEI/PMMA CNFs) can be engineered to achieve excellent CO_2 capture. This is accomplished through straightforward process adjustments, such as manipulating fiber pore size and concentration via the Breath Figures method under varying relative humidity conditions during electrospinning.

This study may provide a reconfigurable manufacture to ensure a reliable adsorbent for CO_2 capture and base materials on those potentially applicable to indoor environments, furthermore, the potential uses of iCO_2-DAC to improve indoor air quality in buildings and boost the circular economy.

This work was supported by a Basic Research Fund (NK249A and NK252H) of the Korea Institute of Machinery and Materials, Republic of Korea, and by the Korea Institute of Marine Science & Technology Promotion (KIMST), funded by the Ministry of Oceans and Fisheries (20220568).

Self-Assembly for Photocatalysis *Sarodi J. Dutta, Florian Schulz and Wolfgang Parak; Universität Hamburg, Germany*

Plasmonic photocatalysis is promising for increased efficiencies and tailored selectivity of catalytic processes, but typically plasmonic materials like gold or silver are catalytically not broad in scope or not very active. However, when combined with a catalytic nanomaterial, for instance, platinum or palladium, a synergistic enhancement of the photocatalytic performance can be achieved. Such bimetallic structures combine strong absorbance of visible light due to the plasmonic nanoparticles and high reactivity due to the activated catalytic material. Unfortunately, their performance in dispersion is limited due to multiple scattering and absorption events which lead to decreased light penetration into the reactor. Here, new geometries based on thin-film optical metamaterials offer an interesting new approach to maximizing light-matter interactions. In this regard, self-assembling plasmonic and catalytic NPs simultaneously into crystalline superlattices with interparticle gaps in the range of 1-6 nm leads to the formation of new polaritonic excitations with favorable properties. Firstly, high densities of so-called hotspots and nanoscale regions with strongly enhanced electromagnetic fields are formed upon interaction with light, which have been shown to significantly enhance catalytic activity. Secondly, as a result of the strong light-matter interactions in densely packed plasmonic nanoparticle supercrystals, the absorption in the material can be strongly reduced, i.e., plasmonic losses are minimized. The promising properties of bimetallic self-assembled nanoparticle supercrystals have been demonstrated recently[1], but systematic parameter studies are yet missing and many aspects of the complex interplay between the light-matter interactions and catalytic activity are not fully

understood. Experimental approaches will be presented and discussed expanding the scope of the approach. Parameters under study include particle size and material, loading of the catalytic particles, structure of the supercrystals, and reaction conditions.

Fabrication and Evaluation of Photonics Ball via Polymer Coating with High-Index Nanoparticles *Yangnan Jiang[1], Ayano Shirai[2], Michinari Kohri[2], Ryosuke Ohnuki[3], Shinya Yoshioka[3], Tetsuya Yamamoto[1] and Yukikazu Takeoka[1]; [1]Nagoya University, Japan; [2]Chiba University, Japan; [3]Tokyo University of Science, Japan*

Recently, structural color materials have garnered significant interest as environmentally friendly color materials. However, their application is limited due to their angle dependence when featuring a colloidal crystal structure. An isotropic spherical colloidal crystal (photonic ball) has been successfully fabricated using mono-disperse particles, such as SiO_2 or polystyrene. These photonic balls can exhibit vibrant colors and decrease the angle dependence of the observed hue, compared to flat colloidal crystals. However, the position of the reflection peak still changes when the light irradiation and the observation direction shifts, similar to traditional flat colloidal crystals.
A practical solution to mitigate these issues could be to use a material with a higher refractive index, which could potentially lessen the angle dependence, even with this observation method. For example, with the [111] plane of the face-centered cubic (FCC) lattice formed on the photonic ball surface, the Bragg reflection formula is displayed as $\lambda=1.633d(n^2_{effctive}-\sin^2\theta)^{0.5}$, where $n_{effctive}=n^2_{particle}\phi_{particle}+n^2_{air}(1-\phi_{particle})$. When simulating the angle dependence of SiO_2 particles （$n_{SiO_2}=1.46$） and CeO_2 particles （$n_{CeO_2}=2.10$）, if θ changes from 10° to 50°, the reflection peak position for the SiO_2 particle photonic ball shifts by 17%. Meanwhile, for the CeO_2 particle photonic ball, the same angle change results in just about an 8% shift of the reflection peak position. Thus, by increasing the refractive index of the constituent materials, we can effectively suppress the angle dependence of photonic balls. In this study, we aimed to fabricate vibrant photonic balls with minimal angle dependence using CeO_2 particles, with high refractive index. The CeO_2 particles we used are coated with polyvinylpyrrolidone (PVP) on the surface, allowing them to disperse in water. However, the suspension method failed to fabricate photonic balls using these particles. In water, CeO_2(@PVP) particles maintain a certain distance even in high concentration areas due to the steric repulsion of polymer chains. As the water evaporates and the particles draw closer, the high Tg of PVP (80-130°C) hinders particle movement, making it difficult to arrange them regularly. Consequently, the dried particles arrange in an amorphous structure.
To overcome this, we modified the surface to provide a repulsive force, ensuring a certain level of movement from evaporation to drying. We used polydopamine (PDA) to give a negative charge to the CeO_2(@PVP) particles by synthesizing CeO_2(@PVP)@PDA particles. The photonic balls made of CeO_2(@PVP)@PDA particles exhibited vivid colors, and when the light irradiation and the observation direction changed from 10° to 50°, the position of the reflection peak shifted by 10.2% . This indicates that the angle dependence is more suppressed than the photonic balls made of SiO_2 particles. To further reduce the angle dependence, we sintered the photonic balls in an oxygen-free environment. The sintered photonic balls shown not only a lower angle dependence (only about 7%) but also exhibited stronger coloration than the photonic balls made of CeO_2(@PVP)@PDA particles. We attribute this to the transformation of the polymer components on the particle surface into graphite carbon with a high refractive index after sintering.

Geometry-Based Histone-DNA Complexes as Building Blocks for Self-Assembled DNA-Protein Hybrid Nanostructures *Hajar AlZarah, Maged Serag, Faisal Alkhaldi and Satoshi Habuchi; King Abdullah University of*

Science and Technology, Saudi Arabia

DNA nanotechnology has made remarkable progress, evolving from nano- and micro-sized structures like DNA origami[1], DNA crystals[2], and DNA bricks[3] to hybrid constructs that integrate DNA with proteins. Although DNA-based structures offer exceptional programmability, their complexity can be limited. Recent studies have integrated various molecules, such as proteins[4] and metals[5], into DNA structures to enhance functionality. A pivotal breakthrough in 2012 introduced DNA-protein hybrids, offering distinct advantages over DNA-only structures[6].

Integrating proteins into DNA nanotechnology has significantly enriched the field, driven by both sequence-specific[7] and non-sequence-based mechanisms[8]. These hybrid structures provide functional platforms[9], fabricate 2D materials[10], and offer structural elements across various applications[11]. In our previous research, we introduced geometry-based DNA-histone building blocks comprising single-stranded DNA (ssDNA) and histone proteins, termed HDs[12,13]. This approach offers flexibility in design and sequence, leveraging histones' ability to interact with DNA non-sequence-dependently.

Building on this, our current study assembles DNA, including pre-designed shapes or tiles of DNA origami, using the ssDNA and histone complex (HDs) without scaffold strands or templates. We successfully fabricated a 2D triangle-shaped DNA nanostructure (2TD) and linked DNA origami tiles, controlled by the location and number of handles designed in the DNA origami. The 2TD, with a thickness of 2 nm, was assembled using HDs to link double-stranded DNA (dsDNA) arms, each 100 base pairs (bp) long, assisted by 35-nucleotide (nt) sticky ends complementary to the ssDNA sequence within the HDs. Similar methods were used to self-assemble the DNA origami tiles. We used four multi-layer cuboid DNA origami constructs (CDO), each with different handle configurations.

We validated the assembly of 2TD nanostructures and DNA origami tiles using imaging techniques, including atomic force microscopy (AFM), electron microscopy (EM), and gel electrophoresis. These findings represent an advancement, potentially offering unique functionalities for creating DNA-protein hybrid nanostructures with enhanced precision and efficiency. While this study focuses on structural aspects, it has broader implications for DNA nanotechnology applications.

Enhancing Device Performance of Field-Effect Transistors Based on 2D Materials Using Nanostructured Substrates via Block Copolymers Self-Assembly *Simon Kim, Ho Jun Jin, Jun Seok Choe and Bong Hoon Kim; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

Two-dimensional (2D) materials are attractive for use in next-generation electronic devices due to their atomically thin structures, high flexibility/transparency, and unique electrical/optical properties. However, despite their vast potential, the practical application of 2D materials devices presents numerous challenges, particularly the substrate effect issue that directly deteriorates device performance. The substrate effect refers to the interactions with the interfacial area between the device substrate and the atomic layer structure of 2D materials. This substrate effect leads to significant performance degradation and poses a major hurdle for applications of 2D materials-based devices. Previous research has proposed to decrease the substrate effect, such as fabricating 2D material devices without substrates, but this severely compromises the mechanical stability of the devices, making them difficult to utilize effectively.

In this study, we employed self-assembly of block copolymers to implement nanostructures on the substrate surface at scales of nanometers, thereby achieving partially supported 2D materials. We fabricated a polystyrene-block-poly(methylmethacrylate) diblock copolymers thin film and induced self-assembly into cylindrical nanostructures through thermal treatment. Using this film as a mask in micro-electromechanical systems (MEMS) processes, we fabricated the substrates with nanostructures on their surfaces, demonstrating partially supported graphene field-effect transistors (FETs). Our strategy enabled us to suspend the channels of the devices in a regular nano-scale manner, preventing channel collapse and ensuring excellent stability in terms of mechanical properties. Minimizing extrinsic scattering of surface phonons using nanostructured substrates, we successfully demonstrated high performance FETs with up to three times higher field-effect mobility than transistors fabricated on conventional flat substrates.

Furthermore, we controlled the size of the nanostructures (diameter = 30~40 nm) on the substrate surface and analyzed their effect on the 2D materials in terms of contact area. Graphene transferred to flat substrates exhibited p-doped properties due to contact doping with the substrate, while graphene transferred to nanopatterned substrates retained its intrinsic properties due to partial suspension. Considering that graphene on nanostructured substrates also showed relatively n-doped characteristics compared to those on flat substrates, it is evident that the geometry of the substrates significantly influences the doping level of graphene.

In conclusion, we addressed the problem of performance degradation caused by the adverse interactions between substrates and 2D materials using the block copolymers nanopatterning process. The implementation of partially supported 2D materials-based FETs using BCP lithography that decreases substrate effect ensures high mechanical stability and device performance. Moreover, FETs on nanostructured substrates exhibited higher mobility than devices on flat substrates, attributed to reduced charge impurities and extrinsic scattering. Therefore, this strategy can contribute to enhance the device performance of next-generation electronic applications based on 2D materials.

NM07.05.18

Unique Reflection Patterns of Spherical Colloidal Clusters with Decahedral Type *Ryosuke Ohnuki[1], Yukikazu Takeoka[2] and Shinya Yoshioka[1]; [1]Tokyo University of Science, Japan; [2]Nagoya University, Japan*

Spherical colloidal clusters exhibit structural colors, owing to the interference of light between colloidal particles. They can be easily prepared using water-in-oil-type emulsions; small water droplets disperse colloidal particles, and evaporation of water into the oil phase results in the aggregation of colloidal particles. Some of the prepared clusters exhibit shell-like stacks of hexagonally arranged particle layers beneath the spherical surface. These layers correspond to the (111) planes of the face centered cubic (fcc) lattice, and this type of spherical cluster is called an onion-like structure because the stacked layers are similar to onion peels[1]. Recent studies have shown that spherical colloidal clusters have different particle arrangements, such as fcc and icosahedral-type structures, *and the structural differences can be attributed to the experimental conditions applied during the preparation processes.When a water droplet rapidly shrinks upon heating, clusters with onion-like structures are formed. However, at a low shrinking speed, which can be controlled via presaturation of water-in-oil systems, highly ordered structures, such as single-crystal spherical fcc structures, are formed[2,3,4,5]. Thus, elucidating the exact particle arrangements and optical properties of each structural type is crucial for the application of spherical colloidal clusters in optical materials and for understanding the formation process.*

A decahedral structure is one of the structural type with a 5-fold axis and is commonly found in clusters of nanometer-sized colloidal particles. However, research on decahedral-type spherical clusters is limited. For example, Mbah et al. used confined self-assembly to investigate the interplay of thermodynamics and reaction kinetics in the crystallization pathways of finite clusters in icosahedral and decahedral structures[6]. Molecular dynamics simulations performed by using hard spheres show that thermodynamics alone is not sufficient to explain the experimental results; instead, the suggested kinetic factors play a crucial role. The optical properties of the decahedral type appear unique because interesting reflection patterns with teardrop and half-moon shapes have been observed using optical microscopy[7]. However, detailed investigations have not yet been conducted.

In this study, the structural and optical properties of decahedral spherical clusters were investigated. In addition to surface observations via scanning electron microscopy (SEM), the internal particle arrangement was investigated by using sequential cross-sectioning and transmission electron microscopy (TEM). Based on these results, we propose a detailed structural model for decahedral-type spherical colloidal clusters. The model comprises five tetrahedral units that differ slightly from the Mackay structure, which is known as the unit to form the icosahedral structure. Next, the optical properties of the decahedral clusters were carefully examined by using an optical microscope equipped with a microspectrophotometer. We observed various reflection patterns depending on the orientation of the cluster, including previously reported patterns, namely, half-moon and teardrop patterns, and a newly discovered edge-ring pattern. In addition, line-like reflections of different colors were observed. We show that these patterns originate from various combinations of two reflection mechanisms with reflectance peaks at different wavelengths[8].

Synthesis of Nanoporous Carbon Material and Carbon Nanospheres Using Sugar

Cindy X. Fan[1], Guangping Xu[1], Raul Barbosa[1,2], Rachel N. Gaines[1], Justin Rosenthal[1,2], Amanda Sanchez[1] and Hongyou Fan[1]; [1]Sandia National Laboratories, United States; [2]The University of Texas at Austin, United States

The mitigation of the impact of anthropogenic carbon dioxide is important to the reversal of the trend of the climate change that has been already observed in the world. One of the key approaches for solving this problem is to capture carbon dioxide (CO_2) from the atmosphere in advance of fixation, conversion, or injection into the aquifers for long-term storage. Successful CO_2 capture is further complicated by the fact that nitrogen (N_2) is the dominant *gas in the Earth's atmosphere. Thus the separation of carbon dioxide from the mixture of carbon dioxide and nitrogen gases requires economic and environmentally friendly technologies is vital to enable anthropogenic intervention to the reverse of the current trend of climate change.*

Current state-of-the-art CO_2 capture technologies involve amine-based chemical sorption in corrosive KOH solution. It is an energy intensive process to regenerate the absorbent. In this work, we synthesized nanoporous carbon material using sugar as precursor to adsorb CO_2 via a physical sorption process to achieve the separation of CO_2 from N_2. We have successfully synthesized both mesoporous and microporous carbon materials utilizing the common table sugar sucrose ($C_{12}H_{22}O_{11}$) as the carbon precursor material. Addition of polystyrene-block-poly(4-vinylpyridine) (PS-P4VP) or n-Dodecyl beta-D-maltoside (DDM) ($C_{24}H_{46}O_{11}$) serve as the sugar surfactant and also enhance product porosity. The mesopores synthesized using PS-P4VP are mostly between ~10 nm and ~40 nm. The micropores synthesized using DDM are between 1 – 2 nm. The carbon spheres with tunable uniform size, ranging from sub-micron to a couple of microns, are also synthesized using sugar.

The synthesis technology developed will have an important impact in mitigating the negative effect of anthropogenic CO_2 on the climate change. Since the precursor materials for producing the nanoporous materials are cost-effective, abundant, and widely available, and the methods developed in this work for generating the nanoporous materials are environmentally friendly and are sustainable.

NM07.05.20

Mechanistic Study on Homolytic H_2O_2 Cleavage Mediated by Brönsted/Lewis Acidic Species Pertaining to Non-Reducible Metal Oxide Surfaces *Jongsik Kim; Kyung Hee University, Korea (the Republic of)*

H_2O_2 is deemed as a conventional precursor of ${}^{\cdot}OH$ (hydroxyl radical), which can destabilize hard-to-degrade, aqueous organics via ${}^{\cdot}OH$ addition or $H^{\cdot}$ abstraction, leading to the mineralization of organics via CO_2/H_2O evolution.[1-11] To facilitate ${}^{\cdot}OH$ production, a reducible transition metal oxide conventionally serves due to its inclusion of Lewis acidic metal cations ($M^{\delta+}$; $\delta \leq 2$) on the surface. $M^{\delta+}$ species enable heterolytic H_2O_2 dissection to form ${}^{\cdot}OH$ and OH^- alongside with $M^{\delta+}$ oxidation ($M^{\delta+}+H_2O_2 \rightarrow M^{(\delta+1)+}+{}^{\cdot}OH+OH^-$).[1-11] However, the recurrence of catalytic H_2O_2 heterolysis is challenging because of the substantial $M^{\delta+/(\delta+1)+}$ leaching from the surface to aqueous phases as well as the use of H_2O_2 for regenerating $M^{\delta+}$ species via H_2O_2-mediated $M^{(\delta+1)+}$ reduction ($M^{(\delta+1)+}+H_2O_2 \rightarrow M^{\delta+}+{}^{\cdot}OOH$).[1-11] It thus is undeniable that a reducible transition metal oxide can act as a shuttle of H_2O-soluble $M^{\delta+}$ cations with their sustainable utilization being viable only under H_2O_2-ample environments.[1-11] Meanwhile, a non-reducible transition metal oxide also contains $M^{\delta+}$ species, which can cleave H_2O_2 in homolytic manner to generate two ${}^{\cdot}OH$ species ($M^{\delta+}+H_2O_2 \rightarrow M^{\delta+}+{}^{\cdot}OH+{}^{\cdot}OH$).[10-11] Notably, catalytic H_2O_2 homolysis is recurrent because $M^{\delta+}$ species are firmly coordinated to proximal O^{2-} anions and therefore are scarcely released from the surface and because H_2O_2 homolysis does not involve intermolecular e^- exchange between $M^{\delta+}$ and H_2O_2 and thereby eliminates the necessity to recover $M^{\delta+}$ species.[10-11] Interestingly, H_2O_2 homolysis is more promising than its heterolytic counterpart, yet, has been under-explore or partially clarified in terms of the identification of major active sites and their catalytic roles, while also leaving its mechanistic elaboration to be undone, as far as we know.[10-11]

In this presentation, we propose the mechanism concerning catalytic H_2O_2 homolysis on ZrO_2 surface, whose Brönsted acidic -OH and Lewis acidic Zr^{4+} species proceed with H_2O_2 adsorption, H_2O_2 distortion, and H_2O_2 dissection prior to ${}^{\cdot}OH$ desorption.[10-11] H_2O_2 distortion and ${}^{\cdot}OH$ desorption stages are featured by endothermicity, whose magnitude is diagnosed to uncover the rate-determining step of H_2O_2 homolysis via a series of control runs.[10-11] Moreover, catalytic functions of -OH/Zr^{4+} species are also examined using a host of characterization *techniques.*[10-11]

Investigating the Impacts of Benzothiophene Regioisomerism and Side Chain Fluorination on Phenylene-Ethynylene Crystal Packing and Fluorescence

Gabrielle A. Buell, Elisa Guzman and Samuel Thomas; Tufts University, United States

The field of organic optoelectronics has shown significant growth in recent years, with an emphasis on the development of new materials for higher performance organic thin films. Engineering chemical structure that incorporate directional non-covalent interactions to dictate packing motifs of these materials is crucial to their rational design, because intermolecular and intramolecular electronic coupling greatly influences solid-state fluorescent and electronic behavior. Our research group has reported on materials based on phenylene-ethynylenes (PEs), which have a low barrier of rotation, that enable cofacial stacking between electron-rich arenes in the backbone, and electron poor perfluoroarenes in the side chains, which cause twisting of the conjugated backbone. More recently, we are investigating how heterocyclic arenes, which are important in most organic optoelectronic materials, impact these stacking interactions. This study seeks to understand how the regiochemistry of benzothiophene rings, as well as degrees of fluorination of pendant fluoroarenes, impact the propensity of these arenes to stack and twist the PE backbones. This investigation will increase understanding of the relatively weak non-covalent electrostatic interactions of moieties used in organic optoelectronics.

Unlocking Catalytic Significance of Binding Modes for Phosphate Modifiers on Metal Vanadate Phases in Humid NO_X Activation

So Hyeon Park and Jongsik Kim; Kyung Hee University, Korea (the Republic of)

A metal vanadate is garnered as an emerging phase for catalyzing NH_3-assisted, selective catalytic reduction of NO_X (SCR) pertaining to a humid, H_3PO_4-containing feed gas.[1-11] *This is because a metal vanadate surface bears Brönsted acidic -OH species (BA^--H^+) distinct from their conjugate bases functioning as labile oxygens ($-O_L$) as well as Lewis acidic metals (LA) proximal to oxygen vacancies (O_V) used to afford/release mobile oxygens (O_M).*[1-11] *Notably, -OH/LA and $-O_L/O_V/O_M$ species are exploited to accelerate the acidic and redox cycles of the SCR, respectively.*[1-11] *However, the traits of -OH species are challenging-to-control and readily poisoned by H_2O, thus severely limiting the efficiency of the acidic cycle mediated by -OH species.*[1-11] *Meanwhile, LA species are prone to occlusion enabled by poisonous H_3PO_4, yet, can function as anchoring spots of mono-/bi-dentate PO_4^{3-} functionalities produced via dehydration of H_3PO_4 poisons under oxidative conditions.*[4, 6] *Of note is that PO_4^{3-} modifiers imparts multiple P^{5+}-O^{2-} bonds that can act as BA^--H^+ species via protonation.*[4, 6] *We thus hypothesize that acidic properties of protonated P^{5+}-O^{2-} bonds pertaining to (protonated) PO_4^{3-} modifiers can rely on their* *binding modes (i.e., mono- or bi-dentate).*

Meanwhile, the properties of -O_L/O_V/O_M species are oftentimes lumped and barely unlocked in terms of catalytic functions, albeit with their significance in facilitating the redox cycle of the SCR.[1-11] *In this regard, we speculate that the redox features of -O_L/O_V/O_M species also hinge on the binding configurations of (protonated) PO_4^{3-} functionalities positioned adjacent to the redox species.*

In this presentation, a series of metal vanadates with distinct PO_4^{3-} binding modes serve as controls to disclose their centrality in directing the features of P^{5+}-O^{2-}-H^+ bonds and -O_L/O_V/O_M species via bunched characterization techniques. In conjunction with the elaboration on the SCR kinetics/mechanisms for the controls, their SCR performance is examined systematically under regulated environments.

An Investigation into Formation Pathway of Peptoid Supramolecular Structures

Zeqian Zhang[1], Renyu Zheng[1] and Chun-Long Chen[2,1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

The functions of nanomaterials assembled from sequence-defined macromolecules are highly determined by their molecular packing and morphologies.[1,2] *Peptoids, N-substituted glycines, are a well-developed type of sequence-defined synthetic polymers that mimic the functions of peptides and proteins. Lacking in hydrogen bond donors, peptoids exhibit unique self-assembly characteristics, forming well-defined supramolecular structures such as nanotubes*[4]*, nanosheets*[4]*, and nano-helices*[6] *through noncovalent interactions. These structures result from the dynamic equilibrium between their intermolecular hydrophobic interactions and amphiphilicity in the surrounding aqueous phase.*[7] *Despite extensive efforts in designing peptoid sequences for hierarchical assembly, the formation pathways of many peptoid-based supramolecular structures remain under explored. Macromolecular self-assembly is influenced not only by sequence and composition but also by exposed environmental conditions. Understanding how these conditions affect peptoid assembly structures aids in predicting the assembly of peptoids into designed supramolecular structures. In this presentation, I will report my systematic studies of peptoid self-assembly process by varying factors such as solvent type, solvent ratio, temperature, and ionic strength. Three typical morphologies, nanotubes, nano-helices and nanosheets are formed in a controllable manner from a single peptoid sequence Npm4Nc2-L-Ala with the change of assembly conditions. In acetonitrile and H_2O, this sequence assembles into helices. In acetone with the same ratio, this peptoid forms both tubes and helices. As the percentage of water increases, the pitch distance of peptoid helices becomes longer, and more rod-like structures appear and are easier to observe. Peptoid nanosheets have a much higher energy barrier than tubes and helices. In either acetonitrile or acetone as organic solvents, nanosheets form whenever a 60 °C annealing is treated on the dissolved peptoid powder before the self-assembly begins. We also find that the change of solution ionic strength can change the nanohelix formation pathways as this sequence typically* *undergoes a fiber intermediate structure while an increased ionic strength leads to the formation of a tubular intermediate structure before nanohelix formation. These findings provide evidence for constructing a peptoid self-assembly energy landscape and support the possibility of achieving precise control over formation pathways.*

Selective Isolation and Colorimetric Detection of Her2-Overexpressing Breast Cancer-Derived Exosomes in Mouse Urine Using Magnetic Nanoparticle Complex Polydiacetylene Nanoparticles

Ryunhyung Kim, Byeonggeol Mun and Seungjoo Haam; Yonsei University, Korea (the Republic of)

Breast cancer (BC) is one of the major health problems worldwide. Approximately 20–25% of BC patients overexpress human epidermal growth factor receptor 2 (HER2), a marker for aggressive BC. Early HER2-overexpression detection greatly increases patient survival; however, appropriate diagnostics and therapeutics are not yet equally available in all countries. We have developed an equipment-free, low-cost, and easy-to-use polydiacetylene (PDA)-based colorimetric sensor for HER2-overexpressing BC detection, designed for use in low- and middle-income countries (LMICs). PDA nanoparticles were first prepared through thin-film hydration. Subsequently, hydrophilic magnetic nanoparticles and HER2 antibodies were sequentially conjugated to them. The synthesized HER2-MPDA can be concentrated and separated by a magnetic field while inheriting the optical characteristics of PDA. The specific binding of the HER2 antibody of HER2-MPDA to the HER2 receptor in HER2-overexpressing exosomes induces a rearrangement of the molecular structure within the PDA backbone, altering its electronic properties and inducing a color change blue to red in HER2-MPDA. This colorimetric sensor, whose color changes upon binding to HER2-overexpressing exosomes, can be separated with a magnet immediately after the reaction. Finally, the performance of HER2-MPDA was evaluated in detecting HER2-overexpressing exosomes in the culture medium of HER2-overexpressing BC cells and mouse urine samples from a HER2-overexpressing BC mouse model. We hope that this sensor can be an effective point-of-care platform to reduce mortality due to HER2-overexpressing BC in LMICs.

NM07.05.25

A Scalable and Sustainable Adsorbent Composed of Self-Assembled Epoxide-Functionalized Polyethyleneimine/Silica for Capturing Carbon Dioxide from Exhaust Gas

Younghun Kim[1,2], Gunhee Lee[1], Jungho Hwang[2], Bangwoo Han[1] and Dae Hoon Park[1]; [1]Korea Institute of Machinery & Materials, Korea (the Republic *of); [2]Yonsei University, Korea (the Republic of)*

Amine-based solid adsorbents, composed of a mixture of amines and porous solid supports, demonstrate excellent carbon capture performance by combining carbon chemisorption by the amines with carbon physisorption by the solid support. This dual functionality has garnered considerable interest from researchers specializing in post-combustion carbon capture.

In most air-based CO_2 capture systems, amine-based solid adsorbents are used in powder form (< 1 mm). However, in continuous flow conditions like diesel engine exhaust emissions, powder adsorbents can be lost due to the drag force of the exhaust flow, resulting in a gradual decrease in CO_2 capture capacity.

Herein, we propose a simple and scalable method to synthesize the self-assembled-CO_2-adsorbent pellets by extruding functionalized polyethylenimine (PEI)/silica for use in exhaust emission aftertreatment. This self-assembled pellet shaping creates a new hierarchical porosity, including nano-sized pores (micropores (< 2 nm), mesopores (2-50 nm)) than those found in the original materials.

Silica-based substrates were extruded with an inert binder to enhance handling and mechanical strength, then formed into pellets. Post-extrusion, the organic binder was calcined at temperatures between 150-750°C. These calcined pellet substrates were subsequently self-assembled with functionalized PEI. To evaluate the CO_2 adsorption capacity and efficiency of the self-assembled solid adsorbents (functionalized PEI/silica adsorbents) at various calcination temperatures, we measured the CO_2 adsorption capacity and efficiency under 5% CO_2 using thermogravimetric analysis (TGA550, TA Instruments, U.S.A) and breakthrough system.

The results showed that the pellet substrates calcined at 550 °C had the highest total pore volume (0.98 cm^3/g), and the highest average carbon dioxide adsorption efficiency over 5 minutes (22.64%). Subsequently, the porous pellet (calcined at 550 °C) could be effectively self-assembled with the functionalized PEI/silica adsorbents due to its higher proportion of nano-sized mesopores compared to the original material (silica powder). The developed self-assembled-CO_2-adsorbent pellets included approximately 45 wt% of the CO_2 adsorption component.

These findings suggest that this scalable and sustainable method for synthesizing and self-assembling solid-supported amine adsorbents into pellets could be an effective solution for carbon capture systems in areas of energy and environment on post-combustion aftertreatment conditions.

Environmental-Friendly Solution-Processable Route to Size-Controlled SnTe Nanocrystals

Thanyarat Phutthaphongloet[1,2,3], Ricky Septianto[1,3], Nobuhiro Matsushita[2], Yoshihiro Iwasa[1] and Satria Bisri[1,3]; [1]RIKEN, Japan; [2]Tokyo Institute of Technology, Japan; [3]Tokyo University of Agriculture & Technology, Japan

Colloidal semiconductor nanocrystals (NCs) have attracted attention as promising materials for various applications.[1] The ability to precisely control their size and shape through solution-processable synthesis allows for fine-tuning their electrical and optical characteristics. Pb- and Hg-based chalcogenides (PbX and HgX, X = S, Se, and Te) have been extensively explored for electronic, optical, and optoelectronic applications.[2] In comparison, less toxic alternatives such as tin(II) telluride (SnTe) have been studied much less and should be further researched to conserve the environment. With its narrow bandgap, SnTe NC is prospective for short-wave *to mid-infrared spectrum photodetection. Also, they are expected to become a lead-free alternative for thermoelectric materials.[3] Significant challenges in synthesizing SnTe NCs stemming from their instability and oxidation-prone precursors hamper their further research.*

Herein, we present a novel, cost-effective, and solution-processable method for synthesizing monodisperse SnTe NCs via the simple reaction of trioctylphosphine telluride (TOPTe) with tin (II) bromide ($SnBr_2$) in conjunction with solely capping ligand oleylamine (OLA). The resulting NCs exhibited a cubic rock-salt crystal structure identical to their bulk of SnTe (space group,). The NC diameters can be tuned from 8.9 to 44 nm by adjusting the reaction temperature and time. Our modified post-treatment process effectively isolated smaller NCs with narrow size distributions by exploiting the distinct solubility properties of the components and employing gradient density ultracentrifugation.

Furthermore, the synthesized SnTe NCs were air-stable and could demonstrate electrical conductivity without introducing short ligands[2] and halide treatments[3], which are typically vital to obtaining conductive pathways in the other NCs. Our observation might suggest the extended reach of the electron Bohr radius of the SnTe NC, signifying its quantum confinement.

The synthetic procedure developed here offers an alternative path for the size-controlled synthesis of other monodisperse chalcogenide NCs using low-cost and environmentally friendly precursors, representing an advancement in colloidally synthesized semiconductors.

Exploring Formaldehyde Gas Sensing Performance of NiO Nanostructures— Experimental and Theoretical Perspectives

Ahmad M. Siddiqui and Mohsen A. Alhammami; Najran University, Saudi Arabia

The research explores hydrothermally synthesized NiO nanostructures, including NiO-NA, NiO-HMDA, and NiO-HMTA, for formaldehyde gas sensing applications. XRD analysis confirmed a cubic crystal structure with space group Fm-3m, exhibiting well-defined and consistent arrangements. The Debye Scherer equation determined average crystallite sizes of 8.49 nm, 9.21 nm, and 8.42 nm for NiO-NA, NiO-HMDA, and NiO-HMTA, respectively. Distinct morphologies emerged, such as net-like structures for NiO-NA, altered nanosheets for NiO-HMDA, and feather-flower patterns for NiO-HMTA. Energy-dispersive X-ray spectroscopy affirmed the uniform distribution of Ni and O elements in all samples. UV-vis. spectra revealed absorption characteristics in the 370-390 nm range, with band gap values of 3.333 eV, 3.234 eV, and 3.243 eV for NiO-NA, NiO-HMDA, and NiO-HMTA, respectively. Gas sensing assessments demonstrated superior performance for NiO-HMTA at 350 °C, attributed to its smaller size and intricate morphology. Linear relationships between gas response and concentration were established, with NiO-HMTA exhibiting the highest precision. Further, rapid response (79 s) and recovery (84 s) times at 350 °C. The proposed mechanism highlights chemisorption-driven redox reactions, elucidating the intricate gas-sensing behavior of NiO-HMTA. The investigation into the interaction dynamics between formaldehyde (HCHO) and NiO was conducted through Density Functional Theory (DFT) simulations, employing the B3LYP/LanL2dz level of theory. The study discerned that the improved sensitivity of the NiO-based sensor to the HCHO molecule likely stems from the deposition of an oxygen atom from the surrounding medium onto the surface of NiO.

NM07.05.28

A Purely Electronic Analog Memristive Device Based on a Squaraine Nanowire Mesh

Gareth Redmond; University College Dublin, Ireland

Analog memristors offer the ability to gradually increment device conductance, akin to synaptic weight updating the human brain, and a path toward emulation of brain-like functionality on a chip. Specifically, purely electronic resistive switching device operation may provide good device stability, fast device response, and microelectronics fabrication compatibility. In this context, nanowires (NWs) based on 2,4-bis[(4-diethylamino)-2-hydroxyphenyl]squaraine were prepared by non-solvent-induced precipitation and characterized in detail. Symmetric, unipolar (hole-only) metal−insulator−metal-type devices were formed by simple deposition of NW meshes on interdigitated gold electrodes. The DC I−V characteristics acquired from devices displayed pinched hysteretic I−V loops indicative of memristive behavior. Analysis of I−V data indicated Ohmic transport at low bias with carrier extraction facilitated by thermionic emission. At high bias, devices exhibited trap-limited space-charge- limited conduction in the presence of traps distributed in energy, which was enhanced by a Poole−Frenkel effect, with carrier extraction facilitated by Fowler−Nordheim tunneling. Overall, the data were consistent with purely electronic conduction. This hypothesis was further supported by DC measurement data acquired from devices under illumination, by AC impedance data acquired in both dark and light conditions, and by variable temperature transport measurements. During voltage sweeps applied to NW mesh devices, I−V hysteresis was observed, consistent with modifications to current flow caused by carrier trapping/detrapping. Device conductance could be increased sweep by sweep, giving conductance tuning through distinct states, with wait time- or voltage-erase options, consistent with trap filling/emptying effects. On this basis, trap-enabled analog memristive device functionality was demonstrated in both rigid and flexible device formats by applying various voltage waveforms. Repeated erase-write-read of multiple distinct states over many voltage cycles during continuous use in air was demonstrated. Also, synaptic functions, e.g., pulse-dependent plasticity, and short- to long-term memory transition, were successfully emulated. Finally, the stable, repeated erase−write−read of multiple distinct conductance states over hundreds of voltage cycles during hours long periods of continuous use in an ambient atmosphere was demonstrated. Overall, squaraine NW mesh devices appear to exhibit many attractive characteristics that make them potential candidates for neuromorphic computing applications.

NM07.05.29
Mechanism Study of Photoactive Morphology Formation in Bulk-Heterojunction Organic Photovoltaics
Jinsung Kim; University of California, Los Angeles, United States

The photoactive morphology of organic photovoltaics (OPVs) is critical for determining both power conversion efficiency and long-term stability. Despite the significant performance advancements by non-fullerene acceptors (NFAs), a comprehensive understanding of the underlying mechanism of morphology formation in bulk-heterojunction (BHJ) OPVs remains lacking. In this work, we employed in-situ UV-Vis spectroscopy to observe the evolution of the polymer donor and NFA network during the film formation process. Our findings reveal that the aggregation of NFA molecules can be controlled through modifications in the drying and solidification during the film formation. Leveraging this insight, we introduced a novel additive that optimizes NFA aggregation and network formation, improving the overall morphology of the BHJ layer. The in-situ analysis was further corroborated by quantitative nanomechanical imaging and depth profiling X-ray photoelectron spectroscopy. The interfacial photoactive domains were visualized, revealing that the new additive blend film exhibited 24% larger NFA domains at the top surface of the BHJ layer compared to control blend, leading to significant improvement in charge extraction and transport. Furthermore, the controlled film formation enhanced device stability, extending the T_{80} lifetime over 1,000 hours. These findings provide a deeper understanding of the photoactive morphology formation mechanisms, with implications for improving both efficiency and stability in next-generation OPV devices.

Influence of Hydrogen on Alloy Catalyst and Growth Mechanism from VLS-Hydride-Vapor-Phase-Epitaxy of GaN Nanowires *Cheng-Chih Hsiang and Yi-Chia Chou; National Taiwan University, Taiwan*

Nanowires, with their unique one-dimensional structure that enhances their electronic performance, are primarily grown via the vapor-liquid-solid (VLS) method. The growth of gallium nitride (GaN) nanowires requires high temperatures; hence, sustainable alloy catalysts must be applied instead of pure metal catalysts in conventional VLS growth. This bottom-up approach, in collaboration with the hydride vapor phase epitaxy (HVPE), is known for its cost-effectiveness and potential for large-scale production. The typical carrier gas in HVPE is nitrogen, while our research found that the addition of hydrogen in the transport of Ga precursor influenced the composition of alloy catalysts. This observation necessitates further investigation to understand the impact on the growth and properties of GaN nanowires.

In this study, we explore GaN nanowires grown from Ni/Au alloy catalysts utilizing either pure nitrogen or nitrogen with hydrogen as carrier gases on substrates of MoS_2, c-sapphire, and Si (111). The morphology of GaN nanowires was significantly altered from wire-like to rod-like after adding hydrogen to the nitrogen carrier gas. The optical quality of GaN nanowires was enhanced, demonstrated by a pronounced PL peak at the near-band edge of GaN and a marked reduction in defect-related PL yellow emissions. These effects were especially notable in the nanowires grown on MoS_2 substrates. Additionally, the microstructural and elemental analyses using scanning transmission electron microscope (STEM) and energy dispersive X-ray spectroscopy (EDXS) reveal that introducing hydrogen into nitrogen carrier gas during GaN nanowire growth substantially influences the catalyst composition and nanowire growth orientation. At the growth temperature, the Ni/Au reacts with Ga precursor gas to form NiGa nanocrystals embedded in the AuGa liquid droplets. In a pure nitrogen growth environment, the overall catalyst droplets are larger in size, containing a floating NiGa crystal embedded in liquid AuGa with a lower Ga atomic concentration. This condition results in the formation of m-oriented GaN nanowires. In comparison, with the hydrogen introduction into the nitrogen carrier gas, the overall catalyst droplets became smaller, where a faceted NiGa nanocrystal was attached to the nanowire growth front, and the liquid AuGa contained the higher Ga atomic concentration. This leads to the predominance of c-oriented GaN nanowires. In other words, the NiGa nanocrystals were observed floating within the catalyst droplets of m-oriented GaN nanowires, whereas, in c-oriented GaN nanowires, they were attached to the growth front, exhibiting the epitaxial relationship with GaN nanowires. It is speculated that the condition of the NiGa nanocrystals within the liquid AuGa enables the control of vapor-liquid-solid (VLS) or vapor-solid-solid (VSS) growth, thus making the growth orientation of nanowires adjustable. These fundamental insights reveal the critical role of the growth environment, whether hydrogen or hydrogen with nitrogen, in enabling precise control of GaN nanowires and expanding their potential applications.

8:30 AM NM07.06.02

DNA Origami as Patchy Colloids—Diamond Cubic Lattice with a Photonic Band Gap in UV *Gregor Posnjak[1], Xin Yin[1], Paul Butler[2], Oliver Bienek[2], Mihir Dass[1], Seungwoo Lee[3], Ian Sharp[2] and Tim Liedl[1]; [1]Ludwig-Maximilians-Universität München, Germany; [2]Technische Universität München, Germany; [3]Korea University, Korea (the Republic of)*

Rational design of the structure of matter on the sub-micron scale can lead to interesting and fundamental material properties, for instance sub-wavelength periodicity of dielectric structures leads to photonic band gaps in photonic crystals(1). The diamond cubic lattice has long been known to possess one of the widest and *experimentally most accessible photonic band gaps. Building such a lattice on the scale of visible wavelengths has proven difficult because either its small feature sizes were not accessible through lithographic methods, or its non-close packed and mechanically unstable structure was challenging to achieve with self-assembly. Tetravalent colloidal particles are the most obvious candidates for building blocks of such a structure, however they are difficult to manufacture and indiscriminately crystallise into either diamond cubic or hexagonal diamond structures(2). Use of torsional potential on the binding patches was proposed to bias their crystallisation exclusively to the diamond cubic lattice(3), but this makes the implementation of the tetravalent particles even more challenging.*

We have solved both issues with the use of DNA origami(4). DNA origami uses the predictable binding of complementary DNA sequences of short oligonucleotides to fold a long (~8000nt) single-stranded DNA scaffold into almost arbitrary shapes on the scale of tens of nanometers(5, 6). With this method we rationally designed four-legged tetrapods with a binding patch at the end of each of the legs. The binding was implemented by DNA overhangs that were positioned in a pattern with a three-fold symmetry to enforce a 60° rotation between neighbours as needed for the diamond cubic structure. With tuning of the binding sequences and crystallisation conditions we were able to grow crystals up to 50 micrometers in size with a periodicity of 170 nm. The pores in the crystals are about 100 nm in diameter, making them an interesting high surface-to-volume ratio material which could be used for catalysis or energy storage.

After crystallisation we mechanically stabilised the crystals by silicifying them with a sol-gel reaction and employed atomic layer deposition for conformal coatings of metal oxides. Deposition of thin layers of high refractive index materials like TiO_2 led to the appearance of a photonic band gap for wavelengths around 300 – 350 nm. The position of the photonic band gap redshifted with increasing thickness of TiO_2 coating as predicted by our numerical calculations.

***Overview of the Development of In Situ Electron Microscopy Technology in the Past Decade** Xiaolong Zhang and Xuanyu Chen; Anhui Zeyou Technology Co., Ltd., China*

The advancement of in-situ electron microscopy technology is crucial for understanding the evolution of the structure-activity relationships in samples. Over the past decade, progress in nanomanipulation and nano environment construction technologies has significantly accelerated the development of in-situ electron microscopy. This talk will introduce several advanced in-situ electron microscopy characterization methods and present application cases, aiming to offer researchers new methods and insights for their studies.

9:00 AM *NM07.06.04

3D Functional Nanomaterials Through DNA-Programmable Assembly *Oleg Gang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States*

Organizing functional nanoscale components into the desired material architectures can enable diverse nanotechnological applications, from engineered biomaterials to metamaterials and electronic devices. However, the conventional nanofabrication methods are limited in controlling the formation of 3D architectures and their nanoscale material composition. The talk will discuss the development of a broadly applicable self-assembly platform for fabricating designed large-scale 3D nanomaterials with targeted organization across multiple scales, from nm to mm, through DNA-programmable assembly. The recent advances in creating periodic and hierarchical organizations based on DNA frameworks inorganic nanoparticles by unifying 3D programmable self-assembly at the mesoscale and directed assembly at the macroscale will be presented. The developed assembly methods are further coupled with nanoscale templating to transform DNA-based frameworks into fully inorganic replicas from metal, metal oxide, and semiconductor materials or their combination. The formed 3D nanomaterial can be integrated with top-down fabrication methods for the creation of functional materials and devices. The application of the developed assembly approaches to enable nano-optical, electrical, and mechanical functions will be demonstrated.

Advanced Materials via Aggregation and Self-Assembly for Drug Delivery Technologies *Wei Tao[1,2]; [1]Harvard Medical School, United States; [2]Brigham and Women\'s Hospital, United States*

Despite all of the coverage of new drugs, it is not enough to just have an effective drug. To enhance therapeutic efficacy and reduce the side effects, the drugs have to be protected and transported to the right location to get an effect at the right time. Over the past few decades, advanced materials-enabled drug delivery platforms have made tremendous advancement in preventing and treating human diseases. Especially, the recent great success achieved by the two highly effective mRNA nanoparticle vaccines during the COVID-19 pandemic has further highlighted the great potential of drug delivery technologies based on nanoscale or microscale materials via aggregation and self-assembly. During the evolution of these drug delivery technologies, materials science innovation has played an important role from drug modification to the synthesis of different drug delivery platforms, which fulfills effective medical applications in various diseases including cancers, cardiovascular diseases, diabetes, infectious diseases, and many others. In this talk, I will introduce our current studies on nano-/microscale materials-enabled drug delivery technologies with the promise to improve health care, as well as our effort in accelerating their translation into the drug development pipeline.

Self-Assembly of Chiral Nanostructures *Nicholas A. Kotov; University of Michigan, United States*

Chiral nanostructures are a large and rapidly evolving class of biomimetic materials. Besides fascinating optical, catalytic, and biological properties, the studies of chiral nanostructures represent a missing link in the emergence of complexity in Nature. Complexity, i.e. purposeful combination of order and disorder, leads to nontrivial combination of properties needed for many technologies. In the context of self-assembled particles, complexity manifests as spontaneous increase of structural hierarchy and correlated disorder seemingly prohibited by thermodynamics. These observations mirror the structural evolution of biological materials that combine nano-, meso- and microscale chirality. Taking an example of complex particles with twisted spikes and layer-by-layer-

assembled nacre-like composites, we found that:
(a) formation of complex structures does not require monodispersity;
(b) competing thermodynamic restrictions in self-limited systems increase their complexity;
(c) synthetic particles can have higher complexity than their biological prototypes.
These findings were possible by applying graph theoretical (GT) measures of complexity to nanoparticle assemblies. Their applicability to 'imperfect' (nano)particles and ability to capture essential structural motifs made possible to include other nanoscale structures, such as complex porous particles and superlattices,[2] creating analogs of chemical formulas for complex particle systems (chiral, racemic and achiral). Understanding of intermolecular forces and expansion of self-limited assembly to bulk dispersions of diverse nano(particles) enabled the design of hierarchically organized bowtie-shaped particles with variable twist, size, and thickness and length.[3]

Hierarchically Structured Materials Assembled from Mixed-Graft Block Copolymers *Mingjiang Zhong and Yazhen Xue; Yale University, United States*

Block copolymers are promising for numerous applications, such as thermoplastics, nanotemplates, and biomaterials. The synthesis of block copolymers with intricate, non-linear architectures has been made possible by recent advancements in living polymerization techniques. This presentation will highlight recent advancements in the design and synthesis of mixed-graft block copolymers (mGBCPs), characterized by multiple types of homopolymeric side chains attached in specific sequences to a linear backbone. These mGBCPs feature covalently bonded side chains that create an interface along the backbone, thereby reducing the entropic penalty during self-assembly. This reduction leads to nanophase-separated structures with domain spacings of less than 3 nm, a size that is challenging to achieve with traditional linear copolymers. Moreover, the addition of a third type of side chain to these polymers broadens the range of achievable nanomorphologies, facilitating the formation of hierarchically assembled structures with adjustable nanodomain spacings from 3 to 400 nm. The distinct assembly behavior dictated by the side chains and the graft architecture enables precise control over the thermomechanical properties and the resulting nanostructures. Additionally, combining mGBCPs with various inorganic fillers, such as metal ions, metal oxide clusters, and metallic nanoparticles, results in the formation of three-dimensional arrays with controlled interfiller spacing and arrangement. Utilizing specific interactions between the fillers and the mGBCP side chains allows for the simultaneous incorporation of multiple types of fillers into the mGBCP matrix. This method results in multifunctional nanocomposites, where each filler type is selectively positioned within specific nanodomains, oriented by the polymer matrix. This talk will discuss innovative synthesis and design strategies for mGBCPs, emphasizing their potential to enhance various technological applications through their unique self-assembly properties and structural versatility.

11:30 AM NM07.06.08

Novel Tools for Studying Crystallization Pathways of Shaped Particles into Complex Crystals *Domagoj Fijan, Philipp W. Schoenhofer, Brandon Butler, Charlotte Zhao, Thomas Waltmann, Joshua A. Anderson, Maria Ward Rashidi and Sharon C. Glotzer; University of Michigan, United States*

Nucleation and crystallization processes are critical in diverse materials, such as colloidal, soft, molecular, metallic, and ionic crystals. While there's considerable understanding of nucleation in simple crystals, research on complex crystals' nucleation is limited due to the lack of suitable computational tools. We address three main areas for improvement: an order parameter that describes local structures with continuous point group symmetry, a new neighbor list for shaped particles, and a tool for efficiently detecting and recording nucleation events in great detail.

Complex crystals exhibit multiple local environments, and to truly understand the nucleation process on a lowest level would require us to somehow track the progression of symmetry elements for each of these environments. However, traditional order parameters such as Steinhardt's (SOP) and its variants merge multiple symmetries into a single value, limiting their effectiveness in detailed analysis. Our novel Point Group Order Parameter (PGOP) overcomes this limitation by providing a per-particle order parameter based on symmetry operations. PGOP compares a particle's bond order diagram (BOD) with a perfect symmetrized BOD using the Pearson correlation coefficient. This quantifies how well the local environment aligns with specific symmetry operations, allowing distinct differentiation of local environments in complex crystals.

The accuracy of PGOP depends on identifying neighboring particles. Traditional methods like Voronoi tessellation and Solid-angle nearest neighbors (SANN) often fail in systems with shaped particles. To resolve this, we introduce Shadow Projection Overlap of Obstacles for Neighbor Exclusion (SPOONE). SPOONE identifies neighbors by casting rays and determining intersections (blocking), providing more accurate neighbor lists for shaped particles and enhancing PGOP's effectiveness. SPOONE can be utilized as a traditional or weighted neighbor list by considering the amount of blockage (shadow). This makes it very suitable in use for order parameter computation.

To facilitate the automatic detection of nucleation events and manage the data-intensive nature of these simulations, we developed Dupin, a Python tool for event detection in molecular simulation trajectories. Dupin promises to automate detection of events offering new potential applications of machine learning in the field. Dupin identifies changes using order parameters and employs change point detection methods to record events with high temporal resolution. Since dupin can work on-the-fly during the simulation it can also serve to minimizes data storage and improves simulation efficiency by selectively recording only significant events.

To showcase the utility of our newly developed tools, we present results from comparisons in traditional situations suitable for each tool. We contrast PGOP with SOP in both simple and complex crystals. SPOONE's effectiveness is demonstrated in systems of elongated shaped particles, with performance comparably effective for nearly spherical particles. Additionally, we explore the impact of different neighbor lists on PGOP and SOP by comparing the results using SPOONE versus Voronoi methods. Additionally, we highlight Dupin's ability to efficiently identify various events in soft matter simulations, including intricate nucleation processes and polymer collapses, for comprehensive post-simulation analysis. These tools collectively promise to advance the study of nucleation and crystallization, potentially opening new research opportunities in large-scale crystallization projects and enabling application of emerging fields such as machine learning in studying nucleation and crystallization pathways.

11:45 AM NM07.06.09

Growth of Nanocrystal Superlattices from Liquid Crystals *Shengsong Yang[1], Yifan Ning[1], Yugang Zhang[2] and Christopher B. Murray[1,1]; [1]University of Pennsylvania, United States; [2]Brookhaven National Laboratory, United States*

The growth of superlattices (SLs) made from self-assembled nanocrystals (NCs) is a powerful method for creating new materials and gaining insight into fundamental molecular dynamics. Previous explorations of NCSL syntheses have mostly compared them to crystallization. However, NCSL synthesis has not broadly shown cooling crystallization from saturated solutions as a reversible crystallization–dissolution process. We demonstrate the reversible growth of NCSLs by dispersing NCs in liquid crystal (LC) "smart solvents," and harnessing the transitions between the isotropic and nematic phases of the LCs. The growth mode and morphology can be tuned.

This process is a model platform for studying crystallization and demonstrates great potential in manufacturing NCSLs as colloidal crystals through liquid-phase epitaxy or colloidal synthesis.

SESSION NM07.07: Particle Aggregation VI
Session Chairs: Yuna Bae, Sijie Chen and Xin Zhang
Wednesday Afternoon, December 4, 2024
Hynes, Level 2, Room 201

1:30 PM *NM07.07.01
***Formation Mechanism and Aggregation of Atomic Clusters for Optical Applications** Jungwon Park; Seoul National University, Korea (the Republic of)*

Metal nanoclusters (NCs), an important class of nanoparticles (NPs), are extremely small in size and possess quasi-molecular properties, exhibiting unique photophysical and chemical properties. Due to accurate stoichiometry of constituent atoms and ligands, NCs have strong structure-property relationship. However, the synthetic procedure of metal NCs is highly convoluted. Reactive ligands can convert metal salts to complexes, actual precursors to metal NCs. This process results in various metal–ligand complexes, which have different coordinations of metal with ligand molecules. Those various metal species have different reactivity and fraction depending on synthetic conditions. It can alter their degree of participation in NC synthesis and the homogeneity of final products. Indeed, NC synthesis occurs through sequential transformations into a series of intermediate NCs before the formation of the desired NCs. We investigate the effects of complex formation on the entire NC synthesis and important roles of ligands in the overall synthesis of NCs. We find that the mechanistic understanding for the formation of the representative NCs (Au NCs) can be universally applied to synthesize Ag, Pt, Pd, and Rh NCs. Furthermore, NCs are prone to the guided aggregation by additional chelating ions. Ligand molecules, again, play an important role as centers for linking many NCs for the formation of aggregated structures. Aggregated NCs often show distinct optical properties. As an important example, we demonstrate that the aggregated Au NCs exhibit strong and sharp blue emission.

2:00 PM *NM07.07.02
***Hierarchical Structure Formation Revealed by Liquid Phase TEM** Haimei Zheng; Lawrence Berkeley National Laboratory, United States*

Nanoscale materials often undergo structural, morphological, or chemical changes, during solution processes, such as nucleation, growth, and self-assembly. Conventional ex-situ spectroscopic or microscopic characterizations provide ensemble averages and lack dynamic information. In-situ liquid phase transmission electron microscopy (TEM) enables tracking the dynamics of individual nanomaterials. Significant advances have been made in the development of liquid phase TEM, including the improved high-resolution imaging at the atomic level and enhanced capabilities in handling complex systems and reactions. We apply liquid phase TEM to investigate hierarchical structure formation including one-dimensional (1D) growth by nanoparticle interaction and attachment; two-dimensional (2D) growth with Moire patterns and interlayer coupling. In this talk, I will highlight the progress we made on the topics of study using liquid phase TEM including the impacts of defects on the transformations of these structures.

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

Colloidal Nanomaterials Self-Assembled by DNA-Patched Nanoparticles *Lintong Wu[1], Le Liang[2], Peng Zheng[1], Tao Ding[2], Krishanu Ray[3] and Ishan Barman[1]; [1]Johns Hopkins University, United States; [2]Wuhan University, China; [3]University of Maryland, United States*

Colloidal nanostructured materials are highly desired synthetic materials that mimic the structure of simple molecules, offering exceptional functionalities derived from the precise organization and specific interactions among their constituent elements. To harness these unique attributes for practical applications, it is crucial to achieve meticulous control over their structural arrangement with utmost accuracy. However, generating molecule-like small clusters of colloidal nanomaterials remains challenging due to the absence of selectively encoded surface chemical heterogeneity necessary for specific recognition interactions. Here, we present a novel approach involving the use of magnetic-bead-assisted DNA cluster transfer to create nanoparticles discretely patched with DNA clusters, facilitating the self-assembly of colloidal nanomaterials. This strategy demonstrates broad applicability and scalability, allowing for robust patching of DNA clusters onto nanoparticles without being hindered by the geometrical, dimensional, and compositional complexities typically encountered in nano- and microscale colloidal materials. We direct judiciously patched nanoparticles into a wide variety of nanoassemblies and present a case study demonstrating the distinct nanomaterial properties in enhancing the spontaneous emission of diamond nanoparticles. This innovative strategy is readily implementable and adaptable, enabling the construction of a variety of structurally intricate architectures with tailored functionalities. It paves the way for manipulating colloidal material functionalities at the nanoscale, thereby opening up new ways in biological sensing, optical engineering, and catalytic chemistry applications.

3:45 PM NM07.07.04

Morphological Phase Diagrams for Self-Assembly *Nivedina Sarma[1,2], Phillip B. Messersmith[1,1] and Ahmad Omar[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States*

While self-assembly has been harnessed to achieve materials with long-range order and emergent properties for decades, approaches to predicting the resulting structures have long been limited to heuristic models. These models are often best suited for specific particle geometries or solvent conditions and cannot describe competition between multiple structures. This highlights the need for a general theory, rooted in thermodynamics, that can predict the morphological phase diagram for any molecular structure. We use statistical mechanics and coarse-grained simulations to highlight driving forces for amphiphile self-assembly and develop a theory that predicts the assembly of a variety of structures, including spherical micelles, fibers, and planar sheets. Our theory describes how the fraction and size of each aggregate changes as a function of tunable parameters such as system concentration, temperature, and molecular topology. We predict the transition between mesoscopic and macroscopic structures as a function of these molecular parameters. Our theory is able to qualitatively reproduce trends observed in silico as well as in experiments of a model polymer prodrug. This theoretical framework offers intriguing rational design strategies for controlling the size and morphology of self-assembling systems.

Illuminating Polymer Stress—The Innovative Use of Aggregachromic Fluorophores for Detection and Analysis *Luca Soldati[1,2], Marco Carlotti[1] and Andrea Pucci[1]; [1]University of Pisa, Italy; [2]ChemieParisTech, France*

In a world where the use of plastics is becoming increasingly common in everyday life, the possibility of detecting damage and changes in properties of materials subjected to different surrounding environments becomes crucial. Therefore, interest in intelligent materials has increased drastically in recent years due to their ability to respond to *an external stimulus through an optical output. Among all the accessible solutions to determine polymer damages, those involving the use of aggregachromic probes appear the most effective due to their high sensitivity, real-time monitoring capabilities, and the potential for non-destructive testing. Aggregachromic fluorophores exhibit unique photophysical properties, notably their fluorescence response to molecular aggregation. This characteristic makes them ideal candidates for sensing and probing various polymer behaviors under different conditions. Unlike conventional fluorophores, which often suffer from quenching when aggregated, aggregachromic fluorophores can either enhance (AIEE) or switch (AIE) their fluorescence emission. This unique behavior is leveraged in various sensing applications, including the detection of mechanical, thermal, and chemical stimuli in polymeric materials. In this contribution, we report the use of different aggregachromic AIEE and AIE fluorophores to monitor mechanical and thermal solicitations. Notably, when a polymer composite embedded with these fluorophores is subjected to mechanical stress, the resultant aggregation changes provide a fluorescent signal corresponding to the level of strain or stress. This application is crucial in structural monitoring, where real-time detection of mechanical damage can prevent catastrophic failures. In addition, the response of aggregachromic fluorophores to thermal changes in polymers can be used to detect temperature variations and phase transitions. These fluorophores can indicate melting, crystallization, or thermal degradation processes within polymeric materials, making them valuable in the thermal management and quality control of polymer products. Continued research and development in this area hold promise for advancing polymer science and expanding the applications of these innovative materials in numerous industrial and scientific fields.*

4:30 PM *NM07.07.06

Molecular Radioafterglow Probes for Cancer Radiodynamic Theranostics *Kanyi Pu; Nanyang Technological University, Singapore*

X-ray induced afterglow and radiodynamic therapy tackle the tissue-penetration issue of optical imaging and phototherapy and hold translational promise for cancer theranostics. However, only inorganic nanophosphors are available, and their radio-afterglow-dynamic function is always-on, limiting detection specificity and treatment efficacy. We herein report the first type of organic luminophores (IDPAs) that can emit near-infrared (NIR) afterglow and produce ${}^1O_2$ *after X-ray irradiation and apply them for precision cancer theranostics. The in vivo radioafterglow of IDPAs is >25 times brighter than reported inorganic nanophosphor, while the radiodynamic production of* ${}^1O_2$ *is >5.5 times higher than the commercially available radiosensitizers. The modular structure of IDPAs allows to develop a smart molecular probe (MRAP) that only turns on its radio-afterglow-dynamic function in the presence of a cancer biomarker. Such a biomarker activation of MRAP enables ultrasensitive detection of diminutive tumor (0.64 mm) with superb contrast (tumor-to-background ratio=234) and tumor-specific radiotherapy for deep-seated brain tumor with molecular precision at low dosage. Thus, our work not only reveals the molecular guidelines towards organic radioafterglow agents but also highlights new opportunities for cancer radio-theranostics.*

5:00 PM NM07.07.07

Cryosoret Nano-Assemblies for Dequenched Steering Fluorescence Spectroscopy and Augmented Interferometric Scattering Microscopy at Photonic Crystal Interfaces *Seemesh Bhaskar, Leyang Liu, Weinan Liu, Joseph Tibbs and Brian T. Cunningham; University of Illinois at Urbana-Champaign, United States*

The ever-growing necessity of augmented sensitivity of various spectroscopy and microscopy-based point-of-care (POC) diagnostic technologies unambiguously dictate the need for improvement of the performance of the associated photonic platforms using effective nano-engineering. The engineered plasmonic nanoassemblies with novel electro-optical, chemical, mechanical, multiferroic properties, coupled with spectroscopic and microscopic tools, has emerged as ‘plasmon-enhanced spectroscopy’ and ‘plasmon-enhanced microscopy’ technologies. An appropriate consideration to drastically alter the response of the nano-moieties is explicitly dependent on the *nature of the local micro-nano-environment. In this work, while the underlying photonic crystal (PC) interface yields a desirable micro-nano-platform for electromagnetic field enhancement, the carefully engineered template-free, linker-less cryosoret nano-assemblies present robust performance towards enhanced spectroscopy (fluorescence) and microscopy (interferometric scattering).*[1]

Among several types of plasmonic nanoparticles (NPs) (Ag, Pt, Pd, Cu, Al, Au, Ni) that are being investigated, gold (AuNPs) stand out on account of unique optical, electronic and chemical properties, elevated charge densities (≈5.90 × 10^{16}), enabling biocompatible physicochemical functionalization in robust configurations for multi-disciplinary research.[2] *The large non-radiative channels fostered by higher ordered plasmonic modes in AuNPs result in the so-called 'zone of inactivity' in the spatial regime of <5 nm, where the quenching effects are dominant, and has remained a long-standing challenge in fluorescence based spectroscopic applications. Essentially, nanogap antennas vis-à-vis pristine NPs assist in the realization of nanogap-driven radiative decay channels which in turn boosts the quantum yield of the proximal luminophores, hence establishing the illustrious 'dequenching the quenched' phenomena.*[3]

In this report, we present the utility of Au cryosorets on the photonic crystal enhanced steering (PCES) emission platform to yield dequenched fluorescence spectrum. The Au cryosorets are fabricated by subjecting the pristine AuNPs solution to adiabatic cooling at -196 °C using liquid nitrogen (LN2), thawing, purification via centrifugation and washing.[1] *The AuNPs, Au cryosorets, and the PC are well-characterized using TEM, SEM and AFM measurements. While the rhodamine B radiating dipoles are interfaced with the guided mode resonance of the PC substrate in PCES emission platform, ~24-fold enhancement in the fluorescence is reported.*[4] *While incorporation of pristine AuNPs to the system quenches the signal to ~10-fold fluorescence, Au cryosorets present dequenched and augmented ~200-fold fluorescence, with all the fluorescence enhancements calculated as the direct ratio of fluorescence counts in the substrate of interest and that over the glass. While we used the PCES emission platform to evaluate the performance of crysoret nano-assemblies for spectroscopic applications, the Photonic Resonator Interferometric Scattering Microscopy (PRISM) platform that enables label-free visualization of nano-objects was utilized for microscopy. The Au cryosorets provide at most 6.77-fold higher signal contrast compared to AuNPs.*[5] *The hybrid coupling between the localized Mie and delocalized Bragg plasmons of cryosorets and the underlying PC's guided mode resonance provides insights for developing nano-assembly-based nano-tags for spectroscopy and microscopy-based biosensing applications.*

2D and 3D Complex Plasmonic Nanoframes and Their Applications *Sungjae Yoo and Sang Ihn Han; Korea Institute of Science and Technology, Korea (the Republic of)*

Arranging the plasmonic nanoframes into a single entity is of important issue due to great potential for improving physicochemical properties of nanostructures. Among various morphologies of nanostructures, nanoframes typically have a unique structural feature that can increase the accessibility of every surface in a given space, offering great potential for interactions with light and surface adsorbates. To date, enormous efforts have been devoted to improving the physicochemical properties of nanoframes by controlling the structural parameters such as shape, size, thickness, and composition. Nevertheless, all the nanoframes synthesized so-far are structurally simple and mainly composed of single-rim structures, limiting the utilization of inner voids, making it difficult to harness efficient light-matter interactions.

To overcome above limitations, we develop the 2D and 3D complex metal nanoframes wherein multiple nanoframes are precisely arranged in a single entity via rationally designed multi-step chemical reactions. In the multi-step synthetic pathway, 2D or 3D Au nanoparticles were used as starting materials and subsequently several chemical reactions such as selective deposition, selective etching, eccentric/concentric/well-faceted deposition were selectively applied. As a result, a library of 2D and 3D complex metal nanoframes having a high level of structural controllability (e.g., shape, size, intra-nanogap distance, the number of nanoframes in a single entity) can be obtained. The resulting complex nanoframes can be considered as a new paradigm in a nano-building block due to their significant improved structural coupling effects.

Furthermore, we coated plasmonic components (gold or silver) onto as-synthesized 2D and 3D complex metal nanoframes to demonstrate significantly amplifying localized surface plasmon resonance resulting from unique structural features of complex nanoframes. Using the single particle Reman spectroscopy, we investigated surface enhanced Raman scattering (SERS) enhancement as function of the number of internal nanoframes and intra-nanogap distance of complex nanoframes. It demonstrates that SERS enhancement can be exponentially increased from ~10^8 to ~10^{10} as increase the number of internal nanoframes or decrease intra-nanogap distance of complex nanoframes, which is result from strong surface plasmon coupling among internal nanoframes. It is noteworthy that the SERS enhancement of complex nanoframes is almost 100 times higher than that of conventional plasmonic nanostructures such as nanodumbell, nanostar, and so on.

Recently, we are using complex plasmonic nanoframes as a nano-building block and trying to assemble them in a controllable fashion using liker molecules. Furthermore, Not only we develop the unique nanostructures but we are developing an ultra-sensitive SERS and fluorescence-based biosensors for early diagnosis of skin and cancer diseases using complex plasmonic nanoframes as a optical signal amplifier. We think that library of complex nanoframe will be applied to wide array of applications such as catalysis, optical devices, and light energy conversion devices.

SESSION NM07.08: Applications of Particle Aggregation I
Session Chairs: Yuna Bae, Honghu Zhang and Xin Zhang

Hynes, Level 2, Room 201

8:00 AM *NM07.08.01
On the Emergence of Complex Phases in Nanoparticle Self-Assembly *Matthew R. Jones; Rice University, United States*

The formation of inorganic nanoparticle (NP)-based materials via directed- and self-assembly approaches has been heralded as a tunable, low-cost, scalable method to generate advanced metamaterials for energy and optics applications. A major challenge in this field has been the development of synthetic strategies that allow for the assembly of low-symmetry configurations of particles, as these have generally been the structures predicted to have the most appealing properties. For example, a longstanding goal for the assembly of dielectric particles has been the low-density diamond lattice, predicted to have the largest angle-independent photonic band gap. Additionally, the assembly of plasmonic particles into chiral superlattices is thought to be a superior route to the formation of metamaterials with negative refractive index. However, because the vast majority of colloidal particle *building blocks consist of highly-symmetric shapes (e.g. spheres), they tend to spontaneously assemble into highly-symmetric lattices, resulting in properties that are unsuitable for these advanced applications. In this talk, I will show that the spontaneous self-assembly of low symmetry nanoparticle building blocks results in the formation of complex superlattice phases, including those that are chiral, quasicrystalline, and mesoporous. I will discuss the proposed mechanisms by which these structures emerge during the assembly process, which involve multi-stage hierarchical and particle rotation-based phase transitions that are extremely sensitive to small degrees of particle tip truncation. Finally, I will present our efforts to scale up the assembly of these materials in order to measure and exploit their superior chiroptical properties.*

8:30 AM NM07.08.02

Enhanced Photocatalysis via Self-Assembled Architectures—Record Low-Temperature Methane Reforming over Ordered Mesoporous and Asymmetrically Porous Block Copolymer-Templated Semiconductors *William Moore[1], Shusaku Shoji[2] and Ulrich Wiesner[1]; [1]Cornell University, United States; [2]National Institute for Materials Science, Japan*

The recent discovery of low-temperature photocatalytic conversion of methane and carbon dioxide to syngas (photocatalytic dry reforming of methane; photo-DRM) transformed an expensive high-temperature process into an appealing low-temperature sustainable process for carbon conversion. This simple reaction, which can proceed under illumination without external heating, could provide an alternative to crude oil for supplying the organic precursors our modern world is built upon, without the coking and catalyst failure of high-temperature solutions. While much attention has been paid to alternative support chemistries or exotic metallic promoters, the 3-D architecture of the semiconductor support itself has been largely overlooked. Our work has developed chemically-simple highly accessible photocatalysts with novel mesoscale architectures, delivering record catalyst activities though self-assembly derived mesostructure.

By utilizing block-copolymer self-assembly templating of common semiconductor supports, we have studied TiO_2 *and* Ta_2O_5 *photocatalyst supports in a range of architectures: from hexagonally packed cylinders to 3-D co-continuous gyroids to asymmetrically porous thin films. This mesoporosity provides enhanced activity across a wide range of volumetric flow rates, delivering record low-temperature performance beyond the expectations of enhanced surface area alone. Beyond surface area, the 3-D accessibility of co-continuous architectures greatly reduces tortuosity, leading to fast facile transport of reactive species through the structure.*

Further, we developed a novel TiO_2 *thin film catalyst architecture derived from liquid filtration membranes that has a thin mesoporous top layer with macroporous support layer. This highly-active low-density membrane architecture delivers the highest reported activity per gram for low-temperature photo-DRM to-date solely through changes in support architecture, delivering 2500x the mass-normalized photo-DRM activity of non-structured* TiO_2 *powder. This combination self-assembly and non-solvent-induced phase separation (SNIPS) technique creates catalyst architectures highly suited to photocatalysis, concentrating highly active material in only the thin illuminated surface region, minimizing non-illuminated mass in the supporting substructure. These self-assembly-based polymer processes for creating 3-D semiconductor architectures are simple, low-cost, and scalable routes to create world-class photocatalyst supports, applicable to a wide-range of gas-phase catalytic reactions.*

8:45 AM NM07.08.03

Tuning Molecular Motion Enhances Intrinsic Fluorescence in Peptide Amphiphile Nanofibers *Natchayaporn Sindhurattavej and Whitney C. Fowler; Harvey Mudd College, United States*

Peptide amphiphiles (PAs) are highly tunable molecules that were recently found to exhibit aggregation-induced *emission (AIE) when they self-assemble into nanofibers. Here, we leverage decades of molecular design and self-assembly study of PAs to strategically tune their molecular motion within nanofibers to enhance AIE, making them a highly useful platform for applications such as sensing, bioimaging, or materials property characterization. Since AIE increases when aggregated molecules are rigidly and closely packed, we altered the four most closely packed amino acids nearest to the hydrophobic core by varying the order and composition of glycine, alanine, and valine pairs. Of the six PA designs studied,* $C_{16}VVAAK_2$ *had the highest quantum yield at 0.17, which is a more than 10-fold increase from other PA designs including the very similar* $C_{16}AAVVK_2$*, highlighting the importance of precise amino acid placement to anchor rigidity closest to the core. We also altered temperature to increase AIE.* $C_{16}VVAAK_2$ *exhibited an additional 4-fold increase in maximum fluorescence intensity when the temperature was raised from 5 to 65 °C. As the temperature increased, the secondary structure transitioned from β-sheet to random coil, indicating that further packing an already aligned molecular system makes it even more readily able to transfer energy between the electron-rich amides. This work both unveils a highly fluorescent AIE PA system design and sheds insights into the molecular orientation and packing design traits that can significantly enhance AIE in self-assembling systems.*

9:00 AM NM07.08.04

Modulation of Photophysical Properties to Enhance Quantum Yield in Fluorogenic Nanoprobes for Multiplexed Detection and Monitoring of Airborne Infectious *Sojeong Lee and Seungjoo Haam; Yonsei University, Korea (the Republic of)*

Airborne viruses, notably COVID-19 and influenza virus, continue to present significant public health challenges due to their prolonged airborne survivability and rapid transmission. Accurate and timely diagnosis of these viruses is essential to preemptive misdiagnosis, inappropriate treatment, and further community spread. While qPCR remains the gold standard for viral detection, its complexity limits large-scale field use, making fluorescent signal-based immunoassays a promising alternative for multiplexed virus diagnosis without nucleic acid extraction. Our study introduces a multiplexed immunoassay leveraging self-quenching nanoprobes integrated with a portable fluorescence reader for efficient field diagnostics against respiratory viruses. Especially multiplex virus predictive immunoassay (shortened MVP assay), comprising magnetic separation and an amplified fluorogenic probing system, achieves a 90% recovery rate of target viruses, high accuracy, and sensitivity with a detection limit of 10^1 $TCID_{50}/mL$ *in under 40 minutes. The stability of the fluorophore, coupled with the significant amplification achieved through the self-quenching effect within the nanoprobe, generates a signal independent of biofluid type, thereby enabling reliable analysis with* R^2 *values of 0.97 even with portable detectors. Furthermore, the test accurately detected the presence or absence of viruses in nasal and saliva samples, demonstrating performance comparable to PCR assays and surpassing commercially available rapid kits in diagnostic accuracy. This underscores the potential of the integrated diagnostic system for rapid and sensitive monitoring of large-scale field tests.*

9:15 AM NM07.08.05

Template-Free Self-Assembly of Multi-Component Magnetic Nanostructures with Tunable Composition, Size and Magnetic Properties *Pau Ternero[1], Mehran Sedrpooshan[1], Bernat Bozzo[2], Anna Palau[2], Rasmus Westerström[1] and Maria Messing[1]; [1]Lund University, Sweden; [2]Institut de Ciència de Materials de Barcelona, Spain*

The ability to tune nanostructures' composition will open up new approaches to produce hard-soft bimagnetic nanomaterials, which provide promising strategies for developing new sustainable permanent magnets for green technologies on a macroscopic scale[1]. Here we present a gas-phase template-free technique for generating multi-component magnetic nanostructures with tunable properties by directed self-assembly of nanoparticles (NPs). We demonstrate that, depending on the carrier gas used during synthesis, the structure and composition, i.e., metallic and oxide phases, of Co-Ni bimetallic NPs can be tuned along with their magnetic properties. The *resulting NPs are self-assembled into 1D nanochains (NCs), which are characterized using XRD, electron microscopy, SQUID magnetometry, and micromagnetic simulations.*

A custom-built spark discharge generator (SDG) is used to study the effect of the carrier gas on the structure and composition of Co-Ni NPs produced with Co-Ni alloyed electrodes (Co:Ni = 66.5:33.5 at.%). Three different carrier gases are used: 95% N_2 *+ 5%* H_2 *(*N_2/H_2*),* N_2*, and air. The structure and composition of the particles is analyzed with powder XRD and TEM. Different crystallinity is observed depending on the carrier gas used. The TEM data confirmed these results. Homogeneous single-phase CoNi (2.05 Å, corresponding to CoNi {111}) and CoO (2.45 Å, corresponding to CoO {111}) are detected for particles produced with* N_2/H_2 *and air, respectively. Two-phase particles, composed of CoNi and CoO, are found to be generated with* N_2*. The oxidative/reductive environment, i.e., the oxygen content, within the SDG explain the different particle compositions obtained*[2]*. Considering that Co and Ni are ferromagnetic and their oxides are antiferromagnetic, these NPs are expected to exhibit different magnetic properties. Metallic particles produced with* N_2/H_2 *show larger coercivity than mixed metallic/oxide particles generated with* N_2*, for which exchange-bias (EB) is observed. The EB phenomenon is extensively studied in this work. As expected, the sample generated with air do not display any magnetic response as the particles were fully oxidized.*

The NPs are then self-assembled by means of an external magnetic field during deposition, which attracts them to the already deposited NPs via dipole-dipole interactions, forming NCs along the external magnetic field direction[3]*. Two particle sizes are employed for this study, 25 and 50 nm, by simple size-selection in the gas-phase using differential mobility analyzers before deposition. When* N_2/H_2 *is used, the NCs present a strong magnetization direction along the chain in agreement with the SQUID measurements. Interestingly, NCs formed by 25 nm particles show a two-fold increase in the remanence magnetization and coercivity compared to NCs formed by 50 nm particles. When* N_2 *is employed, the remanent magnetization and coercivity are decrease, but in turn there is an enormous increase in the EB, especially for NCs formed by 25 nm particles. Additionally, we show that the EB can be increased even further by increasing the length of the NCs, i.e., depositing NPs for longer times, making this system appealing for magnetoresistive read heads and sensors. These results present a promising method for tuning magnetic NPs by simply changing the carrier gas to generate nanostructured materials with designed sizes, compositions, and morphologies tailored for specific applications.*

Gas Phase Synthesis of Pd and Pd-C Nanoparticles—Effect of Spark Frequency, Carrier Gas Flow Rate and Sintering Temperature *Vinod Singh; Delhi Technological University, India*

In the present work, effect of the growth parameters such as, spark frequency, carrier gas flow rate, and sintering temperature on the gas phase synthesis of Pd nanoparticles and Pd-C core-shell nanoparticles have been investigated. Online size and size distribution is measured by the scanning mobility particle sizer. With increase in the spark frequency, particle size distribution is observed to shift towards larger values of the particle size and the particle concentration increases for both Pd and Pd-C nanoparticles. The particle size distribution is observed to shift towards smaller values of the particle size and particle concentration increases, on increasing the carrier gas flow rate. Further, with increasing temperature, size distribution shifts towards smaller values of particle size. Taking into consideration of effect of various deposition parameters on the average size and size distribution of the Pd and Pd-C nanoparticles, three different mobility equivalent diameters of 20, 40 and 60 nm were selected from *the particle size distributions. The study is important to synthesize the size selected Pd and Pd-C core-shell nanoparticles for various size dependent applications.*

9:45 AM NM07.08.07

Thermally Conductive Polyelectrolyte Nanocomposite for Electrical Insulation *Ethan T. Iverson, Hudson Legendre, Sourav Chakravarty, Anil Aryal, Shiyu Zhang, Sarah G. Fisher, Danixa Rodriguez-Melendez, Dallin L. Smith, Kendra Schmieg, Patrick Shamberger, Dion Antao and Jaime C. Grunlan; Texas A&M University, United States*

As electric vehicles continuously advance, higher demands are put on the thermal transport and dielectric properties of dielectric materials to increase electric motor efficiency and power density. Furthermore, due to the increasingly complex winding architectures found in electric motors, traditional insulating procedures struggle to deposit conformal insulation layers. In this work, the layer-by-layer (LbL) assembly of polyethylenimine, mica clay, poly(acrylic acid), and hexagonal boron nitride is exploited to provide a thermally conductive (through-plane thermal conductivity ≈ 1.8 $W\times m^{-1}\times K^{-1}$) yet electrically insulating (breakdown strength ≈ 155 $kV\times mm^{-1}$) dielectric material. A remarkably high through-plane thermal conductivity (i.e., perpendicular to the substrate) is obtained due to mica and hexagonal boron nitride platelets stretching through multiple layers, a result of “jagged” deposition. The nanocomposite’s heat removal efficiency is demonstrated on a mock electric aircraft motor showing reduced max temperatures across the winding-heat sink interface at high power densities when compared to the state-of-the-art polyimide insulation. This is one of the first reports of a thermally conductive yet electrically insulating polyelectrolyte-based self assembled nanocomposite.

Discovery of Isomerization Intermediates in CdS Magic-Size Clusters *Reilly Lynch and Richard Robinson; Cornell University, United States*

Organized assemblies of nanoparticles could benefit from dynamic tunable properties, such as controlled, reversible shifts in the electronic structure. Cadmium chalcogenide magic-size clusters (MSCs) have recently been found to exhibit the remarkable ability to undergo chemically-induced, reversible isomeric transformations between discrete states, with an 140 meV change in bandgap. This diffusionless reconfiguration of the inorganic core follows first order kinetics driven by distortions in ligand binding motifs. The isomerization of these ~1.5 nm CdS clusters bridges small molecule isomerization and large-scale solid-solid transformation, representing a paradigm shift in our understanding of inorganic materials. Our previous study demonstrated that methanol modifies the atomic and electronic structure of the native α-phase (324 nm) MSC to the β-phase (313 nm). Recently we have identified new intermediate states with smaller bandgaps, and larger overall shifts. We report the discovery of new intermediate phases in the isomerization process and a new functional group that facilitates the transformation. Amide organic functional groups not only facilitate the α-phase to β-phase isomerization, but also to evolve three other unique excitonic features. Pair distribution function (PDF) analysis, correlates these features into three intermediate MSC isomers: the β_o-phase, β_1-phase, and β_2-phase. All three of these phases resemble the final β-phase, but have variations in the fit parameters. The β_2-phase shows a nearly exact atomic correspondence with the β-phase despite a significant band gap difference (up to 583 meV). The β_o-phase and β_1-phase are red-shifted from the initial phase, but these bandgaps then then blue shift to reach the final β-phase. FTIR studies combined with density functional theory calculations reveal that the multifunctional nature of amides forms an amphoteric surface binding motif. This motif promotes a change from chelating to bridging binding modes. Kinetic studies indicate a thermodynamic stability trend of α-phase < β_o-phase < β-phases. This finding is *surprising as the α-phase, although natively synthesized, is the least thermodynamically stable. These isomerization reactions provide an ideal testbed for investigating fundamental concepts in tunability for nanomaterial assemblies.*

10:45 AM NM07.08.09

Altering Wettability of Carbonate Rock by In Situ Coating of Functional Nanoparticles at Harsh Reservoir Conditions for Reducing Condensation *Wei Wang and Sehoon Chang; Aramco Americas, United States*

Extraction of hydrocarbons, such as natural gas, may be impeded by a variety of reasons, such as condensate formation in the subsurface formation. Pressure gradients near the well bore of producers often lead to the formation of condensate banks, which subsequently hinder gas production by reducing gas permeability in gas-condensate wells. Research suggests that wettability is a crucial factor in condensate accumulation. Altering the wettability of the rock from liquid-wetting to intermediate gas-wetting can greatly enhance mobility of the liquid phase in a gas–liquid system, thereby significantly improving gas well deliverability in a gas condensate reservoir. In this research, we report a novel wettability alteration method for reducing condensate utilizing functionalized silica nanoparticles in situ formed and assembled to the surface of subsurface formation in extreme reservoir condition at high temperature and high salinity. The process includes introducing a reactive mixture including an aqueous solution, urea, dopamine, a silica nanoparticle precursor, a silane grafting compound, and an alcohol compound into the subsurface formation. Ammonia is generated in situ through thermal decomposition of the urea, which catalyzes the silica nanoparticle precursor to hydrolyze for forming silica nanoparticles. Polymerization of the dopamine at reservoir temperature could enhance the adhesion of nanoparticles on carbonate rock, and meanwhile silane coupling molecules are grafted onto the silica nanoparticles, thereby forming functionalized silica nanoparticles. The functionalized silica nanoparticles are hydrophobic, oleophobic, or both, and the assembled and aggregated nanoparticles on rock can decrease the surface tension of the subsurface formation, resulting increase of relative permeability and decrease of condensate banking at the wellbore.

11:00 AM NM07.08.10

Cyclic Peptide/Polymer Conjugates Nanotubes as Artificial Light-Harvesting Systems and Ultrabright Fluorescent Nanoparticles *Sebastien Perrier; University of Warwick, United Kingdom*

Supramolecular polymeric nanotubes self-assembled from cyclic peptide–polymer conjugates are employed as general scaffolds to fabricate supramolecular artificial light-harvesting systems and ultrabright fluorescent nanoparticles in water.

By aligning hydrophobic chromophores along nanotubes in a slipped manner, we fabricated an artificial light-harvesting system with a two-step Förster resonance energy transfer process, achieving up to 95% energy transfer efficiency and a 30% fluorescence quantum yield, along with high stability. The emission spectrum can be tuned from blue to orange or outputted as white light with a 29.9% quantum yield. These findings offer a versatile method for designing efficient artificial light-harvesting systems and highly emissive organic materials in aqueous media, demonstrating significant potential for various applications.
In addition, using the cylindrical nanoparticles obtained from a cyclic peptide-diblock copolymer conjugate, we develop ultra-bright fluorescent nanoparticles. Applicable to various fluorophore families, including polyaromatic hydrocarbons and cyanines, these systems achieve high fluorescence quantum yield (>30%) and brightness (up to 12,060 m−1 cm−1 nm−3), with some demonstrating a 20-fold increase in NIR emission brightness and photostability. This method effectively transforms existing fluorophores into ultrabright NPs for bioimaging applications.

These sysetms can be used as therapeutic drug delivery vectors imaging their targets (theranostics) or for cell imaging applications. The lecture will present examples of our latest findings in the synthesis, characterisation and also bio-applications of these unique systems.

11:15 AM NM07.08.11

Guanine Biocrystals Form via Templated Nucleation of Crystal Leaflets on Preassembled Scaffolds *Dvir Gur; Weizmann Institute of Science, Israel*

Controlling the morphology of crystalline materials is challenging, as crystals have a strong tendency toward thermodynamically stable structures. Yet, organisms form crystals with distinct morphologies, such as the plate-like guanine crystals produced by many terrestrial and aquatic species for light manipulation. Regulation of crystal morphogenesis was hypothesized to entail physical growth restriction by the surrounding membrane, combined with fine-tuned interactions between organic molecules and the growing crystal. Using cryo-electron tomography of developing zebrafish larvae, we found that guanine crystals form via templated nucleation of thin leaflets on preassembled scaffolds made of 20-nm-thick amyloid fibers. These leaflets then merge and coalesce into a single plate-like crystal. Our findings shed light on the biological regulation of crystal morphogenesis, which determines their optical properties.

11:30 AM NM07.08.12

Tuning Optical, Electrical and Solid-State Structures of Oligothiophenes by Introduction of Di- and Tricyanovinyl Groups *Mamoun M. Bader[1] and Phuong-Truc T. Pham[2]; [1]Alfaisal University, Saudi Arabia; [2]The Pennsylvania State University Scranton, United States*

The presence of dicyanovinyl (DCV) and tricyanovinyl (TCV) groups in oligothiophene molecules imparts several interesting characteristics. They allow oligothiophenes to act as an acceptor in donor-acceptor systems, which is particularly useful in the design of organic electronic materials. They also result in shifting the absorption properties of the molecule, often leading to a bathochromic or red shift in the absorbance, which allows the compound to absorb and emit light at longer wavelengths. These groups also affect the redox characteristics of the molecule, which can be observed through cyclic voltammetry. The shape and polarity of the di- and tricyanovinyl groups can influence the solid-state packing of these molecules, affecting their charge transport properties which are crucial for applications in organic semiconductors. These groups are readily introduced and in the case of EDOT render the molecules more stable and less susceptible to oxidation and polymerization. We summarize our work on 16 thiophene derivatives endowed with one or two DCV and/or TCV groups. We highlight and summarize the impact of these groups on the above-mentioned characteristics. The molecules include: 2T-TCV; 2T-DCV; Br-2T-TCV; FUSED 2T-DCV; DCV-T-DCV; DCV-2T-DCV; DCV-3T-DCV; 3T-TCV; EDOT-TCV; Br-EDOT-TCV; T-CH=CH-T-TCV; Bu2T-CH=CH=T(Bu2)-TCV; TOLYL-3T-TCV; NC-Ph-T-Ph-CN; O2N-2T-NO2. Our results suggest that these groups profoundly impact the electrical, optical and packing and both the molecular geometries and solid-state structures of oligothiophenes. Specifically, they induce planarity, bathochromic shifts, pi stack formation and ease of both oxidation and reduction. All these are thought of as favorable properties for optical, electrical and optoelectronic properties of oligothiophenes. We assume that similar properties can impact other conjugated organic materials. We briefly describe our success with triphenylamines and fused TCNQ-like molecules.

11:45 AM NM07.08.13

Reverse Microemulsion Synthesis as a Method for Production of Catalytic Nanomaterials for CO_2 Conversion to Renewable Fuels and Chemicals *Yue Yu, Zixuan Lin, Yasaman Ghaffarisaeidabad and David Simakov; University of Waterloo, Canada*

In a reverse microemulsion (RME) system, water nano-droplets are surrounded by surfactant molecules and dispersed in a continuous oil phase. Reverse microemulsions are clear, thermodynamically stable isotropic liquid mixtures that form by self-assembly upon mixing their components in appropriate ratios. Water nanodroplets can contain reactants. If two (or more) reverse microemulsions containing different reactants are mixed, the reaction happens when aqueous nanodroplets collide and merge, resulting in a slow, gradual process of self-assembly of nanoparticles. The resulting nanoparticles are extracted by changing the RME composition in such a way that it is not thermodynamically stable anymore. Upon segregation of aqueous and organic phases, nanoparticles undergo aggregation within the aqueous phase, followed by sedimentation allowing for their easy separation. RME method can be used to generate nanomaterials with high specific surface area, since aqueous nano-droplets act as nano-reactors, restraining amounts of reactants and therefore limiting the resulting nanoparticle size.

We present implementation of the RME method for generation of catalytic nanomaterials for converting CO_2 *to renewable fuels and chemicals. Catalytic conversion of* CO_2 *to value-added products is one of the promising ways to reduce our dependence on fossil fuels, while also creating economic benefits. More specifically, thermocatalytic hydrogenation of* CO_2 *using renewable* H_2 *can produce a variety of renewable fuels, including renewable natural gas and aviation fuels, and chemicals such as renewable methanol.*

Various catalytic nanomaterials were synthized via the RME method using aluminum oxide (Al_2O_3*) and cerium oxide (*CeO_2*) as structural support materials and several transition metals (Cu, Fe, Co, Ni and Mo) as highly dispersed active phases in the form of either metal oxide or metal carbide. All nanomaterials generated had high specific surface areas ranging from 200-400* m^2/g *and were composed of nanoparticles typically sized less than 20 nm. The resulting catalytic materials were characterized by a number of analytical techniques (ICP-OES, XPS, XRD, BET, TEM) to investigate their chemical composition, crystallinity, and morphology. Temperature programmed reduction (TPR) and temperature programmed desorption (TPD) were employed to investigate reducibility and adsorption properties of catalytic surfaces, and in situ Fourier transform infrared spectroscopy (FTIR) was used to investigate surface reactivity. In addition, density functional theory (DFT) computations were conducted to investigate the effect of incorporation of foreign transition metals into* CeO_2 *lattice on* CO_2 *adsorption and cleavage properties.*

To assess the implementability of synthesized materials, reaction tests were conducted in a continous flow reactor, using a CO_2/H_2 *mixture as a feed and a wide range of operating conditions such as temperature, pressure and flow rate. The outlet from the reactor was analyzed vi infrared (IR) and Fourier transform infrared (FTIR) spectroscopy, gas chromatography (GC), and mass spectrometry (MS). Synthesized catalytic nanomaterials exhibited different levels of catalytic activity and selectivity to various products, ranging from CO and* CH_4 *to light hydrocarbons. For certain materials,* CO_2 *conversions approaching the chemical equilibrium levels were achieved (95%* CO_2 *conversion and 100% selectivity to desired product generation in some cases), and materials stability was also investigated comprehensively (more than 100 h). The results of catalytic perfomance evaluation were correlated with the results of materials characterization, while focusing on the structure-property relationship. Our work provides an avenue for developing highly efficient methods for* CO_2 *conversion to renewable fuels, while also providing fundamental insights into the relationship between the material synthesis method and its reactive properties.*

SESSION NM07.09: Applications of Particle Aggregation II

Synthesis of Highly Concentrated, Monodispersed Au Nanoparticles for Precise Structural Control in the Self Assembly of Polymer-Grafted Nanoparticle Thin Films *Kyoungweon Park[1,2], Jonathan Karhoff[1,2], Derek E. Huang[1,2], Andrew Gillman[1], Richard A. Vaia[1] and Lawrence Drummy[1]; [1]Air Force Research Laboratory, United States; [2]Bluehalo, United States*

Polymer grafted nanoparticles (PGNs) represent a novel class of materials which are processible using polymer additive manufacturing techniques, and have the additional

functionality of a wide variety of nanoparticle core types with a variety of properties including plasmonic, semiconducting, or magnetic properties. PGNs have a level of structural control that is beyond traditional composite materials, and can be defined by the particle-level and grafted molecular architecture (varying NP core size/shape, polymer grafting density and molecular weight). Gold nanoparticles (AuNPs) are desirable as NP cores due to their tunable size, versatile surface chemistry and added functionality from their strong interaction with optical fields. Despite significant advancements in the synthesis of AuNPs with a precise control over both size and shape, high yield production of AuNPs with a diameter > 10 nm is still challenging. Herein, we demonstrated synthesis of highly concentrated (> 5mg/mL) and monodispersed (RSD < 5%) AuNPs with tunable sizes and shapes ranging from 10 to 50 nm via optimization of reaction parameters based on the seed mediated protocol and strategic regrowth. Macroscale hyperuniform packing was achieved through a meticulously controlled mixture of PGNs with varying core sizes, and the hyperuniformity was assessed and compared with theoretical calculations.

1:45 PM NM07.09.02

Surface-Segregating Zwitterionic Copolymers to Control Poly(dimethylsiloxane) Surface Chemistry *Aslihan Gokaltun[1,2], Luca Mazzaferro[3], Martin Yarmush[1], Ayse Asatekin[4] and O. Berk Usta[1]; [1]Harvard Medical School, United States; [2]Hacettepe University, Turkey; [3]Massachusetts Institute of Technology, United States; [4]Tufts University, United States*

The use of microfluidic devices in biomedicine is growing rapidly in applications such as organs-on-chip and separations. Polydimethylsiloxane (PDMS) is the most popular material for microfluidics due to its ability to replicate features down to the nanoscale, flexibility, gas permeability, and low cost. However, the inherent hydrophobicity of PDMS leads to the adsorption of macromolecules and small molecules on device surfaces. This curtails its use in "organs-on-chip" and other applications. Current technologies to improve PDMS surface hydrophilicity and fouling resistance involve added processing steps or do not create surfaces that remain hydrophilic for long periods. This work describes a novel, simple, fast, and scalable method for improving surface hydrophilicity and preventing the nonspecific adsorption of proteins and small molecules on PDMS through the use of a surface-segregating zwitterionic copolymer as an additive that is blended in during manufacture. These highly branched copolymers spontaneously segregate to surfaces and rearrange in contact with aqueous solutions to resist nonspecific adsorption. We report that mixing a minute amount (0.025 wt%) of the zwitterionic copolymer in PDMS considerably reduces hydrophobicity and nonspecific adsorption of proteins (albumin and lysozyme) and small molecules (vitamin B12 and reactive red). PDMS blended with these zwitterionic copolymers retains its mechanical and physical properties for at least six months. Moreover, this approach is fully compatible with existing PDMS device manufacture protocols without additional processing steps and thus provides a low-cost and user-friendly approach to fabricating reliable biomicrofluidics.

2:00 PM NM07.09.03

Construction and Characterization of Self-Assembled Cyclodextrin Carboxylate/Chitosan Nanocarriers for Controlled Delivery of Phytochemicals *Yao Hu; China Agricultural University, China*

Hydrophobic phytochemicals are poorly dispersed in aqueous matrices and have low stability during storage, processing, and digestion, which significantly limits their bioaccessibility. This study introduces an efficient carrier: self-assembled cyclodextrin carboxylate/chitosan nanoparticles, designed for encapsulating and controlling the release of phytochemicals. The development of these novel carriers addresses the increasing demand for natural compounds in health industries and provides innovative solutions for designing new food materials.

Cyclodextrins (CDs) are ideal carriers for enhancing the aqueous dispersibility of hydrophobic molecules due to their amphiphilic molecular structure. This study introduces a highly effective esterification method to further enhance the performance of CDs through a simple dry-heating process, enabling the grafting of succinic acid (SA) onto CDs. The resulting SA-grafted CDs (SACD) exhibited superior encapsulation properties compared to unmodified CDs (up to 1.41-fold higher). Furthermore, SACD demonstrated significantly enhanced water solubility (over 400%) in comparison to β-CD (approximately 1.85%), indicating its potential for high-dose applications in aqueous formulations. Importantly, SACD showed non-cytotoxicity in intestinal cell models, underscoring its safety for biomedical applications. To our knowledge, there are few reports on dicarboxylic acid-modified CDs with such superior encapsulation performance for phytochemicals.

Using curcumin as a model hydrophobic phytochemical, SACD successfully encapsulated up to 10 mg/g of curcumin, achieving complete solubilization of curcumin in aqueous systems. The study aimed to achieve controlled release of curcumin by immobilizing SACD within a natural polymer network. An electrostatic self-assembly approach was employed to crosslink SACD with chitosan (CS) molecules, leading to the spontaneous formation of spherical SACD/CS nanoparticles with an average size of approximately 500 nm. These nanoparticles exhibited a unique internal molecular arrangement, where SACD served as crosslinking nodes that brought CS molecular chains together during the self-assembly process. Evaluation of the encapsulation properties demonstrated that SACD/CS nanoparticles could load 0.36 mg/g of curcumin. Furthermore, curcumin loaded in these nanoparticles exhibited enhanced stability under physiological conditions and achieved successful controlled release during in vitro digestion.

In summary, the SACD/CS nanoparticles developed in this study represent superior carriers for the controlled release and delivery of hydrophobic phytochemicals such as curcumin. These findings suggest promising applications in the fields of food, medicine, and other health-related fields.

2:15 PM NM07.09.04

Chlorophyll-Rich Carbon Quantum Dots for Detection of Toxic Heavy Metal Ions— Hg(II) and As(III) in Water and Mouse Fibroblast Cell Line NIH-3T3 *Ravi Pratap[1], Nurul Hassan[1], Monica Yadav[2], Saurabh K. Srivastava[3], Shilpi Chaudhary[4], Anita K. Verma[2], Jayeeta Lahiri[1] and Avanish S. Parmar[3]; [1]Banaras Hindu University, India; [2]University of Delhi, India; [3]Indian Institute of Technology (BHU), India; [4]Punjab Engineering College (Deemed to be University), India*

The presence of mercury (Hg(II)) and arsenic (As(III)) in drinking water poses a substantial threat to public health. Mercury exposure can lead to neurological and developmental impairments, while arsenic is a known carcinogen, linked to skin, lung, and bladder cancers among other health issues. Given these significant risks, it is imperative to develop highly efficient, sensitive, and reliable methods for the detection and quantification of these heavy metals in drinking water. In this study, a novel fluorometric sensor based on chlorophyll-rich carbon quantum dots (CQDs) for the detection of Hg(II) and As(III) ions were developed. The dual emitting (blue-green and red) CQDs were synthesized by a one-step solvothermal method using plumeria plant leaves as precursors. When Hg(II) ions were added to CQD solution, the red emission (676 nm) of the CQDs was quenched (OFF), while in the case of of As(III) ions, the blue-green emission (485 nm) was enhanced (ON). The detection limits of 0.99 nM for Hg(II) and

12.15 nM for As(III) were validated for the proposed sensor. The biocompatibility, cytotoxicity, and bioimaging of the CQDs were investigated in the mouse fibroblast cell line NIH-3T3. The cellular uptake was also studied under the influence of Hg(II) and As(III) ions. Moreover, the novel chlorophyll-rich CQD-based fluorometric "ON–OFF" dual probe sensor was successfully applied to detect Hg(II) and As(III) in real water system as well as in the mouse fibroblast cell line.

2:30 PM NM07.09.05

Influence of Temperature and Ion Radiation on Dealloying of Fe-Ni Alloy in Liquid Lead *Wande Cairang[1], Weiyue Zhou[1], Xing Gong[2], Kevin B. Woller[1] and Michael P. Short[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Shenzhen University, China*

Dealloying is a vital technique for fabricating nano- and micro-scale porous materials used in various functional and structural applications, such as catalysts, fuel cells, electrolytic capacitors, and radiation-damage-resistant materials. In the past, dealloying mostly focused on electrochemical processes that employ alloys consisting of active and noble metals together. These processes cause the leaching of the active element, resulting in porosity in the bulk material. However, electrochemical technique limits the dealloying alloy systems to those with a sufficiently large reduction potential difference between the noble and active elements to enable porous structure formation. In contrast, recently, it is found that liquid metal dealloying can overcome this limitation by using a relatively low melting temperature liquid metal as a corrosive medium to selectively dissolve other elements from different alloy systems, thereby expanding the available options.

Liquid metal dealloying is still in the early stages of research, with most work concentrating on understanding the formation processes of different topological and morphological patterns during dealloying. It has been revealed that the diffusion of elements at the liquid metal and bulk interface is the main contributor to the formation of various patterns during dealloying. Researchers have managed to influence the kinetics by varying the concentration of the dissolving element in both bulk and liquid metals. Therefore, we believe that by controlling elemental diffusion at the interface, we can control the topological pattern, which in turn controls the porosity in the bulk material.

We have developed two methods to control elemental diffusion between the liquid metal and bulk: temperature and ion radiation. In this study, we first demonstrate how temperature affects topology formation by exposing an Fe-Ni model alloy with 36 wt.% Ni to different temperatures (500°C, 600°C, and 675°C) in high-purity liquid lead. Additionally, we examine the effects of simultaneous 3 MeV proton radiation and liquid lead dealloying on the Fe-Ni alloy at these same temperatures. By characterizing the samples using SEM, EBSD, and TEM, we show that the topology changes from sponge-like to motif-like to raindrop-like features with increasing temperatures. Interestingly, we found that radiation can shift the topology from sponge-like to motif-like features. We also quantified the porosity by calculating the ratio of lead-penetrated area to fixed-sized original substrate area at different temperatures. This study aims to elucidate how radiation and temperature might be effective ways to manipulate the topological patterns formed during liquid metal dealloying.

2:45 PM NM07.09.06

Controlled pH Alteration Enables Guanine Accumulation and Drives Crystallization Within Lysosome-Related Organelles *Zohar Eyal[1], Anna Gorelick-Ashkenazi[1], Rachael Deis[1], Yuval Barzilay[1], Yonatan Broder[1], Neta Varsano[1], Andrea Sorrentino[2], Michal Hartstein[1], Asher Kellum[1], Katya Rechav[1], Ifat Kaplan-Ashiri[1], Rebecca Metzler[3], Lothar Houben[1], Leeor Kronik[1], Peter Rez[4] and Dvir Gur[1]; [1]Weizmann Institute of Science, Israel; [2]ALBA Synchrotron, Spain; [3]Colgate University, United States; [4]Arizona State University, United States*

Many animals exhibit remarkable colors produced by the constructive interference of light reflected from arrays of intracellular guanine crystals. These systems are utilized for various purposes, including vision, camouflage, communication, and thermal regulation. Each guanine crystal forms within a membrane-bound organelle called an iridosome, where precise control over crystal formation occurs. While the presence of guanine crystals in iridosomes is well-documented, the mechanisms facilitating the accumulation of water-insoluble guanine and driving its crystallization remain unclear. Here, we employ advanced imaging and spectroscopy techniques to characterize the maturation of iridosomes in zebrafish iridophores during development. Using cryo-electron microscopy, we found that amorphous guanine accumulates in early-stage iridosomes. Synchrotron-based soft X-ray microscopy studies revealed that, unlike mature crystals, the accumulated guanine is initially in its protonated state. Live imaging with a pH sensor demonstrated that early-stage iridosomes are acidic and that their pH gradually approaches neutrality during maturation. Additionally, the application of a V-ATPase inhibitor reduced the acidity of iridosomes and significantly decreased crystal formation, suggesting the involvement of V-ATPase in regulating the organelle pH. Our findings reveal new insights into the molecular mechanisms facilitating guanine accumulation and crystallization within iridosomes, emphasizing the pivotal role of pH gradients in the precise formation of biogenic crystals.

Ionic Liquid-Cured Epoxy with Nanostructures of Self-Assembled Block Copolymer—Impact of Different Ionic Liquids on the Material Properties *Yu-Min Wang and Daniel Krogstad; University of Illinois, United States*

Block copolymers (BCPs) self-assembly have garnered significant interest for several decades due to their ability to produce ordered structures with a variety of morphologies, such as spheres, cylinders, lamellas, vesicles, and other complex or hierarchical assemblies. Integrating the nanostructures of self-assembled BCPs into epoxy resin enables tuning many critical material properties, such as the rheological behavior, mechanical strength, and toughness. However, there are a limited number of affordable block copolymers that can self-assemble in traditional amine-cured epoxy resins. Ionic liquid (IL) can not only initiate the polymerization of epoxy via ring opening polymerization but also induce the self-assembly of a wide range of BCPs, including the commercially available Pluronic poly(ethylene oxide-b-propylene oxide-b-ethylene oxide) BCPs. The influence of ILs on the thermomechanical properties of the cured epoxy and the self-assembly of BCPs have been independently reported. However, there has been limited work on the co-design of the materials systems to direct the self-assembled structures, curing reactions, and final thermomechanical properties. We are interested in extending this research on understanding the critical influence of the ILs as both a curing agent and a structure-directing agent.

In this work, we utilized 1-ethyl-3-methylimidazolium dicyanamide (EMI-DCA), 1-ethyl-3-methylimidazolium acetate (EMI-Ac), trihexyltetradecylphosphonium dicyanamide (THTDP-DCA), and trihexyltetradecylphosphonium bis(2,4,4-trimethylpentyl)phosphinate (THTDP-BTP) to observe their impact on the self-assembled nanostructures of the Pluronic BCPs (P-123) and the curing efficiency of bisphenol A diglycidyl ether (BADGE). To thoroughly investigate the effects, we prepared several fixed compositions of BADGE, P123, and nanoclay but with different ILs. Small-angle X-ray scattering (SAXS) analysis was employed to characterize and compare the nanostructures induced by different ILs before curing. We also investigated the effects of the ILs on the curing process through the use of thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). We also observed strong structure-property relationships that showed that the BCP nanostructures influenced both the storage modulus and the flow point during rheological testing as well as the mechanical properties during dynamic mechanical analysis and tensile testing. These results improve our understanding of the role of the IL chemistry as a curing agent and a structure directing agent and how those roles influence the rheological and mechanical properties of *the materials. These understandings will help us design future systems more efficiently.*

Protein Secondary Structure Changes on Silica Nanoparticles with Different Sizes and Surfaces

Naoya Sakaguchi[1], Atsuto Onoda[2] and Masakazu Umezawa[1]; [1]Tokyo University of Science, Japan; [2]Sanyo-Onoda City University, Japan

Nanoparticles (NPs) are expected to have medical applications, yet their toxicity remains a concern [1, 2]. In particular, it is known that proteins aggregate on the NP surface to form a protein corona. Previous, we reported that CeF_3 NPs, which have potential applications in bioimaging, may enhance the formation of the β-sheets structure of amyloid β peptides and increase the risk of developing Alzheimer's disease [1]. Also, it is said that exposure of pregnant mice to low doses of carbon black NPs induces endoplasmic reticulum stress in the perivascular cells associated with accumulation of misfolded proteins in the developing offspring brain [2]. Understanding NPs-protein interactions is crucial for mitigating toxicity concerns and advancing the safe use of NPs in the biomedical field. Important factors governing NPs-protein interactions include the size (curvature) [3], surface charge, surface state of NPs, and coexisting ions in solvents [1]. In our study, we focused on NPs size and surface charge.

Among inorganic NPs that are expected to be used in biological applications, silica NPs (SiNPs) are one of the most used substrates. SiNPs are composed of silicon dioxide (SiO_2) and are expected to be used in biomedical applications such as bioimaging and drug delivery systems due to their biocompatibility and non-toxicity [4].

First, we used silica nanoparticles (SiNPs) of 10 nm, 100 nm, 1 μm, and 10 μm in diameter to evaluate the effect of NPs size. To analyze the secondary structure of bovine serum albumin (BSA) reacted with SiNPs, we employed thioflavin T (ThT) fluorescence and Fourier transform infrared spectroscopy (FT-IR) measurements. Also, we varied the stirring time to 1, 24, and 48 h, and focused on changes in protein secondary structure with reaction time. ThT measurements showed that, the β-sheet ratio of BSA was highest when incubated with SiNPs of 10 nm in diameter for 1 h. This result can be attributed to the characteristics of small SiNPs such as high curvature and large surface area per mass, facilitating more extensive interaction with BSA. Conversely, incubation with larger SiNPs (10 μm in diameter) for an extended period (>24 h) led to an increase in the β-sheet ratio of BSA. This result arises from the reduced total surface area of larger SiNPs, concentrating BSA near their surfaces. The reduced particle mobility associated with varying SiNP diameters also contribute to the prolonged reaction time observed in BSA with larger SiNPs. Interestingly, the dependence of the change in ThT fluorescence intensity on NP diameter did not show a linear pattern. This is potentially caused by a complex interplay of factors, including changes in the curvature and the total surface area of SiNPs. Notably, ultrasmall SiNPs exhibited the potential to induce abnormal protein conformation.

Second, we investigated the effect of SiNPs surface charge. We prepared SiNPs with surface modification $-NH_2$ and -COOH. ThT fluorescence measurements show that no significant difference is observed when SiNPs are modified with -COOH, but modification with $-NH_2$ increases the number of β-sheets of BSA adsorbed on their surfaces. This means that the positive charges on the SiNPs surface caused electrostatic interactions with the amino acid residues of BSA, changing the secondary structure.

When SiNPs are administered in vivo for medical purposes, they may have crucial toxicity. Especially when they are extremely small or have a positive charge on the surface, as they may cause changes in the secondary structure of proteins. By clarifying the mechanism of action between SiNPs and proteins, it may be possible to create biomaterials that are less susceptible to protein adsorption and have lower biotoxicity.

Flame-Made Fractal-Like Inorganic Nanoaggregates as Drug Carriers

Georgios Sotiriou; Karolinska Institutet, Sweden

Biologics (proteins, peptides, nucleotides) dominate the novel therapeutics market. A major obstacle in their employment, however, is their enzymatic degradation and poor stability in vivo demanding high doses that result in side-effects. One way to avoid degradation of biologics is to encapsulate them in nanocarriers, such as lipid-based nanoparticles. An alternative approach is to use biocompatible inorganic nanoparticles, such as calcium phosphate (CaP). CaP nanoparticles have been explored as drug nanocarriers for biologics and as adjuvants in nanovaccines. In this study, we aim to improve the drug loading capacities of biologics by utilizing inorganic CaP nanoaggregates made by flame aerosol technology, with fractal-like morphology and high specific surface area [1-3].

To produce the nanocarriers, we employ flame spray pyrolysis, a technique which allows tuning of NPs properties like composition, size, crystallinity. Most importantly, the as-produced nanoparticles self-assemble into larger sub-micron aggregates with a characteristic fractal-like morphology. These parameters are critical as they determine the mode of cellular uptake. We optimize the loading of CaP nanoaggreates with biologics and other organic molecules. The performance of the developed particles is benchmarked with the state-of-the-art assays.

We have synthesized amorphous CaP and SiO_2 nanpoaggregates with varying silica content totune hydrodynamic size, biologic loading capacity, and cell cytotoxicity. We obtain a high specific surface area of greater 200 m^2/g for all these NPs. Upon loading model biological drugs and polyphenols, we achieved high loading capacity values when compared to the literature. None of these particles showed cytotoxicity on human lung epithelial cells.

As a conclusion, the flame-made nanoaggrates developed on this study exhibit advantageous properties for their employment in drug delivery with high loading values and minimal cytotoxicity.

Flexible Electrodes Decorated with Mesoporous WO_3-Dots Using Electrospray and Evaporation Induced Self-Assembly (EISA)

Geonwook Kim[1], Aneesh Koyappayil[2], Hyunho Seok[1], Sihoon Son[1], Jinhyoung Lee[1], Dongho Lee[1], Hyunbin Choi[1], Seowoo Son[1], Lee Minho[2] and Taesung Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Chung-Ang University, Korea (the Republic of)

Materials fabricated through electrospraying methods exhibit enhanced mechanical and electrical properties for various applications. Mesoporous structures with surface porosities of 20-50 nm provide numerous active sites, enabling high sensitivity, mechanical robustness, and rapid response and recovery. However, surface modification

is essential to improve the electrochemically active sites for high-sensitivity, non-enzymatic biosensors compared to flat surfaces.

Evaporation-induced self-assembly (EISA) is a powerful nanostructuring method that creates electrochemically active surfaces. This technique offers significant advantages in material fabrication and structural control. Tungsten trioxide (WO_3), a metal oxide semiconductor, is notable for its rapid electron transport and diverse structural forms, making it attractive for sensor applications.

This study investigates the fabrication of flexible polyimide (PI) electrodes decorated with mesoporous WO_3 for the highly sensitive detection of catechol (CC) and hydroquinone (HQ), which are critical environmental pollutants due to their low degradability and ecological toxicity. Organic-inorganic composite dots were formed on flexible PI electrodes through EISA and electrospraying. EISA was conducted with high-voltage biasing and substrate heating for a temperature gradient. During solvent evaporation, randomly distributed precursors formed micelles, followed by well-ordered thin films. Partially decomposed organic components were removed using O2 plasma, forming mesoporous structures. The increased specific surface area of the mesoporous structures facilitated effective redox and adsorption-desorption reactions.

Differential pulse voltammetry (DPV) and cyclic voltammetry (CV) measurements confirmed a linear increase in cathodic peak current with increasing sample concentration. Computational studies supported the spontaneous adsorption of CC and HQ molecules on the modeled WO_3 surface.

The proposed sensor successfully measured CC and HQ simultaneously and individually on the WO_3-PI electrode. It demonstrated high sensitivity, wide linear range, and low detection limits when CC and HQ were present either individually or concurrently. The sensor's practicality was validated using real river water samples.

The results indicate that flexible PI electrodes decorated with mesoporous WO_3, fabricated via EISA and electrospraying, provide an efficient and reliable method for detecting these phenolic compounds. This approach suggests a promising method for developing electrochemical sensor materials aimed at environmental safety.

Dual-Sensing Electroluminescent Display Based on Dielectrophoretic-Acoustophoretic Self-Assembly

Jong Woong Park[1,2], Donyoung Kang[1], Hyungsuk Lee[1] and Cheolmin Park[1]; [1]Yonsei University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

Despite the development of technologies utilizing dielectrophoretic (DEP) or acoustophoretic force, dynamic visualization of these forces is rarely explored and remains challenging. Here, we introduce a dielectrophoretic-acoustophoretic dual-sensing electroluminescent display, which direct force visualization is achieved by self-assembly of conductive carbon micro and nanoparticles. The display comprises coplanar electrodes separated by a gap, a polymer composite with electroluminescent (EL) phosphors, and a chamber with field-responsive conductive particles suspended in a medium. When AC field is applied between the coplanar electrodes, DEP force is induced, and the particles migrate towards the electrode gap, forming dendrites that act as a conductive electrode bridge. EL is triggered from the phosphors, and the intensity and area of EL emission is determined by the magnitude of the applied DEP force. Conversely, when ultrasound generated from a surface acoustic wave device is transmitted to the display, the particles are pushed towards the pressure nodes of the standing acoustic wave, detached from the electrode gap. Destruction of the conductive electrode bridge deactivates EL emission, and the response of the display changes by the frequency and intensity of the given acoustic wave. The display can be integrated with existing surface acoustic wave sensors for visualizing temperature changes. Additionally, the

display is further demonstrated for motion tracking or non-invasive monitoring of microfluidic channels. Altogether, our platform outlines a strategy of direct force visualization with particle manipulation, holding great potential for a variety of applications in the fields of electronics and biomedicine.

Controlling the Durability and Optical Properties of Triplet-Triplet Annihilation Upconversion Nanocapsules

Tracy H. Schloemer[1], Conner Harper[2], Jacob Jordan[2], Nicole Heflin[1], Pournima Narayanan[1], Qi Zhou[1], Evan Williams[2] and Daniel Congreve[1]; [1]Stanford University, United States; [2]University of California, Berkeley, United States

Precisely generating high energy photons beyond the surface at depth can significantly transform optically controlled processes like photocatalysis or 3D printing, but direct irradiation with high energy photons is not a feasible method due to absorption and optical scatter. Using triplet-triplet annihilation upconversion (TTA-UC), a nonlinear optical process, we can bypass this challenge by converting two low energy photons into one high energy photon. We recently demonstrated the use of silica-encapsulated oleic acid-cored nanoparticles with upconversion materials dispersed inside for high energy photon generation at depth, with good durability within a variety of chemical environments. To ensure the formation of a durable silica shell, we engineered the synthesis using tetraethyl orthosilicate and 10K MPEG-silane precursors to minimize nanoparticle leakage and aggregation. Simple structural modifications to the TTA-UC materials dispersed inside of the nanoparticle core can increase the overall upconverted light output. Additionally, we use charge detection mass spectrometry to directly monitor the nanocapsule growth kinetics, which helps us understand diverse nanocapsule morphologies. These results show that simple synthetic controls allow us to obtain robust, well-dispersed, bright upconverting nanoparticles for subsequent integration and engineering in light-controlled technologies.

Self-Stabilisation of Water-in-Oil Droplets Through Controlled Spontaneous Emulsification

Kate A. Sanders, Niamh Willis-Fox, Ronan Daly and Michael De Volder; University of Cambridge, United Kingdom

The application of emulsion droplets as confining vessels for confined chemical reactions, reagent encapsulation, and material assembly has been revolutionized by controlled emulsification techniques such as microfluidics, which enable precision control over droplet size, structure and composition. However, without robust stabilisation against thermodynamically favourable coalescence, droplets merge and size distributions broaden over time, restricting the benefits offered by these emulsification tools. Here we present a novel, inexpensive and highly effective strategy to enhance resistance against coalescence through controlled surfactant-assisted spontaneous emulsification at the interface of water-in-oil emulsion droplets. This non-equilibrium process results in the formation of a viscoelastic barrier consisting of micro-droplets that self-organise to surround droplet surfaces. The evolved barrier occurs within minutes of emulsification and can suppress coalescence even for large, close-packed droplets under mechanical agitation, or elevated temperature. We characterize this dynamic self-stabilisation mechanism by microscopy and rheological measurements, which add valuable insights to the current *understanding of spontaneous emulsification behaviour. Importantly, we show that this stabilisation method is not compositionally restricted, and therefore presents an exciting, versatile strategy for improving the utility of emulsions without the need for expensive surfactant or oil systems.*

Engineering the Self-Assembly of $CoFe_2O_4$ - $BiFeO_3$ Nanocomposites *Ryan T. Huynh, Tingyu Su, Pete E. Lauer and Caroline A. Ross; Massachusetts Institute of Technology, United States*

Magnetoelectric multiferroics are promising materials for the development of low-power logic and memory devices. This is due to the coupling between ferroelectric and ferromagnetic orderings, which enables the magnetization to be reoriented by applying an electric field and vice versa [1]. To date, multiple mechanisms have been proposed to create both single-phase and two-phase systems. Vertically aligned self-assembled nanocomposite thin films consisting of magnetic spinel $CoFe_2O_4$ (CFO) and ferroelectric perovskite $BiFeO_3$ (BFO) are attractive because of the strain-mediated indirect magnetoelectric coupling at the interface between magnetic nanostructures and the ferroelectric matrix [2]. Although these epitaxial self-assembled structures are well studied, precise control of their order and geometry remains challenging, limiting the implementation of these nanocomposites into devices. In this study, we use focused ion beam (FIB) and pulsed laser deposition (PLD) to direct the self-assembly of CFO - BFO on (111)-oriented conductive 0.7% Nb-doped $SrTiO_3$ and (111)-oriented insulating $SrTiO_3$ substrates [3]. First, we use FIB to pattern Au-coated substrates, then remove the Au and etch then anneal the substrates to make 2 nm deep pits or trenches with spacings of 100 nm and above. When ~1 nm of CFO is deposited by PLD, it nucleates preferentially in the shallow pits in the substrate. Subsequently, we co-deposit both BFO and CFO. BFO forms a perovskite matrix on the mesa, while CFO continues to grow on top of the initial spinel CFO seeds. Unlike growth on (001)-oriented substrates which yields square or rectangular CFO pillars, the CFO nanostructures preferentially elongate along <110> directions to form fin-shaped features. By patterning trenches along these directions, parallel alternating fins of CFO and BFO were made.

We compare the self-assembled CFO - BFO structure to that made on templates prepared by an additive approach based on electron beam lithography, in which STO topography is generated by patterning a few nm thick STO film on an STO substrate using liftoff followed by crystallization. Finally, we use probe microscopy to characterize the microstructure, ferroelectric, and magnetic properties of these nanocomposites. The BFO nanostructures are taller than the CFO due to a higher growth rate, but the magnetic domain structure of the CFO can be imaged, showing in-plane domains parallel to the fins at remanence that orient parallel to an in situ applied field of 2 kOe.

Creating a Highly Clear and Energy Absorbing Liquid Crystal Elastomer by Using a Dual Network Structure

Jihoon Yang[1], Seung-Yeol Jeon[2] and Woong-ryeol Yu[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Liquid Crystal Elastomers (LCEs) have found applications in various areas such as soft robotics and protective materials due to their reversible actuation and extraordinary energy dissipation capabilities. These properties stem from a unique molecular structure, which allows for a reversible and adjustable phase transition (from nematic to isotropic) and domain configurations (from polydomain to monodomain) when exposed to external stimuli (such as temperature). Furthermore, the polydomain - nematic molecular structure allows for domains, mesogen re-

arrangement under external forces, which makes LCEs move more viscously and dissipate more energy, in addition to the polymer chains relaxing.

However, the inherent polydomain structure of LCEs, composed of a few benzene rings connected by strong pi-pi interactions, causes the emergence of micro-scale polydomains. While this structure enhances the remarkable energy dissipation properties, it also scatters visible light, producing hazy polymer films. LCEs typically exhibit reduced energy dissipation with smaller domain structures, resulting in clearer properties. Transparent display and glass protection films require clear LCEs films, which are challenging to produce. In response, we developed Double Network Liquid Crystal Elastomers (DNLCEs) wherein polyurethane serves as a secondary network to promote the segregation of liquid crystal molecules into minute phases. This makes the domain size very small, reducing light scattering and improving transparency. Significantly, it keeps the domain structure, which preserves the high energy dissipation of polydomain LCEs.

Using Dynamic Mechanical Analysis (DMA) and Small-Angle X-ray Scattering(SAXS), DNLCEs were tested for how well they dissipate energy and their nanoscale molecular structure under large cyclic load, and UV-VIS spectroscopy measured their transparency to visible light. The findings highlight that DNLCEs offer distinct advantages over conventional LCEs, positioning them as promising materials for applications requiring both transparency and superior energy dissipation.

Self-Assembly of Metastable $CoCu_2O_3$ for Molecular Sensing and Catalysis *Matteo D'Andria, Tiago Elias Abi-Ramia Silva, Edoardo Consogno, Frank Krumeich and Andreas Güntner; ETH Zürich, Switzerland*

Metastable nanostructures are kinetically trapped in local energy minima featuring intriguing surface and material properties.[1] *To build these advanced materials, there is a need for non-equilibrium processes capable of stabilizing a large range of crystal phases outside thermodynamic equilibrium conditions by closely and flexibly controlling atomic reactant composition, spatial temperature distribution and residence time. Here,*[2] *we demonstrate the capture of metastable pseudo-binary metal oxides at room temperature with scalable combustion-aerosol processes.*[3] *By a combination of X-ray diffraction, electron microscopy and on-line flame characterization, we investigate the occurrence of metastable $CoCu_2O_3$ with controlled crystal size (4 – 16 nm) over thermodynamically stable CuO and Co_3O_4.*[4] *We found that not only are precursor composition and flame temperatures key to successfully "freeze“ high-temperature phases at room temperature, but also the as-produced nanoparticles need to reside long enough at such high temperatures to effectively nucleate and develop the metastable crystalline phase. Immediate practical impact is demonstrated by exceptional sensing and catalytic performance for air pollutant detection (e.g., 15 parts-per-billion benzene). This is attributed to the acidic (Brønsted and Lewis) surface features,*[5] *revealed by oxidation kinetics experiments and infrared spectroscopy of adsorbed pyridine.*

Development and Exploration of Mechanically Interlocking Molecules for Their Use as Imaging and Electronic Devices *Niamh A. O'Shea and Thorfinnur Gunnlaugsson; Trinity College Dublin, The University of Dublin, Ireland*

The world of mechanically interlocking molecules (MIMs) has gained providence since the 2016 Nobel Prize Awards, for which Stoddart and Sauvage received the prize for their pioneering work on molecular machines. The world of interlocking molecules has continued to be investigated and developed due to their versatility and flexibility. . In particular, this project will look at rotaxanes and their potential uses within ever-growing imaging, electronic and magnetic industries. Rotaxanes are becoming more and more prominent in the world of mechanostereochemistry as their potentials are neverending. These types of MIMs possess a mechanical bond, but what element is intriguing is that in order to break apart these units, one must break a chemical bond. Rotaxanes comprise a ring and a dumbbell component; interestingly, these components are noncovalently bonded, but to break the components apart, a covalent bond must be broken. This project aims to synthesise rotaxanes with click chemistry through the btp [2,6-bis(1,2,3-triazole-4-yl)pyridine] binding motif. This ***btp*** *motif offers versatility due to the triazoles and pyridine units present, offering the unique opportunity to template out MIM through hydrogen bonding. Including this, the btp motif has the ability to bind the trivalent compounds; in particular, we look at lanthanide (III) ion, including Eu(III), Tb(III), Ln(III) and Gd(III). This enhances the motif possibility within imaging Technologies due to the phosphorescent and fluoresces capabilities of Ln(III) ions. The aim of this project was to thread a* ***btp*** *macrocycle with a* ***btp*** *thread (ligand) and then incorporate cyclen complexes as the stoppers to prevent the dethreading of the macrocycle from the thread. This project harnesses the copper azide-alkyne cycloaddition (click chemistry) to build our components whilst also employing various other organic chemistry reactions to yield the desired targets.*

Our project has made significant strides, having successfully built pseudorotaxane units along with a rotaxane unit, which could potentially be developed into a switchable rotaxane. We have conducted in-depth ultra-violet spectroscopy, Nuclear magnetic resonance spectroscopy, and Mass spectrometry on all samples and components. A key area of interest for us is how building these MIMs can impact their yield and versatility, leading us to explore alternative approaches and methodologies to evaluate which route best suits the system we are trying to build. These MIMs have shown promising magnetic properties, including ferromagnetic and paramagnetic potentials, with the use of Ln(III) ions. We have investigated this with AFM measurements and Scanning Transmission Microscopy to observe the surface and internal structure when the magnetism is exploited. Further characterization and analysis of the produced rotaxanes and self-assemble behaviour was conducted using various microscopy techniques, such as SEM, AFM, and TEM, with crystallization also being noted. With the emerging outlook on the world of nanomaterials and the technologies encompassing them, our project is at the forefront of this exciting field with these self-assembling Ln(III) MIMs.

10:30 AM NM07.10.07

Light-Directed DNA-Programmable Assembly of 3D Superlattices on Surfaces *Changan Li[1], Feiyue Teng[2] and Oleg Gang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States*

Functional nanomaterials hold significant potential due to their unique properties, impacting fields such as biosensing, optical metamaterials, and many advanced manufacturing applications. However, creating a broadly applicable fabrication platform to harness these properties in functional devices remains challenging. Herein, we present a scalable method for nanomaterial fabrication, establishing a reliable foundation for constructing complex, reconfigurable nano- to macro-scale architectures on solid supports. By integrating DNA self-assembly with light-directed DNA lithography, we engineer patterned substrates with site-specific precision, thus controlling the spatial placement and alignment of self-assembled 3D nanomaterials.

Our approach utilizes light-directed covalent surface patterning of unmodified DNA to nucleate site-specifically and promote the growth of self-assembling structures. In contrast to conventional photo-crossing linking methods *relying on pre-labeled docking strands and biotin-streptavidin binding, our approach eliminates the need for docking DNA strands and chemical modification of complementary strands. By introducing a photoreactive moiety via a heterobifunctional crosslinking reagent, we immobilize DNA through a photochemical reaction in designated surface location over macroscale areas, thus, enabling site-specific programmable assembly of nanomaterial components. The method is promising for developing photonic and electronic devices, and spatially-controlled catalytic surfaces.*

10:45 AM NM07.10.08

Functional Hierarchical Nano/Micro-Architectures from Liquid-Polymer-Particle Aggregation Induced by Phase Separation *Anton Resing and Joerg G. Werner; Boston University, United States*

Control over multi-scale structural features, including precise nanoparticle arrangement and the embedded meso- and macropores are of paramount importance for electrodes used in mass-transfer limited devices such as batteries, fuel cells and carbon capture systems. To meet the demand for application-tailored electrode architectures, we have developed a facile, scalable, and bottom-up approach, termed Hybrid Inorganic Phase Inversion (HIPI). HIPI enables us to create monolithic materials with controlled hierarchical structures of nano- and micro-particles with channel-like micron-scale pores and tunable nanoporosity by exploiting the driving forces of liquid-polymer phase separation, gelation, and aggregation. HIPI is a material-agnostic self-assembly process which reaches across all four classes of materials, resulting in free-standing hierarchically porous ceramics, metals, polymers and composites.

Despite HIPI being a fast non-equilibrium aggregation process, we have developed rational design criteria to gain precise control over the multi-scale porosity and architecture. To this end, we tune the density of the nucleating phase of the particle-polymer-liquid suspension using the thermodynamics of phase separation to control and tailor the pore density on the micron scale. Further, by adjusting the relative kinetics of solidification and phase separation we control the shape of the micron scale pores from cylindrical to graded to conical. Lastly, exploiting transient gel states allows us to dial in the degree of nanoporosity. The range of multi-scale architectural features both accessible and tunable put HIPI at the forefront of fabrication concepts to enable scalable designer electrodes.

11:00 AM NM07.10.09

Order, Disorder and Hyperuniformity in Self-Assembled Thin Films of Polymer-Grafted Nanoparticles *Derek E. Huang, Kenya Hazell, Jonathan Karhoff, Kyoungweon Park, Andrew Gillman and Lawrence Drummy; Air Force Research Laboratory, United States*

The formation of ordered and disordered structures in materials can strongly influence their macroscopic behavior. Hyperuniform structures, which are characterized by the suppression of density fluctuations at long length scales, have recently been recognized for their potential to control critical properties like toughness as well as electromagnetic and mechanical waveguiding. In polymer-grafted nanoparticle (PGN) composites, this structure and order arises from many different processing parameters and plays a critical role at multiple length scales, from particle-polymer interfaces to particle morphology to large-scale particle arrangements. Understanding and controlling the structure at these scales is key to understanding the measured macroscopic properties. The self-assembly of PGN thin films can be influenced by factors such as polydispersity, composition, and film deposition method. Here, we tailor the synthesis and assembly of thin films from bimodal size distributions of spherical polymer-grafted nanoparticles, relying on a flow-coating process for its scalability and ease of implementation. By varying the solution concentration, flow-coating geometry, and particle size distribution, we can control large-scale self-assembly of the particle microstructure, which we characterize via *microscopy and scattering to assess the degree of orientational disorder and hyperuniformity. This multiscale process-structure-property understanding will influence the design of materials for a variety of applications and environments.*

11:15 AM NM07.10.10

Cassian Nanoparticles—A Novel Method for DNA Delivery into Plant Cells *Guy Mechrez[1] and Avital Ben Haim[1,2]; [1]Volcani Center, ARO, Israel; [2]The Hebrew University of Jerusalem, Israel*

This research presents for the first time gene expression after DNA delivery into intact plant cells by protein nanoparticles. The successful DNA delivery was carried out by casein nanoparticles (CNPs). The CNPs are self-assembled by the addition of calcium chloride to casein sodium salt solution. A plasmid carrying the red fluorescent protein DsRed sequence was electrostatically bound to CNPs, serving as the model DNA in this study. Tuning the CNPs' zeta potential by adjusting pH facilitated electrostatic interaction with the DsRed plasmid for effective DNA delivery into Nicotiana benthamiana cells. CNPs were covalently modified with the green fluorescent dye 6-Aminofluorescein (6-AF) to track their location in the plant. Infiltration of CNP/DsRed plasmid electrostatic conjugates into N. benthamiana leaves showed successful intracellular and nucleus uptake of CNPs/6-AF/DsRed plasmid conjugates at pH 4.5 (+13.0 mV, 214 nm) and a concentration of 2 mg/mL, with a CNP:plasmid ratio of 1:0.01, confirmed by confocal fluorescence microscopy. RT-PCR analysis confirmed successful gene expression through DsRed protein fluorescence. The initial appearance of the red signal from the DsRed protein was observed 24 hr post-infiltration and persisted for 48 hr.[1]

11:30 AM NM07.10.11

Anatomy of a Complex Crystallization Pathway *Charlotte Zhao, Domagoj Fijan and Sharon C. Glotzer; University of Michigan–Ann Arbor, United States*

Crystallization is ubiquitous in nature. For example, it occurs in cloud formation and precipitation, and the Earth's crust is a tapestry of crystalline structures, shaping landscapes and ecosystems. Despite its ubiquity, however, our understanding of crystallization remains incomplete, especially for complex crystals, which exist in a plethora of systems spanning many length scales, such as intermetallic compounds and colloidal assemblies. In this work, we study and compare the macroscopic and microscopic crystallization pathways of two prototype systems in which the components have fundamentally different interactions. One system has particles with interactions characteristic of those in metallic compounds, the other one with shaped particles whose interactions are emergent entropic forces. By examining the pathways on the macroscopic level, we found that both systems are polymorphic and share the same crystal polymorphs. More remarkably, the microscopic pathways of the two systems exhibit similar traits due to the similarities in their local structural environments (LSEs), despite the stark difference in the origins of their particle interactions.

11:45 AM NM07.10.12

Self-Organization of Fiber Assemblies Driven by Adhesive Interactions—Emerging Structures and Properties *Catalin R. Picu and Syed N. Amjad; Rensselaer Polytechnic Institute, United States*

Materials made from fibers are ubiquitous in biology and engineering. These include collagen-based biomaterials, gels, molecular networks such as rubber, buckypaper, nanocellulose, and many others. Fiber self-organization *may take place due to adhesive interactions, provided the fibers are free to move (are not embedded in a solid matrix) and are thin enough. We consider two cases, in which self-organization takes place without crosslinking, and in which crosslinking occurs concomitantly with adhesion-driven self-organization. In both cases, the self-organization process leads to complex structures. We determine using models of fibrous assemblies the types of structures that emerge function of the parameters of the system, such as the fiber length, fiber density and the strength of adhesion. Further, we investigate the mechanical properties of the resulting structures and conclude that these are controlled primarily by adhesive interactions and less by the deformation of fibers. Hence, fibrous networks with adhesion behave differently from their counterparts without adhesion. Further, we study the interplay between crosslinking and adhesion-driven self-organization and its effect on the overall mechanical behaviour of fiber networks. The conclusions obtained are of importance for understanding the mechanical behavior of biological fibrous materials self-organized due to the adhesion between proto-filaments, and for the development of new functional fibrous materials.*

Highly Ordered 3D Interconnected Structures in a Block Copolymer by Directed Self-Assembly *Mingchao Ma, Baopu Zhang and Caroline A. Ross; Massachusetts Institute of Technology, United States*

Block copolymers (BCP) thin films designed to have specific microdomain geometries such as interconnected cylinders could enable the fabrication of three-dimensional devices for photovoltaics and microelectronics. In our preliminary work, we made inverted-T structures consisting of a layer of in-plane cylinders at the bottom of the film connected to vertical cylinders spanning the remainder of the film thickness. These structures were made from a polystyrene-b-poly(2-vinylpyridine) (PS-b-P2VP) BCP which in bulk forms close-packed P2VP cylinders within a matrix of PS. The inverted-T structure is favored by selection of film thickness and solvent annealing conditions. However, on a bare silicon wafer the bottom cylinders formed a fingerprint pattern, lacking long range order of in-plane orientation and hence limiting potential device applications.
We show here how the 3D structure can be ordered using substrate templating. We use electron-beam lithography (EBL) on a resist-coated oxidized silicon substrate to generate grating patterns with widths from 200 nm to 500 nm and then transfer the pattern into the silica by reactive ion etching (RIE). The trenches have a trapezoidal cross section with the base width slightly narrower than the top width of the trench. The BCP is spin-coated over the substrate and solvent-annealed to induce microphase separation, which is revealed by loading the P2VP microdomains with Pt from an acid solution of a Pt salt and then etching in oxygen to remove the PS. By selection of trench geometry, BCP thickness and annealing conditions, we achieve highly ordered structures in the trenches, in which the out-of-plane cylinders are hexagonally packed and the underlying connected in-plane cylinders are parallel to the trenches. The parallel orientation of the bottom layer of cylinders depends on the bottom trench width (w_{bottom}). It is crucial to match w_{bottom} with the periodicity of the BCP (L_0 = 49 nm), i.e., w_{bottom} close to an integer multiple of L_0 (nL_0), so the parallel orientation is preferred. The structure of the top layer is determined by w_{bottom} and film thickness (t). Due to the tapered trench wall of 7° originating from the RIE process, w increases towards the top of the trench. Deeper trenches (depth = d) therefore have a larger difference between the widths of the top and bottom surfaces of the BCP within the trench. If the width at the top of film during annealing (w_{top}) is close to w_{bottom}

= nL_0, highly ordered inverted-T structures are generated with each in-plane cylinder connected to one row of vertical cylinders. If w_{top} is closer to (n+1) L_0, the mismatch of period results in a split in one of the rows of vertical cylinders, yielding Y-shaped structures. These highly ordered templated 3D structures fabricated by directed self-assembly widen the opportunities for BCP-derived nanofabrication.

Signature of Interdot Electronic Coupling from Photoelectron Spectra of Quantum Dot Molecules *Sara Talebi and Arindam Chakraborty; Syracuse University, United States*

The research focuses on examining the electronic coupling between quantum dots in quantum dot molecules. The study involves calculating and analyzing the photoelectron spectra to understand the dot-to-dot interaction in these systems. The interaction between quantum dots can result in unique electronic and optical properties, with electron tunneling playing a significant role. The photoelectron spectra of PbS-PbS, PbS-CdS, and CdS-CdS systems were analyzed using an electron-propagator approach and Dyson equation within the 2nd-order approximation. The results of this study indicate that the primary photoelectron spectral line demonstrates splitting, which is strongly influenced by the separation between quantum dot molecules. Theoretical analysis revealed that the two lowest occupied molecular orbital states exhibit significant differences in their light-matter coupling strengths, leading to distinctive and asymmetrical spectral signature lines. The results of the study provide insights into quantifying dot-to-dot electronic coupling through photoelectron spectra, taking into account factors such as inter-dot separation distance, dot size, semiconductor type, and energy alignment of single-particle states.

Uncovering Tunable Self-Assembly Pathways in Halide Perovskite Nanoplatelets Through Post-Synthetic Chiral Organic Ligand Addition, or Halide Anion Exchange Techniques *Progna Banerjee[1,2], Stefano Toso[3], Richard D. Schaller[2], Nicholas A. Kotov[4], Liberato Manna[3] and Elena Shevchenko[2]; [1]Loyola University Chicago, United States; [2]Argonne National Laboratory, United States; [3]Istituto Italiano di Tecnologia, Italy; [4]University of Michigan-Ann Arbor, United States*

Self-assembly mechanisms in colloidal $CsPbBr_3$ nanoplatelets or quantum wells were studied using either (a) post-synthetic ligand or (b) anion exchange techniques. (a) Although chirality in hybrid organic-inorganic single crystals have been studied in detail, we present a comprehensive investigation in into the intriguing morphological transformations observed when chiral organic ligands interact with $CsPbBr_3$ nanoplatelets. Our study encompasses a multi-faceted approach, combining optical, chiral, and transmission electron microscopy (TEM) techniques, shedding light on the emergence of chiral intermediates and their dependence on ligand chirality. Our optical and chiral spectroscopic studies of various aliquots of ligands added to the nanoplatelets allowed us to elucidate the spectral fingerprints associated with the emergence of these chiral intermediates. Notably, our findings highlight the intricate interplay between ligand chirality and the evolution of intermediates in the spectra. Our results reveal distinct pathways and morphological transformations driven by both the absolute configuration r-/s- of the ligands through unusual, oriented attachment mechanisms. Furthermore, we investigated the lifetime of these intermediates and found a strong dependence on the chirality of the ligands added. Our study not only advances our fundamental understanding of chiral ligand-nanoplatelet interactions, but also opens exciting possibilities for the rational design and manipulation of chiral nanostructures for various technological applications employing sensitivity to light polarization.
(b) We present a study on anion exchange techniques in colloidal $CsPbBr_3$ nanoplatelets using various inorganic precursors, examining the resulting structural, emissive, and morphological transformations. Our findings indicate that the selection of precursors and reaction conditions can be strategically utilized to control self-assembly

behavior and induce morphological transformations in these materials. This technique offers significant improvements and experimental ease over existing synthetic protocols, which typically involve high temperatures and etching agents to elucidate more rigid ion exchange transformation pathways. Our approach not only simplifies the experimentation process but also provides greater flexibility in tuning the properties of $CsPbBr_3$ nanoplatelets.

2:15 PM NM07.11.04

Development of Mechanically Stable Long-Lived Room Temperature Phosphorescence Network by Controlling Intramicellar and Intermicellar Interaction *Seongeun Cho and Jinkee Hong; Yonsei University, Korea (the Republic of)*

Room temperature phosphorescence (RTP) is one of the widely researched luminescent phenomena these days. This involves continued emission of light from the triplet excitons at room temperature for more than 0.1s even after the excitation source has been removed. In particular, organic RTP materials attract interest due to their low cost and easy molecular modification, exhibiting potential use in the fields of information security, wearable devices, and lasers. A concern of the organic RTP materials is their short lifespan and low light intensity. Recent strategies to achieve long-lived organic RTP (LRTP) include crystallization, matrix rigidification, and host-guest systems to restrict molecular motion and prevent quenching by external quenchers such as oxygen. However, these strategies severely hinder the practical use of LRTP materials because of their brittle, fragile nature and low mechanical properties. Therefore, a new approach to satisfy both mechanical properties and LRTP is needed.
In this work, we synthesized a phosphorescent amphiphilic random copolymer that forms micelles in water, and controlled the intramicellar and intermicellar interactions within micelles to optimize the mechanical properties and phosphorescent performance. For synthesizing an amphiphilic random copolymer with LRTP properties, we introduced a phosphorescent chromophore based on organic quaternary phosphonium salts into an acrylamide and phenylboronic acid backbone with hydrogen bonds to restrict molecular motions of the phosphor. It showed naked-eye observable, blue-colored light emission for over 5s duration after 365 nm UV excitation. We confirmed that the phosphorescent polymer could be self-assembled into micelles with a hydrophobic core and a hydrophilic shell structure.
Afterward, we introduced a doping material, bPEI (branched polyethyleneimine) into the polymer to control intermicellar interactions. With doping bPEI at room temperature, the composite solution showed no gelation. However, the composite solution containing over 30 wt% bPEI underwent gelation with shrinking by syneresis upon heating above 65°C. This meant that a higher content of bPEI could accelerate micelle gelation kinetic. We demonstrated aggregation under external heat and bPEI linker by enhancing physical entanglement and hydrogen-bonding interaction in intermicellar domain. By analyzing the effect of bPEI content on mechanical properties and LRTP, we confirmed that higher bPEI led to enhanced mechanical properties but lower LRTP due to the high mobility of bPEI molecule. Furthermore, intramicellar chemical crosslinking of the inner core of the micelle was achieved with heating in the drying process of the composite. When dried at a temperature of 65°C, the boronic acid structure in the polymer backbone was maintained without any reaction. But when dried above 90°C, the boronic acids formed chemical crosslinking in boroxine structure by dehydration, leading to shrinking of the inner core of the micelle and the composite material itself. By analyzing the effect of drying temperature, it was verified that high temperature enabled the composite to possess improved LRTP.
Lastly, we employed the suggested LRTP system in films, patterns, and coatings for various substrates from its eco-friendly water-processibility. Such a stable LRTP material with easy preparation and broad-range applications highlights its practical use.

2:30 PM NM07.11.05

CMOS-Compatible Synthesis and Magnetic Evaluation of Spinel Ferrite Nanostructures Naveen

Narasimhachar Joshi[1,2,3] and Shivashankar S[2]; [1]North Carolina State University, United States; [2]Indian Institute of Science, India; [3]Indian Institute of Technology Kharagpur, India

Spinel ferrites (AB_2O_4, A = transition metal ion; B = Fe) are promising candidates as the magnetic core of RF inductors, to enable the next generation 5G wireless systems, with a low form factor and high Q factor. If the particles prepared are nanosized, the superparamagnetic (SPM) behavior of spinel ferrites can be suitably tuned by controlling the size and composition of the nanoparticles. Thus, nanocrystalline spinel ferrites with crystallite size less than the SPM limit can be a good choice to upshift the ferromagnetic resonance (FMR) frequency and stem the magnetic loss in RF inductors. Such functionalities are usually achieved by inducing the far-from-equilibrium distribution of cations on tetrahedrally coordinated sites (A-site) and octahedrally coordinated sites (B-sites) in a spinel structure. Typically, high-temperature annealing followed by quenching is needed to achieve such non-thermodynamic conditions. However, any temperature above 400 °C is prohibited for on-chip integration. Recently, a low temperature (< 200 °C) kinetically driven, solution-based, microwave-assisted solvothermal (MAS) technique has been explored as a CMOS-compatible process to produce spinel ferrite powders and films of high quality with desired crystallite size (< 20 nm) and intriguing magnetic properties.
Here in, we report the single-step formation of spinel ferrite ($CoFe_2O_4$ and $NiFe_2O_4$) nanostructures through the microwave-assisted irradiation of β-ketoester complexes at a temperature < 200 °C and pressure < 150 psi, without the aid of any surfactants or catalysts, for the first time. We show that as-synthesized nanostructures comprise very small crystallites (~4 nm ($CoFe_2O_4$) and ~6 nm ($NiFe_2O_4$)) and are homogeneous on a macroscopic scale with robust magnetic properties. The isothermal field-dependent magnetization plots show the presence of superparamagnetic interactions in both the ferrite nanostructures with a saturation magnetization (M_S) of ~50 emu/g and ~30 emu/g and negligible coercivity at 300 K in $CoFe_2O_4$ and $NiFe_2O_4$ respectively. We show that the M_S value of the as-prepared samples is significantly lower than that of their respective bulk values due to the surface-spin cantering effect in the nanostructures. Temperature-dependent magnetization data indicates a very low blocking temperature (T_B) of 160 K in $CoFe_2O_4$ and 60 K in $NiFe_2O_4$, with no significant differences in the magnetization between the zero-field cooled (ZFC) and field-cooled (FC) curves above T_B. A narrow ZFC curve implies that the crystallite size distribution is not broad, indicating the superparamagnetic interactions in the samples. We envisage that the low-temperature growth of spinel ferrites with tunable magnetic properties opens avenues for new applications in novel magnetic devices and sensors.

Unlocking the Potential of Cesium Lead Bromide Nanocrystals—Stability and Growth Insights from High-Throughput Synthesis

Sheryl L. Sanchez, Yipeng Tang, Bin Hu, Jonghee Yang and Mahshid Ahmadi; The University of Tennessee, Knoxville, United States

Cesium lead bromide ($CsPbBr_3$) nanocrystals are at the forefront of optoelectronic innovation, offering exciting possibilities for next-generation devices. However, the widely-used ligand-assisted reprecipitation (LARP) method for synthesizing these nanocrystals often struggles with stability. Our research employs a cutting-edge automated platform to delve into the growth dynamics and stability of $CsPbBr_3$ nanocrystals produced via LARP. By systematically exploring the impact of various ligands, we reveal that short-chain ligands fall short in achieving desirable nanocrystal sizes and shapes. In contrast, long-chain ligands foster the formation of uniform and stable nanocrystals. Moreover, we discovered that an overabundance of amines or polar antisolvents can drive the transformation of nanocrystals into Cs-rich non-perovskite structures, characterized by inferior emission properties and increased size variability. This study [1] underscores the pivotal role of ligand diffusion in dictating nanocrystal structure and functionality, providing crucial guidelines for optimizing synthesis methods and enhancing the performance of these promising materials.

Classification of cOmplex Local Environments in Systems of Particle Shapes Through Shape-sYmmetry Encoded Data Augmentation *Shih-Kuang Lee, Sun-Ting Tsai and Sharon C. Glotzer; University of Michigan, United States*

Detecting and analyzing the local environment is crucial for investigating the dynamical processes of crystal nucleation and shape colloidal particle self-assembly. Recent developments in machine learning provide a promising avenue for better order parameters in complex systems that are challenging to study using traditional approaches. However, the application of machine learning to self-assembly on systems of particle shapes is still underexplored. To address this gap, we propose a simple, physics-agnostic, yet powerful approach that involves training a multilayer perceptron (MLP) as a local environment classifier for systems of particle shapes, using input features such as particle distances and orientations. Our MLP classifier is trained in a supervised manner with a shape symmetry-encoded data augmentation technique without the need for any conventional roto-translations invariant symmetry functions. We evaluate the performance of our classifiers on four different scenarios involving self-assembly of cubic structures, 2-dimensional and 3-dimensional patchy particle shape systems, hexagonal bipyramids with varying aspect ratios, and truncated shapes with different degrees of truncation. The proposed training process and data augmentation technique are both straightforward and flexible, enabling easy application of the classifier to other processes involving particle orientations. Our work thus presents a valuable tool for investigating self-assembly processes on systems of particle shapes, with potential applications in structure identification of any particle-based or molecular system where orientations can be defined.

Programmable Assembly of Semiconductor Mesostructures via Artificial Phototropism *Azhar I. Carim and Nathan S. Lewis; California Institute of Technology, United States*

Plants direct the addition of new biomass to optimize collection of solar insolation via the phototropic response. Artificial phototropism enables the programmable assembly of complex 3D nanoarchitectures with instruction by an incoherent, unstructured, mW cm^{-2} intensity light beam. Artificial phototropism has been demonstrated via the light-mediated electrochemical assembly of semiconductor deposits from solution-phase precursor ions. Ordered nanoscale features were uniformly assembled over full macroscale (cm^{2}) areas with feature heights on the order of several um with growth times < 5 min despite no use of patterning or masking agents. In-plane anisotropy was a function of the input polarization. Linearly polarized light resulted in anisotropic lamellar structures with in-plane orientations set by the polarization direction. The structure pitch was dependent on the spectral distribution of the input light with shorter wavelengths effecting higher feature densities. The out-of-plane growth direction was related to the propagation direction of the input light. Time-varying optical inputs enabled programming of 3D intricacy by evolving the in-plane structure along the out-of-plane dimension, e.g. an abrupt reduction in the input wavelength resulted in a concomitant increase in the interfacial density resulting in tuning fork structures. Additional morphological control has also been effected by using multiple simultaneous illumination inputs. Optically based growth modeling indicated that assembly was directed by evolution of the growth front to maximize spatial anisotropy in light collection.

4:00 PM NM07.11.09
Study of Energy Transfer in Aqueously Dispersed Polymeric Nanoparticles and Their Use for Photovoltaic Applications *Maiara Bassi[1], Luana Wouk[2,1,3], Wesley Renzi[4], Camilla K. Oliveira[1], José Leonil Duarte[5], Ismael Heisler[6] and Lucimara S. Roman[1]; [1]Universidade Federal do Paraná, Brazil; [2]CSEM Brazil, Brazil; [3]UNB, Brazil; [4]Instituto Federal do Paraná, Brazil; [5]Universidade Estadual de Londrina, Brazil; [6]Universidade Federal do Rio Grande do Sul, Brazil*

In this study, polymeric nanoparticles dispersed in an aqueous medium were synthesized using the miniemulsion technique. The nanoparticles were composed of copolymer F8T2 or the homopolymer MDMO-PPV and a mixture of both and were investigated to unravel the interaction between these materials. The results showed that, by decreasing the distance between the nanostructured materials, a higher Förster resonance energy transfer (FRET) was observed from F8T2 to MDMO-PPV. When the nanoparticles were applied as an active layer in organic photovoltaic devices, the resulted enhanced of energy transfer could generate more free charge carriers, increasing the short circuit current density, influencing the increase in the efficiency of these devices.

Genetic Control Over Biogenic Crystal Morphogenesis in Zebrafish *Dvir Gur; Weizmann Institute of Science, Israel*

Organisms had to evolve mechanisms that regulate the properties of biogenic crystals to support a wide range of *functions, from vision and camouflage to communication and thermal regulation. Yet, the mechanism underlying the formation of diverse intracellular crystals remains enigmatic. Here, we unraveled the bio-chemical control over crystal morphogenesis in zebrafish iridophores. We show that the chemical composition of the crystals determines their shape, specifically by the ratio between the nucleobases guanine and hypoxanthine. We reveal that these variations in composition are genetically controlled through tissue-specific expression of specialized paralogues, which exhibits remarkable substrate selectivity. This orchestrated combination grants the organism with the capacity to generate a broad spectrum of crystal morphologies. Overall, our findings suggest a new mechanism for the morphological and functional diversity of biogenic crystals and may thus inspire the development of genetically designed biomaterials and medical therapeutics.*

11:00 AM *PM01.01.02

The Formation Mechanisms of Biogenic Guanine Crystals *Avital Wagner and Benjamin Palmer; Ben-Gurion University of the Negev, Israel*

Many optical phenomena in animal coloration and vision are generated by interactions of light with assemblies of guanine crystals.[1,2] *Guanine crystals comprise π-stacked, H-bonded layers, with a high in-plane refractive index. Organisms precisely control crystal morphology to form plate-like crystals preferentially expressing the highly reflective, hydrophobic (100) crystal face parallel to the H-bonds. While crystals grown in vitro form bulky prismatic morphologies that are not particularly optically useful. Our objective is to discover the strategies organisms use to exquisitely regulate crystal morphology and harness these strategies to develop new optically functional molecular materials. We approached this by following crystal formation in model organisms undergoing development using electron microscopy and in situ diffraction techniques. By studying hatchling white-widow spiders, we found that guanine crystals are composites and that their crystallization is a 'non-classical', multi-step process involving a progressive ordering of states.*[3] *In juvenile scallop eyes, we showed that pre-assembled, fibrillar sheets provide an interface for nucleation and direct the growth and orientation of plate-like guanine crystals.*[4] *In addition, we test these strategies by in vitro crystallization experiments, providing a rationalization for the crystal morphologies found in organisms. Thus, crystal-producing organisms can inspire new approaches for manipulating the morphologies and properties of molecular materials.*

Unveiling the Remarkable Architecture of Rodent Incisors—Iron-Rich Enamel for Superior Mechanical and Chemical Resilience *Vesna Srot[1], Gregor Kapun[2], Sophia Houari[3], Felicitas Predel[1], Birgit Bussmann[1], Bostjan Pokorny[4], Elena Buzan[5], Bernhard Fenk[1] and Peter A. Van Aken[1]; [1]Max Planck Institute, Germany; [2]National Institute of Chemistry, Slovenia; [3]Université Paris Cité, France; [4]Faculty of Environmental Protection, Slovenia; [5]University of Primorska, Slovenia*

Teeth are a perfect example of biogenic composites, consisting of optimally arranged simple inorganic and organic compounds. Continuously growing elongated rodent incisors show adaptations and optimizations that are *superior when compared to human teeth. They are recognizable by their orange-brown color and their specific construction, in which hard enamel selectively covers only the labial side of the incisors, making them a self-sharpening device [1]. When fully formed, enamel consists of approximately 96 wt% of elongated hydroxyapatite (HA) crystals, with the remainder being organic material and water [2]. The complexity of the enamel structure depends on the region; in the outer radial enamel, the rods are arranged in parallel, while in the inner enamel, the rods within a layer are parallel to each other, while adjacent rows are inclined in opposite directions. Only a finite outer part of the outer radial enamel is occupied by iron-rich material, resulting in the formation of acid-resistant enamel with exceptional physical, chemical and mechanical properties [3-5].*

In this study [6], we have followed the complete structural and chemical development of rodent incisors from seven species (beavers, coypus, marmots, squirrels, voles, rats, mice) from the macro to the nano scale.

First, we studied ameloblasts during their pigmentation stage while they were filled with ferritin nanoparticles. These nanoparticles showed a crystalline structure with a high Fe/P ratio being consistent with the values for mammalian ferritin. Their crystalline ferrhydrite core with Fe in the 3+ state suggests an iron storage mechanism that protects cells from potential toxicity.

Next, as enamel matures, iron-rich material penetrates the outer layer of radial enamel and occupies the empty spaces between the elongated hydroxyapatite crystals. We call these tiny and irregularly shaped structures pockets. The outer radial enamel is filled with iron-rich material to a certain depth, forming an acid-resistant, iron-rich enamel. The infiltrated pockets are arranged in a 3D network and form a secondary phase with a ferrihydrite-like composition and iron in the 3+ oxidation state. Although they make up less than 2% of the volume of the iron-rich enamel, they contribute to improved mechanical properties and increased resistance to acid attack.

Finally, an organic/inorganic surface layer formed parallel to the surface of the incisors was observed at different stages of development. The variable iron-calcium-phosphorous composition is observed not only between different species but also within the incisors of the same individual. The final thickness of the surface layer is variable and can be influenced by mechanical abrasion during the gnawing. Our observations suggest that there is a strong correlation between the color of the incisors and the thickness of the surface layer. Moreover, we observed a striking effect of color propagation only through the thickness of iron-rich enamel, although its color resembles that of regular enamel. Consequently, we propose to redefine the existing nomenclature and to rename ``pigmented enamel`` to iron-rich enamel.

Our findings have significant consequences and implications for human health, the development of dental materials, and restorative dentistry.

Exploring Crystal-Cell Interactions in Breast and Thyroid Tumor Microenvironments *Netta Vidavsky; Ben-Gurion University of the Negev, Israel*

Microcalcifications (MCs) commonly found in precancerous breast lesions and cancerous thyroid nodules, detected through ultrasound and mammography, offer more than just visual markers. Their physiochemical properties hold promise in addressing key challenges in cancer diagnosis and prognosis. For thyroid nodules, the prevalence of indeterminate diagnoses necessitates repetitive tests and costly procedures. In breast precancer, predicting progression to invasive cancer remains elusive, leading to a universal treatment approach despite the likelihood that most cases might not progress. We investigate the interactions between MCs and cancer cells, focusing on MC crystal properties to explore connections to disease progression and to enhance existing diagnostic and prognostic algorithms. CaP MCs are associated with either benign or malignant lesions, while calcium oxalate dihydrate (COD) MCs are almost always found in benign lesions. We created a library of synthetic MC analogs encompassing different compositions, ion substitutions, particle sizes, morphologies, crystallinities, hydration states, and surface charges. We exposed human breast and thyroid cancer cells to these synthetic MC analogs in 2D and 3D by using multicellular spheroids embedded with synthetic MC analogs. COD crystals are not cytotoxic and affect the behavior of breast cancer cells according to their crystal characteristics. When COD crystals have a similar morphology to clinical MCs, they reduce Her2 expression, cell proliferation, and migration, suggesting that COD is not randomly located only in benign lesions but may be actively contributing to suppressing precancer progression in its surroundings. When breast precancer cells are exposed to various CaP minerals, the factors influencing cell proliferation the most are the mineral phase and whether the mineral is in the form of discrete particles or particle aggregates. For thyroid cancer cells, high crystallinity, decreased carbonate and Zn fractions, and less negative zeta potential of CaP minerals are associated with increased malignancy potential. Our model provides an easy-to-manipulate platform for a better understanding of the interactions between cancer cells and crystals, potentially providing new directions for prognosis, diagnosis, and treatment.

2:00 PM *PM01.02.02

Biomineralogical Signatures of Pathlogical Mineralization *Lara A. Estroff, Stephan Sutter, Alex Cruz, Chih-Yi Wang and Jonathan Butcher; Cornell University, United States*

Pathological calcification is a wide-spread phenomenon in the human body, in which calcium minerals form in soft tissues and are found in both healthy and diseased tissues. One example is calcific aortic valve disease (CAVD), which affects roughly 26% of people over the age of 65. In CAVD, mineralized lesions form in the leaflets of the aortic valve. Progressive mineralization causes valve leaflets to stiffen and impairs their ability to regulate blood flow into the aorta, leading to an increased risk of heart failure. The goal of this work is to characterize the "biomineralogical signatures" of a range of disease conditions and develop an in vitro model that recapitulates key aspects of the early stages of CAVD that precede the onset of symptoms. We hypothesize that the formation and growth of calcific nodules in the aortic valve is modulated by interactions of valve endothelial and valve interstitial cells with calcium phosphate nanoparticles in the extracellular matrix. From characterization of excised human heart valve leaflets, we know that there are multiple types of calcium phosphate nanoparticles present during disease progression. We explore these interactions through tissue engineered constructs mimicking human aortic valve leaflets. The in vitro tissue models of aortic valve leaflets consist of a collagen hydrogel under uniform static stress, seeded with porcine valve interstitial cells (VICs) and a surface layer of porcine valve endothelial cells (VECs). These 3D collagen constructs can also be seeded with synthetic calcium phosphate nanoparticles of varying phase – hydroxyapatite (HAp; $Ca_{10}(PO_4)_6(OH)_2$) and whitlockite (Wh; $(Ca,Mg)_3(PO_4)_2$). We have synthesized *nanoparticles of HAp and Wh (phase validated by x-ray diffraction and Raman spectroscopy) and incorporated them into the cellularized spring gel constructs to create a 3D in vitro model of calcific aortic valve lesions. Incubation in general (GM) and osteogenic media (OGM) leads to rapid (~1 week) formation of lesions within the constructs; these lesions and their environment are characterized by Raman mapping, immunofluorescence, and histology. Raman mapping of these tissue engineered constructs has revealed that lesion composition and morphology varies with the type of growth media used, and the type of added nanoparticles. Ongoing and future experiments will aim to expand our understanding of the role that mineral plays in driving the disease progression of CAVD, ultimately applying our understanding of calcific lesion development towards strategies for prevention and treatment of CAVD.*

2:30 PM *PM01.02.03

Proteins's Role in Determining the Optical Properties of the Arthropod Cuticle *Oliver Spaeker[1], Yin Chang[1], Alice Ludewig[1], Gavin J. Taylor[2], Bodo D. Wilts[3], Clemens N. Z. Schmitt[4], Ernesto Scoppola[4], Peter Fratzl[4], Luca Bertinetti[1] and Yael Politi[1]; [1]Technische Universität Dresden, Germany; [2]Institute for Globally Distributed Open Research and Education, Brazil; [3]Universität Salzburg, Austria; [4]Max Planck Institute of Colloids and Interfaces, Germany*

The cuticle of arthropods is made of crystalline chitin fibres embedded in an amorphous matrix. It forms the exoskeleton of the animal providing a protective shield as well as a skeleton for structural support and muscle attachment. But the cuticle also serve multiple optical functions, such as providing structural- and pigment-based coloration as well as constructing transparent cornea and lenses. While the role of chitin fibres as well as of pigments are well established, it is not completely clear what is the role of cuticular proteins in determining the optical properties of the cuticle. In this talk we describe the case of the eyes of the horseshoe crab, Limulus polyphemus, in which gradients of RI stem from structural and compositional gradients of cuticular proteins in the cornea, followed by a discussion of the composition of butterfly and beetles reflecting scales.

Plate-Like Guanine Biocrystals Form via Templated Nucleation of Crystal Leaflets on Preassembled Scaffolds *Zohar Eyal, Rachael Deis, Neta Varsano, Nili Dezorella, Katya Rechav, Lothar Houben and Dvir Gur; Weizmann Institute of Science, Israel*

Controlling the morphology of crystalline materials is challenging, as crystals have a strong tendency toward thermodynamically stable structures. Yet, organisms form crystals with distinct morphologies, such as the plate-like guanine crystals produced by many terrestrial and aquatic species for light manipulation. Regulation of crystal morphogenesis was hypothesized to entail physical growth restriction by the surrounding membrane, combined with fine-tuned interactions between organic molecules and the growing crystal. Using cryo-electron tomography of developing zebrafish larvae, we found that guanine crystals form via templated nucleation of thin leaflets on preassembled scaffolds made of 20-nm-thick amyloid fibers. These leaflets then merge and coalesce into a single plate-like crystal. Our findings shed light on the biological regulation of crystal morphogenesis, which determines their optical properties.

X-Ray Scattering and Diffraction Combined with Tensor Tomography—Alignment and Texture at Different Hierarchical Levels *Marianne Liebi[1,2]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Paul Scherrer Insitut PSI, Switzerland*

X-ray diffraction (XRD) continues to be an essential tool for the analysis of crystals structure and texture. With synchrotron techniques local variations within extended samples can be probed by raster-scanning the sample with a focused X-ray beam.[1] By probing small angle X-ray scattering, the nanometer structure can be probed, corresponding to either the size of nano-sized crystal, for example the hydroxy-apetite crystals in bone and tooth, or also the surrounding organic matrix, such as collagen.[2] On 2D detectors the anisotropy of SAXS pattern and texture of XRD can be detected. To resolve this orientation information in extended three-dimensional samples different tensor tomography algorithms have been developed. [3,4]. This results in a 3D reciprocal space map in each voxel, extending the method to 6 dimensions. As an example, the arrangement of mineralized collagen fibrils in the nanoscale can be studied over mm-cm of bone, providing a complementary tool to high resolution techniques, which often are limited in field of view.
Extension of the technique to include WAXS data has been demonstrated for the case of bone where the diffraction pattern still shows smooth texture variations from the nanocrystals of hydroxy apatite. [4] By combining the nanostructure arrangement with the crystallographic texture information in three-dimensional samples provides thereby new insight in its organisation. New developments also allow the reconstruction of more complicated texture.[3,5] Since WAXS-TT does not rely on identification and indexing of individual Bragg-peaks, as the case for 3D-XRD techniques [6], it is well suited for crystals which are too deformed or too small to yield isolated diffraction spots, as often the case for biominerals. Different application examples will be shown highlighting recent advances of the technique.

4:15 PM *PM01.02.06
Multiscale and Multimodal X-Ray Imaging of Biominerals Henrik Birkedal; Aarhus University, Denmark

Biominerals such as bone have hierarchical structures (1), which makes their characterization challenging. X-rays can be used in multiple ways to shed light on these complex structures. Using 3D X-ray imaging, length scales from the nanoscale upwards can be investigated (2). X-ray diffraction provides information on the atomic scale while X-ray fluorescence reveals the distribution of chemical elements. Both methods can be implemented in a tomographic fashion, which has for example allowed revealing the bone mineral is spatially heterogeneous in human cortical bone (3). Orientation information can be obtained by tensor tomographic approaches for both nanoscale (small angle scattering) and atomic scale (diffraction) information (4). Many of these experiments benefit dramatically from the improved source characteristics of fourth generation synchrotrons such as MAX-IV, ESRF-EBS and the upgraded APS. I will discuss how these approaches provide insights into the hierarchical structure of bone and of osteoderms from lizards.

In the case of bone (1-5), we investigated the lacuno-canalicular network that houses bone cells, osteocytes, *within the mineralized bone matrix (1, 2, 5). Very high resolution 3D tomography in the form of holotomography allowed mapping the lacunae and the few-hundred nm thick canaliculi (5) revealing the presence of canalicular junctions in the network. Ptychography with <100 nm 3D resolution further reveals details of the peri-lacunar region and also provides information on the mineralization of lacuno-canalicular network upon cell death. Using X-ray diffraction and fluorescence CT revealed that the characteristics of bone biomineral depends on localization with human osteonal bone (3, 6) indicating that the exact biological context should be considered when studying bone structure.*

I will further discuss findings on lizard osteoderms. We studied osteoderms, bony scales in the skin, of species presenting an additional capping layer known to be more mineralized than the bone base of the osteoderm (7). We find that the stiff capping layer reaches mechanical properties similar to those of enamel. The crystallites are enlarged compared to bone but, in contrast to both bone and enamel, are almost untextured. These results indicate that osteodermal capping tissues can possess surprisingly different structures with significantly enhanced mechanical properties but seemingly without the archetypical texture known from very stiff biominerals like enamel.

Engineering Proteins and Peptoids to Direct and Accelerate Calcium Carbonate Nucleation and Growth

Mingyi Zhang[1], Ying Chen[1], Fatima Davila-Hernandez[2,2], Biao Jin[1], Harley Pyles[2,2], Zheming Wang[1], Timothy Huddy[2,2], Shuai Zhang[1,2], David Baker[2,2], Jinhui Tao[1], Chun-Long Chen[1,2] and James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

The extensive deposits of $CaCO_3$ generated by marine organisms constitute the largest and oldest CO_2 reservoir on the planet. These organisms utilize macromolecules, like proteins, to facilitate the nucleation and growth of carbonate minerals, serving as effective agents of CO_2 sequestration. However, despite the opportunity mineralization presents for extracting anthropogenic CO_2 from the environment, neither the precise mechanisms behind this process nor the design principles required to create potent modulators of carbonate mineralization are known. Here we report on two related research efforts to design proteins and protein-like molecules that direct and accelerate $CaCO_3$ nucleation and growth: one focused on amphiphilic peptoids that increase calcite growth rates by an order of magnitude, and another directed towards de novo design of proteins to template $CaCO_3$ nucleation. To understand the mechanism of growth acceleration by peptoids, we used: 1) in situ AFM to measure *the growth rates, roughness, fluctuations and critical lengths of atomic steps on calcite as a function of peptoid sequence, supersaturation, and* Ca^{2+}:CO_3^{2-} *ratio, 2) 3D AFM to probe the effect of peptoids on interfacial solution structure, and 3) liquid state NMR to determine their impact on desolvation and deprotonation rates. The results show that growth acceleration comes primarily from enhanced deprotonation of* HCO_3^- *combined with an increase in step roughness and step-edge fluctuations, as well as disruption of the interfacial hydration structure. To create proteins that template* $CaCO_3$ *nucleation, we designed helical repeat proteins displaying periodic, planar arrays of carboxylates and used in situ TEM and FTIR to investigate their effect on nucleation. The results show that both protein monomers and protein-*Ca^{2+} *supramolecular assemblies directly nucleate nano-calcite with non-natural {110} or {202} faces while vaterite, which forms first in the absence of the proteins, is bypassed. These protein-stabilized nanocrystals then assemble by oriented attachment into calcite mesocrystals. We find further that nanocrystal size and polymorph can be tuned by varying the length and surface chemistry of the designed protein templates. Taken together, these two studies provide a potential route to design of effective synthetic proteins and biomimetic polymers for removal of* CO_2 *from the environment via enhanced mineralization.*

9:30 AM *PM01.03.02
Witnessing the Birth of Crystals by Laser-Induced Nucleation *Andrew J. Alexander; The University of Edinburgh, United Kingdom*

Nucleation of solid crystals from liquids is a process of significant value in many areas of materials science. The underlying mechanisms are not well defined, mostly due to the stochastic nature of nucleation and the putative small size of a critical nucleus. Laser-induced nucleation is one method that has enabled us to study the birth of crystals. In this talk, I will summarize our latest results from studies using both non-photochemical laser-induced nucleation (NPLIN) and optical-trapping induced crystallization (OTIC). In particular we will show that nucleation of simple inorganic salts and small organic molecules from aqueous solution, using nanosecond laser pulses, is preceded by formation of small gas bubbles, which can be persistent for milliseconds before rapid crystal growth. We will illustrate the use of NPLIN to control nucleation of anhydrous crystals, and discuss possible mechanisms for control of polymorphism via laser polarization. Finally, we will elucidate the involvement of small, concentrated nanodroplets of solute in the nucleation of amino acids from aqueous solutions.

10:00 AM BREAK

10:30 AM PM01.03.03
Branched Polymeric Prenucleation Assemblies Initiate Calcium Phosphate Precipitation *Ieva Goldberga[1], Ertan Turhan[2], Christopher Pötzl[2], Waldemar Keil[2], Jean-Michel Guigner[1], Martin Hassler[2], Herwig Peterlik[2], Dennis Kurzbach[2] and Thierry Azais[1]; [1]Sorbonne Université, France; [2]University of Vienna, Austria*

The formation of crystalline calcium phosphate (CaP) has recently gained ample attention as it does not follow the classic nucleation-and-growth mechanism of solid formation.[1] Instead, the precipitation mechanisms can involve numerous intermediates, including soluble prenucleation species such as clusters, oligomers or dense liquid phases in presence of organic additives. However, structural characteristics, stability, and transformation of such solution-state precursors remain largely undisclosed. Recently our group reported that the proportion and lifetime of CaP prenucleation clusters is determined by simple synthesis parameters, namely ionic concentrations, pH and ionic strength.[2] Moreover, our consortium has shown the strength of NMR approaches to provide structural and dynamical information at the molecular scale. As an example, we have shown through in situ ^{31}P *NMR that simulated body fluid (SBF) is subject to the formation and aggregation of PNC for 24h after its preparation[3] and that dissolution dynamic nuclear polarization (dDNP) combined with* ^{31}P *NMR is a suitable technique to monitor fast precipitation processes (< 20 s) and to access to the size and dynamical parameters of PNC, such as formation,* *aggregation and exchange rates.[4]*

In this communication, we report a detailed and comprehensive characterization of the sequential events involved in calcium phosphate crystallization starting from the very early prenucleation stage. We integrated an extensive set of time-resolved methods, including NMR, SAXS, DLS, cryo-TEM, and calcium-potentiometry to show that CaP nucleation is initiated by the transformation of "branched" polymeric prenucleation assemblies into amorphous calcium phosphate spheres. Such a mineralization process starts with the spontaneous formation of so-called nanometric prenucleation clusters (PNC) that later assemble into those soluble branched polymeric assemblies without calcium ion uptake from the solution. Importantly, these macromolecular species are invisible to many techniques (NMR, turbidity, calcium-potentiometry) but can readily be evidenced by time-resolved SAXS and cryo-TEM. We find that the branched polymeric assemblies constitute the origin of amorphous calcium phosphate (ACP) precipitation through an unexpected process: spontaneous dissolution is followed by local densification of 100-200 nm wide domains leading to ACP spheres of similar size. Hence, our study demonstrates that ACP nucleation does not necessarily proceed through simple aggregation of prenucleation clusters. Finally, we show that the timing of the successive events involved in the CaP mineralization pathway can be kinetically controlled by the Ca^{2+}/Pi molar ratio, such that the lifetime of the soluble transient species can be increased up to hours when decreasing it.

Revisiting Thermodynamic Arguments and Cystallization Pathways to Understand the Phase Stability of Oxide Nanocrystals

Edson R. Leite[1,2], Icamira C. Nogueira[3], Ricardo Castro[4] and Cleocir J. Dalmaschio[5];
[1]Universidade Federal de São Carlos, Brazil; [2]Brazilian Center for Research in Energy and Materials, Brazil; [3]Universidade Federal do Amazonas, Brazil; [4]Lehigh University, United States; [5]Universidade Federal do Espirito Santo, Brazil

Colloidal nanocrystals of functional materials have been a significant focus on materials chemistry and synthesis for academic and industrial scientists and engineers over the past few decades. By studying nanocrystal synthesis through a colloidal approach, we can gain new insights into the nucleation and growth process and its phase stability. In this context, we use a case study focused on synthesizing Zirconium oxide (ZrO_2) nanocrystals to demonstrate how a thermodynamic surface energy analysis can elucidate the phase stability at the nanoscale. ZrO_2 is an excellent model material for this investigation due to the well-documented crystallization process involving amorphism and polymorphism in the existing literature. We illustrate that the crossover points and regions of phase stability can be influenced by altering the surface energy of the phases. <div>Moreover, we offer a plausible explanation for the correlation between the reaction pathway and the variation in surface energy by examining the ability of organic ligands to coat the surface of the formed nanocrystal. Additionally, we introduce a new criterion for phase formation based on chemoselectivity. We suggest that chemoselectivity could be determined by factors such as the acid dissociation constant (pKa) of the ligand and other molecules present in the reaction medium, the ligand's conformational entropy, and the degree of ligand-ligand packing on the nucleus surface.</div>

Molecular Materials Nucleation from Solution—Insights from Seeded and Unseeded Atomistic Simulations

Up-to-date as of November 14, 2024

Matteo Salvalaglio; University College London, United Kingdom

Nucleation, the initial step in forming crystalline materials from solutions, is a rate-determining process that dictates the structure of materials and thus has a crucial impact on many of their emergent properties. Atomistic simulations directly resolve the hardly accessible length scales at which nucleation develops, providing valuable insight into its mechanisms and, ideally, enabling the prediction of nucleation rates as a function of the environment and the conditions in which the process takes place.

Nevertheless, the inherent finite size of atomistic simulations can lead to simulated emergent behaviours that differ substantially from their macroscopic counterpart. Similarly, the fine resolution of atomistic simulation often limits the timescales accessible via brute force approaches, even under the effect of large driving forces. Recently, significant strides have been made in developing molecular simulation methods to bridge some of these gaps, enabling computational studies of nucleation processes in relatively complex systems.[1]

In this talk, I will present complementary advances aimed at i. obtaining information on nucleation mechanisms from unseeded simulations using enhanced sampling and machine learning methods[2,3] *and ii. efficiently estimating the nucleation rate of complex materials such as molecular crystals or dense (bio)polymeric liquid phases within a classical nucleation theory framework building on the theoretical understanding of the thermodynamics of nucleation in confined volumes.*[4,5]

Results will include systems of increasing complexity, from simple colloidal crystals to complex organic materials such as glutamic acid and olanzapine polymorphs, passing through sodium chloride precipitation in aqueous environments. Open challenges, questions, and current limitations of the methods presented will be critically discussed.

Understanding Crystallization from First Principles *Pablo M. Piaggi[1,2]; [1]CIC nanoGUNE, Spain; [2]Ikerbasque, the Basque Foundation for Science, Spain*

Crystallization is a process of key importance for many modern technologies, and it also plays a central role in geological, planetary, and climate sciences. Over the years, molecular dynamics simulations have proved essential to complement experiments, and to give insight into crystal nucleation and growth mechanisms. However, such simulations frequently rely on simple empirical models for the interatomic interactions, which fail to describe accurately the properties of the system under study, or cannot capture important physical processes, *such as the cleavage and formation of chemical bonds. An alternative to this approach are first principles, or ab initio, molecular dynamics simulations based on forces calculated on-the-fly from ground-state quantum-mechanical electronic-structure calculations. Although highly accurate, ab initio molecular dynamics come at a great computational cost, an issue that hampered their application to study crystallization for several decades. Recent advances in artificial intelligence have allowed for the construction of ab-initio machine-learning interatomic potentials, a ground-breaking simulation tool which decreases the cost of ab initio molecular dynamics by more than three orders of magnitude and also provides access to systems with millions of atoms. In this talk, I will provide an overview of this simulation methodology, and show a variety of applications, including crystallization from the bulk, at interfaces, and in solution. In particular, I will present results for the calculation of homogeneous ice nucleation rates from first principles [1], some insights into the formation of ice at the surface of the mineral feldspar [2], and the development of a force field for calcite and calcium carbonate aqueous solutions.<div> </div><div>[1] Piaggi, Weis, Panagiotopoulos, Debenedetti, and Car, Proc. SESSION PM01.04: Crystallization Mechanism II
Session Chairs: Ling Li and Benjamin Palmer
Tuesday Afternoon, December 3, 2024
Sheraton, Second Floor, Liberty B/C

1:30 PM *PM01.04.01

***The Unique and Multifaceted Impact of Tautomerism on Biogenic Crystallization** Jeffrey D. Rimer; University of Houston, United States*

There is growing interest in elucidating the role(s) of isomers as modifiers of crystal nucleation and growth. In this presentation, we will discuss several examples of biogenic crystals where the solute molecule is a tautomer (structural isomer) exhibiting highly unusual crystallization behavior in comparison to conventional systems where the modifier is a foreign species.[1] We recently demonstrated for ammonium urate crystallization (cetacean renal stones) that the minor tautomer, which is non-native to the crystal structure, functions as a crystal growth inhibitor that can fully suppress crystal growth at certain supersaturation and solution pH, and can also lead to the introduction of defects that impact crystal morphology and physical properties (e.g., rate of dissolution).[2] We have also shown through combined experiments[3,4] and simulations that analogues of urate (i.e., molecular imposters) function in a distinct manner with roles that vary from crystal growth inhibitor to promoter. Here we will discuss how molecular imposters and the minor tautomer cooperatively impact crystal growth using a combination of techniques that include in situ atomic force microscopy and microfluidics to track growth in real time at molecular and macroscopic length scales, respectively. Several of the modifiers selected for these studies have been identified from metabolomic analysis of biological samples. In a broader sense, we have observed similar trends for other tautomeric biogenic crystals (e.g., guanine, hypoxanthine) and synthetic molecules that are used as therapeutics for human diseases (e.g., allopurinol). We will briefly discuss each of these systems, outlining the effects of tautomerism that are seemingly general and those that are specific to each system. Knowledge gained from these studies provides insight into the putative role(s) of isomers in biological environments as well as strategies for designing modifiers in applications that benefit from crystal engineering.

2:00 PM PM01.04.02
Photothermal Conversion-Enabled Temperature Modulation for the Growth of Complex Polymorphic Architectures of Calcium Carbonate *Boning Shi[1], Lifu Zhang[2], Zeda Yang[1], Wen Shang[1] and Tao Deng[1]; [1]Shanghai Jiao Tong University, China; [2]Rensselaer Polytechnic Institute, United States*

As a highly efficient and eco-friendly heat generation approach, the photothermal conversion process has been applied to many important areas such as evaporation, desalination, and medical treatments. In this study, we explored the application of photothermal conversion in the synthesis of complex polymorphic calcium carbonate ($CaCO_3$) structures. We chose $CaCO_3$ as our model system for this study due to the significant role in biomineralization. Furthermore, the temperature-dependent growth property of different $CaCO_3$ polymorphic phases (calcite, aragonite and vaterite) also provides potential for this study exploration. By leveraging quick temperature change enabled by photothermal conversion, we achieved the stepwise temperature modulation between "cold" and "hot" and successfully fabricated architectures composed of multiple polymorphic phases, specifically aragonite@calcite, calcite@aragonite, and calcite@aragonite@calcite. The coexistence of these distinct polymorphic phases within the same architecture was confirmed through confocal Raman micro-spectroscopy analysis. Furthermore, substrate modification was achieved via patterned self-assembled monolayers using soft lithography, which allowed the growth of arrays of complex polymorphic $CaCO_3$ structures on the surface. This study provides an efficient and promising methodology for thermally controlling of the growth of materials with desired multi-phases and multi-functionalities. The ability to manipulate the phase composition and spatial arrangement of calcite carbonate on a single substrate provides new opportunities for developing multifunctional materials with both tailored properties and at designated positions. This study may potentially impact various fields, including biomineralization, photonic materials, and industrial fabrication processes.

2:15 PM PM01.04.03
Solvothermal Synthesis of Soluble, Surface Modified Hybrid Metal Oxide Nanocrystals *Peter W. Dunne[1], Christian Heinekamp[1,2], Clodagh R. Nerney[1], Aoife Kavanagh[1], Andrew S. Bathe[1], Adrián Sanz Arjona[1,3] and Annie Regan[1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Bundesanstalt für Materialforschung und – prüfung (BAM), Germany; [3]University of Copenhagen, Denmark*

Metal oxides, such as titanium and tin oxide, exhibit an array of properties which have made them integral to many applications, from the mundane, to the exotic. Both titanium oxide and tin oxide have long been exploited as pigments, for example, later becoming known as the prototypical photocatalytic and gas-sensing materials, respectively. They also find extensive use in glass-coatings for energy efficient and self-cleaning windows, and as components in photovoltaic devices, batteries, and more. While many of their applications require these materials to be in the form of coatings or thin films, as with many oxides titanium and tin oxide are generally intractable *solids, requiring the development of sometimes complex and/or expensive deposition methods, such as CVD or PVD for the generation of coatings. Alternative approaches such as sol-gel methods are generally cheaper and more robust, but come with a lack of control. An increasingly popular alternative to these methods is the generation of solution processable metal oxide nanoparticles. This approach offers exceptional flexibility, both chemically — simple wet-chemical techniques permit the synthesis of a wide range of compositions — and physically, as dispersions of preformed colloidal nanocrystals may be used to coat flat substrates, irregularly shaped objects or may be used to generate supported catalysts or composites and gels.*

Here we report the production of highly dispersible (doped) titanium and tin oxide nanocrystals by post-synthetic modification of hydrous oxide precursors by solvothermal treatment with trifluoroacetic acid. Solvothermal treatment of amorphous titania in trifluoroacetic acid yields highly dispersible surface modified anatase phase nanoparticles. The reaction of the amorphous precursor with trifluoroacetic acid led to the crystallisation and growth of anatase phase titania, initially by an internal rearrangement yielding 4.5 nm particles, which undergo further growth at higher temperatures and longer reaction times by interparticle fusion. In addition to inducing crystallisation of the anatase phase, the solvothermal treatment in trifluoroacetic acid results in the complete coordination of all available titanium sites by trifluoroacetate leading to complete surface coverage of the obtained anatase nanoparticles, with almost complete surface titanium ions coordinated by trifluoroacetate groups. This surface modification renders the obtained hybrid nanoparticles highly dispersible in polar aprotic solvents such as acetone. The incorporation of dopant metals does not compromise the particle properties, making this procedure very promising for the many and varied applications in which the use of solution processable nanoparticles with tuneable optoelectronic properties are critical.

Interestingly, while applying this approach to tin oxide also yields dispersible nanocrystals, it has been found that extended solvothermal treatment of hydrous tin oxide in trifluoroacetic acid leads to the emergence of an apparently new tin oxide phase, exhibiting a diffraction pattern consistent with the braking of the 4_2 screw axis symmetry of the rutile structure. This new modification of the rutile structure is tentatively attributed to fluorination of the tin oxide nanocrystals under solvothermal conditions.

Material Structures Form via Particle Assembly Dongsheng Li; Pacific Northwest National Laboratory, United States

Particle assembly has been recognized as a common pathway for forming material structures, such as superlattices. Understanding particle interactions is necessary to control material structures and the corresponding properties, e.g. electronic and optoelectronic performance of devices based on nanoparticle-superlattices. However, a key challenge remains to understand nanoparticle interactions: defect self-elimination during the assembly processes, especially with anisotropic NPs which cause rotational dynamics and torques. We investigate the role of ligands and electrolytes in solution during nanoparticle assembly and defect self-elimination processes by integrating liquid phase transmission electron microscopy, continuum theories, and molecular dynamics simulations. We find that electrolytes and ligands can determine the particle separation depending on the conditions. Ligand interactions can dominate over the forces from Brownian motions and van der Waals interactions. Unbalanced forces and torques induce defect self-elimination. The mechanistic understanding will further enable the design and fabrication of defect-free superlattices and those with tailored defects via the assembly of anisotropic particles.

3:30 PM *PM01.04.05

Advancing Biomineralization Research with Liquid Transmission Electron Microscopy *Liza-Anastasia DiCecco[1,2], Ruixin Gao[3], Jing Zhang[1], Eli Sone[3] and Kathryn Grandfield[1]; [1]McMaster University, Canada; [2]The Pennsylvania State University, United States; [3]University of Toronto, Canada*

Biomineralization is a crucial process in the formation and maintenance of hard tissues and the integration of biomedical devices, yet its mechanisms remain elusive due to the limitations of traditional electron microscopy techniques which often involve static, dehydrated, or frozen samples. This talk will present new liquid transmission electron microscopy (liquid-EM) methodologies that overcome these limitations by enabling the visualization of mineralization processes in their native liquid environments. Thin-film enclosures and flow cells were used to explore collagen mineralization in the presence of a calcium phosphate and polyaspartic acid solution, capturing the progressive crystallization of mineral particles and eventual attachment along collagen fibrils. The findings, which capture non-classical crystallization in real time, align well with findings using cryo-TEM. Further, a new method combining the nanofabrication of titanium lamellae by focused ion beam microscopy with in situ liquid-EM to investigate calcium phosphate-titanium interfacial mineralization will be introduced. This technique revealed multiphasic CaP particles nucleating, adhering, and assembling on and around titanium surfaces. This highlights the potential of liquid-TEM to explore nanoscale interactions between biomaterials and liquids as a platform for enhancing implant osseointegration and developing new treatments for mineralized tissue diseases. Other applications of advanced electron microscopy for understanding biomineralization will be highlighted.

Mechanistic Insights into the Nucleation and Growth of Bimetallic Gold Nano-Stars *Daniela Dobrynin, Ivan Zlotver, Iryna Polishchuk, Lucas Khurts, Alexander Katsman, Alejandro Sosnik and Boaz Pokroy; Technion-Israel Institute of Technology, Israel*

Gold nanoparticles (GNPs) are renowned for their chemical and physical stability, reproducibility, ease of modification, and biocompatibility. Their synthesis through various methods allows for the creation of a wide range of structures, morphologies, porosities, and shapes. Bimetallic nanoparticles (BMNPs) represent an advanced class of nanostructures with enhanced technological properties, which vary based on their size, shape, composition, and structure. In particular, gold and silver-based BMNPs are highly valued for their superior sensitivity as surface-enhanced Raman scattering (SERS) substrates, benefiting from the synergistic enhancement of the properties of both elements. The combination of gold with silver and silver chloride (Ag-AgCl) has demonstrated superior absorbance and localized surface plasmon resonance (LSPR) properties compared to Ag-AgCl alone, along with increased stability and reproducibility, making them ideal for use in catalysis and sensing applications.

Gold nanostars (GNSs) are extensively studied for their applications in biosensing, bioimaging, and photothermal therapy, due to their enhanced local optical and electromagnetic properties, particularly in their star-like protrusions. A simple, rapid, and efficient method to produce GNSs is a one-pot, seedless, bottom-up synthesis. This method involves the reduction of $HAuCl_4$ and $AgNO_3$ by ascorbic acid (AA) under acidic conditions, avoiding the use of toxic materials. The final morphology of GNSs depends on several factors, including the gold-to-silver ratio, reaction time, pH, and the amount of AA. However, the exact mechanism of GNS synthesis using $HAuCl_4$, $AgNO_3$, and AA is not yet fully understood. It is hypothesized that gold and silver distribute evenly throughout the particles, forming an alloy composition.

In our study, we investigated the complex process of nucleation and growth of these bimetallic GNSs. We focused on the effects of temperature and the timing of silver ion introduction on the morphology, size, particle concentration, stability, and optical properties of the BMNPs. Chemical analysis was conducted using high-angle annular dark-field scanning transmission electron microscopy (HAADF STEM) and 3D tomography in a high-

resolution transmission electron microscope (HR-TEM), providing detailed insights into the synthesized GNSs. Additionally, synchrotron high-resolution powder X-ray diffraction and other experimental data helped us propose a nucleation and growth mechanism for GNSs. We developed a theoretical model and calculated the energy barriers for nucleation and the energy required for particle growth.

Diffusion Controlled Growth of $CsPbBr_3$ Nanocrystals Using a Liquid-Liquid Interface *Sohom Chandra and Yitong Dong; The University of Oklahoma, United States*

Lead halide perovskite nanocrystals have emerged as promising semiconductor materials due to their size-tuneable emissive properties, solution processability, and high quantum yields. The controlled synthesis of these nanocrystals is an extensive area of research and allows one to obtain precise sizes and optical properties. However, the ionic nature of these nanocrystals causes instantaneous formation, disfavouring the monitoring of continuous crystal growth and, consequently, its regulation. It is important to reduce the crystal growth kinetics to monitor the growth kinetics. To achieve this; a diffusion-controlled growth approach has been utilized in this work. A confined liquid-liquid (L/L) interface is used to grow $CsPbBr_3$ nanocrystals, and the slow diffusion of ions into the interface allows continuous growth to be monitored using in-situ photoluminescence (PL). Altering the precursor ions' concentration reduces the nanocrystal growth rate, supporting the diffusion-controlled growth kinetics. Moreover, we also demonstrate the regulation of the growth kinetics by tuning the diffusion field and the size of the L/L interface.Through this study, insights on the growth kinetics can be obtained for $CsPbBr_3$ without the use of any tight binding ligands, therefore providing alternate routes to modify the crystal growth.

Corrosion Resistant Copper Metal−Organic Decomposition Ink *Jun Zhang and Shenqiang Ren; University of Maryland, United States*

In recent years, the demand for materials that can withstand extreme environments, like those in energy conversion processes and harsh industrial applications, has increased. Copper is known for its excellent electrical and thermal conductivity, but it often suffers from oxidation and corrosion under such conditions. Traditional methods to improve copper's corrosion resistance include alloying or surface coatings. These methods can reduce copper's conductivity or may not be durable in extreme conditions. Additionally, traditional copper nanoparticle synthesis requires oxygen-free glove boxes, which significantly increases production costs.
We have developed a new method by adding reductive organic small molecules to assist the decomposition and reduction of copper precursors, allowing the reaction to occur in air. These molecules also control the morphology and crystal facet development of copper nanoparticles during Ostwald ripening and their surface energy. Our study shows that the reductive molecules form a uniform passivating layer on the copper surface, greatly enhancing its stability and conductivity under acidic and basic conditions. The results provide a clear

understanding of how organic molecules control copper nanoparticle synthesis. This opens new paths for developing advanced copper-based materials for high-performance applications in extreme environments.

A Possible Biomineralized Light Guiding Structure in the Ossicular Skeletons of Starfish Protoreaster Nodosus

Liuni Chen[1], Hannah Feldstein[2], Ting Yang[2], Chenhao Hu[1], Hongshun Chen[3], Emily Peterman[4], Carla Slebodnick[5], Mathias Kolle[2] and Ling Li[1]; [1]University of Pennsylvania, United States; [2]Massachusetts Institute of Technology, United States; [3]Northwestern University, United States; [4]Bowdoin College, United States; [5]Virginia Tech, United States

Skeletal elements at the distal end of each arm ray known as terminal plates in Starfish, Protoreaster nodosus, possess truncated cone-shaped structures embedded within the rather stochastic porous stereom. Previous works have shown some starfish species possess compound eyes at the arm tip and are capable of image formation. In this study, we hypothesize that the unique biomineral-based structures at the arm tip serve as Light Guiding Structures (LGSs) for photoreception purposes in addition to their mechanical protection of the underlying tissue. Combining quantitative three-dimensional (3D) structural characterization along with X-ray diffraction (XRD) and electron backscatter diffraction (EBSD) measurements, we showed that the entire terminal plate, though with an irregular micro-lattice, diffracted as a single crystal calcite. The channeling of light within individual LGS was achieved by total internal reflection. The radial arrangement of LGSs allowed the guided light to converge at the center of the interior cavity beneath the terminal plate. Ray-trace simulation on a single LGS and optical experiment on the entire terminal plate confirmed the light transmitting and converging capability of the LGS assembly. Our findings may provide another example, in addition to brittle stars, blue-rayed limpet, and certain chiton species, of how organisms modify their biomineralized structure to achieve multifunctionality, specifically, serving dual optical-mechanical roles.

PM01.05.03

Piezoelectricity in Chitosan—How Does Crystallization Influence Piezoelectric Response?

Sofia Papa[1], Margherita Montorsi[2], Francesco Greco[1,3,4] and Massimiliano Labardi[2]; [1]Scuola Superiore Sant’Anna, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]Sant’Anna School of Advanced Studies, Italy; [4]Institute of Solid State Physics, Graz University of Technology, Austria

In recent years, there has been a growing interest in sustainable technology, which has led to increased attention to biopolymers due to their diverse physical and chemical properties. Chitosan, the second most abundant natural semi-crystalline polymer after cellulose, stands out as a low-cost, bioderived, and biodegradable material with significant potential for biomedical engineering, pharmaceuticals, and environmental science applications. Recent studies have indicated that a particular crystal polymorph of chitosan may possess notable electromechanical properties [1], suggesting the possibility of using it as an active piezoelectric material in flexible device design [1,2]. However, achieving piezoelectric performances comparable to those of classical fully crystalline piezoceramics is challenging for biopolymers due to their semi-crystalline nature, making it difficult to create functional piezoelectric devices.

Over the past decade, significant efforts have been directed towards enhancing the crystallinity and piezoelectricity of biopolymers. This study takes a step further by focusing on enhancing chitosan's crystal formation and investigating the piezoelectric behavior of these crystals. A unique approach was taken, using a water solution of chitosan and formic acid, and studying the crystallization process on the surface of chitosan spin-coated nanofilm, induced by thermal annealing and NaOH neutralization or by their combination. NaOH, known for its ability to induce chemical changes and the formation of crystalline phases by promoting stronger chitosan interchain hydrogen bonding, was a key component of this innovative method [3,4]. The study also aims

to explore whether different treatments lead to distinct chitosan crystal polymorphisms, possibly correlated with different piezoelectric responses [5]. The surface topography of the spin-coated chitosan films was examined using Atomic Force Microscopy (AFM), and the piezoelectric responses were measured using the Piezo response mode of the same instrument (PFM). This mode enables the local characterization of piezoelectricity at the nanoscale, allowing for accurate discrimination between crystalline and amorphous responses. Additionally, the instrument is used to characterize local dielectric properties, which are expected to differ significantly between the crystal and amorphous phases. The nanofilms' structural properties and crystalline form are analyzed using additional techniques such as transmission electron microscopy (TEM) and small-angle X-ray scattering (SAXS), respectively.

AFM topographical characterization revealed the presence of distinct ellipsoidal-shaped crystals even without any post-fabrication treatment. After neutralization treatment, these crystal structures numerically increased, while with the annealing treatment, no topographical effects indicating the formation of crystals are observed. A first, preliminary, assessment of the films piezoelectric response confirms the presence of a significant signal on the neutralized samples with respect to the not neutralized or thermal annealed ones.

The study will serve as a foundation for optimizing chitosan crystallinity, a crucial step in enhancing its piezoelectric output in macroscopic devices. The potential implications of this research are far-reaching, with the possibility of revolutionizing the field of sustainable technology and opening new avenues for the use of biopolymers in piezoelectric applications.

Polymer-Mineral Interaction Influences the Mineralization of Hydroxyapatite in Agarose and Polyacrylamide Hydrogels

Yongjian Ma, Jiheon Kwon, Rui Ji and Rosa M. Espinosa-Marzal; University of Illinois at Urbana-Champaign, United States

Bone mineralization relies on the interaction between collagen and mineral phases like hydroxyapatite (HAP) to control bone growth and multi-scale hierarchical structure. Urged by the increasing need for bone defect repairs, tissue engineering searches for biocompatible materials and synthesis protocols to assist and enhance repairs. One potential avenue is to use hydrogels as the organic scaffolds to control nucleation and growth of bone-like minerals, lowering energy barriers and directing crystal assembly. Here, two biocompatible polymers, polyacrylamide and agarose, were selected for the mineralization of hydroxyapatite, and the mineralization kinetics was investigated in the presence of calcium carbonate to simulate early bone formation conditions, and its absence. The mineralization process is characterized by FTIR, XRD, and SEM to confirm the chemical composition and morphology transformation of the newly formed mineral. The physical properties of the two materials are measured by TGA, DMA, and Rheology to investigate the mechanical strength variation caused by mineralization process. The results of this work show that agarose and polyacrylamide lead to different polymer-mineral interactions, which influence the stabilization of carbonate and phosphate precursors and thereby the onset of the crystallization of hydroxyapatite, and more so in the presence of carbonate. Under all conditions, amorphous calcium carbonate and hydroxyapatite are non-congruent, and amorphous calcium phosphate forms as a precursor. This distinct interaction between the mineral and agarose vs. polyacrylamide leads to different microstructures and thereby mechanical response. In polyacrylamide, the increase in storage and loss modulus

indicates there is a transition towards more brittle behavior, leading to an increased stiffness and reduced ductility. On the other hand, agarose hydrogels display enhanced storage and loss moduli as well as thermal stability upon mineralization. In addition, we propose a potential origin for the faster crystallization of HAP via ACP clusters. This research not only advances our understanding of the influence of mineral-polymer interactions on hydroxyapatite mineralization, but also provides new opportunities for designing biomaterials for specific applications.

Elucidating Guanine Nucleation Pathways *Shashanka S. Indri; Ben-Gurion University of the Negev, Israel*

Highly reflective molecular crystals are used to produce a plethora of optical phenomena in animal coloration and vision.[1,2] Guanine is the most common biogenic molecular crystal, formed from planar, H-bonded molecular layers, which are π*-stacked along the a-axis. While this material has been intensively studied over the last decade, little is known about the fundamental chemical mechanisms underlying the crystal formation in biological systems.*

Recent studies have provided new insights on guanine formation in developing white widow spiders[3], indicating a 'non-classical' crystallization mechanism, involving a progressive ordering of states. Wagner et. al. also showed that organisms use macromolecular sheets to direct the morphology of plate like guanine crystals[4]. However, the complexity of studying nucleation in-vivo limited the scope of the studies largely to morphological conclusions and precluded a detailed mechanistic rationalization of the nucleation process. We were thus motivated to devise in-vitro crystallization experiments to probe guanine nucleation in detail. Cryo-TEM imaging of crystallization solutions at high pH, vitrified at different stages of crystallization, reveals that prior to nucleation, guanine assembles into 1-dimensional fibers. These fibers consist of π*-stacked guanine molecules (as indicated by a single diffraction peak at 3.2 Å in SAED), where the stacking is oriented along the long axis of the fibers. Over time, the fibers coalesce into bundles via lateral attachment, from which a nanoscopic guanine crystal (exhibiting faceting and a characteristic chevron twinning morphology[5]) nucleates. Synchrotron PXRD patterns obtained from droplets of similar crystallization solutions exhibit a single highly intense (100) peak at early crystallization stages. This is indicative of the presence of molecular ordering only along the* π*-stacking direction, in agreement with cryo-TEM results. Subsequently, additional peaks appear, corresponding to the emergence of intermolecular bonding along the H-bonded plane. In-situ Raman spectroscopy shows the gradual emergence of different low frequency phonon peaks during progressive ordering of molecules during crystallization. These spectral changes are currently being assigned and rationalized by DFT calculations. We propose that guanine crystallization follows a non-classical mechanism both in-vitro and in-vivo, which involves the formation of* π*-stacked assemblies in solution, which undergo attachment and reorientation into a guanine nucleus with 3-dimensional ordering. A comprehensive understanding of guanine nucleation and growth holds promise for designing organic crystalline materials with tailored morphologies.*

Do Nucleators or Processing Methods Affect the Thermal Transport in RacoPP?

Ina Klein, María E. Marroquin Lacayo, Thomas Blesch, Sabine Rosenfeldt, Patrick Länger, Stefan M. Rettinger, Hans W. Schmidt and Markus Retsch; Universität Bayreuth, Germany

Polypropylene (PP) and its copolymers are widely used plastics due to their low density, good mechanical properties, thermal stability, and cost effectiveness.[1] The properties of PP or propylene-ethylene random copolymer (racoPP) can be further enhanced by adding substituted 1,3,5-benzenetrisamides (BTAs), which are an excellent and versatile family of nucleating agents. Their influence on the melt temperature and enhancement of optical and mechanical properties are intensively studied and desired effects.[2-4]
In contrast, the thermal conductivity is commonly desired independent of factors such as processing conditions or nucleation rate. However, the polymer crystal structure is affected by processing and the addition of nucleating agents, rendering variations in thermal conductivity likely.[5] The utilization of PP copolymers in electronic housings, automotive components, or food packaging necessitates an understanding of the thermal transport properties. Therefore, we investigate how the presence of an efficient BTA nucleator (N,N',N''-tris(iso-pentyl)benzene-1,3,5-tricarboxamide) affects the thermal diffusivity of injection-molded and hot-pressed racoPP using Lock-In Thermography and Light Flash Analysis. It is compared with a structurally similar BTA additive that has a lower nucleation efficiency (N,N',N''-tris(n-butyl)benzene-1,3,5-tricarboxamide), and with no additive at all. By supplementing this data with XRD, SAXS and IR spectroscopy results, we link our thermal characterizations to the polymer crystallinity and structural anisotropy. Ultimately, we assess whether BTA nucleators or processing methods affect the thermal transport in racoPP.

Advanced Structural Characterization of $BaSn(OH)_3(OOH)(OO)$ Nanoclusters and $BaSnO_3$ Nanoparticles

Derik T. Machado[1,2], Naga V. Mogili[2], Tarcisio M. Perfecto[2] and Edson R. Leite[1,2]; [1]Univerdade Federal de São Carlos, Brazil; [2]Laboratório Nacional de Nanotecnologia, Brazil

Barium stannate ($BaSnO_3$) is a cubic perovskite with n-type semiconductor characteristics, high optical transparency and electronic mobility, which is used as an essential component of optoelectronic devices such as solar cells or gas detectors.[1–3] The synthesis and proper crystallization of the perovskite phase requires harsh conditions, such as elevated temperature (>1000 °C), pressure, or are time consuming, which normally result in samples with low control of the particle's size distribution, stoichiometric and crystallinity.[2–4] A low-temperature synthesis route of BaSnO3 nanoparticles has been reported and can overcome those problems of classical synthesis approaches.[1] A crystalline molecular cluster identified as $BaSn(OH)_3(OOH)(OO)$ can be obtained by basic precipitation in a concentrated hydrogen peroxide solution.[1,5] This cluster has cubic structure with replacement of the oxygen atoms of the classical perovskite structure by $(OH)^-$, $(OOH)^-$ and $(OO)^-$ groups, and can also be converted to the desired $BaSnO_3$ perovskite phase upon heating at temperatures as low as 300 °C.[1,5] When the molecular cluster is thermally treated it loses ~18% of its total mass by releasing H_2O and O_2 from the *decomposition of the $(OH)^-$, $(OOH)^-$ and $(OO)^-$ groups which causes a decrease in the parameters of the cubic network due to the contraction of the cell.*[1,5] *We treated this molecular cluster in vacuum at different temperatures (200-800 °C) and performed structural analyzes of the obtained materials by X-ray Diffraction (XRD) and transmission electron microscopy techniques such as Pair Distribution Function from Electron Diffraction (e-PDF).*[6] *Our data indicate that the crystalline molecular cluster presents amorphous features with short-range order radius of 1.3 nm. All heat-treated samples resulted in the formation of perovskite $BaSnO_3$ nanoparticles, including the one treated at 200°C, and have short-range order radius of 2.0 nm (200 °C), 2.7 nm (400 °C), 3.6 nm (600 °C) and 4.6 nm (800 °C).*

The Alignment of Silver Nanowires Under the Influence of Surfactant *Yewon Han and Ildoo Kim; Konkuk University, Korea (the Republic of)*

Silver nanowires are conventional material to make a thin sheet of conducting layer. There are many ways to process the nanowires, but the coat-and-dry is perhaps the most common technique. However, the evaporation of complex fluid usually accompanies the emergence of strong internal flow effect, which sometimes changes the deposition pattern. In this study, we report the spontaneous patterning of silver nanowires when the solution of silver nanowire includes surfactant. We simply coat a substrate with a solution of mixture of silver nanowire, surfactant, and water, and we let it dry by heating the substrate. Our visual inspection reveals that the dried pattern may be anisotropic depending on the surfactant concentration.

PM01.05.09

Investigating Intracrystalline Composition and Structure of Biogenic Guanine Crystals *Tali Lemcoff[1], Alexander Veber[2], Ljiljana Puskar[2], Yevgeny Rakita[1] and Benjamin Palmer[1]; [1]Ben-Gurion University of the Negev, Israel; [2]Helmholtz-Zentrum Berlin, Germany*

Organisms exhibit exceptional control over crystal nucleation, morphology, and the assembly of crystals into complex ultra-structures. While inorganic biominerals have been acknowledged for their remarkable material properties, such as superior damage resistance due to their composite structure, the composite nature biogenic organic crystals remains largely unexplored. It has recently been shown that biogenic guanine crystals are solid solutions in which guanine host crystals occlude mixtures of other purines (hypoxanthine and xanthine), without

significantly altering the crystal structure of the host.[1] *However, these dopants change the local structural properties of the crystals, resulting in the presence of nano-domains and defects which are important in dictating crystal formation, morphology, and molecular orientation. Our work focuses on utilizing synchrotron radiation characterization methods with nano-scale spatial resolution to reveal the local chemistry and structure of biogenic guanine crystals. Investigating the local composition, structure and textural properties of mature crystals may be used to retrospectively map the growth history of a crystal, e.g., to understand dynamic changes in the chemical environment of the growing crystal.*

The Formation Mechanism of Guanine Crystals in Snake Iridophores *Anna Praiz[1], Pierre-Yves Helleboid[2], Adrian Lutz[3], Avital Wagner[1], Alexander Upcher[1], Mariela Jorgelina Pavan[1], Devi Stuart-Fox[3], Athanasia Tzika[2] and Benjamin Palmer[1]; [1]Ben-Gurion University of the Negev, Israel; [2]University of Geneva, Switzerland; [3]The University of Melbourne, Australia*

Coloration in vertebrates is a complex phenomenon and plays an essential role in survival and communication. Snakes exhibit a range of vibrant colors and patterns through the interaction of light with pigments or reflective guanine crystals found within specialized color-producing cells (chromatophores) in the dermis. The formation and development of these chromatophores and their underlying optical materials remain unexplored. Our research shows striking similarities in guanine crystal formation mechanisms across phylogenetically distant species [1,2], supporting the existing hypothesis that macromolecular sheets within the crystal-containing vesicles universally act as templates for crystal growth [2]. We have conducted in vitro studies examining several factors that affect the biomineralization process. Our research adopts a bottom-up approach to gain insights into the composition and the mechanisms by which macromolecular templates guide the crystallization of guanine. The findings enhance our knowledge of the intricate mechanisms behind color-producing systems in animals, opening possibilities for developing biomimetic materials with tailored optical properties.

Low-Temperature Solid-State NMR Analysis of Polymer-Mediated Biomineral Formation Processes *Syrine Khaled; Sorbonne Université, France*

Crystallization is a subtle process governed by numerous physicochemical parameters involving two main events: nucleation and crystal growth. In biomineralization, the process of forming biogenic minerals, the onset of this process is critical as it influences the final crystal structure. Unlike the classical nucleation theory (CNT), which proposes nucleation through the formation of a critical size nucleus[1], recent studies have identified that biominerals formation may follow alternative routes termed non-classical nucleation and growth pathways that involve the formation of (meta)stable prenucleation species, such as ionic clusters, existing in equilibrium with free ions in solution.[2,3]

In aqueous solutions containing calcium carbonate and calcium phosphate, prenucleation clusters (PNCs) have been found to exhibit stability before the nucleation of the first solid[4]. Furthermore, proteins involved in *biomineralization have been observed to undergo a liquid-liquid phase separation (LLPS) induced by calcium ions. These observations suggest a significant interplay between PNCs and LLPS, where the formation of liquid-like nanodroplets during LLPS appears crucial for stabilizing and regulating PNCs.*

This hypothesis is supported by in vitro observations that show certain acidic polymers involved in biomineralization exhibiting similar behavior, generating calcium ion-induced LLPS. For instance, polyaspartic acid (polyAsp) has been observed to stabilize calcium carbonate and calcium phosphate PNCs through a process called Polymer-Induced Liquid Precursor (PILP). This system is supposed to mimic biomineralization key features, in particular organic- inorganic interactions before solid deposition[5]*. However, the mechanisms and dynamic interactions involved in this process remain poorly understood, and the interactions between the polymer and the existing species in solution, in particular PNCs, are still under investigation.*

To address these challenges, low-temperature solid-state NMR of cryo-fixed solutions is employed. This original technique aims to detail the organic-inorganic interactions at the molecular level between the polymer and the PNCs. In this communication we provide preliminary results on 1) the cryofixation of the polyAsp+calcium carbonate/phosphate solutions, 2) the subsequent analysis by low temperature solid state NMR analysis. This approach provides deeper insights into the stabilization mechanisms and the roles of PNCs and LLPS in biomineralization.

Characterizing, Classifying and Manipulating Gas Hydrate Crystaline Interfaces and Associated Liquid-Like Layers to Understand Their Nucleation and Growth

Samuel Mathews, Phillip Servio and Alejandro D. Rey; McGill University, Canada

Gas hydrates are inclusion compounds comprising a backbone of water molecules that enclose guest molecules in separate cages. Each volume of hydrate contains 160 volume equivalents of gas. The formation of these structures is a sophisticated crystallization process governed by heat and mass transfer considerations. It is composed of two steps: initial hydrate nucleation and subsequent growth. Water and gaseous guest molecules form small clusters, eventually reaching some critical size and yielding sustained growth. However, the exact mechanisms of the formation of small clusters, the diffusion of these nuclei, as well as the controllable phases of this process are unknown or poorly characterized. The labile cluster nucleation hypothesis maintains that water molecules form locally ordered arrangements that may form hydrate cage precursors. Pentagons, hexagons, and half-formed cages may form spontaneously and around gas molecules. The polygons may join to form cages, or the half-formed cages may close with another part of a cage before dissociation. These dynamics are too fast to reliably capture experimentally. With these challenges and dynamics in mind, the work uses molecular dynamics, graph theory, and geometric modeling to characterize, classify, and manipulate the different phases and elements *of gas hydrate nucleation and growth to improve the understanding of crystallization and its potential applications in green science and engineering. Geometric modeling provides computationally inexpensive opportunities to create an analog of the energy landscape inside the gas hydrate cages. Examining the effect of the placements of spherical, linear, planar, and more complex guest molecules, we show that there are preferred orientations of guest molecules in the crystal structures. We resolve these orientations into points, lines, and planes of minimum energy and confirm the findings with rigorous density functional theory simulations. Additionally, we highlight the power of geometric modeling in providing accurate initial estimates of ground state atomic configurations but note the shortcomings of not including quantum effects and other electronic interactions. We subsequently use graph theory to provide an efficient and accurate cage recognition algorithm to obtain precise values of the lifetime of prenucleation clusters. Importantly, we identify the location of the formation of polygons, half-cages, and full cages in gas hydrate systems and their precursors. Combined with the results on minimum energy orientations of guest molecules, we can identify potential nucleation sites for hydrates in a simulation box. These results will lead to spatially and temporally resolved concentration profiles for the various subunits of critical hydrate nuclei relative to the interface of the system. With information regarding prenucleation clusters, energy landscape, and cluster distributions, we employ molecular dynamics simulations to control nucleation and growth behaviors. By examining the dipole moment distribution, we show that the water molecules in the novel liquid-like interfacial layer show strong parallel orientations with the surface of the hydrate. We then manipulate the interfacial layer and distribution of clusters by applying an external electric field. Preliminary results show that an electric field is a tool for controlling the spreading of the interface, the mass transfer within the interfacial layer, and disrupting the formation of prenucleation clusters in the bulk liquid phase as well as interrupting the organization in the liquid-like layer, tuning the nucleation kinetics of the gas hydrate system and providing avenues to go beyond classical nucleation theory and providing novel characterization of the multistep, multiphase crystallization process.*

PM01.05.13

Recrystallization of Ion Implantation Damage in GeSn Thin Films by Thermal and Laser Annealing *Shangda Li[1], Hryhorii Stanchu[2], Grey Abernathy[2,3], Shang Liu[1], Baohua Li[3], Shui-Qing Yu[2], Xiaoxin Wang[1] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]University of Arkansas, Fayetteville, United States; [3]Arktonics, LLC, United States*

GeSn alloys are emerging as promising materials for infrared photonics due to their tunable direct bandgap and compatibility with silicon technology. Compared to in situ doping with limitations in doping area and possible Sn loss [1], ex situ doping via ion implantation offers greater customizability and potential for advanced device structures. Being the most commonly used doping method for high doping level, ion implantation faces challenges in repairing the damaged layers post-implantation, which would otherwise degrade optical and electrical properties of the material. The annealing condition of GeSn amorphized by implantation is limited by the low solubility of Sn in Ge, leading to the possibility of Sn diffusion and segregation [2]. While rapid thermal annealing (RTA) is a valid method to recrystallize amorphized epilayers [3], a consolidated understanding of crystallinity recovery of implanted GeSn and Sn segregation mechanism therein remains lacking.

In this work, we investigate the recovery of crystallinity in epitaxially grown $Ge_{0.89}Sn_{0.11}$ implanted with arsenic at two doses of 2×10^{13} cm^{-2} and 1×10^{14} cm^{-2} at 40 kV, corresponding to peak doping concentrations of 5×10^{18} cm^{-3} and 2.5×10^{19} cm^{-3}, using RTA and laser annealing. We propose a model of Sn diffusion pathways in segregation events based on strain relaxation through misfit and threading dislocation formation, consistent with distinct Sn segregation patterns in GeSn layers with varying degrees of ion-induced amorphization. Our results show the critical role of temperature in the repair of ion-damaged GeSn crystal. RTA at 400 °C effectively restores crystallinity in $Ge_{0.89}Sn_{0.11}$ films. Photoluminescence (PL), electron backscatter diffraction (EBSD) and Raman spectroscopy analyses reveal the evolution of crystallinity of $Ge_{0.89}Sn_{0.11}$ epilayers subjected to implantation and *subsequent annealing and verifies the effective lattice restoration. These characterizations, combined with ion implantation modeling, suggest that a full damage recovery can be achieved by RTA for implantation peak concentration < 1×10^{19} cm^{-3}. At a higher implantation dose corresponding to 2.5×10^{19} cm^{-3} peak doping concentration, most of the layer can be recovered except for some of the very top region within ~20 nm of the surface that suffers heavier implantation damage. To this end, continuous wave laser annealing at a 532 nm wavelength and a power density of ~200 kW/cm^2 achieves better recrystallization without Sn segregation compared to RTA results with sporadic surface segregation. This highlights the improved effectiveness of laser annealing in lattice recrystallization particularly for high-dose implantation, where traditional RTA may fall short. These findings not only extend previous knowledge of implantation damage in GeSn epilayers [4] and offer insights into macroscale Sn segregation mechanisms, but also provide guidelines for optimizing the annealing conditions for GeSn post-implantation. The study further supports the integration of GeSn in silicon photonics and paves the way for more sophisticated doping profiles and enhanced device functionalities.*

Molecular Dynamics Simulations of Heterogeneous Nucleation in Aluminium Alloys Under Rapid Heating and Cooling in Powder-Bed Fusion Type Additive Manufacturing

Masayuki Okugawa, Hirotaka Takashima and Yuichiro Koizumi; Osaka University, Japan

Additive manufacturing (AM) has garnered substantial attention owing to its capability to fabricate parts with complex shapes. In addition, the powder-bed fusion (PBF) type AM process can also control internal microstructures by controlling the rapid cooling conditions unique to the PBF process [1]. On the other hand, we previously reported that the rapid heating condition during the melting process also affects the microstructure formation in Al-Si eutectic alloy, in which the solid-Si particles with high melting temperature remained after the rapid melting and act as heterogeneous nucleation sites during subsequent solidification [2]. The remaining Si particles in the remelting process are caused not only by the fast cooling but also by the significantly large heating rates in the PBF process. However, the heterogeneous nucleation cannot be explained by classical nucleation theory. It is supposed that the results and the theory do not agree because the crystallization occurs from a non-equilibrium heterogeneous liquid containing remaining Si particles due to the rapid heating and cooling conditions of the PBF process. In this study, we conducted molecular dynamics (MD) simulations of heterogeneous nucleation of Al from the Si solid/liquid interface to clarify the heterogeneous nucleation behavior during the PBF process. For comparison, we also performed the MD simulations on $L1_2$-type Al_3Zr crystal substrates, which cause the frequently heterogeneous nucleation in the PBF process [3].

The MD simulations were performed using the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS). The Modified Embedded-Atomic Method (MEAM) potential [4,5] was used as the interatomic potential. First, the Si diamond crystal, $L1_2$ type Al_3Zr crystal, and Al liquid models were equilibrated at 973 K, which is the Al melting point of the used MEAM potential. Si solid/Al liquid phase models and Al3Zr solid/Al liquid phase models with 10 nm × 10 nm × 10 nm were prepared from these equilibrated models. The solid-liquid models were held

isothermally in the temperature range from 300 K to 850 K, and time-temperature-transformation (TTT) diagrams were obtained.
All solid/liquid models crystalized the shortest time under isothermal treatment, around 600 K. On the other hand, the time and undercooling required for the crystallizations largely depend on the substrate and its orientation: crystallization occurred in the shortest time and wider temperature range in the model with the [111] orientated Si and [100] oriented Al_3Zr substrates and the time and the temperature range are the almost the same. We found that Al liquid forms an ordered structure near the solid-liquid interface in the model with the [111] oriented Si substrate, and the development of Al crystals started from the ordered region. These results suggest that the ordering of Al liquid near the solid-liquid interface is a key to frequently heterogeneous nucleation observed in the PBF process of the Al-Si eutectic alloy.

Crystallization of VO_2 Via Hydrothermal Synthesis–A Study on Reaction Conditions and Crystal Formation

Daniel Mann; TNO, Netherlands

Vanadium dioxide can exist in a number of stable and metastable polymorphs with different unit cell parameters, including the VO_2 A, B, D, M1, M2, P and R phase. Each of these polymorphs has very specific properties and characteristics that can be used in various applications. The changing requirements make it important to be able to synthesize individual polymorphs at high purity and crystallinity to match their properties with targeted applications. An application area, where VO_2 has garnered increased interest from the scientific community as well as industry, is smart windows which autonomously adapt their solar heat gain to a buildings energy and comfort needs.[1] Here the structural phase transition (STP) between the M1 and R phase of VO_2 is used to trigger a change in solar infrared light transmission at a specific temperature. For this application it is important to selectively synthesize the highly pure and crystalline M1 phase to realize optimized optical properties in thermochromic glass coatings, combining high visible transparency with high solar modulation. Furthermore, precise and selective metal ion doping of the VO_2 crystals, replacing a small number of V ions with metal ions of a different ionic radius, is crucial to generate distortion and defects in the crystal lattice, leading to a reduction of the phase transition temperature to application oriented regions. Finally, the crystallite size is important for transparent applications. Here the size of individual VO_2 crystals within a coating matrix needs to be kept below a certain threshold size to prevent Mie scattering, which induces opacity. Additionally, it has been shown that plasmonic absorption can be triggered within metallic VO_2 (R) nanoparticles in the correct size range, further increasing the solar modulation capacity. All these parameters make it very important to have a prices control over the crystallization behavior of VO_2.
Here we present an in depth study on the crystallization behavior of VO_2 within a hydrothermal reaction.[2] We investigate various reaction parameters, such as temperature, time, reactants and concentrations and their influence on the crystallization of VO_2 into various polymorphs. Furthermore, we add tungsten ions as dopant to change the phase transition temperature. We show that the addition of W plays a crucial role in the crystallization behavior of VO_2 and investigate the impact of different dopant concentrations on the formation of the VO2 A, B and M polymorphs. Our here developed process excludes the use of hazardous reagents, making it compatible with the concept of green chemistry and industrial production processes. Since the precursor complex also plays a crucial role in the crystallization behavior of VO_2, we present a comparative analysis of the crystallization of the here used vanadyl oxalate precursor with other precursors used in literature, that were obtained from reactions

using hazardous reagents. Finally, we present an optimized reaction procedure within a Teflon lined hydrothermal reactor exposing an aqueous solution of vanadyl oxalate in the presence of $(NH_4)_6H_2W_{12}O_{40}$ *for 96 hours to a temperature of 230°C. Using his process, we realized highly crystalline, phase pure W-doped* VO_2 *(M1) microparticles of uniform size and asterisk shape (*$\Delta H = 28.30\ J\times g^{-1}$*, arm length = 6.7 ± 0.4 µm, arm width = 0.46 ± 0.06 µm). Furthermore, we give an outlook to reduce the particle size during crystal growth, which is essential to realize* VO_2 *nanoparticles applicable for smart window coatings.*

Synthesis of Semicondutor Nanocrystals in the Molten Inorganic Salt *Zirui Zhou, Justin Ondry and Dmitri V. Talapin; The University of Chicago, United States*

With the size-tunable optoelectronic properties and scalable synthesis, colloidal quantum dots enable applications where inexpensive high-performance semiconductors are needed. Synthesis science breakthroughs have been key to the realization of quantum dot technologies. However, high-quality III-V materials cannot be synthesized by the existing method which utilizes high-boiling-point organic solvent. Herein, we report here a bunch of new methods that introduce molten inorganic salt as a solvent. By using dehalosilylation chemistry or redox chemistry, III-V nanocrystals could be made from molten inorganic salt. We also showed that high temperature is crucial to see a well-defined Raman signal which means that high temperature is important to eliminate the defects in the as-synthesized nanocrystals.

PM01.05.17
In Situ Observation of Dynamic Crystal Growth of CuInP2S6 van der Waals Crystals *Kigozi Musazi[1], Kit Sze[2], Ramesh Budhani[1] and Yucheng Lan[1]; [1]Morgan State University, United States; [2]Brown University, United States*

CuInP2S6 (CIPS) 2D van der Waals material has recently received significant attention due to its multifunctional properties, such as ferroelectricity, pyroelectricity, electrocaloricity, and negative piezoelectricity. The material is a promising candidate for applications in ferroelectric field-effect transistors, photodetectors, and electrocaloric cooling devices. High quality CIPS crystals are the key to these applications. Up to date, CIPS crystals have been grown using solid-state reactions and chemical vapor transport techniques while the underlying growth mechanism remains poorly understood. In this study, we employed laser-based interferometry to observe the in-situ nucleation and growth of CIPS crystals. By reconstructing the amplitude and phase of the scattered light from the crystal surfaces using a Python library, we were able to characterize the microscale nucleation and growth topography of the crystals. The growth rates were also determined. The in-situ work laid a groundwork for growth high-quality and large-scale CuInP2S6 crystals.

Deciphering Non-Classical Molecular Mechanisms Controlling Calcium Carbonate Formation *Stephan E. Wolf; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany*

The catch-all term "biominerals" misses the complexity and functionality of bioinorganic solid-state materials — neither from a materials science nor a chemical viewpoint. They hardly share traits with pure minerals as they are biogenic hybrid ceramics with hierarchical organization, honed to high performance and high functional density. The biosynthesis processes of these "bioceramics" contrast with classic ceramics synthesis routes as they form at mildest and environmentally benign conditions. How can we tap their potential for biomimetic and sustainable material synthesis? The key to this question lies in elucidating the crucial role of transient amorphous phases in biomineral biosynthesis and how biomineralizing organisms exert control over forming a solid-amorphous phase. Hence, we will discuss structural and chemical evidence for a formation pathway via aggregating prenucleation clusters, in which they appear better describable as coordination polymers. We present unforeseen molecular mechanisms by which small-molecular weight additives act as solution stabilizers but also dictate phase stability chemical composition of the amorphous precipitate. The underlying molecular mechanisms operate beyond established mechanistic conceptions of nucleation, demonstrating non-classical schemes of mineral nucleation inhibition. We demonstrate further that similar interaction mechanisms are at play in the case of the pronounced process-directing effect of biologically relevant peptides and polyelectrolytes.
Kinetic enforcement of these unforeseen coordination polymers-governed routes allows us to override standard crystallization processes. Under well-controlled conditions, we can push a mineralizing system even toward spinodal decomposition. Thus, a phase separation behavior is only known for soft matter systems. Our novel synthesis approach grants access to nanoporous materials with excellent pore accessibility and structural isotropy. Thereby, we also revoke a long-standing tenet that spinodal demixing of small solid solutes is experimentally infeasible.

9:30 AM *PM01.06.02
Crystallization Kinetics of Amorphous Carbonates in Confinement *Derk Joester; Northwestern University, United States*

Metastable precursors are integral to the biosynthesis of mineralized tissues with intricate architecture and emergent properties.[1] They are also used in bio-inspired syntheses of structures and compositions far from equilibrium.[2-4] While simulations predict the structures of myriad materials with highly desirable properties, the ability to synthesize lags behind significantly. The difficulty often lies in determining accurate transformation rates between competing metastable phases. I will report on recent progress towards solving this problem by studying phase transformations of amorphous carbonates in confinement. Specifically, I will discuss insights into the crystallization of amorphous calcium carbonate (ACC) in the absence of additives that were gained using a microfluidic droplet assay;[5] the switch from constant to highly dynamic barriers to nucleation as a function of barium concentration in the barium-calcium-carbonate-water system,[6] and the polymorph-specific scaling of the nucleation rate of calcium carbonate with the radius of the confining droplet.

10:30 AM PM01.06.03
Halochromic Amorphous Calcium Carbonate Crystallization Inspired by Biomineral Pigmentation in Sea Urchins *Marie Albéric[1], Vaskar Sardhalia[1], Anne Vallée[1], Marta De Frutos[2], Iryna Plishchuk[3], Boaz Pokroy[3], Shahrouz Amini[4], Peter Fratzl[4], Nadine Nassif[1] and Thierry Azais[1]; [1]Sorbonne Université, France; [2]CNRS, Université Paris Saclay, France; [3]Technion–Israel Institute of Technology, Israel; [4]Max Planck Institute of Colloids and Interfaces, Germany*

Marine life fascinates by its ability of producing a large variety of multifunctional biomineralized structures that often exhibit striking colors. For example, the wide range of hues observed in calcium carbonate ($CaCO_3$)-based biominerals of sea urchins is due to the occlusion of small organic pigment molecules (polyhydroxy-1,4-naphthoquinone molecules, PHNQs) within their skeletal elements. Synthesized by sea urchins, PHNQs are bio-active secondary metabolites responsible for the red colors displayed by the immune red-spherule cells as well as for the green and purple hues observed in the biomineralized spines. The latter are known to form through amorphous $CaCO_3$ (ACC) precursors. Biomineralization and pigmentation processes are two intertwined metabolic pathways, however the role of secondary metabolites, such as organic pigment molecules, on ACC formation and crystallization mechanisms remains unexplored. Therefore, inspired by the growth of pigmented calcite in sea urchins occurring through ACC precursors and in the presence of PHNQs, we co-precipitated ACC with naphthazarin (NZ) (an analogue to PHNQ) and studied its crystallization mechanisms in solution. Our results show that NZ produces intense colored hybrid pigments but has little effect on ACC structure and stability against crystallization while it promotes calcite formation after ACC crystallization and tends to stabilize the vaterite phase before its conversion into calcite. In addition, NZ, which is red at acidic pH and blue before ACC precipitation, leads to a lavender blue ACC powder that further crystallizes in solution into a violet blue calcite powder. We propose that these remarkable changes in color are due to successive OH deprotonations of NZ driven by pH variations imposed by ACC precipitation and crystallization likely during a dissolution/reprecipitation mechanism. Thus, by controlling the speciation of NZ in solution and capturing its partial deprotonation state within amorphous and then crystalline hybrid pigments, we evidence an halochromic ACC crystallization pathway that could unveil color changes during the pigmentation of $CaCO_3$-biominerals formed through amorphous phases. Blue colors that mostly originate from structural color in nature, can thus be obtained by tweaking red pigments using pH shift, a strategy already recognized in some plants.

10:45 AM PM01.06.04
Bio-Inspired Patterning of Amorphous Calcium Carbonate Through Laser-Induced Crystallization *Hadar Shaked, Iryna Polishchuk, Daniela Dobrynin, Alexander Katsman and Boaz Pokroy; Technion-Israel Institute of Technology, Israel*

The precise control in biomineralization over various phases has inspired us to study a novel laser-induced crystallization route. To this end, we employed laser-induced crystallization in a magnesium-stabilized ACC environment to generate four distinct phases: calcite, stable dehydrated ACC, monohydrocalcite, and hydromagnesite in a patterned manner. We characterized the energy range, determined by laser power and speed, required for each phase formation and demonstrated the reproducibility of this process. Our approach enables precise patterning in the ACC environment, where laser-affected areas undergo phase changes while the rest *remains unaltered. Furthermore, we investigated the controlled production of monohydrocalcite and hydromagnesite under varying thermal conditions, examining the influence of substrate composition, ACC stability, and repeated exposure on phase formation. We propose an explanation for the observed phases and demonstrate impressive control over polymorph location, enabling calcite patterning within an ACC matrix. This research explores laser patterning within a bio-inspired framework and advances our understanding of out-of-equilibrium phase formation processes inspired by biomineralization.*

11:00 AM *PM01.06.05

Mineral Formation in Twisted Plywood Structures

Nadine Nassif[1,2]; [1]Centre National de la Recherche Scientifique, France; [2]Sorbonne Université, France

Many biological tissues exhibit fibrillar organizations known as twisted plywood or helicoid. This arrangement is similar to that of molecules in cholesteric liquid crystalline phases, though the liquid character is abolished (1). Cholesteric and other liquid crystalline-like organizations are encountered in various extracellular matrices composed of different components, especially collagen, chitin, cellulose and DNA. This structural analogy between living tissues and liquid crystals emphasizes the importance of the structure-properties relationship in biological tissues and suggests similar self-assembly mechanisms in both systems as recently shown in bone (2). The twisted plywood structure of mineralized collagen fibrils is a hallmark of trabecular and cortical bones, and our team's work aims to demonstrate the importance of reproducing this structure in terms of composition and structure. Collagen fibril order induces the formation of restrictive gaps allowing for the supersaturation of molecules (proteins, ions) and the establishment of unconventional thermodynamic conditions. Indeed, proteins can exhibit opposite activities depending on their surrounding state, whether in diluted or condensed conditions (3), which might have significant implications on mineral formation.

Our team work aims to enhance our understanding of fundamental questions in morphogenesis and to develop competitive biomaterials. We use the lyotropic properties of Type I collagen, the major structural protein of connective tissue. The phase diagram of collagen molecules, in acid solution at high concentration exhibits successively nematic, precholesteric (4)/precholesteric, and cholesteric phases (5). After a sol/gel transition, collagen fibrils form while preserving the cholesteric geometry (6). The materials were successfully scaled up (from drop to 3D bulk material) using a bioinspired process based on the continuous injection of collagen, mimicking protein secretion by cells (7). In parallel, we set an apatite mineralization process that led to synthetic platelets whose structure and behavior in water mimic those of biological apatite (8). Combining these processes leads to build collagen/apatite composites with high similarity to bone tissue (9). In vitro and in vivo investigations were also performed to control their cyto- and biocompatibility and to evaluate their potential for bone repair (10, 11).*

We will show that reproducing this bone building block provides efficient models to study fundamental questions on tissue morphogenesis and, more particularly, bone biomineralization. This approach also serves as a strong starting point for applications in bone tissue engineering through the design of new implantable materials, as autologous bone is still considered the gold standard. Overall, it shows the importance of physico-chemical processes occurring in biomineralization, as usually discussed from a biological control point of view.

Low-Temperature ^{13}C Solid-State NMR Study of Cryo-Fixed $NaHCO_3$ Solutions *Trevys Chanal, Ieva Goldberga and Thierry Azais; Sorbonne Université, France*

Calcium carbonate ($CaCO_3$) is one of the most abundant minerals on Earth, and is mainly present in limestone and sea waters. $CaCO_3$ is also of major importance in Biology as it is involved in biomineralization processes at the origin of shells and skeletons of many invertebrates such as mollusks, corals, urchins…[1]. $CaCO_3$ can be found in 3 polymorphic forms: calcite, aragonite and vaterite, from the most to the least stable form, respectively. However, amorphous calcium carbonate (ACC) is often observed as the first nucleated solid before the formation of the crystalline phases, in line with the Ostwald's rule of stage. The nucleation mechanism has been described by Gibbs through the so-called classical nucleation theory (CNT), which involves the formation of critical size nucleus by monomer addition[2]. Nevertheless, $CaCO_3$ has been intensively studied by its tendency to not follow a classical pathway of nucleation. As such, it has been reported the existence of stable and soluble entities before the first nucleation of any solid phase. These so-called prenucleation clusters (PNC) are described as nanometric and highly dynamic entities in equilibrium with free ions in solution[3]. Since this discovery, no consensus has emerged concerning their composition and structure as well as their mechanism of formation and transformation[4].
In order to progress on the comprehension of the local environment and the dynamical behavior of these clusters, we used low-temperature (-120°C) solid-state NMR spectrometry. To allow such analysis we use a stopped flow instrument coupled to a freeze quench device. First, the solution containing PNC is prepared with the stopped-flow allowing to access very short mixing time (~10 ms). Then, the resulting out-of-equilibrium solution is vitrified by spraying it into cold isopentane (» -140°C). Thus, PNC are cryo-fixed and stay stable during the solid-state NMR analysis. We already successfully used this approach to investigate amino-acid stabilized prenucleation clusters as well as dense liquid phases of $CaCO_3$ but the vitrification process was not automatized.[5]
As the carbonate speciation (HCO_3^- vs CO_3^{2-}) is a key parameter of PNC structure, a preliminary low-temperature ^{13}C solid-state NMR study has been conducted on cryo-fixed $NaHCO_3$ solutions at various pH (from 7 to 11), concentrations (from 25 to 400 mM) and temperature (from -120 to -50°C). The main ^{13}C NMR parameters, including ^{13}C isotropic chemical shift, line width and chemical shift anisotropy (CSA), have been systematically investigated. We show that the HCO_3^-/CO_3^{2-} molar ratio is depending on the pH and that at low temperature the "apparent" HCO_3^-/CO_3^{2-} pKa is shifted to lower values compared to ambient temperature. Surprisingly, we also evidence the impact of the initial concentrations on this "apparent" HCO_3^-/CO_3^{2-} pKa, which is increasing with the molarity. Finally, analysis of ^{13}C CSA parameters shows that carbonate dynamics in the vitrified solutions does not drastically change when the temperature is varied from -120 to -50°C. Hence, the present low temperature solid-state NMR study of vitrified carbonate solution is the first step toward structural investigation of $CaCO_3$ PNC in similar conditions.

Harnessing Crystal Defects to Tailor Bio-Inspired Materials *Boaz Pokroy; Technion-Israel Institute of Technology, Israel*

The field of crystal growth and design has been researched thoroughly, specifically the ability to form crystals with tunable dimensions, morphologies, and functional properties. Notably, various crystallographic defects have been found to enhance material properties. For instance, atomic doping alters electrical properties, screw dislocations facilitate spiral crystal growth, while dislocation outcrops and vacancies enhance catalytic activity and strengthen materials. In this talk, I will show several examples of crystal defects found in biomineralized tissues that serve as a source of inspiration to create bio-inspired crystals with tuned physical characteristics. Some examples are the electronic and magnetic properties.

Make It With Minerals—Self-Organizing Matter for Functional Materials *Willem Noorduin; AMOLF, Netherlands*

Shaping, sculpting, and forging customizable compounds into arbitrary forms has the potential to revolutionize technologies for advanced functional materials. Current self-assembly strategies allow for impressive levels of control over either shape or chemical composition, but not both, as self-assembly inherently entangles shape and composition. Inspired by natural and biologically controlled mineralization processes, we here achieveindependent control over shape and composition by performing chemical conversion reactions on nanocrystals which were first self-assembled in nanocomposites with programmable microscopic shapes. We show that these conversion reactions are surprisingly materials agnostic, allowing a large diversity of chemical pathways, and develop conversion pathways yielding a wide selection of shape-controlled compositions ranging from perovskites to transition metal chalcogenides. Moreover, we introduce new strategies to control the self-assembly of the initial composite shapes using light, to direct the assembly process following exact user-defined patterns that subsequently can undergo conversion. Previously unimaginable customization of shape and composition is now achievable for assembling advanced functional components using bioinspired mineralization strategies.

Morphology Control via Manipulation of Chirality *Chiao-Jung Su[1], Hui Taou Kok[1], Holly M. Johnson[1], Marta*

Rzeszutko[1], Prakruti Raghunarayan[2] and Barry P. Rand[1,1]; [1]Princeton University, United States; [2]The University of Texas at Austin, United States

Conjugated organic semiconductors have proven to be a credible optoelectronic device platform, revolutionizing the display industry, with other foreseen promising applications to photovoltaics and bioelectronics. Compared to their inorganic counterparts, their remarkable mechanical properties and vast chemical diversity make them incredibly versatile. Additionally, amongst molecular options are chiral materials which can selectively manipulate circularly-polarized light or dictate spin transport, holding potential for optical tuning and innovations in data storage, advanced sensors, and immersive 3D displays (Adv. Photonics Res. ***2021****, 2 (4), 2000136). For such applications, having crystalline chiral materials is important to make the most of these chiral properties. To unlock such possibilities, here we study the influence of molecular chirality on the crystallization of conjugated organic thin films.*

We focus on 2,2-bis-(diphenylphosphino)-1,1-naphthalene (BINAP), an axially chiral molecule, and how chiral ratios influence crystallization. Thermally evaporated and subsequently annealed films of the racemic mixture (rac-BINAP) exhibit micron-scale platelet crystals with smooth molecular terraces consistent with predictions based on their thermal properties (J. Phys. Chem. C ***2020****, 124 (49), 27213-27221), and we found that the preparation of such films is possible on various substrates (e.g., glass, quartz, transparent conducting oxides, silicon, etc.). In contrast, enantiopure BINAPs (R- and S-BINAP) form spherulitic crystals with comparatively rougher surfaces. Systems with varying R- and S-BINAP ratios exhibit platelet-like crystallization morphology and large-area coverage with S-BINAP loadings of 35% to 80%, showing a higher tolerance to an excess of S-BINAP. Notably, identical crystallization behavior was observed from films regardless of whether they were produced via co-evaporation (simultaneous evaporation of R- and S-BINAP) or in a layered system with two discrete S-BINAP and R-BINAP layers, implying considerable molecular mobility upon annealing. The tolerance of lattice mismatch in epitaxially grown systems is also investigated by co-depositing varying ratios of R- and S-BINAP on crystalline template layers of BINAP, grown with the same or different ratios as the epitaxial layer.*

Overall, this work highlights the distinct crystallization behaviors of chiral BINAPs and provides insights into controlling crystal morphology in chiral organic materials, an important step toward their applications in optoelectronic devices.

Microfluidic Tools for the Bioinspired Synthesis of Artificial Functional Materials Josep Puigmartí-Luis[1,2]; [1]Universitat de Barcelona, Spain; [2]ICREA, Spain

The incorporation of both covalent and non-covalent interactions has been pivotal in crafting artificial functional materials capable of mimicking the properties and functions observed in natural counterparts. Similar to nature, achieving precise control over the positioning of functional artificial building blocks holds the key to establishing rationalized structure-property correlations, a longstanding pursuit in the realms of chemistry, physics, and materials science. Despite its potential, understanding the pathways and mechanisms governing the formation of artificial functional materials remains a formidable challenge. To advance the engineering of artificial functional materials, it is crucial to understand the complexities of their nucleation and growth mechanisms, which can ultimately lead to the realization of nature-inspired functions. This presentation will highlight the innovative use of microfluidic devices to replicate reaction conditions found in nature. I will show that microfluidic approaches not only unravel the complexity of crystallization pathways but also enable the manipulation of pathway selection.

Crystallization in Drying Drops—Machine Learning Reveals Chemical Composition and Concentration from Simple Photos *Bruno C. Batista, Amrutha S. V. and Oliver Steinbock; Florida State University, United States*

Under nonequilibrium conditions, inorganic systems can produce a wealth of life-like shapes and patterns which, compared to well-formed crystalline materials, remain widely unexplored. A seemingly simple example is the formation of salt deposits during the evaporation of sessile droplets. These evaporites show great variations in their specific patterns, including single rings, creep, small crystals, fractals, and featureless disks. We have explored these patterns for about 50 different inorganic salts. Based on a manually collected database of 7,500 images and using machine learning, we can identify composition with surprisingly high accuracy solely from photos of the final deposit. Encouraged by this finding, we constructed a Robotic Drop Imager (RODI) and compiled a second database of over 21,000 additional photos. Analyses of this image library show that we can also determine the concentration of the initial solution from the deposit photos. My talk will also present a novel workflow that reduces the image data to small sets of < 50 numbers per sample that characterize the deposit patterns' shape and texture. This geometric reduction allows efficient data storage and rapid ML/AI analyses. Our findings suggest possible applications including smartphone-based analyses, lightweight tools for space missions, and low-cost medical tests.

4:30 PM PM01.07.06

Enthalpic and Entropic Controls on 2D Self-Assembly of Proteins on Substrates *Ying Xia[1,2], Zhiyin Zhang[3], Charlotte Zhao[4], Shuai Zhang[2,1], Mingyi Zhang[2], Timothy Moore[4], Sharon C. Glotzer[4], Akif Tezcan[3] and James J. De Yoreo[2,1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States; [3]University of California, San Diego, United States; [4]University of Michigan-Ann Arbor, United States*

Enthalpic and entropic forces are two knobs that can be used to control the assembly of colloidal particles. On the one hand, driving assembly through the enthalpy of binding can be achieved by functionalizing the particles with ligands, such as DNA strands, to enable fine control. On the other hand, particle assembly can also be driven by entropy maximization; particles can spontaneously align and assemble into structures to increase the configurational space available to the system. This phenomenon typically drives the particles into a close-packed geometry to maximize the free volume of free solvent and release the waters of hydration that are otherwise bound to free particles, which results in an effective directional entropic force. Although colloidal particle assembly has been extensively investigated from the perspective of understanding and controlling these entropic and enthalpic drivers, the assembly of biomacromolecules, like proteins, is a rapidly growing field in which such efforts have been limited.

Herein, we create patchy proteins, L-rhamnulose-1-phosphate aldolase (RhuA), with tunable bonding interactions by varying the chemistry of appended functional groups to manipulate the enthalpic driver of assembly. In addition, because the proteins have a well-defined 3D shape and the length and size of the functional groups can be varied, the entropic driver of assembly — shape complementarity — provides a knob with which to tune the resulting structure. In this project, we used in-situ atomic force microscopy (AFM) to observe 2D assembly of distinct assembled phases of specially designed β-cyclodextrin and azobenzene modified RhuA (^{CD}RhuA and ^{Azo}RhuA) at mica-water interfaces, as well as the transition between them. In the case of ^{Azo}RhuA, the presence of suitable long functional groups and weak inter-protein interactions leads to the formation of various polymorphs and between which phase transitions occur via two distinct pathways. However, when functional groups become excessively long or large, as with ^{CD}RhuA, densely packed configurations are obtained. We hypothesize these configurations arise because the entropic interaction, driven by shape complementarity, becomes the dominant factor in determining the outcome of assembly. We also find that ^{CD}RhuA follows an unusual multistep assembly and disassembly pathway on substrates due to crowding near the crystal edge in a substrate-controlled unfavorable configuration prior to forming the densely packed crystal. To test our proposed picture of competing *enthalpic and entropic interactions, we applied coarse grain simulations in which we varied the relative contributions of protein-substrate interaction and protein-protein interactions, which include both enthalpic attractive interactions and entropic forces due to the shape of the protein. Our findings indicate that, indeed, adjusting the strength and flexibility of the inter-molecular bonds can modulate the entropic forces associated with shape complementarity and the enthalpic forces that facilitate polymorph formation and phase transitions. This insight suggests fundamental design principles for the synthesis of novel 2D macromolecular materials.*

4:45 PM PM01.07.07

Charge Frustration Drives Ion Ordering and Microphase Separation at Mica-Electrolyte Interfaces *Mingyi Zhang[1], Benjamin A. Helfrecht[1], Zhang Yuanzhong[2], Shuai Tan[1], Venkateshkumar Prabhakaran[1], Younjin Min[2], Christopher J. Mundy[1,3], Benjamin A. Legg[1] and James J. De Yoreo[1,3]; [1]Pacific Northwest National Laboratory, United States; [2]University of California, Riverside, United States; [3]University of Washington, United States*

The significance of surface charge at solid-liquid interfaces extends to crucial roles in diverse chemical processes that include crystallization and self-assembly. One aspect of these processes that remains largely unexplored is the dynamics of ion adsorption and cluster formation leading up to the formation of crystalline films or self-assembled structures. Building upon the classical mean field description derived from the Gouy–Chapman model, the electrostatic attraction between a charged interface and counterions in solutions prompts oppositely charged ions from the solution to accumulate at the interface, forming an electric double layer (EDL), with distinct properties from those observed in bulk solutions. While the model accounts for the distribution of ions based on their spatial average perpendicular to the surface, the discussion regarding the lateral structure at the interface, particularly the local molecular-level details, is relatively limited.

In this study, we explored the interfacial structure of mica, a mineral with an atomically flat surface and intrinsic negative charge, in electrolytes containing different multi-valent cations, utilizing in-situ liquid phase atomic force microscopy (LP-AFM) prior to and during the formation of crystalline films. We find that, as the solution pH is gradually raised, cations adsorb and form a monolayer hydroxide film on mica surface. Divalent ions, such as Mg^{2+}, Ni^{2+}, Zn^{2+}, *and* Co^{2+}, *form large continuous monolayers in a manner that aligns with expectations based on classical nucleation theory. For trivalent ions like* Al^{3+}, Fe^{3+}, *and* Cr^{3+}, *hydrolyzed species adsorb in increasing amounts as pH is increased. However, instead of exhibiting a random distribution, these ions reveal intricate lateral ordering and eventually evolve into an ordered ion network. Upon further pH increase, the ion network undergoes a transition to a discontinuous film with a persistent network of gaps. The links between the surface nanostructure and local surface charge were investigated using three-dimensional fast force mapping (3D FFM) and complementary streaming potential apparatus (SPA) measurements. As films form, an inversion from negative to positive zeta potential on mica is observed through SPA and is accompanied by the appearance of a long-range tip-sample forces through 3D FFM. These findings suggest that electrostatic interactions between positively charged ions/films and a negatively charged substrate stabilize the surface nanostructure. Furthermore, films created by trivalent ions are more strongly charged compared to those formed by divalent ions.*

The lateral structure at mica-electrolyte interfaces was simulated using a charge-frustrated lattice gas model, where the ions experience competing interactions between short-range chemical bonding and long-range electrostatic forces. For weak charge effects, the film undergoes a first-order transition from sparse adsorbates to large continuous sheets, aligning with the behavior observed with divalent ions. When the charge effect is sufficiently strong, the surface forms various states, including ordered patterns of ions, ion clusters, and microphase-separated partial films, corresponding to the behavior observed with trivalent ions. This study provides molecular-level understanding of how electric fields control the spontaneous formation of interfacial nanostructures and offers valuable insights into using electric fields to control crystallization processes for the development of functional materials.

5:00 PM PM01.07.08
Two-Dimensional Silk *Chenyang Shi and James J. De Yoreo; Pacific Northwest National Laboratory, United States*

Early insights into native silk fibroin (SF) architecture suggested that its unique structures and properties are determined by its multiscale assembly and the evolution of its secondary structure. Yet the pathways of assembly and the relationship to that evolution are poorly understood. Here we investigate SF self-assembly using in situ AFM and liquid phase infrared nanospectroscopy (nano-FTIR) and molecular dynamics. To do so, we assemble the silk at the interface between water and highly ordered pyrolytic graphite (HOPG). We find that SF grows heteroepitaxially on HOPG into highly ordered, monolayer-thick 2D nanocrystals consisting of 1D lamellae that exhibit β-sheet secondary structure and lie along the armchair direction of HOPG. Molecular dynamics simulations show that the armchair orientation is indeed energetically favored, as is polar packing to form a bilayer. As the SF concentration increases, SF assembles into multi-layers via two pathways that can occur concomitantly. One is a non-classical pathway by which a disordered metastable film forms on top of the lamellae of the first monolayer and gradually converts into the lamellar structure. The second is a classical layer-by-layer pathway by which new lamellae grow homoepitaxially on the underlying 2D lamellae nanocrystals without any evidence of an intermediate state. Appling synchrotron based tip-enhanced nano-IR to SF assembly for the first time, we demonstrate that the β-sheet conformation is adopted from largely unstructured SF in solution as the lamellae advance along the classical pathway or during the process of film transformation along the non-classical pathway. These new findings fill in the missing pieces of the puzzle showing how SF structure evolves at the liquid-solid interface and provides inspiration for the design of heterogeneous 2D SF composites.

SYMPOSIUM PM02

Additive and Digital Manufacturing of Multifunctional Materials
December 2 - December 6, 2024

Symposium Organizers

10:30 AM PM02.01.01

Innovative Synthesis of Auxetic Metamaterials with Enhanced Energy Absorption Using Liquid Crystal Elastomers *HyeJi Kim[1], Seung-Yeol Jeon[2] and Woong-ryeol Yu[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)*

This work presents a novel method for synthesizing auxetic liquid crystal elastomer (LCE) foam, a metamaterial with the potential to revolutionize energy absorption. Auxetic structures, characterized by their negative Poisson's ratio (expansion upon compression), are known for their exceptional energy dissipation capabilities. Liquid crystal elastomers (LCEs) possess another intuitive property for energy dissipation: their rigid liquid crystal molecules can reorient under stress. By combining these two remarkable properties, we propose a novel approach to create a material with extraordinary impact absorption features. This approach utilizes a foaming agent, cyclopentane, for the first time ever to create a porous LCE base structure. We are not aware of any research that has developed a foaming agent of LCE. This novel foaming agent method offers a simpler approach to fabricate LCE foams, avoiding the need for time-consuming and complex methods like salt leaching, nickel etching, or 3D printing. Then, this LCE foam is transformed into an auxetic foam through a combined pressure and heat treatment. This method takes advantage of the synergistic energy dissipation mechanisms of auxetic structures and LCEs, potentially leading to a new class of metamaterial with significantly enhanced energy absorption characteristics. Such metamaterials could find applications in various fields, including impact protection in sports equipment, vibration damping for noise reduction, and energy harvesting devices.

10:45 AM PM02.01.02

Improved Compression Stability of 3D-Printed Lattice Structures with Polymer Foam Reinforcement *Ehsanul Azim and Mohammad R. Islam; The University of Texas at Rio Grande Valley, United States*

Additively manufactured lattice structures provide high specific stiffness and strength but cannot sustain large compression due to buckling instability of struts. In contrast, cellular foams are relatively soft, but can withstand large compression with bending deformation. For light-weighting and energy absorption applications, it is desirable to combine the mechanical properties of lattice structures and foams. This work focuses on the mechanics of an inter-penetrating composite that combines these two material systems. Specifically, the composite material has a stiff lattice structure, and its pore space is filled with a relatively soft foam matrix. We developed a representative volume element-based 3D finite element model to study the emergent mechanics of such two-phase composite under quasi-static compression. The 3D solid model of a lattice structure was generated first in CAD software and next, the solid model of foam matrix was generated by the boolean operation of a cube and the lattice geometry. The two solids were meshed with linear tetrahedral elements and the interface between the phases was assumed to be perfectly bonded. The matrix (foam) phase was modeled as a crushable foam material with a hyperelastic material model to mimic the compression behavior of flexible polymer foams. The reinforcement (lattice) phase was modeled as an elastic-plastic material to represent the resin material commonly used in Stereolithography (SLA) 3D printing of polymeric lattice structures. The material model parameters of both phases were calibrated from experimental measurements. We simulated the FE model under displacement boundary condition in compression and investigated the structure-property relations of the composite as a function of relative density and lattice topology. Our results show that the foam matrix reduces the strut buckling even at the low-density regime of the matrix and the effect becomes more pronounced with increase in the relative density of foam matrix. The addition of a foam matrix also leads to reduction in localized strain in the struts and nodal junctions, which indicates improved stability of lattice struts under compression in presence of the foam matrix. The compressive elastic modulus and yield strength can also be improved significantly by the *addition of a foam matrix. The composite mechanics also depends on the lattice topology. A stretching-dominated lattice topology (octet-truss lattice) shows a more pronounced enhancement in mechanical properties than a bending-dominated lattice topology (body-centered cubic lattice). Overall, the results indicate that the composite design approach of filling the pore space of a lattice structure with a flexible foam matrix provides a rational strategy to achieve a tunable combination of mechanical properties.*

11:00 AM PM02.01.03

High Absorptivity Nanotextured Powders for Additive Manufacturing *Ottman Tertuliano[1], Philip Depond[2], Andrew Lee[2], Jiho Hong[2], David Doan[2], Luc N. Capaldi[1], Mark L. Brongersma[2], Wendy Gu[2], Manyalibo Matthews[3], Wei Cai[2] and Adrian Lew[2]; [1]University of Pennsylvania, United States; [2]Stanford University, United States; [3]Lawrence Livermore National Laboratory, United States*

The widespread application of metal additive manufacturing (AM) is limited by the ability to control the complex interactions between the energy source and the feedstock material. Here we develop a generalizable process to introduce nanoscale grooves to the surface of metal powders which increases the powder absorptivity by up to 70\% during laser powder bed fusion. Absorptivity enhancements in copper, copper-silver, and tungsten enables energy efficient manufacturing, with printing of pure copper at relative densities up to 92\% using laser energy densities as low as 82 J/mm^3. Simulations show the enhanced powder absorptivity results from plasmon-enabled light concentration in nanoscale grooves combined with multiple scattering events. The approach taken here demonstrates a general method to enhance the absorptivity and printability of reflective and refractory metal powders by changing the surface morphology of the feedstock without altering its composition.

11:15 AM PM02.01.04

Microstructural Insights to NiTiNb Shape Memory Alloys Made via Extrusion AM *Rebecca A. Gallivan, Nerea Abando, Arnold Muller, Christof Vockenhuber and Ralph Spolenak; ETH Zürich, Switzerland*

Additively manufactured NiTi with Nb as a sintering aid has been shown to demonstrate shape memory properties, opening opportunities for advanced multifunctional design. However, the microscale mechanical behavior of these alloys remains an open area of exploration, particularly regarding high strain-rate deformation and the impact of sintering alloys on local mechanical properties. Through nanoindentation mapping, we investigate the hardness of local microstructures in 3D printed NiTi with varying concentrations of Nb over strain rates across several orders of magnitude. Alloys are produced via filament extrusion 3D printing and undergo a post-printing sintering process to reduce porosity. The microstructural features are characterized through a suite of experiments including SEM, EDX, XRD, Rutherford backscattering spectroscopy (RBD), and elastic recoil detection analysis (ERDA). By illuminating the contributions of specific features like Nb-rich regions, oxide inclusions, and interfaces, we highlight the role of specific microstructural features in localized mechanical response. We also quantify the role of small impurities and solutes unique to the printing process as compared to traditional powder sintering. These findings help provide insight for future microstructural design and reveal the relationship between the additive process and micromechanical response.

11:30 AM PM02.01.05

Prospects of Laser Powder Directed Energy Deposition (LP-DED) of Ceramics for Extreme Conditions *Shir Andreev Batat, Vladimir Popov and Noam Eliaz; Tel Aviv University, Israel*

Laser Powder Directed Energy Deposition (LP-DED) is an additive manufacturing (AM) process that uses laser beam with high energy density to locally melt selected powder material/s. High melting point materials, such as refractory metals and ceramics, are challenging to produce with cracks and other defects by AM. In this work, *tungsten and Inconel 625 were first DED'ed, aiming at obtaining dense and uniform samples with good adhesion to the base plate. Next, SiC was DED'ed on top of these two materials. The as-deposited samples were characterized by optical and electron microscopy, energy dispersive spectroscopy, cathodoluminescence measurements, X-ray diffraction, hardness and adhesion tests. Chemically graded dense SiC coatings with good adhesion to the substrate were observed. Intermixing between SiC and the refractory metal resulted in a continuous gradual change in microstructure, leading to enhanced microhardness compared to the conventionally manufactured pure materials, as well as to several phases containing W, Si and C.*

11:45 AM PM02.01.06

Development of Silicon Carbide Based Nanocomposites Using Additive Manufacturing Techniques *Li Cao; University of Dayton, United States*

In modern applications, there is a constant demand for high-performance components. Silicon Carbide (SiC), an advanced ceramic material, has exceptional physical, chemical, thermal, mechanical, and electrical properties, making it suitable for many applications, such as aerospace, defense, and automotive. The growing need for advanced ceramic materials and their functional components requires advanced manufacturing technologies to meet specific applications. However, high-quality ceramic components are often challenging to fabricate because of the inherent physical and chemical properties of ceramics. Therefore, the fabrication of high-quality advanced ceramic materials and their products necessitates the adoption of appropriate advanced manufacturing technologies that can be well-suited for diverse applications. Additive Manufacturing (AM) has numerous advantages compared to other manufacturing technologies, such as the flexibility to modify designs, accommodate complex geometries, save materials, shorten production time for prototypes, and reduce costs. Integrating advanced ceramic material development and AM techniques has drawn significant attention as it overcomes the limitations and challenges of conventional fabrication approaches. This research focuses on developing SiC-based ceramic composites using the Digital Light Processing (DLP) and Direct Ink Writing (DIW) techniques. The results showed that the 3D-printed SiC composite components exhibited reduced shrinkage and enhanced mechanical properties. This research demonstrated the potential of the AM for material development and fabrication of high-performance SiC-based ceramic composites for various applications.

SESSION PM02.02: Printed Electronics and Optics I
Session Chairs: Yu Jun Tan and Daryl Yee
Monday Afternoon, December 2, 2024
Sheraton, Second Floor, Constitution A

1:30 PM PM02.02.01

Geometry and Function of Antireflective Leafhopper Brochosomes *Lin Wang[1], Zhuo Li[2], Sheng Shen[2] and Tak-Sing Wong[1]; [1]The Pennsylvania State University, United States; [2]Carnegie Mellon University, United States*

Leafhopper-produced brochosomes are hollow, buckyball-shaped, nanoscopic spheroids with through-holes distributed across their surface. However, since their discovery in the 1950s [1, 2], it remains unknown why the sizes of brochosomes and their through-holes consistently fall within hundreds of nanometers across different leafhopper species [3]. Here, we demonstrated that the hierarchical geometries of brochosomes are engineered within a narrow size range with hollow architecture to significantly reduce light reflection. We fabricated high-fidelity synthetic brochosomes at the microscale using two-photon polymerization 3D printing and demonstrated *that the brochosomes can reduce light reflection by up to 94% through a synergistic effect of broadband Mie scattering and through-hole light absorption [4]. Brochosomes represent the first biological example showing short wavelength, low-pass antireflection functionality enabled by their through-holes and hollow structures. These findings suggest that brochosome geometries may have evolved to optimize leafhoppers' camouflage by reducing reflection from ultraviolet to visible light [4, 5]. Our study suggests a novel strategy for optical manipulation at the micro- and nanoscale, such as multispectral antireflective coatings and information encryption [4 – 6].*

1:45 PM PM02.02.02

Mechanically Tunable Electronic Ink for Additive Manufacturing of Body-Temperature Softening Bioelectronics

Do A Kwon[1,1], Simok Lee[1] and Jae-Woong Jeong[1,2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]KAIST Institute for Health Science and Technology, Korea (the Republic of)

Bioelectronics, encompassing wearable and implantable devices, hold immense potential for health monitoring and therapeutic intervention by interfacing directly with biological organs. However, conventional rigid bioelectronics often induce discomfort, inflammation, or tissue injuries due to mechanical mismatches with biological tissues, despite their convenience and robustness. While soft electronics mimic tissue mechanics, challenges persist in handling, maintaining shape, and precise positioning. Transformative bioelectronics, which integrate advantages of rigid and soft electronics into a single device, have emerged as a promising solution. As its core material, gallium stood out for its exceptional stiffness tuning ratio (~10^4) and a melting point (~29.8°C) close to body temperature. Yet, its poor rheological traits (i.e. ultrahigh surface tension and low viscosity) have challenged high-resolution patterning, limiting manufacturing techniques to mold casting or microfluidics. This, despite its high conductivity (3.4×10^6 S m^{-1}), has resulted in poor patterning resolution, with gallium primarily used as mechanical frameworks for building transformative electronics.

Here, we propose a one-step preparable, body-temperature softening electronic ink for high-resolution (~50 µm) additive manufacturing of mechanically transformative bioelectronics. Through direct-ink-write (DIW) printing, we deposit highly viscous inks layer-by-layer to form intricate 3-dimensional structures with high precision. To optimize the ink rheology for high printing stability, we sonicate 5.0 wt% of copper microparticles and gallium to form a gallium-copper composite. Exceptional thermal conductivity of copper (320.72 W m^{-1} K^{-1}) lowers the ink's melting temperature to 27°C, which accelerates its solid-to-liquid phase transition time by 31% (from 64.18 to 16.96 seconds) at body temperature (~37°C). The ink showcases enhanced electrical conductivity (3.69×10^6 S m^{-1}) and an exceptional mechanical tuning ratio (a negligible elastic modulus at the soft mode and a high modulus comparable to pure gallium (~10 GPa) at the rigid mode), highlighting its dual functionality: electrical functionality and mechanical adaptability.

Our electronic ink showcases excellent rheological, thermal, electrical, and mechanical properties, as demonstrated through DIW of two transformative bioelectronic devices: an epidermal PPG (Photoplethysmogram) sensor for pulse monitoring and a wireless optoelectronic device for optogenetics and phototherapy. The transformative epidermal PPG sensor maintains rigid at room temperature for easy handling and transitions to a soft, skin-like texture at body temperature for comfortable wear, even during motion. Meanwhile, the stiffness-tunable wireless optoelectronic device is intricately patterned with interconnects of varying widths and *thicknesses (100 - 400 µm) and built with 15 vertical interconnect accesses and 17 surface-mounted devices, designed to optimize wireless power transfer efficiency by accommodating skin effects in RF antenna design. Additionally, it transitions bidirectionally between stiff and stretchable states (>206% strain) with temperature changes, adapting to tissue deformation. These demonstrations underscore the ink's transformative nature, substrate versatility, and compatibility with high-resolution additive manufacturing techniques, thus amplifying its potential in transformative electronics for consumer electronics, robotics, sensors, and more.*

2:00 PM PM02.02.03

3D Printing of PEDOT:PSS Based Photoresin for Manufacturing Metastructure Architected Pressure Sensors with High Sensitivity *Ozan Karakaya[1,2], Naroa Lopez-Larrea[3], Ali Tunc[1,2], Mikel Rincón Iglesias[1,2,4], David Mecerreyes[3,5], Miryam Criado-Gonzalez[3] and Gerardo Hernandez-Sosa[1,2,1]; [1]Karlsruhe Institute of Technology, Germany; [2]InnovationLab, Germany; [3]University of the Basque Country, Spain; [4]BCMaterials, Basque Center Centre for Materials, Applications and Nanostructures, UPV/EHU, Spain; [5]Basque Foundation for Science, Spain*

There is a growing demand for flexible pressure sensors designed to meet the requirements of a wide range of applications, such as wearable electronics and robotics.[1] Compared with traditional templates, pressure sensors utilizing 3D metastructure designs can offer high sensitivity, wide sensing range, design flexibility, and adjustable performance.[2] However, manufacturing these multifunctional micro-detailed structures can be challenging, as it requires additional steps to cast the active material onto the printed structures.

Here, we utilize a PEDOT:PSS based photoresin to 3D print body-centered cubic lattice-based pressure sensors.[3] Using this photoresin in a DLP printer enables the manufacturing of conductive PEDOT:PSS polymer composites with high resolution (27 µm planar and 50 µm thickness) in a single step, eliminating the need for additional processes. As for the sensor design, body-centered cubic lattices are chosen due to their adjustable mechanical properties, which can help in fine-tuning the device's conductivity under applied stress.

Sensors were characterized by applying compression onto samples while recording the corresponding displacement and electrical resistance. The resistance response was defined as $\Delta R/R_0 = (R_0 - R)/R_0$*, where R and* R_0 *represent the resistance with and without compressive stress, respectively. The sensor with 30% relative density has a Young's Moduli of 0.21 MPa and it can be adjusted by varying the relative density, as evidenced by sensors with 40% and 20% relative densities exhibiting Young's Moduli of 0.61 MPa and 0.07 MPa, respectively. Moreover, the sensor with 30% relative density exhibited an instant response to pressure, showing a dramatic increase in* $\Delta R/R_0$ *of 0.96 within the pressure range of 0-10 kPa. The sensitivity of the sensor was measured 0.86* kPa^{-1} *at 0-0.5 kPa, 0.19* kPa^{-1} *at 1-2 kPa, and 0.01* kPa^{-1} *at 2-10 kPa range, demonstrating its capability to operate effectively across different pressure ranges. This process has been visualized by connecting the sensor in a circuit where the LED illuminates upon applying pressure to the sensor. The intensity of the light increases with additional pressure, indicating a decrease in electrical resistance.*

In the future, we plan to print various lattice designs with different mechanical properties including anisotropic characteristics to manufacture sensors with a large range of sensitivities. Manufactured sensors will be used in proof of concept applications in pressure mapping or directional pressure sensing.

Fully Printed Submicron Carbon Nanotube Thin-Film Transistors *Brittany N. Smith, Faris M. Albarghouthi, Jay Doherty, Xuancheng Pei, Quentin Macfarlane, Matthew Salfity, Daniel Badia and Aaron D. Franklin; Duke University, United States*

Printed carbon nanotube thin-film transistors (CNT-TFTs) show promise for flexible, sustainable electronics due to their compatibility with a wide range of printing approaches and demonstrated recyclability. However, the limited resolution of printers has been a major barrier to realizing commercial applications of printed CNT-TFTs such as display backplane electronics, sensors, and back-end-of-line devices for chips. Previous reports have shown creative approaches to realizing submicron channel lengths using chemical processes, such as ink-to-ink repulsion and self-assembled monolayers, or mechanical manipulation in the form of post-print line-splitting. While these workarounds show possibility, there are challenges of repeatability due to process complexity, reliance on homogeneous chemical functionalization, and the difficulty of achieving fine control of transistor channel dimensions due to variability in line-edge roughness. In this work, we present fully printed submicron CNT-TFT channel lengths without chemical modification or physical manipulation post-printing using a new form of direct ink writing called capillary flow printing (CFP). The versatility of this printing technique is demonstrated by printing conducting (Ag), semiconducting (CNTs), and insulating (ion gel) inks on several types of substrates (SiO_2, Kapton, and paper) and through the fabrication of various TFT device structures. Notably, CFP of these CNT-TFTs yielded on-currents of 1.12 mA/mm when back-gated on Si/SiO_2, and 490 μA/mm when side-gated through ion gel on Kapton, demonstrating the strong transistor performance achievable with CFP. Mechanical bending and sweep rate resilience of devices printed on Kapton show the wide utility of CFP-fabricated devices for flexible applications. When benchmarked against state-of-the-art thin-film technology, the on-current of the fully printed CFP CNT-TFTs on Kapton rivals that of IGZO and LTPS devices at a channel length smaller than a tenth of the cleanroom-manufactured TFTs. In summary, the advancements of this work are three-fold: 1) the demonstration of submicron gaps between as-printed silver nanoparticle (AgNP) electrodes; 2) the development of a printing procedure to realize dense CNT films with a line width below 20 μm; and 3) the demonstration of fully printed CNT-TFTs with submicron channel lengths on a flexible substrate. Overall, this work highlights CFP as a viable fabrication method for submicron electronics through cleanroom-free printing techniques.

2:30 PM PM02.02.05

Metal Surface Coloring with Subpixel Control via Nanosecond Laser Pulses *Chia-Hung Chou and Hung-Wen Chen; National Tsing Hua University, Taiwan*

In the field of advanced manufacturing, the marking and coloring of metal surfaces not only serve practical purposes but also enhance aesthetic appeal. Traditional techniques like electroplating and anodizing offer a limited color spectrum and carry significant environmental drawbacks, primarily due to the intensive use of chemicals and the production of waste. Alternatively, pulsed laser irradiation stands out as a superior method, allowing for the precise application of color directly onto metal substrates. This innovative approach facilitates the generation of intricate and multicolored designs, while concurrently mitigating environmental impacts. Moreover, it improves product longevity and aesthetic quality without the use of hazardous materials. Therefore, this technique aligns with the Sustainable Development Goals (SDGs) by minimizing emissions and eliminating the reliance on hazardous chemicals.

Laser-induced coloring technology utilizes pulsed lasers to create permanent, precise color markings by manipulating the energy dynamics on material surfaces. Prior research has predominantly focused on analyzing the parameters that influence laser coloring, evaluating the impact of thermal effects on color fidelity, assessing color stability across different distances, and generating a spectrum of colors within a single area through multiple treatments. Nonetheless, the diversity of achievable colors, dictated by the distribution of laser energy and the absorption properties of the material, frequently remains limited.

This study introduces a novel approach that arranges non-overlapping subpixels within a single pixel. Inspired by the RGB color mixing method used in liquid crystal displays, this technique offers enhanced flexibility beyond the traditional RGB primary colors. The number and pattern of subpixels can be freely designed, facilitating the mixing *of a broader spectrum of colors and thereby extending the color gamut range. Our experiments, applied to stainless steel (SUS304) and titanium (Grade 2), confirm the feasibility of achieving refined color blending at a micro-scale. We employed the CMYK color model, specifically focusing on the manipulation of yellow (Y) and black (K) as foundational colors within a pixel structure measuring 100 x 100 μm*^{2}*. Each pixel was engineered to systematically vary sub-pixel sizes, resulting in a gradient color bar that visually exemplifies the efficacy of our color mixing strategy. While the total area occupied by the two subpixels within each pixel remained constant, the proportion of the yellow subpixel systematically decreased from 100% to 0%, moving from left to right across the bar, with the proportion of the black subpixel increasing inversely. This demonstrated gradient color transition from Y to K not only underscores our capability in micro-level color blending but also significantly expands the achievable color gamut, demonstrating potential for advanced color applications in various industrial contexts.*

3D Printing of a Self-powered Auxetic Photonic Skin *Yu Jun Tan; National University of Singapore, Singapore*

Mechanoluminescence (ML) is a remarkable luminescent phenomenon in which materials emit visible or ultraviolet light in response to mechanical actions like compression, bending, or stretching. Compared to other forms of luminescence, such as photoluminescence (light emission due to photon absorption) or electroluminescence (light emission from an applied electric field), ML stands out for its self-powered feature - the light emission does not require external power sources. The light emission in ML is induced by changes in mechanical stress, allowing it to sense and visualize stress distributions in real-time. This real-time monitoring capability is highly advantageous for dynamic applications and time-sensitive experiments, such as monitoring the motion of the human body during exercise. In this work, we present a self-powered auxetic photonic skin that does not require external power. Periodic cellular reentrant structures were fabricated to achieve uniform and intense ML emission. We systematically characterized the ML performance in terms of phosphor content, strain, stretching frequency, and fatigue resistance.

3:30 PM PM02.02.07
Three-Dimensional Printing of Bottlebrush Block Copolymer for Structural Color with Dynamic Control *Xiao Huan, Yash L. Kamble, Jiachun Shi, Haisu Kang, Johnny A. Lomas, Sanghyun Jeon, Charles E. Sing, Simon Rogers, Damien Guironnet and Ying Diao; University of Illinois at Urbana-Champaign, United States*

Materials with structural color can reflect light of different wavelengths depending on their nanostructures, creating various colors without the use of chemical pigments. This eco-friendly alternative to traditional synthetic dyes helps prevent environmental pollution from industrial waste. Structural color also exhibits high brightness and dynamic photonic properties that are difficult to achieve with synthetical dyes. Advanced additive techniques can utilize controlled self-assembly to create 3D objects with multiple structural colors from materials such as liquid crystals, nanoparticles, and block copolymers. Among these materials, bottlebrush block copolymers (BBCPs) are particularly promising for mimicking biological structural color due to their ability to self-assemble into diverse nanoscale morphologies with tunable domain sizes. However, printing complex 3D structures with dynamic properties remains a challenge due to the trade-off between controlling assembly kinetics and maintaining mechanical stability. In this study, we demonstrate an evaporation-driven direct-ink-writing method to construct 3D structures with high-density BBCPs. By controlling printing parameters such as speed and ink concentration, we can adjust the aspect ratio of the liquid bridge at the nozzle opening, thereby controlling the evaporation rate during printing. This allows us to kinetically trap different non-equilibrium states of self-assembly. The tunable reflective spectrum of the printed objects is achieved through varying domain sizes confirmed by *spectrometry and scanning electron microscopy. This mechanism enables 3D freeform printing with dynamically controlled structural color from a single ink.*

3:45 PM PM02.02.08

Additive Manufacturing of Polymer Composites with Printing-Direction-Independent Properties *Shani Ligati Schleifer; Ben-Gurion University of the Negev, Israel*

The implementation of additive manufacturing techniques for thermal management applications necessitates the development of printable materials with enhanced properties. This study focuses on enhancing the thermal and mechanical properties of 3D-printed polymer composites (UV-based vat photopolymerization; VPP), starting by loading graphene nanoplatelets (GNP) as fillers into a monomer solution. GNP stabilization in the solution is achieved via the addition of sepiolite, a fiber-like clay, that traps them in dispersion. However, the inherent GNP-UV blocking limits its concentration in the VPP-printed composite, and its 2D nature yields parts with undesired anisotropic properties. We overcome this GNP concentration limit by using the excluded volume approach, namely, adding micron-sized diamonds to increase the GNP effective concentration. This approach also transforms the anisotropic VPP-printed composite into an isotropic structure, ensuring consistent thermal and mechanical enhancement regardless of the printing direction. Thermal conductivity (TC) and fracture toughness (FT) are enhanced by 180% and 100%, respectively (vs. the neat polymer). However, the electrical conductivity (EC) is also enhanced, which is undesirable in thermal management systems (risk of short-circuiting). Therefore, hexagonal boron nitride is added to reduce the EC, producing composites with enhanced TC and 140% FT enhancement. Our approach holds promise for various applications, especially in advanced heat management solutions, where enhanced TC, light weight, and low EC are imperative.

4:00 PM PM02.02.09

Multi-Material 3D Printing of Organic Semiconductor-Carbon Nanotube Microstructures via Multi-Photon Laser Lithography for Flexible Electronics and Bioelectronics *Omid Dadras-Toussi and Mohammad Reza Abidian; University of Houston, United States*

Development of flexible organic electronics has attracted tremendous attention in various areas of micro and nano-technology research including electronics, energy storage, and biomedical science. Among numerous three-dimensional (3D) printing methods, direct laser writing (DLW) based on muti-photon laser lithography (MPL) is state-of-the-art maskless optical lithographic technique that enables creation of large-scale complex 3D microstructures with submicron features sizes at the highest resolution (<100nm).
Here we report a homogenous MPL compatible ink which consists of photosensitive polymer poly(ethylene glycol) diacrylate (PEGDA), photo-initiator (ethyl (2,4,6-trimethylbenzoyl) phenylphosphinate), two miscible agents (dimethyl sulfoxide and pentaerythritol tetrakis(3-mercaptopropionate)) and conductive fillers poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) and Multi-Walled Carbon Nano Tubes (MWCNTs). Electrical characterizations showed that incorporation of 0.15 wt% MWCNTs and 0.4 wt% PEDOT:PSS increased the electrical conductivity of 3D conductive microstructures from 4.2E-05 ± 3E-05S m^{-1} to 1.4E05 ± 2.9E04 S m^{-1}. We further introduced an MPL-based method for fabrication of flexible high quality metamaterial 3D microstructures with surface roughness of 258 ± 2 nm, such as micro- printed circuit boards, micro resistors, micro capacitors, and multi-site neural microprobes with enhanced electrical properties. For example, neural microprobe with diameters of 20μm exhibited impedance of 1.8 ± 0.3 kHz at ~ 1 kHz and charge storage capacity of 48.1 ± 4.7 mC cm^{-2}. 3D printing of PEDOT-MWCNTs based multi-material microelectronics via MLP holds a significant promise in printed circuitry and implanted bioelectronics.

4:15 PM PM02.02.10

Printable Ionic Liquid-Polymer Hybrid Materials for Sensors and Bending Actuators *Daniela Correia[1], Liliana Fernandes[1], Carmen R. Tubio[2], Nelson Pereira[1] and Senentxu Lanceros-Mendez[2,1]; [1]Universidade do Minho, Portugal; [2]BCMaterials, Spain*

The rapid digitalization of the society and the economy, associated to concepts like Internet of Things and Industry 4.0 is boosting the increasing implementation of sensors and actuators. Printing technologies are called to play a major role in this field, as it allows the necessary steps towards sustainable digitalization.

In recent years, printable smart materials incorporating ionic Liquids (ILs) [1] have garnered significant attention due to their ability to develop smart flexible and conformable devices, including sensors, actuators and energy harvesting devices, among others. Those approaches rely on properly tunning the functional properties of the ionic liquid by adequate selection of anion and cation, on the compatibility between IL and polymer and the printability of the developed inks.

In this work, different IL have been used for the development of functional inks and have been applied for the development of force and deformation sensors, bending actuators and optically responsive systems. $[Bmim][N(CN)_2]$ has been use to optimize the piezoionic response of different polymer matrices, including electroactive (PVDF) and biobased (e.g. sodium alginate) ones; $[C_4mim]$ $[FeCl_4]$ Has been used to induced magnetoelectric sensing and bending actuation response and $[Bmim]_2[NiCl_4]$ for thermochromic, thermoelectric and humidity sensing, response within a PVDF polymer matrix. Finally, optically responsive materials are obtained based on $[Bmim][Eu(tta)_4]$ and $Na[Eu(tta)_4]$.

The design rules and processing strategies will be discussed together with a complete physical-chemical characterization of the printed materials, their functional response and device demonstration.

Development of Conductive Metal Layers-Integrated 3D-Printed Polymers Driven by Thiol-Mediated Electroless Plating Process *Hyunseung Yang, Dongmin Lee, Gwajeong Jeong and Subin Cho; Korea Electronics Technology Institute, Korea (the Republic of)*

Metalizing three-dimensional (3D)-printed polymers has attracted significant attention for the fabrication of high-end, customized electrical components. In this study, we introduce a simple yet highly effective method for integrating conductive metal layers onto 3D-printed polymers. A photocurable 3D printing resin was specifically designed to introduce thiol groups onto the surface of the 3D-printed structures. These thiol groups served as active sites for metal ion complexation via strong metal–sulfur bonds, enabling the deposition of metal layers through an electroless plating process. This approach facilitated the uniform and robust adhesion of various metal layers, including copper (Cu) and silver (Ag), on arbitrary 3D-printed structures, demonstrating its compatibility with a range of metals. To demonstrate the potential of this method, we fabricated a Cu-layered 3D-printed *electrode and successfully employed it as a functional electrochemical sensor. This strategy provides valuable insights for designing functional metallic structures and paves the way for manufacturing lightweight, customizable electrical components.*

Data Driven Design of 3D Stiffness Gradient Acoustic Metamaterials for Impedance Matching *Catherine Brinson, Rayehe Karimi Mahabadi, Rudin Cynthia and Han Zhang; Duke University, United States*

Metamaterials are artificially engineered materials designed to exhibit properties not commonly found in natural materials. Acoustic metamaterials, a subset of metamaterials, manipulate sound waves in ways that conventional materials cannot. Acoustic waves play a crucial role in various applications, including medical imaging, non-destructive testing, and sonar systems. One of the significant challenges in the application of acoustic waves is impedance matching, which is essential for minimizing reflections and maximizing the transfer of acoustic energy between different media. Our project focuses on designing 3D stiffness gradient acoustic metamaterials for impedance matching, particularly targeting the creation of a metamaterial with acoustic impedance comparable to that of water using metals. This has significant implications for medical ultrasound devices, where we need a material that transitions from softer at the patient interface to stiffer at the transducer interface. We propose a comprehensive framework capable of designing metamaterials with desired acoustic impedance and gradient stiffness. The key steps in our approach include generating initial designs using a periodic covariance function, ensuring that the unit cells are both periodic and random. Furthermore, we integrated manufacturing constraints into the design process, ensuring that the structures are connected and feasible for fabrication. Therefore, we developed an algorithm to ensure that the generated designs are connected and remain connected throughout the optimization process. We developed both single and multi-objective optimization algorithms, including both a genetic algorithm and other machine learning approaches, to achieve the target stiffness and acoustic impedance. Our approach resulted in the design of metal-based metamaterials that exhibit acoustic impedance near that of water. This project demonstrates the feasibility of designing acoustic metamaterials with gradient stiffness and specific impedance properties through advanced optimization techniques. These innovations pave the way for improved materials in various acoustic applications, particularly in ultrasound devices, by providing better impedance matching and thereby improving the efficiency of acoustic energy transfer.

8:30 AM PM02.03.02
3D Woven Metamaterials via Additive Manufacturing and Computational Design *Carlos M. Portela, Molly Carton, James Surjadi and Bastien F. Aymon; Massachusetts Institute of Technology, United States*

Three-dimensional (3D) architected materials (or mechanical metamaterials) provide a pathway to defy the limitations of monolithic materials through their engineered internal microstructures, allowing them to exhibit unique and extreme properties. Thus far, research on the design of these architected materials has been primarily dominated by the quest to achieve extreme stiffness and strength, which limits their applicability in various fields. Unlike conventional truss-based architectures which induce stress concentrations and fail at strains lower than

their constituent material, compliant woven architectures have recently been demonstrated to be able to sustain large tensile strains (several times larger than its constituent). However, the complex mechanics of woven architectures remain to be fully understood, and substantial bottlenecks exist in their design.
Here, we provide a computational design framework for woven metamaterials that allows for spatial variation of fiber- and lattice-level parameters, allowing rapid generation of functionally graded metamaterials that can be additively manufactured at the micron scale and beyond. Variation of parameters at the sub-unit-cell level (on individual truss elements) greatly extends the design space and facilitates new modeling methods for these materials. Through reducing the lattice to a graph representation in order to create the weave topology, we facilitate the creation of woven architected materials with tailorable mechanical properties. Using this design framework, we present two modeling routes (high-fidelity and reducer-order) to quantify the architecture-dependent nonlinear properties, attributing contributions to nonlinear material properties and frictional contact. Through in situ micro-tension experiments to validate our models, we demonstrate that hybrid woven architectures can not only exhibit higher stiffness (more than an order of magnitude) than pure woven architectures, but also attain higher dissipated energy densities than the sum of their counterparts. This work aims to provide a pathway for the design of compliant metamaterials—with arbitrary tunability—via an integrated computational design and modeling framework geared for production via additive manufacturing.

8:45 AM *PM02.03.03
Molecular Control via Dynamic Chemical Bonding Enables Material-level Responsiveness in Additively Manufactured Metallo Polyelectrolytes (MPEC) *Julia R. Greer, Seola Lee and Seneca J. Velling; California Institute of Technology, United States*

One class of materials, metallo-polyelectrolyte complexes (MPEC), is unique in that it contains organic frameworks that can undergo reversible electrostatic interactions through the formation and dissociation of dynamic bonds. They consists of negatively charged polyanions crosslinked by metal cations via electrostatic interactions. These molecular-level processes give rise to a wide range of material dynamic responses, for example, stimuli-responsiveness, self-healing, dissolution in solvent, and improved toughness through enhanced energy dissipation. The knowledge gap between molecular-level chemistry of dynamic bonds and continuum-level material properties have limited the development and utilization of these materials in real-world applications. Existing state-of-the-art fabrication methods typically involve cumbersome, multi-step solution-based synthesis, and the multitude of time/length scales in actuation and stimulus-driven response of MPECs presents computational challenges, which limits theoretical guidance for experiments.

We demonstrate a single-step stereolithography-based additive manufacturing (AM) method to produce MPEC gels, which produces homogeneous, stable, and long-lasting materials using a straightforward synthesis route. We demonstrate that the AM-fabricated MPEC gels
allow for tunability in their mechanical response via two control parameters: (1) metal ion valency and (2) polymer charge sparsity. We discover that the mono-, di-, and trivalent metal ions afford control of the coordination environment and bond strength within the polymer matrix, which propagates to the macroscale properties where higher valency ions result in stiffer and tougher materials. This work provides a comprehensive understanding of the metallo-polyelectrolyte behavior and lays out their parameter space, enabling selective design of advanced compliant and multifunctional materials.

9:15 AM PM02.03.04
Formulating Liquid Crystal Elastomer Resins for Digital Light Projection Additive Manufacturing *Dominique Porcincula and Catherine Reyes; Lawrence Livermore National Laboratory, United States*

Liquid crystal elastomers (LCEs) are a novel class of responsive polymer-based materials that change shape upon exposure to external stimuli such as heat, light, and pH. To formulate elastomers capable of exhibiting a maximum degree of shape change, resins must be comprised of functional monomer "reactive mesogens" linked to thiol or amine based "spacers", that when oligomerized, form a viscous ink. While such an ink is suitable for facile extrusion based processing via Direct Ink Write (DIW) additive manufacturing(AM) methods, it is incompatible for processing using digital light projection (DLP) due its high viscosity. Because of this the additive manufacturing of LCEs via digital light processing (DLP) remains a nascent field, with many of the current uncertainties related to how low viscosity and suitable ink formulations can be made for DLP, while still maintaining the alignment capability, and thus, actuation of LCEs. Moreover,a more general understanding of how additives in oligomer inks can alter properties like viscosity, alignment, and transition temperature, without inhibiting actuation has yet to be systematically investigated. . Here, we screen various synthetic pathways to highlight property features that lead us to the ideal LCE formulation for DLP processing. This includes tuning the oligomer size by monomer type, spacer composition, use of additives, and evaluating their effect on resin viscosity and printed LCE actuation. This tuning process enables some of the first truly 3D printed LCE parts with 3D-to-3D shape change, enabling us with the knowledge to move towards printing parts with greater complexity, as seen with more conventional photopolymer resins but which are incapable of shape change.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Geometric Templating of Shellular Structures with Liquid Crystalline Soap Films for Superior Mechanical Strength *Shu Yang; University of Pennsylvania, United States*

Cellular structures are common building blocks in natural systems, as seen in bones and shells, offering lightweight and high strength. The mechanical properties of these truss-based structures, however, heavily rely on the underlying cellular geometries. Therefore, the cellular structures could be brittle. In contrast, shellular structures, which are also lightweight, exhibit high stiffness-to-weight ratio, enhanced mechanical energy absorption, and large surface area to volume ratios.

When coating a thin shell on the cellular structure, a shellular structure of a continuous minimal surface is formed, demonstrating dramatically increased toughness and resilience. Through the design of various 3D printed cellular structures and varying subdivided cell densities and coating materials, we explore the effect of geometry, molecular and nanosheet alignment with liquid crystalline ordering, and their combination to the mechanical performance. The 3D shellular structures have potential applications such as impact energy absorbers, stress sensors, and high-strength and lightweight structural materials.

10:30 AM PM02.03.06

Polycatenated Architected Materials *Wenjie Zhou, Sujeeka Nadarajah and Chiara Daraio; California Institute of Technology, United States*

Architected materials derive their properties from the geometric arrangement of their internal structural elements, rather than solely from their chemical composition. They can display remarkable behaviors such as high strength while being lightweight, negative Poisson's ratios, and shear-normal coupling. However, architected materials so far have either exhibited solid-like or fluid-like behavior, but not both. Here, we introduce a class of materials that *consist of linked particles assembled in three-dimensional domains, forming polycatenated architected materials (PAMs). We propose a general framework for PAMs that translates arbitrary crystalline networks into particles' concatenations and design particles' geometry. The resulting materials are cohesive, yet the individual particles retain some kinematic freedom. In response to small external loads, PAMs behave like non-Newtonian fluids, showing both shear-thinning and shear-thickening responses. At larger strains, PAMs behave like solids, showing a nonlinear stress-strain relation, like lattices and foams. These responses are regulated by a jamming transition determined by the particles' arrangement and the direction of loading. PAMs are scalable, showing comparable mechanical responses at both millimeter- and micrometer-scales. However, micro-PAMs can change shape in response to electrostatic charges. PAM's properties are relevant for developing stimuli-responsive materials, energy-absorbing systems and morphing architectures.*

10:45 AM PM02.03.07

Additive Manufacturing of Multifunctional Meta-Sandwich Composites—Lightweight, Load-Bearing and Broadband Electromagnetic Wave-Absorbing Structures *Daniel D. Lim[1], Jeongwoo Lee[2], Jinwoo Park[3], Jaemin Lee[2], Dowon Noh[2], Sujin Park[2], Grace Gu[1] and Wonjoon Choi[2]; [1]University of California, Berkeley, United States; [2]Korea University, Korea (the Republic of); [3]Agency for Defense Development, Korea (the Republic of)*

The use of lossy material-based mechanical metamaterials, featuring engineered porous geometries like an octet-truss, has emerged as a promising multifunctional structure for broadband absorption. The porous nature of these metamaterials not only improves mechanical characteristics but also enables structural electromagnetic wave attenuation through impedance matching, internal scattering, and reflection. However, the exposed cellular lattice structure poses challenges for real-world applications. Packaging the cellular structure as a sandwich panel is a viable solution to mitigate this challenge, as the additional faceplates increase mechanical strength and stiffness while protecting the cellular structure from the external environment. Despite this, the fabrication and assembly of multifunctional meta-sandwich composites remain challenging using conventional manufacturing processes such as cutting, engraving, dipping, molding, and heat treatment. In this study, we utilize multi-material additive manufacturing to present a multifunctional meta-sandwich structure as a seamlessly integrated component comprising functional faceplates and dielectric lossy material-based octet-truss geometries. This multifunctional structure is lightweight, load-bearing, and a high-performance broadband EM wave absorber. The EM responses are explored within the 4–18 GHz range, with varying material combinations and multilayers of the upper-lower faceplates and the octet-truss core. Numerical analysis elucidates the absorbing mechanisms of the meta-sandwich structures. The fabricated composite, in a thin, single-layer structure comprising a transmitting upper faceplate, a dielectric lossy core, and a reflecting lower faceplate, achieves an average absorption rate of 95.0% and a broadband reflection loss (≤-10 dB) over the entire measured bandwidth (5.8 – 18 GHz). Furthermore, flexural testing confirms superior bending resistance compared to conventional honeycomb structures. The multi-material meta-sandwich design will inspire versatile multifunctionality enabled by rationally combining mechanical metamaterials and functional housing.

11:00 AM PM02.03.08

A Polymeric 3D Printing Material System Exhibiting an Extensive Range of Mechanical Properties *Zefang Li[1], Sarah Propst[1], Carmel Majidi[2] and Jochen Mueller[1]; [1]Johns Hopkins University, United States; [2]Carnegie Mellon University, United States*

In nature, structures and systems frequently employ multiple materials with significantly varying stiffnesses to optimize their overall mechanical performance and functionality. The integration of such highly dissimilar materials in multi-material 3D printing promises to substantially enhance the design space across various applications, including biomedical devices, mechanical metamaterials, and soft robotics. However, materials with *extreme mechanical property differences typically exhibit also substantial differences in their chemical and physical properties, such as surface energy and thermal expansion coefficients. This often leads to reduced adhesion and thermal interfacial stresses, rendering them incompatible with each other and, consequently, limiting the design space. In this work, we propose a polymeric thiol-ene elastomer material system that spans a large range (e.g., ~5 orders of magnitude in the elastic modulus) of mechanical properties while maintaining compatible chemical and physical properties. The extremes —specifically, the soft and stiff materials that can be mixed at any ratio—exhibit the same photo-crosslinking mechanism but vary in crosslinking densities, resulting in significantly different mechanical properties. This material system is compatible with various 3D printing technologies, as demonstrated through vat photopolymerization and direct ink writing. The ability to print materials with extreme differences together enables improved structural performances in applications such as soft electronics and shock absorption.*

11:15 AM PM02.03.09

Controlling the Temperature Distribution of 3D Printed All-PE Material *Ina Klein[1], Thomas Tran[1], René L. Reiser[2,3], Maximilian Theis[1], Sabine Rosenfeldt[1], Marius Schöttle[1], Carl Schirmeister[2,3], Peter Bösecke[4], Stefan M. Rettinger[1], Rolf Mülhaupt[2] and Markus Retsch[1]; [1]Universität Bayreuth, Germany; [2]Albert-Ludwigs-Universität Freiburg, Germany; [3]LyondellBasel Industries, Germany; [4]European Synchrotron Radiation Facility, France*

Ongoing miniaturization and weight reduction in portable electronic devices present a growing challenge for thermal management. Efficient heat dissipation is crucial to prevent malfunctions and early failure. This problem is typically tackled by incorporating highly conducting fillers into lightweight polymers. However, the thermal resistance between the filler and matrix often requires high filler loadings, leading to increased costs, compromised weight advantages, and reduced processability.[1] Moreover, recycling of multi-material composites is complex, expensive and energy-consuming.[2] All-PE composite represents a single-material alternative, comprising HDPE wax, HDPE and UHMWPE. Exposure to shear force and extensional flow orients the UHMWPE, leading to formation of self-reinforcing fiber-like shish-kebab nanostructures.[3] The continuous shish crystals are expected to efficiently conduct heat along the fiber axis, which increases the thermal conductivity in that direction. 3D printing through fused filament fabrication applies the necessary forces for the shish-kebab formation and also allows precise control over the orientation of the fibrous structures.[3] Here, we demonstrate how the printing parameters influence the anisotropic thermal diffusivity, which is measured using lock-in thermography on thin films. The findings are used to provide the first example of digitally defined control of temperature distributions in 3D-printed all-PE specimens.[4] Therefore, all-PE material implies a great potential for directing heat without the requirement for multiple materials or multi-material composites.

Bringing Mechanically-Activated Chemical Reactions into Additive Manufacturing *Erica Watchorn-Rokutan[1], Niamh Willis-Fox[2,1], Etienne Rognin[1] and Ronan Daly[1]; [1]University of Cambridge, United Kingdom; [2]The University of Manchester, United Kingdom*

Targeted chemical reactions can be achieved in fluid flow using mechanical forces alone to activate a stress-sensitive functional molecule embedded within a polymer chain [1]. This polymeric mechanically-activated chemistry can deliver changes in colour or conductivity and can trigger cascade reactions or crosslinking. These stress-sensitive 'mechanophores' have been extensively studied at the molecular level but there have only recently been steps to understand how they react to macroscopic stresses, such as when included in additive manufacturing techniques or translated into real applications [2,3].

This presentation studies the highly controllable and repeatable velocity gradients and forces experienced within the nozzles of additive manufacturing processes such as inkjet printing and extrusion-based additive manufacturing. Most often these are studied to ensure functional and biological materials do not experience significant stresses and retain their structure after printing [4]. Here, instead, we present a range of custom-made experimental techniques to precisely control the fluid flow and forces experienced by solutions and hydrogels within nozzles to deliberately drive chemical changes and then couple these experiments with significant rheological analyses and simulations to reveal new insights and tools for the translation of mechanochemistry to direct-write additive manufacturing. This new level of understanding, along with our ability to better control the forces experienced by mechanically sensitive molecules, suggest an exciting future with spatial tuning of physico-chemical properties by simply tuning flow properties from a single material.

Highly Deformable Microfluidic Liquid Metal Antennas Based on Direct Ink Writing 3D-Printed Microchannels

Kento Yamagishi[1,2], Terry T. Ching[2,3], Wenshen Zhou[2], Shaoying Huang[2] and Michinao Hashimoto[2]; [1]The University of Tokyo, Japan; [2]Singapore University of Technology and Design, Singapore; [3]Boston University, United States

Three-dimensional (3D) printing is emerging as a promising alternative to soft lithography for fabricating microfluidic structures and devices due to its digital control, automation, and assembly-free capabilities. Current 3D printing technologies face challenges in simultaneously achieving direct printing of multilayered microfluidic structures without sacrificial or support materials, integrating electronic components with microchannels during printing, and ensuring flexibility and stretchability in the resulting devices. This study introduces a novel method using direct ink writing (DIW) 3D printing to fabricate flexible and stretchable microfluidic structures and devices [1,2]. Our approach allows for the direct printing of interconnected, multilayered microchannels using silicone sealant without the need for supporting materials or complex post-processing. During the printing process, electronic components are seamlessly integrated with the microchannels. Infusing liquid metal into the 3D-printed microchannels establishes electrical connections, enabling the creation of functional microfluidic electronics.

To demonstrate the capabilities of this technology, we designed and fabricated liquid metal antenna coils powered by a standard near-field communication (NFC) system operating at 13.56 MHz. These microfluidic devices exhibit significant advancements in deformability compared to traditional metal-based systems. Practical applications of this technology are showcased through two prototypes: a skin-attachable radio-frequency identification (RFID) tag using a commercial skin-adhesive plaster as the substrate, and free-standing flexible wireless light-emitting devices targeted for potential implantable applications. This advanced fabrication method facilitates the *automated production of stretchable 3D electrical circuits, particularly beneficial for devices requiring seamless integration with biological tissues and soft robots. This research paves the way for new advancements in flexible and stretchable microfluidic electronics, offering innovative solutions for next-generation soft electronic devices.*

SESSION PM02.04: Multimaterial Assembly
Session Chairs: Ryan Truby and Daryl Yee
Tuesday Afternoon, December 3, 2024
Sheraton, Second Floor, Constitution A

1:30 PM PM02.04.01
***Additively Manufactured Aquatic Animals Inspired Adhesive Biopatch** Nazek El-Atab and Aljawharah Alsharif; King Abdullah University of Science and Technology, Saudi Arabia*

The healthcare landscape is poised for a paradigm shift with the emergence of bioinspired micro-architectures for diagnostic and therapeutic devices. These novel architectures hold immense promise for revolutionizing patient care by offering a combination of enhanced performance, superior biocompatibility, and improved breathability and flexibility. This translates to minimized side effects and improved patient comfort, particularly for vulnerable populations like neonates, infants, and individuals with chronic skin conditions [1].
Traditional adhesive-based solutions often present limitations, including skin irritation, potential injury, and interference with biosignal monitoring near moist environments. Bioinspired micro-architectures address these challenges by promoting a paradigm shift towards reusable, drainable, and contaminant-free transdermal patches. These innovative patches, when integrated with therapeutic systems or attachable diagnostic sensors, have the potential to become the cornerstone of long-term diagnostic, therapeutic, and rehabilitation strategies for patients requiring specialized medical interventions [2].
Towards these goals, in this work, we show a hybrid additive manufacturing process, based on stereolithography and direct-in-writing, for the development of a multifunctional self-adhesive patch capable of collecting electrophysiological signals. The patch includes microscale suction cups – inspired by the skin of the octopus – to enable a self-adhesion capability without the need for chemical adhesives, in addition to microfluidic channels to make it breathable as well as electrodes to monitor biosignals. Biocompatibiliy tests show that such patches cause no skin irritation and leave no residues, as opposed to commercially available patches using chemical adhesives [3].

***3D-Printable High-Mixed-Conductivity Ionogel Composites for Soft Multifunctional Devices** Sergey Nechausov and Aslan Miriyev; Ben-Gurion University of the Negev, Israel*

Soft multifunctional components are crucial for synthetic robots, mimicking the multifaceted roles observed in natural organisms. The development of soft multifunctional components is hindered by the rigidity and intricate assembly of monofunctional parts and the difficulty of designing materials that respond distinctly to multiple stimuli. A key challenge in developing these devices is co-evolving multistimuli-responsive materials and their advanced fabrication methods. In this context, mixed ionic-electronic conductivity (MIEC) materials are distinguished for their dual conductivity, enabling simultaneous processing of diverse signals. However, the lack of precise fabrication methods has limited their full utilization in creating complex, hierarchically structured multifunctional devices. We present high-conductivity soft ionogel/single-walled carbon nanotube (SWCNT) MIEC composites (hereafter: ISMCs), which are 3D-printed with fine detail using vat photopolymerization (VPP). We leveraged the dual benefits of integrating imidazolium-based ionic liquids (ILs) into photopolymer compositions, which enabled us to produce ionogels with enhanced ionic conductivity and to achieve stable dispersions of SWCNTs that provide high electronic conductivity. We also adjusted the rheological properties and polymerization process of ISMCs to develop their precise VPP-3D-printing method. We 3D-printed ISMC micropyramids with gradient structures of three different heights, demonstrating their effectiveness as durable, multifunctional pressure-temperature sensors. These multifunctional ISMC pressure-temperature sensors are capable of detecting pressure thanks to a SWCNT network and sensing temperature in a broad range with a high sensitivity owing to the ionic conductivity of an IL. We suggest that the high electronic (1.82 mS/cm) and ionic (1.02 mS/cm) conductivities, combined with precise, single-step VPP 3D printing, lay the groundwork for versatile, soft multifunctional devices for various applications, thus potentially transforming domains from haptics to healthcare.

2:00 PM PM02.04.03

Programmable Soft Robotic Materials via Rotational Multimaterial 3D Printing *Jackson K. Wilt[1], Natalie M. Larson[2] and Jennifer A. Lewis[1,1]; [1]Harvard University, United States; [2]Stanford University, United States*

The rapid design and fabrication of soft robotic materials is of growing interest for shape-morphing, actuating, and wearable devices. Here, we have developed a method to parameterize and programmatically print soft robotic materials via rotational multimaterial 3D printing. Specifically, we pattern asymmetrical core-shell filaments in both 1D and 2D motifs, which are composed of an elastomeric shell and a fugitive core that serve as fluidic actuators. Our fabrication process allows precise control over the print path as well as pneumatic channel orientation, shape, and volume along each filament. We employ an automated Fermat spiral pathing approach to automatically path 2D designs by combining known curvature responses and relative resolution on surface actuators. This pathing method enables localized property assignment and design iteration through an interactive online code repository. Our integrated design and printing approach allows one to programmably generate soft robotic matter with complex shape morphing behavior on demand.

2:15 PM *PM02.04.04

Harnessing Chaotic Advection to Improve the Capabilities and Capacity of Multi-Material Direct Ink Writing Nozzles *Patrick McCauley, Juliana Nam, Minh Tran and Alexandra V. Bayles; University of Delaware, United States*

Multi-material additive manufacturing incorporates multiple species within a single 3D printed object to enhance its mechanical properties and functionality. Recent advances in multi-material direct ink writing, for example, allow users to selectively embed stimuli-responsive material in printed parts and program macroscopic deformations with exquisite control. In comparison to other soft actuator manufacturing techniques, direct ink writing (DIW) offers high templating precision and flexibility in architectural design. However, DIW of soft actuators suffers from some of the same drawbacks as encountered in layer-by-layer additive manufacturing. Sequential deposition of layers requires long build times, limits the resolution to the diameter of the print nozzle, and excludes ink materials that exhibit poor interfacial adhesion. While these manufacturing constraints may be perfectly *manageable during actuator prototyping, they limit generalizability and capacity on larger production scales.*

To circumvent some of these manufacturing bottlenecks, we leverage principles of chaotic advection to structure multi-material filaments in the printhead prior to deposition. Inspired by static mixers optimized to layer polymeric melts, we design modular millifluidic nozzles that force disparate streams through serpentine splitting, rotation, and recombination junctions. These junctions multiply the incoming 2D composition field across the cross-sectional area while preserving its relative spacing and orientation. Serial repetition of junctions compounds multiplication, allowing the heterogeneous distribution to be efficiently shrunk before it is dissipated by diffusive mixing. The 'advective assemblers' extrude precisely structured multi-material filaments, which can then be arranged into objects along a conventional 3D printing path or extruded into a support bath. Preassembling the lower levels of hierarchy in flow overcomes intrinsic challenges in layer-by-layer deposition, including improving interlayer adhesion and maintaining high volumetric throughput while maintaining fine layer resolution.

Unlike self-assembly or directed-assembly, advective assembly is dictated by rheology rather than chemistry. Granular inks with sufficiently high yield stress flow as a plug and stabilize streamlines even through abrupt flow junctions. Provided that the flowing streams are rheologically matched, materials with different chemistries can be predictively structured and extruded in a single processing step. We exploit this universality to manufacture hydrogel actuators sensitive to different environmental triggers, specifically water, salt, heat, and light. Gel precursors containing poly(ethylene glycol) diacrylate and poly(n-isopropyl acrylamide) are first dispersed with a poly(acrylic acid) microgel suspension. The microgels serve as a viscoplastic carrier fluid that preserves the fidelity of patterned concentration maps. After polymerization, the distribution of stimuli-responsive components causes gel filaments to swell differentially when triggered, giving rise to shape changes that persist over tens of centimeters. Deformation is predictively programmed by changing the concentration density map by simply adjusting the relative flow rates of incoming streams. The unique structures produced by advective assembly nozzles, and the geometrically dictated, chemistry-agnostic operating principles used to achieve them, provide an efficient route to fabricate designer functional materials.

2:45 PM BREAK

3:15 PM *PM02.04.05

Additive Manufacturing of Liquid Metal Emulsions, Polymer Composites and Synthetic Fascia for Soft, Stiff and Tough Multifunctional Materials *John W. Boley; Boston University, United States*

Materials of the future require burgeoning combinations of outstanding properties (e.g.'s, mechanical, electrical, and stimuli-responsive), which can only be realized through the careful design of new feedstocks, digital designs, and additive manufacturing. My talk will cover two broad examples of current and ongoing work from our group towards this effort. The first example will cover our work on designing liquid metal emulsions for 3D printed soft conductors and new types of soft power sources. For the former, we will present liquid metal emulsions that are compatible with direct ink writing (DIW) and can be combined with multi-material printing and automated pick-and-place to realize integrated soft and stretchable electronic devices and wearable haptics displays. For the latter we will present new liquid metal emulsions that can be molded into soft packaging to form soft galvanic cells that for stretchable power sources and self-powered keypads. The second example will highlight our work on developing new heterogeneous multiscale epoxy composites and synthetic fascia for high stiffness and high toughness 4D printed electrically controllable multifunctional structures that detect and tolerate damage. We employ these materials to print designs in a flat configuration that change shape into a lifting robot. The actuators formed by these materials exhibit maximum actuation stresses and specific forces that are larger than any other 3D printed actuators to date, with self-sensing and closed loop control capabilities. Our synthetic fascia *toughening approach allows these actuators to detect damage and retain a significant amount of their performance even after the actuators are fractured. By printing these materials into various lattice designs we demonstrate flat configurations that change shape into various 3D surfaces with a range of mean and double curvatures. Finally, we combine these materials to create a 3D lattice-based quadruped robot that can crawl, and a 3D sensing hemispherical cap that can detect and tolerate being run over by a car.*

3:45 PM PM02.04.06

Time Code for Multifunctional 3D Printhead Controls *Sarah Propst and Jochen Mueller; Johns Hopkins University, United States*

Direct ink writing (DIW), an extrusion-based 3D printing technique, holds substantial potential due to its ability to process a broad range of materials and integrate multifunctional printheads with features such as shape-changing nozzles, in situ curing, material switching, and material mixing. Despite these advancements, incorporating auxiliary controls into Geometry Code (G-Code), the standard programming language for these printers, remains challenging. G-Code's line-by-line execution requires auxiliary control commands to interrupt the print path motion, causing defects in the printed structure. We propose a generalizable time-based synchronization approach called Time Code (T-Code), which decouples auxiliary control from G-Code, enabling uninterrupted print path enrichment. We demonstrate the method's effectiveness with both high-end and affordable 3D printers by fabricating functional gradients and parallelizing printhead auxiliary devices for mass customization. Our method reduces defects, enhances print speed, and minimizes the mechanical burden on 3D printers, enabling the rapid creation of complex multimaterial structures.

4:00 PM PM02.04.07

On-Demand Programming of Liquid Metal-Composite Properties Through Direct Ink Write 3D Printing *Michael D. Bartlett[1], Eric J. Markvicka[2], Ravi Tutika[1], Spencer Pak[2], Ohnyoung Hur[1], Gwyneth M. Schloer[1] and Aaron Haake[2]; [1]Virginia Tech, United States; [2]University of Nebraska–Lincoln, United States*

Soft, elastically deformable composites with liquid metal (LM) droplets can enable new generations of soft electronics, robotics, and reconfigurable structures. However, techniques to control local composite microstructure, which ultimately governs material properties and performance, is lacking. Here, a direct ink writing technique is developed to program the LM microstructure (i.e., shape, orientation, and connectivity) on-demand throughout elastomer composites. This technique enables the creation of filaments, films, and 3D structures with unique LM microstructures that are generated on-demand and locked in during printing. By tuning ink rheology, the microstructure of LM droplets can be controlled in a wide range of ink materials. Through this control of microstructure, we show the ability to systematically tune mechanical and functional properties throughout a printed part with a single ink and a single nozzle. This is highlighted with anisotropic thermal conductivity, enhanced electrical conductivity, and unique mechanical properties such as tunable modulus and toughness due to the microstructure of LM inclusions. This methodology for programming properties in soft multifunctional materials combines material composition and process parameters, leading to greatly enhanced performance for emerging technologies that demand mechanical compliance with multifunctional response.

4:15 PM PM02.04.08

Enhancing Mechanical Behaviors with Liquid-Infused 3D Printed Architectures *Man Chen and Yanyu Chen; University of Louisville, United States*

Architected materials are a class of materials that can achieve remarkable mechanical properties beyond their base materials by tailoring their geometries. These properties include lightweight, high stiffness, strength, and *energy absorption. Additionally, advanced additive manufacturing enables the realization of architected materials with complex designs. Despite this, most of the existing architected materials composed of monolithic base materials, which hinders the exploration of unprecedented mechanical properties and functionalities. Recently, liquid-infilled materials such as nanomaterials, foams, and honeycombs, have shown improved mechanical properties, due to the liquid infiltration and its interaction with solid phases. However, the solid-liquid interaction in 3D printed architected materials and its resultant mechanical properties have not been uncovered, also the mechanical behaviors of solid-liquid structures via one-step fabrication are remain unexplored. Here, we designed a group of solid-liquid architected materials composed of beam, plate, shell, and solid structural elements, which are subsequently printed by the PolyJet 3D printer for one-step manufacturing. Quasi-static compressive tests were conducted to investigate the compressive behavior in multiphase structures. Experimental results demonstrate that solid-liquid architected materials exhibit higher stiffness, strength, and energy absorption compared to monolithic solid architected scaffolds. The solid element based simple cubic solid-liquid architected material shows highest energy absorption, which is approximately 1.8 times that of monolithic counterparts. Moreover, the strength and stiffness are approximately 44% and 31% higher, respectively. This enhancement is attributed to the unique deformation mechanisms during the compression tests. Initially, the solid and liquid phases worked synergistically to carry the applied load. With the increase of compressive strain, liquid flows out after cracks appear in the outer box, followed by the box gradually fails. Finally, the solid phase bears the load until it fails. This is quite different from the catastrophic failure modes of their monolithic counterparts, which bear all compressive load once the outer box collapses. Our multiphase architected materials are scalable and can be subjected to different loading conditions ranging from static to high velocity impacts. The design and deformation mechanisms can be used to design structurally resilient components that can be used in mechanically harsh environmental conditions, such as defense, aerospace, and automotive.*

4:30 PM *PM02.04.09
Design and Printing Micro-Acousto-Mechanical Metamaterials *Xiaoyu Zheng; University of California, Berkeley, United States*

Additive manufacturing has shown the promise of freedom of designs, enabling parts customization and tailorable properties where superior structural performances can be achieved by a fraction of weight density compared to bulk material. However, it is presently difficult to combine multiple classes of materials (structural, dielectric, conducting and ferroelectrics) and create features with hierarchical lengthscales. Unlike biological systems where functions, including sensing, actuation, and control, are closely integrated, few materials have comparable system complexity.
In this talk, I will present the design and printing of energy transduction devices composed of heterogeneous 3D microarchitectures. The printed materials consist of a network of micro-unit cells enabling programmed sensitivity and directivity of external stimuli coming from different directions. I will lay out design and printing principles that enable a new class of materials capable of acoustics, tactile and haptics generation. I will present the manufacturing and synthesis of these materials, as well as their mechanics and design methods underpinning their novel behaviors.

SESSION PM02.05: New Chemistries in Additive and Digital Manufacturing I
Session Chairs: Grace Gu and Ryan Truby
Wednesday Morning, December 4, 2024
Sheraton, Second Floor, Constitution A

8:30 AM PM02.05.01

Effect of Polymer Network Formation in the Two-Photon Polymerization Process on Polymer Properties and Their Applications *Madelyn P. Jeske[1], Sarah M. Fess[1], Mark Bonino[1], Yongfeng Lu[2], Mitch Anthamatten[1] and David R. Harding[1]; [1]University of Rochester, United States; [2]University of Nebraska–Lincoln, United States*

Two-photon polymerization (2PP) has been used extensively for a decade to print a wide range of 3D structures with nanoscale features. Less well known is the relationship between molecular networks that are formed and the properties of the resulting polymer. This is due in part to the chemistry of conventional 2PP resins that use photo-generated free radicals to initiate reactions; a process that is difficult to control and results in limited conversion and unwanted side reactions, that in turn causes brittleness and shrinkage-induced stresses and deformation. This work investigates the benefits of using a base-catalyzed polymerization process to improve the structure's mechanical properties (strength, fracture toughness) and reduced shrinkage (for better control of dimensions). Resins with photogenerated bases encourage highly selective thiol-Michael addition between monomers resulting in uniform chemical networks that are glassy and soften at 60-70C. Examples of applications that are possible with these resins include structures with shape-memory properties that respond external stimuli and microstructured metasurfaces for dry adhesion. Merging high-resolution 3D printing with molecular engineering of shape-memory networks can expand applications for printed structures in microfluidics, photonics, and structures that require tight dimensional control and fine resolution.

This material is based upon work supported by the Department of Energy [National Nuclear Security Administration] University of Rochester "National Inertial Confinement Fusion Program" under Award Number DE-NA0004144

8:45 AM PM02.05.02

Expanding Materials Selection for Self-Limiting Electrospray Deposition Postprocessing of 3D Geometries *Sarah Park, Ayman Rouf, Isha Shah, Jouan Yu, Robert A. Green-Warren, Emily Li and Jonathan P. Singer; Rutgers, The State University of New Jersey, United States*

Electrospray deposition is a spray coating process that utilizes a high voltage to atomize a flowing solution into charged microdroplets. These self-repulsive droplets evaporate as they travel to a target grounded substrate, depositing the solution solids. In self-limiting electrospray deposition (SLED), specific manipulation of the electrostatic repulsion, hydrodynamic forces, and evaporation kinetics can be employed to conformally cover 3D architectures or targeted microscale electrodes with microcoatings. The generated coatings are hierarchical, possessing either nanoshell or nanowire microstructure. For these reasons, SLED is a spray method that is highly compatible with additive manufacturing due to its ability to coat re-entrant and shadowed features. Here, we report on strategies to expand the materials selection possible with SLED including: (1) deposition on non-conducting substrates, (2) deposition using only materials that would be considered not compatible with SLED, and (3) deposition at nanoscopic coating thickness. These capabilities expand the applicability of SLED for the functionalization of a wide range of surfaces with (i) bioactive vaccine or drug, (ii) plasmonic, (iii) elastomerically-toughened composite, (iv) anti-corrosive epoxy or sol gel, (v) catalytic, or (vi) electrically conductive coatings.

9:00 AM PM02.05.03

Remarkable Dielectric Breakdown Strength of 3D Printable Polyelectrolyte Photopolymer Complexes *Ethan T. Iverson[1], Hudson Legendre[1], Jason Killgore[2], Jaime C. Grunlan[1,1,1] and Thomas J. Kolibaba[2]; [1]Texas A&M University, United States; [2]National Institute of Standards and Technology, United States*

Polymer-based dielectrics are struggling to keep pace with the increasing demands of modern electronics. This lag in dielectric performance has spurred significant interest in the production of advanced dielectrics via novel chemistries and processing techniques. Polyelectrolyte complexes (PECs) have recently shown great promise as dielectric insulation, but processing challenges presented by these ionically bound networks limit their use to conformal thin films. Recent advances have enabled the additive manufacturing of PECs with vat photopolymerization, allowing the creation of a polyelectrolyte complex of arbitrary shape. Herein, multiple polyelectrolyte resin formulations, comprised of polyethylenimine and methacrylic acid (with varying amounts of 2-hydroxyethyl methacrylate and/or N,N-dimethylacrylamide), are investigated for the production of additively manufactured dielectric insulators. These dielectrics not only possess high dielectric breakdown strengths (> 300 kV/mm), but their dielectric behavior can also be readily tailored through resin formulation and post processing conditions. The presented vat photopolymerization of PECs not only allows for the creation of bulk dielectrics, but it also provides a practical route forward for the precise production of dielectrics tailored for specific applications.

9:15 AM PM02.05.04

Frontal Polymerization Assisted Printing of Biobased Epoxy Composites Aolin Hou, Xiaofei Wu, Jingjing Qiu and Shiren Wang; *Texas A&M University, United States*

Frontal polymerization, when applied to additive manufacturing, substantially reduces energy consumption and enhances printing efficiency. Additionally, this technology facilitates the fabrication of free-standing structures, eliminating the need for support structures. However, most resins utilized for frontal polymerization are predominantly derived from petroleum feedstocks. In this research, an innovative resin was developed using a bio-derived epoxy composed of sorbitol polyglycidyl ether (SPGE) and methyl cellulose (MC), cured with m-xylylenediamine (m-XDA) and 4-dimethylaminopyridine (DMAP). The formulation was optimized to enhance reactivity and rheological behavior, facilitating the printing of intricate, self-supporting structures. The addition of MC notably increased the resin's viscosity at elevated temperatures, thus improving the stability during printing. Increasing the proportion of DMAP was found to raise the frontal temperature and speed of the polymerization front, corroborated by differential scanning calorimetry (DSC) results. Optimal results were achieved with a resin composition containing 5 wt% MC and 4 wt% DMAP, demonstrating suitability for frontal printing applications. Mechanical testing of both molded and frontally printed specimens indicated that the specimens produced through frontal polymerization assisted printing possessed comparable tensile strength (45MPa) and flexural strength (65MPa). The capability to print diverse geometries using a desktop 3D printer was successfully demonstrated, marking a significant advancement in the field of additive manufacturing with the potential for increased use of bio-derived materials.

9:30 AM BREAK

10:00 AM *PM02.05.05

Unconventional 2D and 3D Printing Tools with Hard and Soft Material Compatibilities Chad A. Mirkin; *Northwestern University, United States*

The ability to arrange molecules in precise 2D or 3D configurations underpins numerous applications, including the writing, printing, prototyping, manufacturing, and construction of new materials. Importantly, these diverse applications require tools that can operate across length scales, from nano to macro. Here, we will discuss the transition of Dip-Pen Nanolithography (DPN) from an atomic force microscopy-based imaging tool to a 2D writing tool to a tip-based synthesis and high-throughput materials discovery tool that is impacting fields spanning medicine to clean energy. DPN, a technique where molecules are transferred to a surface via the capillary effect, *gave rise to Polymer Pen Lithography (PPL), a highly parallelized cantilever-free tool that can be used to simultaneously create millions of features comprised of hard or soft matter on surfaces. With the advent of Beam-Pen Lithography (BPL), another successor of DPN, light, instead of the physical contact of tips on a surface, was exploited to independently control each tip in arrays of thousands of them to allow for the printing of materials with dimensions below the diffraction limit (100 nm). Insights gained from the development of these molecular printers ultimately led to the development of the world's highest throughput 3D printers based on High Area Rapid Printing (HARP) technology. HARP is a continuous printing technique that facilitates the production of large objects at speeds previously unattainable in traditional 3D printing processes, and it enhances the practical utility of additive manufacturing to the industrial-scale production of customized parts. This presentation will delve into the underlying materials chemistry behind each of these techniques and a broad swath of their potential applications.*

10:30 AM PM02.05.06

Additive Manufacturing of Mechanically Stable, Hollow, Polymer Microneedles onto Microfluidic Chips *Tiago Elias Abi-Ramia Silva, Stephan Kohler, Nicolas Bartzsch and Andreas Güntner; ETH Zürich, Switzerland*

Traditional microneedle (MN) devices face significant biocompatibility challenges,[1] for instance, when based on silicon.[2] 3D printing offers flexibility in material choice and rapid prototyping capabilities while accessing complex geometries. Here, we demonstrate the 3D printing of hollow and polymer-based MNs onto silicon microfluidics from standard cleanroom processes using two-photon polymerization. Our FEM-simulation-driven microneedle design underwent mechanical and fluidic characterization. The fabricated microneedles exhibited high replicability in length, centerline alignment, and feature size. Mechanical testing confirmed that the MN arrays could withstand compressive forces exceeding those required for insertion into simulated skin and human subjects. We successfully extracted interstitial fluid (ISF) from a human subject and conducted a 72-hour in-vivo biocompatibility test, which yielded positive results, demonstrating the system's potential for continuous health monitoring. This platform's capability for minimally invasive, continuous monitoring of ISF offers a promising avenue for enhancing personalized medical treatments as it presents a rich source of biomarkers.[3]

10:45 AM PM02.05.07

Voxelated Additive Manufacturing of Liquid Crystal Elastomers *Caitlyn C. Krikorian (Cook)[1], Elaine Lee[1], Dominique Porcincula[1], Logan Bekker[1], Catherine Reyes[1], Jorge-Luis Barrera Cruz[1], Drew Melchert[1], Peter Miller[1], Martin De Beer[1], Rodrigo Telles[2,1], Julie Mancini[1], Michael Ford[1], TengTeng Tang[1], Shu Yang[3] and Jennifer A. Lewis[2]; [1]Lawrence Livermore National Laboratory, United States; [2]Harvard University, United States; [3]University of Pennsylvania, United States*

Responsive feedstocks for additive manufacturing have opened a new regime of material design & manufacturing, where printed architectures can morph from the as-printed state to a programmed state with exposure from a specific stimulus. Liquid crystal elastomers (LCEs) are being developed for additive manufacturing (AM) where programming can be instated during the printing of complex shapes and shape morphing can be triggered reversibly and repeatably over many cycles of stimuli exposure. Until recently, most AM of LCE efforts were *focused on Direct Ink Write, limiting shape change programming to unidirectional liquid crystal alignment and part complexity. By using digital light projection platforms to not only print, but also address liquid crystal alignment on a voxel-level, complex printed architectures can exhibit repeatable, precise, and targeted three-dimensional shape change. Providing this capability will be a paradigm shift for applications such as soft robotics, stimuli-responsive control systems, anisotropic and tunable energy absorption, on-demand pumping for carbon capture and health care, and more.*

Here we will report on two pathways of voxelated alignment digital light projection methods implemented at LLNL using either magnetic fields or photoalignment approaches. To achieve a targeted three-dimensional shape change, high performance computing simulation and design optimization at LLNL has informed the digital voxelated alignment maps applied during printing. In addition, liquid crystal elastomer resins have be optimized to flow during printing while maintaining a high degree of shape change. As a result, voxelated AM of LCEs will be presented, demonstrating 3D-to-3D targeted shape change.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS- LLNL-ABS-865922.

Multimaterial Thermoplastic Architectures via Vat Photopolymerization *Alex Commisso and Samuel C. Leguizamon; Sandia National Laboratories, United States*

Stereolithographic additive manufacturing (SLA) processes provide agility and complex design development of components necessary for a wide range of critical applications. Yet this technique is traditionally limited to thermoset materials with singular bulk properties. We present a novel technique that breaks from these paradigms to manufacture high-resolution, multi-material thermoplastic architectures. Multimaterial printing is achieved through facile in-situ control of polyolefin backbone chemistry (i.e., cis/trans content) using greyscale irradiation. Thus, a wide range of mechanical properties can be patterned, varying from viscoelastic to hard crystalline polymers, at the micron scale and implemented into complex three-dimension geometries using vat printing and a single vat of resin without the need for a secondary cure mechanism.

3D Printed Spacers Modulate Selectivity in Membrane-Less Electrochemical Separation of Ammonium and Urea *Max A. Saccone, Amilton Botelho Junior, Philip Onffroy, William Tarpeh and Joseph DeSimone; Stanford University, United States*

Systems that simultaneously optimize transport and reaction parameters are crucial for chemical process intensification. In this talk, we discuss recent progress towards additively manufactured materials that control flow in electrochemical systems with forced convection. For example, we demonstrate how 3D printed porous spacers can modulate selectivity in the membrane-less electrochemical separation of ammonium and urea by tuning the relative rates of transport via diffusion and electromigration in an undivided cell. The separation of ammonium and urea, important in wastewater treatment applications, relies on the electromigration of ammonium under an electric potential gradient, while the neutral urea molecule does not experience electromigration. In contrast to typical electrodialysis systems, which make use of ion-exchange membranes, the membrane-less system relies on the geometry of a 3D printed spacer to adjust the flow fields within the system to mitigate diffusion-driven crossover from a feed stream to a receiving stream. This approach has the potential to not only reduce the cost of these types of reactors by obviating the need for a membrane, which can degrade and foul over time, but also yield strategies for increasing selectivity in many systems, including those that do make use of membranes.

Finite element simulations of flow and electromigration were used to computationally screen spacer designs to select for those that showed promise for the separation of urea and ammonium. Spacers were 3D printed using epoxy dual-cure resins which are stable under the acidic and/or basic conditions that are present in many electrochemical separation processes. Separation efficiency was measured experimentally for several spacer designs in flow cells with and without membranes. Finally, we demonstrate the ability to metalize 3D printed spacers through electroless deposition of nickel metal, showing a path towards using 3D printed parts not just as flow-directing spacers, but as "flow directing electrodes" in a variety of electrochemical systems, leading to the ability to explore an extensive landscape of multifunctional device designs.

11:30 AM *PM02.05.10

Digital Light Processing 3D Printing of Multimodulus Objects *Zachariah A. Page; The University of Texas at Austin, United States*

Structures in nature have evolved to combine hard and soft materials in precise 3D arrangements, which imbues bulk properties and functionality that remain elusive to mimic synthetically. However, the potential for biomimetic analogs to seamlessly interface hard materials with soft surfaces for applications ranging from soft robotics and sealants to medical devices (e.g., prosthetics and wearable health monitors) has driven the demand for innovative chemistries and manufacturing approaches. This presentation will discuss efforts in the ZAP research group to address this challenge through developing liquid resin formulations that enable rapid, high resolution digital light processing (DLP) 3D printing of multimaterial objects with a wide range of mechanical properties.

SESSION PM02.06: Volumetric Additive Manufacturing

1:30 PM PM02.06.01

One-Pot Grayscale Patterning of Sacrificial Polymer Networks to Enable Supportless 3D Printing *Isabel F. Arias[1,2], Maxim Shusteff[1] and Sijia Huang[1]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Santa Barbara, United States*

Recent advances in additive manufacturing (AM) have demonstrated the fabrication of complex geometries with high degrees of freedom and rapid processing times. Projection based micro-stereolithography (PμSL) is a popular AM technique due to its high precision and high efficiency in patterning micron-scale structures. Demand for high resolution AM encompasses many fields from rapid prototyping to microelectronics, tissue engineering, and metamaterials. However, fabricating features that are unsupported by previous cured layers is difficult to achieve due to the risk of collapse, misshaping, and misalignment of subsequent layers under gravity. This limits the ability of AM to construct some geometries, including overhangs, arches, and channels, which may require the digital generation of support structures. While these structures improve upon the geometric fidelity of manufactured parts, they can also lead to unnecessary material consumption and result in a loss of relevant features. Upon completion of the print process, support structures must be removed from the final product which lengthens processing time and often results in surface irregularities or structural damage.
To overcome this challenge, we study a dual cure radical-cationic resin to print geometries with soluble supports

in a single pot. The resin patterns permanent features using deep blue light (405 nm) at high intensity and sacrificial support structures at low intensity to be dissolved under basic conditions. By simply irradiating a grayscale pattern, the permanent cationic network is localized to areas that are brightly illuminated, while the sacrificial radical network is patterned under dim light. The cationic network consists of an epoxide crosslinker and comonomer, while the radical network consists of a methacrylated sebacic acid (MSA) crosslinker and comonomer. The MSA crosslinker hydrolyzes by simply soaking it in basic conditions (0.1-1 M NaOH), thereby dissolving the supporting structures patterned with low intensity light. FTIR data shows conversion of only the radical network at low power (30 mW/cm^2), while conversion of both the radical and cationic network is observed at high power (90 mW/cm^2). The FTIR results were further confirmed by photorheological measurements which show gelation of the radical network at low light intensity and gelation of the cationic network at high light intensity. Finally, 3D printed structures patterned with low light intensities (< 39 mW/cm^2) were sacrificed under basic conditions (1M NaOH, ~15 min), while structures patterned with high light intensities (> 40 mW/cm^2) survived basic conditions which indicates the presence of the cationic network. This AM approach to pattern sacrificial structures could be easily adapted to commercial printers that use 405 nm visible light to enable supportless 3D printing of complex geometries.

1:45 PM PM02.06.02

Multiphysics Material Screening for Microwave Volumetric Additive Manufacturing *Ethan R. Rosenberg, Johanna Vandenbrande, Emeraldo Baluyot, Diana L. Morales, Saptarshi Mukherjee, Johanna J. Schwartz, Maxim Shusteff, James Kelly and Joseph W. Tringe; Lawrence Livermore National Laboratory, United States*

Volumetric Additive Manufacturing (VAM) shows a great deal of promise for rapidly printing complex objects with no support material. However, conventional VAM techniques require an optically transparent feedstock. To surpass this limitation, we have been developing a microwave VAM (MVAM) system which uses focused and/or shaped microwave radiation to locally and controllably cure materials inaccessible to conventional VAM. Specifically, we have been concentrating on highly-loaded (~50% v/v) ceramic/binder mixtures which can be sintered into fully-dense ceramic parts following an initial MVAM step. The development of material formulations for this new MVAM paradigm requires us to consider numerous coupled phenomena – microwave heating, thermal diffusion, and curing kinetics – which all can affect process variables such as resolution and time-to-cure. Here, we use fully-coupled multiphysics modeling to screen the full material parameter space and identify ideal formulations for MVAM processing. These simulations are informed by thermal, chemical, and dielectric characterization of representative MVAM feedstock material. We also investigate the role that additives can play in further optimizing the thermal and chemical response of MVAM feedstock. Finally, we perform controlled microwave curing experiments in a waveguide to test and validate our model. This work is instrumental to the rational design of materials for rapid, high-resolution MVAM processes.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

2:00 PM PM02.06.03

Volumetric Additive Manufacturing of Multimaterial Glass *Dominique Porcincula and Beck Walton; Lawrence Livermore National Laboratory, United States*

Additive manufacturing (AM) of glass has enabled fabrication of novel glass geometries typically not available via conventional manufacturing. Fabrication of glass structures via the direct ink-write (DIW) technique has enabled facile fabrication of glass in addition to enabling novel multimaterial gradient refractive index (GRIN) optics, thereby creating new methods for fabrication of novel optics in an otherwise difficult fabrication process. Despite *these successes, fabrication of glass optics and other structures via DIW still faces hurdles related to quality due to the persistence of layer lines that decrease the optical homogeneity of glass parts while also still requiring significant post-processing to achieve optical smoothness. Other vat photopolymerization approaches have enabled fine features, but still face limitations with surface roughness and multimaterial approaches. The volumetric additive manufacturing (VAM) approach has the potential to bypass these challenges through its all-in-one fabrication approach that enables rapid fabrication of parts with comparatively much smoother surfaces. Here, we report on our work with fabrication of silica glass optics and other structures using the VAM technique. We first report on the development of a robust photopolymer resin for high fidelity glass printing in addition to associated techniques for enhancing print quality. We also report on the development of photopolymer resins with various dopants for altering the refractive index and other optical properties of printed glass. Lastly, we report on the development of a novel technique combined with the VAM approach to fabricate GRIN optics, thereby paving the path for the next generation of novel optics fabrication.*

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

2:15 PM PM02.06.04

Microwave Radiation in Volumetric Additive Manufacturing to Create 3D Ceramics *Johanna Vandenbrande[1], Saptarshi Mukherjee[1], Ethan R. Rosenberg[1], Johanna J. Schwartz[1], Gretchen Brown[1,2], Emeraldo Baluyot[1], James Kelly[1], Joseph W. Tringe[1] and Maxim Shusteff[1]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Berkeley, United States*

Additive manufacturing has come a long way in the past 20 years to create complex 3D architecture that are hard to produce using traditional manufacturing methods. Many advances in the last 10 years have focused on expediting the time to create the 3D objects to rival methods aimed at industrial or large-scale production. One printing method of interest is volumetric additive manufacturing (VAM) using optical light, which can print a single object in one projection. However, VAM is unable to process resins that are opaque or have high loadings of powder. Our team has devised a strategy to overcome these limitations through microwave curing of ceramic binder mixtures to produce 3D ceramic objects. The microwave radiation thermally cures the epoxide-based binder in place to create 3D ceramic green body, and sintering the object forms the ceramic part. Current efforts in the materials side of the project revolve around identifying how the initiator concentration and the loading of the silicon nitride powder in the binder influences the exothermic reaction to enable the localization of the cured spot within the ceramic binder mixture, and identifying how the binder is removed during the post-processing sintering to form a solid ceramic object. Current investigations have shown successful cure of highly loaded (~50% v/v) ceramic/binder mixtures, and the binder is successfully removed in the post-processing thermal treatment.

High-Throughput Combinatorial Printing of Multifunctional Materials and Devices *Yanliang Zhang; University of Notre Dame, United States*

The development of new materials and their compositional and microstructural optimizations are essential to next-generation technologies. However, materials discovery and optimization have been a frustratingly slow process. The Edisonian trial-and-error process is time-consuming and resource-inefficient, particularly when contrasted to vast materials design spaces. While traditional combinatorial deposition methods can generate material libraries, it suffers from limited material options and inability to leverage immense breakthroughs in nanomaterials synthesis. Here we present a high-throughput combinatorial printing (HTCP) method capable of fabricating materials with compositional gradients with microscale spatial resolution. The in situ "mix and print" in the aerosol phase allows instantaneous tuning of the mixing ratio of a broad range of materials on the fly, which is an important feature unobtainable in conventional multi-materials printing using feedstocks in liquid/liquid or solid/solid phases. We demonstrate a variety of high-throughput printing strategies and applications in combinatorial materials discovery, functional grading, and chemical reaction, enabling materials explorations of doped chalcogenides and compositionally graded materials with gradient properties. The versatile aerosol based HTCP enables universal printing and integration of a broad range of materials including metals, semiconductors, dielectrics, as well as polymers and biomaterials, leading to facile fabrication of multifunctional and flexible/wearable devices for energy conversion/storage, sensing, and health monitoring. The ability to combine the top-down design freedom of additive manufacturing with bottom-up control over the local material compositions promises compositionally complex materials inaccessible via conventional manufacturing approaches. The fabrication freedom and data-rich nature of HTCP along with machine learning and artificial intelligence guided design strategies is expected to accelerate the discovery and development of a broad range of materials with intriguing and unprecedented properties for emerging applications.

4:00 PM PM02.07.02
Development of 3D Printable Low-Loss Dielectric Photoresins for 5G/6G Applications *Bhavana Deore[1], Chantal Paquet[1], Tabitha Arulpragasam[1], Hojjat Jamshidi[2], Amir Akbari[2] and Rony Amaya[2]; [1]National Research Council Canada, Canada; [2]Carleton University, Canada*

The next generation of 5G/6G wireless networks based on RF and mmWave devices promise to bringing fast, stable and low latency connectivity at low cost. Dielectric materials are utilized in many parts of 5G/6G devices (antennas, filters, power dividers, lenses). In order to meet the stringent requirements of future 5G/6G networks, the development of low-loss tangent (dissipation factor) dielectric materials is key in high-frequency and high-speed environments. Many of these devices could have enhanced performances if the dielectric materials could be designed with complex geometries. For instance, Luneburg lenses, components that focus RF and mm waves are used to improve the gain of signal transmission. These can be manufactured as complex lattices with gradients in their porosity. Similarly, power dividers and dielectric resonator antennas, can be designed with geometric complexity to enhance their performance. Components with complex 3D geometries cannot easily and cost effectively be produced using traditional manufacturing methods. In general, RF and mmWave dielectric components are fabricated using traditional manufacturing methods with organic and inorganic low loss materials available in the market. Most of these materials have not been developed as 3D printable materials. 3D printing provides a means to manufacture low-cost lenses/antennas with complex 3D designs. In particular, light-based 3D printing methods (SLA, DLP) are particularly attractive for manufacturing RF and mmWave components as the printing platform prints to higher print quality, which will ensure higher performance in the device. Therefore, the development of new 3D printable low-loss dielectric photoresins is highly desirable in order to fabricate the high resolution, light-weight, complex, miniaturized and high-performance (gain, beamforming etc.) mm-wave devices for 5G technologies. In this presentation, we discuss the development of highly customizable low-loss dielectric *materials compatible with vat polymerizable 3D printing through the selection of monomers, crosslinkers and fillers. The materials properties can be tuned at the molecular level (formulation) and at the microscale (through printing parameters) to obtain optimized 3D printed lenses/antennas and further their performance in mmWave region.*

4:15 PM PM02.07.03

3D Printing of Metal Halide Perovskite Whispering-Gallery-Mode Microring Lasers *Tianyu Jiang[1] and Ji Tae Kim[1,2]; [1]The University of Hong Kong, Hong Kong; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Metal halide perovskite nanocrystals, or quantum dots, due to their size-dependent, narrow-band photoluminescence (PL) characteristics originating from the quantum confinement effect [1], hold significant potential as gain materials for various technologies [2]. Their solution processability and size-tunable optical transitions make them versatile across the visible and infrared spectrum [3] by controlling the size, and they have been considered promising materials for optoelectronic applications. However, a lack of techniques for high-precision and high-resolution deposition and patterning of perovskite quantum dots on a selected area of a substrate limits the realization of such devices [1]. In the field of semiconductor lasers, there is a growing demand for low-threshold and narrow linewidth lasers. Perovskite whispering gallery mode (WGM) micro-resonators, known for their low optical losses and miniature sizes, have emerged as excellent candidates for meeting these requirements to establish high-performance lasing [4]. However, the current fabrication technique of perovskite WGM resonator highly relies on electron beam lithography, photolithography, nanoimprinting, etc. which are energy- and labour-intensive, in stark contrast with the industrial low-cost requirements [5].

Here, we report on the utilization of electrohydrodynamic (EHD) 3D printing to produce WGM laser resonators with the assembly of $CsPbBr_3$ quantum dots. We demonstrate that EHD 3D printing provides a flexible and scalable manufacturing method for fabricating microring laser resonators with high-precision and programmed lasing characteristics. Unlike traditional lithography techniques, EHD printing allows for the direct deposition of perovskite quantum dots in a layer-by-layer fashion, enabling the creation of intricate 3D laser cavities with submicron and nanoscale features. By leveraging the benefits of EHD printing, such as flexibility, scalability, and cost-effectiveness, this approach eliminates the need for expensive lithography equipment and complex processes [6], making it a promising technique for high-performance optical device development, particularly in laser technology. Overall, our research contributes to advancing additive manufacturing technologies in the fabrication of micro light sources and expanding the applications of perovskite quantum dots in laser technology.

4:30 PM PM02.07.04

3D Printing of Functionally Graded Thermoelectric Materials for Improving Performance *Hyunjin Han, Seong Eun Yang and Jae Sung Son; Pohang University of Science and Technology, Korea (the Republic of)*

Functionally graded materials (FGMs) are noted for their heterogeneous characteristics, with spatial variations in composition, particularly in terms of dopant concentrations and structural configurations. These materials are carefully engineered to meet specific properties and functionalities for a variety of applications. Recently, 3D printing has emerged as a promising technique for creating FGMs with complex geometries and precise material distributions. Despite this, 3D printing's use in FGMs has largely been confined to structural materials, with less frequent application in energy and electronic sectors. Thermoelectric power generation, which converts waste heat into electrical energy, holds significant promise; however, the performance of thermoelectric materials is highly temperature-dependent, limiting their broader use. In this study, we present a sequential 3D printing method to fabricate n-type Bi_2Te_3-based thermoelectric materials with gradients in both electronic dopants and structural voids. By formulating Na-doped thermoelectric colloid inks with suitable viscoelastic properties for 3D printing, we achieved the fabrication of materials with intricate architectures and 150 μm precision. These materials exhibited atomic-level doping and macroscopic void gradients. The thermoelectric peak temperatures of the printed materials varied from room temperature to 450 K, depending on the doping levels. Designed to operate over a wide temperature range, these graded thermoelectric materials, fabricated via 3D printing, demonstrated enhanced power-generating performance compared to homogeneous materials. This method offers a fast and cost-efficient approach to producing functionally graded thermoelectric materials, making it well-suited for applications in energy and electronic devices.

4:45 PM PM02.07.05

3D Heterogeneous Integration—Printing of Ultrafine-Resolution Interconnects and Traces *G. Cagatay Ozseker, Ahmed Abdelaziz and Ahmed Busnaina; Northeastern University, United States*

With the rising demand for smaller, mass-produced complex electronic devices, the time required for manufacturing has increased exponentially over the past few decades. Advanced packaging requirements and 3D heterogeneous integration followed a similar rise in demand. Today's industry can achieve high precision down to 3 nm, but the overall processing time of a chip is more than six months. To accommodate these limitations, additive manufacturing of electronic components provides a significant alternative approach that can be very beneficial to 3D heterogeneous integration. This paper introduces a scalable, fully additive, directed-assembly-based process to print interconnects and electrical components at the micro and nanoscales at high throughput (one layer per minute for a 4-inch substrate regardless of minimum feature size). Fluidic directed-assembly utilizes highly concentrated metallic inks to print 2D and 3D structures – such as flip chip fan-out patterns, traces, interconnects, and touch screen display grids – on rigid and flexible substrates. This technique utilizes external fields that interact with suspended particles in inks and guides them to site-selective patterned areas on the substrates. Furthermore, the additive nature and bottom-up approach of fluidic directed-assembly make this process highly controllable and implementable across many applications. Touch screen display grids, flip chip fan-out patterns, and inorganic dielectric layers for 3D heterogeneous integration are additively printed using silver and dielectric inks on both rigid and flexible substrates with this technique. The current industry trend is moving away from large monolithic chips towards integrating discrete dies on a silicon substrate to increase yield and lower cost. This requires fine resolution and pitch for interconnects and trace to integrate these dies. The EMIB (Embedded Multi-Die Interconnect Bridge) was released by Intel in 2017 to connect multiple heterogeneous dies in a single package. It allows for tighter interconnect density by embedding small bridges into the package substrate. These structures are used to enhance system performance by allowing high-density interconnections with minimal *signal loss. With these benefits, they became a supporting scalable solution for modern computing needs. Results show that printed touch screen display grids had 2- and 0.3-micron line widths while EMIB-like structure shows 2-micron line widths with 2-micron spacings while having 50 to 500 length-to-width ratios. AFM and confocal microscope measurements show that both patterns had similar silver thicknesses of 400 nm after sintering. To compare printed silver flip chip fan-out structure to conventional methods, the same pattern is fabricated with copper sputtering at the same thickness of 800 nm. Both chips are electrically characterized with IdVd sweep. Results showed that printed silver had 3.3 ohms resistance compared to that of copper's 3.75 ohms. Inorganic dielectric layers (Aluminium oxide and Silica) are printed and characterized by XPS and SEM. XPS data show the quality of the printed AlO_x film via densification and chemical composition analysis. XPS results show a strong match between the chemical composition of the printed AlO_x and the ALD deposited counterpart. SEM results show that the printed film's thickness decreases with the increase in annealing temperature. The printing process utilized has been shown to reduce cost by 10 – 100x and increase throughput by 10 – 100x compared to conventional fabrication in addition to a 1000x reduction in materials use. In addition, it is more than 1000x faster than inkjet or 3D printing.*

SESSION PM02.08: New Chemistries in Additive and Digital Manufacturing II

Sheraton, Second Floor, Constitution A

8:30 AM PM02.08.01
***Low Durometer, High Performance Silicones for Direct Ink Write** Spencer Schmidt; Lawrence Livermore National Laboratory, United States*

From a production perspective, 3D printing techniques such as Direct Ink Write (DIW) provide the opportunity to tailor the mechanical response of soft device architectures by enabling precise spatial control of their support structure. Mechanical response is further tailored via formulation control of the printed material. Formulation science is critical to the development of new DIW feedstocks as typical "inks" must exhibit low yield stress thixotropy to enable extrusion out of a nozzle and avoid post-extrusion flow to retain the resolution of the printed product; all while meeting the requisite performance of the final product. Low durometer silicones employed in soft device applications often suffer from low ultimate mechanical properties that prove detrimental to practical utility. To address the need for higher performance silicones for DIW, a new set of ca. 20 – 50 ShoreA silicone elastomers exhibiting ca. 7.5MPa ultimate tensile strength and ca. 400 – 1200% elongation at break are presented. Proof-of-concept prints demonstrate the potential for these new DIW silicones to find use as support material for soft device applications.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

8:45 AM PM02.08.02
***Enhanced Coalescence and Tailored Properties in Polymeric Powder Bed Fusion by Molecular Design of Feedstocks** Akan George[1], Jackson Bryant[2], Christopher Williams[2] and Mark Dadmun[1]; [1]The University of Tennessee, Knoxville, United States; [2]Virginia Tech, United States*

Coalescence is a crucial step in 3D printing that directly impacts the strength, quality, and properties of printed parts. In this presentation, we will discuss our recent work that utilizes a processing protocol based on liquid-liquid phase separation to controllably create polypropylene (PP) powders from 12k, 250k, and 340k PP molecular weight (Mw) along with their blends, which tunes their coalescence dynamics, impacting powder bed fusion. Monitoring the particle coalescence of these powders shows that the addition of 12k PP significantly increases the coalescence rate of high Mw PP, consequently reducing the void space and increasing the mechanical strength of the resultant printed parts. The coalescence of these multi-components powders follows the Hopper model, offering insight into the underlying mechanisms governing particle consolidation. A holistic interpretation of the data shows that the 12k PP does not surface segregate in the powder but is homogeneously distributed, improving the coalescence process by lowering the extensional viscosity of the polymer melt. These findings provide a straightforward mechanism to molecularly design powder coalescence properties and offer avenues to broaden the feedstocks available for powder bed fusion.

9:00 AM PM02.08.03

Approaches to Minimizing Limitations Inherent to the Two-Photon Printing Process *Sarah M. Fess[1], Madelyn P. Jeske[1,1], David R. Harding[1,1], Mark Bonino[1], Dayna C. Wasilewski[1], Mitch Anthamatten[1,1], Neil Redden[1], Lance Ulrich[1,1], Yong-Feng Lu[2] and Aofei Mao[2]; [1]University of Rochester, United States; [2]University of Nebraska–Lincoln, United States*

A unique but impactful application for two-photon printing that emerged in recent years is to print millimeter-scale polymeric components for nuclear fusion experiments. While turnkey two-photon printers such as Nanoscribe's PPGT+ are extremely sophisticated and capable, this application requires print fidelity at the limits of what is possible with available software and resins. Inherent properties of greatest concern are the roughness of printed structures, particularly at stitching interfaces, and waviness of thin curved surfaces that result from shrinkage-induced stresses. Challenging designs of interest include high-surface-area lattices with sub-micron features and high-aspect-ratio structures. These designs are too complicated to be constructed with geometric modeling kernels so a field-driven algorithm that is more suited for modeling complex lattice geometries was used. Resulting structures processed in a traditional way possess unacceptably large stitching features (>1µm peak-to-valley) and an undulating profile with nodes at print block interfaces.

Strategies to mitigate these issues include using third-party software such as nTop to better control the size, print sequence, and mesh quality of individual print blocks; scripts to batch process thousands of image files into a 2.5D lithographic-type print; direct coding an analytical expression to print the structure, forgoing the need to process a CAD model; and the development of low-shrinkage resins using base-catalyzed rather than free-radical chemistry. Examples of structures with improved quality that can be made using these methods include thin-wall spherical shells, hemi-shells, planar foils, and stochastic lattices with features < 0.5µm. Print processes were qualified and components characterized using a suite of techniques including optical, confocal, atomic force, x-ray, and scanning electron microscopy. In this talk, the methods and representative prints will be discussed in greater detail, along with recommendations that may prove beneficial for others using first generation two-photon printers.

This material is based upon work supported by the Department of Energy [National Nuclear Security Administration] University of Rochester "National Inertial Confinement Fusion Program" under Award Number DE-NA0004144.

9:15 AM PM02.08.04

Digitally Driven Mesoscopic Self-Assembly of Functional Materials by Selective Plasma Induced Super-

Hydrophilicity *Luke J. Tinsley, Prakash Karipoth, James Chandler, Silvia Taccola, Pietro Valdastri and Russell Harris; University of Leeds, United Kingdom*

Digitally driven bottom-up manufacturing approaches promise new devices with unprecedented functionality by enabling the realisation of complex heterogeneous multi-material structures. However, the next generation of devices demands substantial progression beyond the capabilities of current manufacturing technologies. Presently, there are shortcomings associated with digital techniques concerning process resolution, compatible materials, production time, and unit cost. Presented here is progress on a novel manufacturing technology, whereby water-based inks containing functional materials self-assemble into user-defined patterns. The self-assembly is driven by selective surface functionalisation resulting from a localised plasma discharge created by a computer-controlled micro atmospheric plasma jet. This functionalisation corresponds to a replacement of the hydrophobic methyl groups of a polydimethylsiloxane substrate with hydrophilic silanol groups. Subsequently, inks are attracted to the regions of high silanol concentration. Through control of the voltage and frequency used to ignite the plasma, in combination with its motion, the ability to continuously vary the spatial distribution of the functionalisation to create self-assembled structures between 10^{-1}*m and* 10^{-5} *m is demonstrated. Moreover, digital control over the ignition parameters enables efficient fabrication across these dimensional scales. Inks loaded with silver nanoparticles, poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate), and hard magnetic cobalt ferrite are demonstrated to be compatible. This range of mechanical, electrical, and magnetic properties already offers the opportunity to create functional devices across a diverse range of fields. Furthermore, we present a rapid characterisation technique to accelerate the future expansion of material libraries for both substrates and inks. We demonstrate the potential of this technique through the fabrication of demonstration devices within the fields of flexible electronics and magnetically actuated robotics. This fabrication technology addresses the shortcomings of current bottom-up fabrication approaches, offering a high-resolution, accurate, flexible, sustainable, and economically scalable manufacturing solution for the next generation of devices.*

The Delicate Interplay Between Light, Interfaces and Design—The Complex Dance that Allows 3D Printing to Scale to Manufacturing *Joseph DeSimone and Max A. Saccone; Stanford University, United States*

The production of polymeric products relies largely on age-old molding techniques. In this talk, I will describe a breakthrough in additive manufacturing—3D printing—referred to as Continuous Liquid Interface Production (CLIP) technology (Science 2015). CLIP, and its recently introduced cousin injection CLIP (iCLIP; Science Advances 2022), embody a convergence of advances in
software, hardware, and materials to bring the digital revolution to the design and manufacturing of polymeric products. CLIP uses software-controlled chemistry to produce commercial quality parts rapidly and at scale by capitalizing on the principle of oxygen-inhibited photopolymerization to generate a continual liquid interface of uncured resin between a forming part and a printer's
exposure window. Instead of printing layer-by-layer, this allows layerless parts to 'grow' from a pool of resin, formed by light. Compatible with a wide range of polymers, CLIP opens major opportunities for innovative products across diverse industries. Previously unmakeable products are already manufactured at scale with CLIP, including the large-scale production of running shoes by Adidas (Futurecraft 4D); mass-customized football helmets by Riddell; the world's first
FDA-approved 3D printed dentures; and numerous parts in automotive, consumer electronics, and medicine. At Stanford, we are pursuing new advances including digital therapeutic devices in pediatric medicine, new multi-materials printing approaches, recyclable materials, and the design of a high-resolution printer to advance

technologies in the microelectronics and drug/vaccine delivery areas, including novel microneedle designs as a potent vaccine delivery platform and for the sampling of interstitial fluids for health monitoring and the early detection
of disease.

10:30 AM PM02.08.06
Three-Dimensional Architected Carbon Composites via Additive Manufacturing *Andrew Y. Chen, Carlo Pignagnoli and Carlos M. Portela; Massachusetts Institute of Technology, United States*

The design of modern composite materials, as used in a wide range of engineering applications, is largely derived from a traditional framework based on laminates. While resulting in desirable strength and stiffness properties, the laminate-based structure leads to a high degree of anisotropy and unique failure modalities like interlaminar failure, limiting the performance of these composites under complex loading conditions. Meanwhile, recent work in the field of architected materials has yielded a thorough understanding of geometry-dependent material behavior, enabling the development of highly robust architectures with tunable (an)isotropy. In particular, the framework of architected interpenetrating phase composites (IPCs), i.e., two-phase materials consisting of an architected structure surrounded by a matrix, has led to the development of strong, resilient, and damage-resistant materials. However, such advances have focused primarily on describing the response of polymer-polymer composites due to the ubiquity of polymer-based freeform fabrication methods, with performances that hinder the applicability of IPC-based architectures to many real-world applications.

Here, we establish a facile and scalable fabrication method based on desktop 3D-printing followed by pyrolysis to create carbon-based, three-dimensional architected interpenetrating phase composite (IPC) materials. This fabrication method yields centimeter-scale pyrolytic carbon specimens with feature sizes smaller than 100 microns, enabling a true separation of scales. Moreover, the freeform fabrication enabled by 3D printing allows for geometries of arbitrary complexity to be fabricated, carbonized, and subsequently infiltrated, creating scalable carbon-based IPCs.

To understand the effect of morphology on the mechanical behavior of carbon-based 3D architected IPCs, we fabricate and test samples with periodic and aperiodic microstructures, determining their uniaxial compressive response with particular emphasis on the non-linear and failure regimes. Using X-ray computed tomography (XCT), we visualize the evolution of damage in the composite and show that the presence of a load-bearing matrix contributes to a high-strength, high-toughness, stable failure behavior. Together with computational models, we use the XCT reconstructions to understand how the development of a 3D, highly tortuous pathway for stress delays or prevents catastrophic failure of the traditionally brittle architecture phase, resulting in energy dissipation performance of the composite that is 1.6 times higher than the sum of its constituent parts, reaching a specific energy absorption comparable with automotive-grade wound fiber tubes. Altogether, this work broadens our established understanding of the link between architecture and mechanics in composite materials and provides an avenue for the additive manufacturing-based fabrication of centimeter-scale carbon-based composites with sub-millimeter feature sizes.

10:45 AM PM02.08.07
Low Shrinkage Hydrogel Infusion Additive Manufacturing of Ceramics and Metals *Yiming Ji and Daryl W. Yee; École Polytechnique Fédérale de Lausanne, Switzerland*

Additive manufacturing has emerged as one of the most powerful manufacturing tools available today. In particular, vat photopolymerization (VP) techniques are especially promising as they are inexpensive, and capable *of achieving high resolutions and throughputs. However, the fabrication of ceramics and metals materials with VP still poses many challenges — particle-filled photosensitive slurries are hard to use due to high viscosities and often have poor resolutions due to light scattering. Inorganic-organic photoresins are limited in their compositions and are often difficult to synthesize.*

We recently pioneered a method called hydrogel infusion additive manufacturing (HIAM) that circumvents some of these challenges. In HIAM, a metal-ion infused hydrogel is thermally treated to convert it into a metal oxide or metal. While a facile and versatile process, the conversion of the polymer into the ceramic/metal is often accompanied by a significant amount of shrinkage, often upwards of 60%. The large shrinkages observed limits the utility of this process.

Here, we report the next generation of HIAM technology (HIAM Gen2) for the low-shrinkage fabrication of ceramics and metals. Using a series of intermediate processing steps, we show that we can increase the loading of the inorganic phase within the hydrogel by almost an order of magnitude. Accordingly, the linear shrinkage of ceramics made using this new HIAM Gen2 technology is now approximate 20%, 3x lower than the current state of the art. We anticipate that the chemistries and processing techniques developed in HIAM Gen2 will be broadly applicable to other gel-based polymer-derived material technologies, and enable the use of VP for the fabrication of ceramics and metals.

11:00 AM PM02.08.08

Multi-Material Interpenetrating Lattices via Sacrificial 3D Printed Molds *Derek J. Bischoff, Javier Morales-Ferrer and Eric Wetzel; U.S. Army Research Laboratory, United States*

Additively manufactured (AM) polymer lattice structures are highly tailorable geometries used to achieve a tunable compressive mechanical response, leading to emerging commercial applications such as helmet impact pads and shoe soles. AM polymer lattices can be directly manufactured using a variety of techniques including vat photopolymerization (VPP) and fused filament fabrication (FFF), however, present AM methods are limited in the range of mechanical properties available (e.g., durometer, strain to failure) for printable feedstocks, and integrating multiple elastomers into the same lattice can prove challenging. In the present study, dissolvable polymer molds fabricated via FFF are used to cast lattices from conventional elastomeric resins that are not generally amenable to direct 3D printing. Because the molds are dissolved after casting, complex and interpenetrating lattices can be formed. Furthermore, interpenetrating lattices comprising multiple elastomer material grades can also be implemented. A range of polymers and solvents (i.e., polyvinyl alcohol & water; butenediol vinyl alcohol copolymer & water; and high impact polystyrene & d-limonene) are evaluated. Lattice designs are parameterized to consider unit cell size, truss angles, and spacings. The interpenetrating lattice molds feature ports to infuse resin from a syringe with vacuum assistance to produce fully dense lattices; print and fill conditions designed to eliminate air or casting leaks; and are mechanically robust to withstand vacuum pressures. Both urethane and silicone casting resins are considered. Lattices are subject to compressive testing to determine mechanical response and downselect to designs that exhibit stress-strain behaviors that are advantageous for impact energy absorption. This study shows how dissolvable printed molds can be used to efficiently create complex functional shapes from materials that are not specifically formulated for 3D printing.

11:15 AM PM02.08.09

Scalable 3D Nanofabrication via Upconversion *Qi Zhou, Hao-Chi Yen, Arynn O. Gallegos and Daniel Congreve; Stanford University, United States*

Triplet-Triplet Annihilation Upconversion (TTA-UC) offers a groundbreaking method for volumetric 3D printing at the micro- and nanoscale, applicable to fields like plasmonics, nanophotonics, and biomedicine. Unlike the traditional two-photon absorption process, TTA-UC can be activated by low-power light sources while maintaining *the desired quadratic nature for the spatially confined generation of high-energy photons, enabling localized polymerization reactions. Enhanced by advanced resin formulations, sophisticated optical systems, and state-of-the-art deconvolution algorithms, this technology holds significant promise for revolutionizing next-generation micro- and nanoscale fabrication. It uniquely combines high resolution, low power consumption, rapid processing, and scalability, making it a versatile and powerful tool for future developments in various scientific and industrial applications.*

11:30 AM PM02.08.10

Printing A Heatsink—The Emergent Properties Of 3D Printable Thermally Conductive Polymer Composites

Daniel Braconnier[1,2], Evan Toth[1], Ryan Dunn[3], Eric Wetzel[3] and Randall M. Erb[1]; [1]Northeastern University, United States; [2]Massachusetts Institute of Technology, United States; [3]U.S. Army Research Laboratory, United States

While everyday device sizes continue to shrink, the power being packed into them increases drastically, driving internal heat generation to the point of overwhelming current thermal management solutions and to the point of limiting system-level performance. Incumbent materials solutions including metals like copper and aluminum can satisfy many applications, however they are heavy and cannot be placed adjacent to electronics or in the proximity of radio frequency components due to their intrinsic electrical conductivities. Therefore, a lightweight and dielectric thermal management materials solution is desirable to support higher energy density electronics. Certain dielectric ceramics, known as phononic conductors, can effectively transport heat through atomic vibrations without electron movement. Due to the manufacturing complexities associated with these ceramics, interest in filling thermoplastic polymers with these phononic conductors has grown. Additive manufacturing paired with fine-tuned composite creation can enable the lightweight and geometrically complex thermal management solutions required for future energy dense electronics. Here we present a collection of new understandings around process-structure-property relationships that will help enable higher performing thermal parts via additive manufacturing. This work focuses on the interplay between the filament composition, the processing conditions of fused filament fabrication (FFF), and the post-processing of printed parts (annealing). The goal of this research is to enable emergent properties in FFF printed composites through material interface and interphase engineering, flow-induced self-assembly of mesostructure, and temperature-induced self-assembly of polymeric nanostructure. We demonstrate that for common electronic and radiofrequency device applications, this new class of advanced thermal management materials can be used to produce heat sinks that cool as effectively as their heavier metal counterparts currently in use in industry.

11:45 AM PM02.08.11

Integration of Auxetic Structures Through 3D Printing and Hot Embossing into Polyethylene Fabrics for Aerospace Applications

Domingo R. Flores[1,2], Duo Xu[1], Kenneth Oranga[1] and Svetlana V. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]Tecnológico de Monterrey, Mexico

Additive manufacturing (AM) significantly enhances material design and functionality. Our research leverages advanced AM techniques, specifically knitting of melt-spun polymer fibers, electrospinning, and the combination of 3D printing and hot embossing, to develop innovative polyethylene (PE)-based composite materials primarily for aerospace applications to provide passive thermoregulation, radiation shielding, and auxetic capabilities.

The core technologies employed in our additive manufacturing processes include knitting, electropinning, FDM 3D printing, and hot embossing. Knitting involves interloping yarns to create flexible and elastic fabrics, while electrospinning produces ultra-fine fibers from polymer solutions, forming non-woven fabrics with a high surface area-to-mass ratio [1]. Hot embossing is used to imprint patterns onto material surfaces, enhancing their mechanical properties such as indentation resistance and energy absorption, relevant in protective gear applications [2]. Lastly, FDM 3D printing builds objects layer by layer from digital models, allowing for the creation

of complex geometries [3]. Both 3D printing and hot embossing can produce auxetic structures (materials that thicken perpendicular to applied force) offering significant advantages to develop materials with high impact resistance and mechanical integrity [4]. While 3D printing serves as a quick prototyping tool, hot embossing may act as a bridge to high-volume production of such prototypes.

For aerospace applications, polyethylene's (PE) high hydrogen content makes it one of the best materials for radiation shielding while being durable, recyclable, and chemically resistant [5]. Also, the addition of fillers can improve shielding against high-penetration sources such as neutrons. Conveniently, the addition of fillers is straightforward in FDM printing, electrospinning, and polymer extrusion for yarn making. Therefore, it is possible to integrate knitted fabrics with high elasticity and flexibility, electrospun fibers with a high surface area-to-mass ratio, versatility in composition, and lightweight, and auxetic structures with enhanced mechanical properties and highly customizable architectures. Our integrated AM approach significantly enhances the effectiveness of radiation shields in aerospace applications. The lightweight nature of the designed materials contributes to lower launch costs and increased payload efficiency, while their enhanced protective properties ensure greater safety for spacecraft and satellites. The applications of the developed techniques are not limited to aerospace; with the proper selection of materials and architectures, they can potentially be extended to the automotive industry and healthcare, due to their versatility.

This work has been supported by the ONR-Global Award N62909-23-1-2109, Tec-MIT collaborative research program in Nanotechnology, Partially funded by the Challenge Research Funding Program of Tecnologico de Monterrey, and the MIT MechE MathWorks fellowship to Duo Xu. We acknowledge also the MIT UROP office for supporting Kenneth Oranga.

3D Printable κ-carrageenan-Based Granular Hydrogels Reinforced with Sugar-Mediated Metal Ion Coordination

<u>Francesca Bono</u>, Sophie H. Strässle Zuniga and Esther Amstad; École Polytechnique Fédérale de Lausanne, Switzerland

The ocean covers a much larger surface area than land, where plants have long been used for food and construction. Similarly, the ocean provides abundant bioactive substances that can be extracted from marine

organisms like algae. From the latter, κ-carrageenan, a polysaccharide, known for its emulsifying and stabilizing properties, is extracted and commonly used in food and beauty products [1] [2]. Its abundance, resemblance to natural glycosaminoglycans, and biocompatibility have recently made it a promising alternative to animal gelatin for tissue engineering applications. However, its intrinsic thermorheological properties pose challenges for continuous processing methods, such as direct ink writing (DIW)-based 3D printing.
*Here, I will introduce a κ-carrageenan-based formulation that can be direct ink written at room temperature. This is achieved by formulating κ-carrageenan as microgels that when jammed have rheological properties ideal for DIW. These microgels can be connected with a covalently crosslinked second network, resulting in double network granular hydrogels (DNGH) after they have been imparted the final shape [3]. The stiffness and strength of the DNGHs can be enhanced even more through the addition of metal ions and glucose. The reinforced κ-carrageenan-based gels reach Young's moduli up to 0.9 MPa under tension and stiffnesses up to 1.1 MPa under compression. The metal ion/glucose reinforcement increases the work of fracture up to 1.1 MJ*m^{-3}, 50 times higher than that of unmodified κ-carrageenan DNGHs. We harness the rheological properties of the polysaccharide-based ink to 3D print cm-sized free standing and load-bearing structures at room temperature. Our κ-carrageenan-based granular gels show great potential for implant and tissue engineering and food applications, for instance as encouraging alternative to animal gelatin.*

3D Printing of Nanocomposite Membrane and Piezoelectric Sensors—Towards ML-Guided Design and Characterization *Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States*

Separations based on designed transport are a hierarchical phenomenon that requires an appreciation of surface chemistry, polarization effects, and pore characteristics. Applications in energy and sustainability materials will use new materials and fabrication technologies. 3D Printing combines materials design and geometric-function-based manufacturing at the macroscopic level. This talk will focus on controlled transport from layers and patterns in thin films and using 3D printing methods to control function: 1) the 3D Printing of polyvinylidene fluoride (PVDF) membranes and surface morphology control that enable oil-water separation and emulsion breaking. 2) the 3D Printing of multi-material silicone materials with controlled wetting and high resolution. And 3) using percolation theory, the 3D-printing actuators and sensors with hyper PVDF-MXcene piezoelectric materials. Thus, these examples demonstrate the potential for multi-scale materials with geometric and digital design strategies in the digital manufacturing of polymer and composite systems.

Additive Manufacturing of Degradable, Recyclable Poly(dicyclopentadiene) Thermosets via Photoinitiated Ring-Opening Metathesis Polymerization *Hayden Fowler and Samuel C. Leguizamon; Sandia National Laboratories, United States*

Additive manufacturing has enabled the quick and efficient development of polymeric components. However, with the ongoing plastics pollution crisis, it has become increasingly important to consider the end-of-life cycle of these materials. This is especially true for high performance thermoset materials, which are generally difficult to reprocess, break down, and recycle. PhotoROMP has recently been introduced as a promising method for vat photopolymerization of high-performance thermoset pDCPD. The ability to incorporate cyclic comonomers with cleavable units, such as DHF, has also enabled degradation of printed components. Here, we explore a recently developed cyclic silyl ether comonomer permitting degradation of pDCPD networks and further recycling of broken-down material. We demonstrate the ability to print, degrade, and reprint pDCPD components with recycled materials, enabling efficient and sustainable additive manufacturing of these important thermosets.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Room Temperature Extrusion Printing of Polymer Composites *Chia-Min Hsieh, Bilal Hassan, Krista Schoonover, Peiran Wei and Emily Pentzer; Texas A&M University, United States*

This presentation will address the use of the additive manufacturing technique direct ink writing (DIW) for the production of polymer composites. DIW is a scalable room temperature process in which a shear thinning and thixotropic ink is extruded onto a substrate to give a printed structures that is cured by chemical cross-linking or solvent removal. A variety of feedstocks can be used as inks for DIW, including polymer solutions or liquid polymer with granular particles, hydrogels, liquid metals, emulsions, and foams. The Pentzer group has developed inks for DIW by tailoring the particle filler and polymer matrix towards different applications. This presentation will address the development of polymer matrix for degradable and modifiable porous structures and printing of aerogels into inks for thermal insulation.

3:45 PM PM02.09.05
Binder Jetting 4D Printing of Functionally Graded Porous Multi-Materials for Biodegradable, Untethered and Multi-Stimuli-Responsive Soft Robots *Soo Young Cho, Yonghyun A. Kwon, InCheol Kwak, Seonkwon Kim, Jihyeon You, Seung Yeon Ki and Seonmi Eom; Yonsei University, Korea (the Republic of)*

Recent advances in functionally graded additive manufacturing (FGAM) have enabled the smooth integration of multiple functionalities into a single structure. The present development greatly enhances soft robotics by utilizing an efficient four-dimensional (4D) FGAM procedure, and intelligent stimuli-responsive mechanical functions in printed objects. Our study introduces a facile binder jetting approach for 4D printing functionally graded porous multi-materials (FGMM) which utilizes meticulously created graded multiphase feeder beds. These beds use compositionally graded cross-linking agents to form stable porous network structures within aqueous polymer particles, allowing for programmable hygroscopic deformation without requiring complex mechanical designs. Furthermore, a well-organized bed design with additional functional agents produces a multi-stimuli-responsive, untethered soft robot with precise stimulus selectivity. The biodegradability of the 4D-printed soft robot promotes sustainability, with a remarkable degradation rate of 96.6% within 72 hours. This novel 4D printing approach for FGMMs opens up new possibilities for intelligent and sustainable additive manufacturing in soft robotics.

4:00 PM PM02.09.06
Transforming 3D Printed Polymer Microlattices into High-Performance Co/CoO$_x$/C Electrodes for Water Splitting *William J. Scheideler and Anand P. Tiwari; Dartmouth College, United States*

Additive manufacturing offers an opportunity to push the limits of electrocatalyst performance and stability via deep control over gas and liquid phase mass-transport from the nanoscale to the mesoscale. Here, we report a generalizable method known as polymer infusion additive manufacturing (PIAM) for transforming 3D printed polymers into microlattice electrodes for electrocatalytic water splitting in alkaline media. Our method produces core-shell structured free-standing microlattices bearing nanoporous functional transition metal / metal oxide heterointerfaces suitable for performing both hydrogen evolution ($Cu/CuO_x/C$) as well as oxygen evolution ($Co/CoO_x/C$). In this talk we focus on the 3D printing of $Co/CoO_x/C$ microlattice electrodes that displaying exceptional electrocatalytic activity with an extremely low overpotential (1.40 V to reach 10 mA/cm^2). This overpotential of Co/CoO_x for OER is, to our knowledge, among the best reported PGM-free electrodes.

The outstanding electrocatalytic performance and long-term stability of 3D microlattice electrodes leverages their mesoscale (100-300 μm) pores, providing accessibility of electrolytes within the structures, maximizing the utilization of active sites, and ensuring the rapid discharge of gas bubbles for promoting electrode stability. We explore the gas phase mass-transport properties of these 3D printed microlattices via microscopic imaging of bubble evolution. Through direct comparison of periodic lattices and random foams, we reveal how the high electrochemical stability of these electrodes may be attributed to the rapid elimination of gas bubbles within 3D lattices with aligned pores. These results provide a viable route to fabricating free-standing, integrated catalyst / electrode structures in a single scalable process with a high degree of design freedom, simultaneously optimizing liquid and gas-phase mass-transport beyond the fundamental limits of random porous foams.

4:15 PM *PM02.09.07
3D Printing and Adaptive Soft Materials for Sustainable Ecorobots *Barbara Mazzolai, Emanuela Del Dottore and Laura Margheri; Istituto Italiano di Tecnologia, Italy*

EcoRobotics is a new trend in robotics research, envisioning robots as technologies for sustainable monitoring, remediation, and preservation of terrestrial, aerial, and marine ecosystems. In this context, sustainability means finding solutions for harvesting energy from the environment, designing actuation mechanisms that are energy-efficient by design, and using materials that are biocompatible or biodegradable. This allows EcoRobots to grow, adapt, safely interact with the environment, reduce their impact on energy consumption, and reintegrate into natural ecosystems. An effective approach to achieving these goals is designing EcoRobots by imitating the adaptability of living organisms, enabling them to navigate and operate effectively in complex and unstructured environments. To maximize adaptability and effectiveness in artificial bioinspired machines, the role of materials and the approach to design and fabrication are fundamental. Among many examples from nature, plants exhibit remarkable adaptive capabilities to changing conditions in their surroundings. For instance, we can draw inspiration from plants' structural-functional materials, distributed sensing, and intelligent behavioral responses to external conditions. Additionally, nature provides examples of biodegradable or recyclable materials, enabling the development of robotic systems that can be sustainably managed at the end of their (artificial) life cycle. This presentation will outline our approach to designing and developing EcoRobots inspired by the characteristics of plants, and report on how 3D and 4D printing technologies have been employed to match bioinspired features and performance. The goal of the research is twofold: first, to identify and extract the fundamental principles that underlie the biological functions of plants and translate them into technological solutions; and second, to advance our scientific understanding of the biological systems we draw inspiration from. Examples will include additive manufacturing-based growing robots, designed by taking inspiration from the apical growth and body adaptation of plant roots and climbing plants, and seed-inspired robots, which are soft, biodegradable miniaturized robots inspired by the morphology and dispersion abilities of plant seeds. These systems are fabricated with 3D and 4D printing techniques and integrated with sensing for applications in environmental monitoring, exploration, *navigation of unstructured multi-environment ecosystems, remediation, and reforestation.*

Computational Fluid Dynamics Simulation of Lattice Structures Toward Computational Design of Heat Sink Structures Applicable to Additive Manufacturing *Soya Nakagawa, Asuka Suzuki, Naoki Takata and Makoto Kobashi; Nagoya University, Japan*

Thermal management has become an important issue in automobiles and electronic devices. Heat sinks dissipate heat generated by electric devices, resulting in extending their life. Conventional manufacturing processes of heat sinks, including extrusions, forging, and machining have limited the manufacturable shapes to fin or pin. Recently, additive manufacturing (AM) has expanded the freedom of manufacturable shapes and enabled complex architected materials including lattice structures. Lattice structures are composed of periodically arranged unit cells and have a large surface area compared to fin or pin heat sinks. Therefore, more efficient heat transfer will be expected by using lattice structures as heat sinks instead of fin or pin structures.
Heat sinks are used under natural or forced convection. When heat sinks are used under forced convection, fluid is supplied to the heat sinks by using a fan or rotating the heat sinks themselves. A small pressure loss generated by the heat sinks should be preferable to minimize the energy required to supply the fluid. In addition, heat transfer characteristics are affected not only by surface area but also by the flow around the solids, which varies with the structure of heat sinks. A good balance between low-pressure loss and high heat transfer rate is practically important for heat sinks. In order to overcome current limitations, it is required to identify structural features dominating pressure loss and heat transfer in lattice structures. In this study, the heat transfer characteristics and pressure loss of various lattice structures and conventional heat sinks (fin and pin) were investigated numerically using computational fluid dynamics (CFD) to clarify dominant structural features for heat transfer and pressure loss.
The structures used in this study were BCC, Kelvin, Cubic, Lotus, fin, and pin with a fixed solid volume fraction of 20%. The number of unit cells was varied in the range of 1^3–3^3. A finite element analysis software (Femtet) was used for the CFD calculations. The analytical model consists of fluid (air), base, and heat sink structures and has an overall dimension of 30 × 150 × 30 mm^3. The dimensions of the base and heat sink structures are 30 × 30 × 10 mm^3 and 30 × 30 × 30 mm^3, respectively. The thermal conductivity of the base and heat sink structures was set at 110 $W \cdot m^{-1} \cdot K^{-1}$, assuming laser powder bed fused AlSi10Mg alloy. Flow velocity of 1.0–4.0 $m \cdot s^{-1}$ was applied to the fluid inlet surface, whereas natural outflow was set at the fluid outlet surface. A slip wall with zero flow velocity only in the normal direction was set at the other surfaces of the model. A heat of 4.5 W was applied to the bottom of the base, and the temperature rise of the base and pressure loss at steady state were calculated.
In the balance between low-temperature rise and low-pressure loss, Kelvin and Lotus were superior under low-pressure loss, and BCC was superior under high-pressure loss. Under a constant flow velocity, BCC and Kelvin exhibited a low-temperature rise of the base and high-pressure loss, whereas Lotus and fin exhibited high-temperature rise and low-pressure loss. Based on Newton's cooling law and the Darcy-Weisbach equation, surface area and hydraulic diameter are important for the low-temperature rise and low-pressure loss,

respectively. However, even when the heat transfer coefficient and Darcy friction factor were evaluated to exclude the effects of surface area and hydraulic diameter, the same tendencies as the temperature rise and pressure loss were retained. To clarify the dominant structural features, local heat flux and pressure were analyzed. Heat transfer was most active at the inlet of the lattice structures, while the rear parts did not contribute significantly to heat transfer. In addition, pressure significantly dropped at flow paths with locally narrow areas or greatly varied areas. These results could guide the design of suitable structures for heat sinks.

PM02.10.02

Optimizing Victoria Water Lily Inspired Lattices with Generative Design for Enhanced Strength and Tunable Directional Stiffness *Brennan Birn, Kyle Woody, Dominique Sun and Grace Gu; University of California, Berkeley, United States*

The Victoria Amazonica, also known as the Victoria Water Lily, is one of the most impressive plants in the rivers of the Amazon Rainforest. Its leaves grow up to 3 meters in size and can support up to 70 kg of weight. Previous studies noted the high stiffness of this structure when developing a tessellated unit cell inspired by the center structure of the water lily. Inspired by the lily pad, these studies developed a 3D structure of 9 beams and flipped the structure on itself to ensure vertical symmetry. This 3D structure outperforms many other bioinspired structures in the literature. Although this structure shows promise, it has yet to be optimized for the unidirectional compression it was designed for, and it has a nonideal stiffness matrix. Here, we show how the Victoria Water Lily lattice can achieve greater relative stiffness, strength, and isotropy when optimized using generative design. We found that optimizing the lily pad resulted in a substantial increase in stiffness with a more transversely isotropic stiffness matrix, ideal for unidirectional compression. Our results demonstrate that generative design tunes the stiffness distribution of bioinspired lattice structures while decreasing the overall anisotropy. We anticipate this will kickstart generative design for lattice structure optimization for various properties and applications due to the growing availability of generative design tools and the fact that generative design produces parts with a significantly smoother finish than other methods, such as topology optimization. It can, therefore, produce parts that are immediately ready for additive manufacturing and testing without the need for extensive user modification or an incredibly fine mesh.

PM02.10.03

The Curious Case of Ni-P-O—Insights for Unusual Materials Printing at the Nanoscale *Rebecca A. Gallivan, Tingyi Wang, Yuan Gao, Arthur Barras and Ralph Spolenak; ETH Zürich, Switzerland*

Expanding the materials selection in nanoscale additive manufacturing (AM) remains a critical aim for venturing into new applications and enhancing functionality through complex integrated components. The electrohydrodynamic redox printing (EHD-RP) technique has already made promising advancements through printing a variety of metals, oxides, and alloys. However, to more deeply understand potential pathways and limitations in pushing EHD-RP to more unusual and extreme materials, we investigate the unusual case of Ni-P-O materials produced with this method. Through printing parameter studies, we highlight the critical conditions necessary for material deposition and elucidate some key insights to the kinetics underlying materials formation from mixed ion-sources. Using a variety of spectroscopy and microscopy techniques, we also highlight the chemistry, structure, and stability of these materials and highlight pathways for functional and multifunctional design. Through the lessons and findings of this particularly curious Ni-P-O system, we uncover new understanding of how to push into new, unusual, and exotic materials at the nanoscale.

PM02.10.04

Conch-Inspired Design for Introducing Strain-Hardening and Increasing Energy Absorption in Lightweight

Architected Lattices *Charlotte Lendlein*[1,2] *and Nicholas Yew Jin Tan*[2]*;* [1]*Technische Universität Berlin, Germany;* [2]*Agency for Science, Technology and Research, Singapore*

The Pink Queen Conch Shell's superior energy absorption is rooted in its smallest organizational level: Nano-sized building blocks are rotated generating symmetrical boundaries that can deflect cracks in different directions, leading to a blunter crack tip. The area around the crack enters a mechanically ductile and plastic deformation which dissipates energy. This effect is potentially relevant for introducing inherent damage-tolerance and strength into additively manufactured products where printing defects commonly cause early failure of whole systems. Enabling the production of macroscopic technical applications such as protective armor or unmanned aerial vehicles, it is explored how the shell's nanoscale toughening effect can be implemented into a macroscale lattice. For this translation a lattice design with a variation of 3 unit-cell parameters is created.

A cube of dimensions of 3x3x3 cm^3 *consists of a periodic repetition of body-centered cubic unit cells. Within each cube, a number of parameters can be varied. This includes the thickness of the struts within each cell, their orientations and distribution of symmetrical boundaries. The proportion of the enlarged to reduced strut diameter within one unit cell is 0.617. These variations are implemented into the computational design which is manufactured additively for compression testing.*

The deformation mechanism is analyzed in a uniaxial quasistatic compression test with resin samples prepared by Digital Light Processing and directly compared to the mechanical behavior of the standard body-centered cubic lattice design which displays a homogenous strut diameter of 0.5 mm. The energy absorption characteristics of the lattice design and a direct comparison to the conventional material are enabled through analysis of the compression curves that characterize the mechanical behavior during compression. These diagrams enable the detection of correlations between the plastic deformation characteristics and energy absorbing behavior of the designs.

During compression, the difference in strut thickness within the unit cell is supposed to steer stresses in different directions, thus enlarging the area of plastic deformation and dissipating more energy before failure leading to a higher specific energy absorption of the conch-mimicking to the conventional design. At the same time, the deflection of mechanical deformation along the symmetrical boundary planes introduces strain-hardening into the compliant lattice structure. The resulting compression curves of shell-mimicking lattice design with a variation of strut thickness and the conventional design differ in their mechanical behavior: The plateau stress rises 34%, from 0.643±0.073 MPa in the conventional design to 0.973±0.124 MPa in the conch shell lattice. The strain hardening effect that can be observed during the plateau stage is enlarged by 32%, from 0.845±0.005 MPa to 1.243±0.088 MPa. The strain hardening and increased level of stresses during plastic deformation lead to a larger area under the compression curve expressed by the increase of 19% in specific (weight-independent) energy absorption, from 2.027±0.395 kJ/kg to 2.460±0.647 kJ/kg.

This way, the compliancy of the lattice is increased while simultaneously introducing an inherent hardening and toughening mechanism into the structure preventing it from early failure. In future experiments, the influence of the size effect, the choice of base material or unit cell configuration can be explored to complete the understanding of the structure-function relationship. In this way, a knowledge-based material design will be enabled.

PM02.10.05

3D-Printable Self-Healing Soft Materials in Response to Ambient Humidity and Temperature *Xuan Zhang and Yu Jun Tan; National University of Singapore, Singapore*

Stimuli-responsive soft materials exhibit tunable properties in response to external stimuli like heat, light, humidity, or magnetic fields, making them attractive for various applications in smart electronics. Long-term durability and reliability are crucial for these applications, and bioinspired self-healing properties can be incorporated to ensure functionality. Here we have created a moisture-induced, self-healing smart material that *exhibits reversible property changes in response to ambient humidity and temperature. This spontaneous smart response is attributed to the synergetic interactions between PPGurea, a polymer with urea linkages, and an ionic liquid, which readily conducts electricity. This material is soft, transparent, and conductive, readily self-healing when hydrated. Dehydration, on the other hand, transforms it into an opaque and less conductive state, while significantly increasing its stiffness, strength, and toughness. The humidity/temperature-responsive smart material holds great promise for 3D-printed optoelectronics and smart windows, adapting seamlessly to ambient changes.*

PM02.10.06

Absorption-Dominant EMI Shielding Materials with Conductivity Gradient and Porous Structures Using MXene Nanoflake-Based FDM Printable Filaments

Junghyo Nah[1], Pangun Park[1], Sol Lee[1,2] and Nam Khanh Nguyen[1]; [1]Chungnam National University, Korea (the Republic of); [2]University of California, Los Angeles, United States

Traditional methods for producing EMI shielding materials often face limitations in terms of structure, uniformity, and adaptability. To address these issues, 3D printing (3DP) methods offer customizable electrical conductivity and complex structural designs. However, commercially available options for building such structures are limited. Recently, MXene nanoflake-based EMI shielding materials have demonstrated excellent performance due to their superior properties. Thus, developing composite filament structures for 3DP using MXene nanoflakes is essential to realize high-performance EMI shielding materials.

In this study, we developed a method for fabricating FDM (Fused Deposition Modeling) printable filaments with various conductivities based on MXene nanoflakes. These filaments were used to create high-performance EMI shielding materials with conductivity gradient and porous structures, achieving absorption-dominant shielding. By precisely controlling the conductivity and porosity, we developed EMI shielding materials with a Shielding Effectiveness (SE) of over 65 dB and an absorption rate of 75% in the X-band. Compared to previously reported 3D-printed EMI shielding materials, our method offers significantly higher performance and uniformity.

This method is highly effective for fabricating absorption-based shielding materials applicable to various structures and for developing uniform and reproducible EMI shielding materials. The development of MXene-based FDM printable filaments and the gradient conductivity and porosity structures printed using them provide new possibilities for the fabrication of high-performance EMI shielding materials. This method represents a significant advancement in the field of EMI shielding, offering a versatile and effective solution for various applications.

PM02.10.07

Process Optimization of Projection Stereolithography for Assembly-Free Fabrication of Micro Transmission Mechanisms

Mingpei Cang[1,1] and Huachen Cui[1,2]; [1]The Hong Kong University of Science and Technology, China; [2]The Hong Kong University of Science and Technology (Guangzhou), China

Micro transmission mechanisms (μTMs) hold significant potential in the automobile, MEMS, and aerospace industries; however, their fabrication and assembly present challenges due to their diminutive size. Projection Micro Stereolithography (PμSL) offers a promising solution, achieving micron-level pixel resolution for efficient μTM fabrication. Nevertheless, the Gaussian distribution of pixel radiance in PμSL poses a limitation by causing unintended bonding of clearance between two workpieces, hindering assembly-free fabrication of μTMs. Increasing the designed clearance is one solution, yet it compromises the transmission efficiency and compactness of μTMs. Aiming to achieve assembly-free fabrication of μTMs with small clearance between workpieces, we propose an optimized additive manufacturing method for PμSL system. Firstly, we developed a model to simulate cured region based on pixel-level Gaussian irradiance distribution. Based on experiments of curing profile characterization in horizontal and depth directions, the model was calibrated per photosensitive resins and PμSL system. Our findings indicate that the unintended bonding of clearance results from the residual

irradiance exceeding the critical exposure dose, initiating photopolymerization at gaps. To address this, we introduced a grayscale pixel compensation method to minimize overexposure and underexposure. Additionally, we implemented a novel exposure strategy, which divides the projection pattern into several segments and project them separately. This approach allows the residual irradiance at clearance to dissipate, preventing it from reaching the critical dose and thereby reducing the minimum achievable clearance to 34 μm (equivalent to the size of four pixels in our PμSL system), which is notably small given the Gaussian radius is six pixels in our PμSL system. Our method has proven effective in the assembly-free fabrication of various microstructures, including micro planetary herringbone gears, bar-linkage mechanisms, and microchannels, using a range of materials such as photo-sensitive resin, polymer-derived ceramics, and alumina ceramics. The proposed exposure strategy holds high potential for various applications, such as micro-transmission mechanisms, MEMS, and microfluidics.

PM02.10.08
Process-Dependent Control of Bacterial Adhesion and Growth on Additive Manufacturing Surfaces *Julianna B. Harding[1,2], Jabria Hooker[1,2], Angela Truxillo[1], Rustin Bellanger[1,2], Wendy M. Schluchter[1] and Damon Smith[1,2]; [1]The University of New Orleans, United States; [2]Advanced Materials Research Institute (AMRI), United States*

Additive manufacturing processes are gaining popularity for the production of patient-specific biomedical devices such as prosthetics, orthotics, and splints as well as a variety of hospital supplies and equipment. For these applications, it is important that the materials are not prone to spreading infection. Therefore, it is crucial to learn more about how bacteria adhere to the surfaces of printed objects. In this study we examine how the fused filament fabrication (FFF) process influences the presence and morphology of surface grooves and how this can affect bacterial adhesion and growth. We have measured the growth of Escherichia coli (E. coli) and Staphylococcus aureus (S. aureus) on polylactic acid (PLA) surfaces printed with a variety of infill geometries and layer heights. The results showed that the adhesion and growth of E. coli was more sensitive to the morphology of surface grooves compared to S. aureus. While it was found that some process conditions produced topographies that reduced the growth of E. coli when compared to molded control specimens with smooth surfaces, the presence of surface grooves dramatically increased the growth of S. aureus in all cases. This suggests that the differing adhesion mechanisms of the two organisms plays an important role. The findings of this research can be used to better understand how to manufacture objects with surfaces that inhibit microbial adhesion and growth.

PM02.10.09
Direct-Write Capacitive Touchscreen Fabrication to Provide Insights into Fringe Field Interactions and Affordable Sensing *Josephine Tumwesige, Dushanth Seevaratnam, Elizabeth A. Hall and Ronan Daly; University of Cambridge, United Kingdom*

The widespread adoption of smart mobile technologies has revolutionised daily life, yet their potential for addressing global challenges remains largely untapped. In particular, the potential for affordable sensing, recording and communicating data with a capacitive touchscreen has been identified but is underexplored [1, 2], with no definitive studies into fringe field control for selective and quantitative sensing applications.

This presentation studies the direct-write fabrication of multiple capacitive sensing structures, including a range of coplanar interdigitated structures and two-layer variations of the Manhattan and diamond structures, as found in current mobile technologies. We carefully tune electrode dimensions, spacings and electrical behaviours through a combination of direct-write techniques, such as functional inkjet printing, aerosol printing, and laser ablation techniques. We couple detailed analyses of these surfaces with simulations and experimental sensing results to provide new insights into the links between structure, resulting fringe fields and key sensing parameters. This allows us to dramatically improve response time and sensitivity to target electrolytes, suggesting an exciting *unexplored potential for numerous applications.*

Our findings show that micromolar sensing can be readily achieved with simple, direct deposition of water droplets onto touchscreen sensors, which is ideal for environmental and agricultural monitoring applications looking at harmful metal ion contamination or nutrient level detection. The tuneability and link to smart mobile technologies open the door to using affordable and existing technologies for real-time, in-situ analysis with simple integration into existing digital communications and analysis techniques, enabling widespread adoption and impact.

PM02.10.10

Device Integration Using 3D Printed Glass Micro-Optics

Keldy Mason[1], Emily Huntley[1], Joseph Furgal[2], Samuel C. Leguizamon[1], Alejandro Grine[1], Darwin Serkland[1] and Bryan Kaehr[1,3]; [1]Sandia National Laboratories, United States; [2]Bowling Green State University, United States; [3]Center for Integrated Nanotechnologies, United States

The integration of micro-scale optical systems for use as sensors, medical devices and photonic platforms is challenging using typical assembly practices that often result in low efficiency light coupling (<10%). The ability to 3D print micro-optics directly onto light sources, fibers, detectors, photonic integrated circuits, etc., could drastically simplify design, iteration and implementation of advanced optical systems. Using a free-from design approach such as multiphoton lithography (MPL) affords the ability for print-on polymer optics with nano/micro scale resolution. Moreover, recent work showing MPL fabrication of silica glass processed under low temperature provides a possible route for direct integration of mechanically robust, environmentally rugged optical grade materials. The use of molecular/polymeric materials (polyhedral oligomeric silsesquioxanes, POSS; polydimethylsiloxane; PDMS) versus nano-silica precursors used previously [1], enables printed forms to be processed into silica glass at relatively low temperatures (<650C; [2]) or using deep-UV/ozone approaches (~220C; [3]). Here, we investigate 3D printed glass micro-optics for chip to fiber connections by quantifying design fidelity, shrinkage, surface roughness and coupling efficiency of microlenses printed using standard layer-by-layer MPL as well the dynamic voxel approach (two-photon grayscale lithography; 2GL[4]). We investigate incorporation of POSS derivatives (such as octa(dimethylsiloxy) silsesquioxane) to increase initial SiO_2 content and decrease shrinkage upon thermal decomposition. Finally, we fabricate a multi-lens optic for fiber/detector connection and demonstrate high efficiency coupling (>10%) using an all-glass integrated assembly. This ability to make mechanically robust and accurately aligned glass micro-optical assemblies promises to revolutionize the design and performance of advanced optical systems.

Additive Solution-Based Process to Fabricate Metal Oxide FETs Enabled by Directed Fluidic Assembly

Ahmed Hafez[1,2], Charles Schetter[2], Yash Sahoo[2] and Ahmed Busnaina[2]; [1]NASA Goddard Space Flight Center, United States; [2]Northeastern University, United States

Semiconductor electronics miniaturization conventionally requires sophisticated and complex fabrication

processes, which are typically conducted at high end semiconductor foundries at elevated price tags. Researchers nowadays work on incorporating new additive fabrication techniques to alleviate the overall fabrication cost of such devices. Semiconductors' doping represents a fundamental challenge in this regard, particularly, controlling doping of impurities into intrinsic semiconductor materials down to nano-scale resolution. This doping process is conventionally conducted through complicated deposition and dry etching processes, which drastically increases the fabrication cost of such devices. Additive manufacturing, however, can be incorporated to replace some of these complicated techniques, which can provide similar results at much lower cost. Here, we report a novel, reliable, and cost-effective additive fabrication approach that allows controlled doping of n-type dopants into silicon substrates. This is achieved using two steps: first, additively coating of dopants from their liquid dispersions directly over chemically engineered Si substrates at micro- to nanoscale precision, using fast fluidic assembly technique (FFA). Second, diffusing the dopants inside the Si substrate using controlled rapid thermal annealing process (RTA). This novel approach facilitates injecting semiconductors with impurities down to micro scale resolution at designated locations. Time of flight ion mass spectroscopy (TOF-SIMS) was conducted to investigate the distribution of the dopants inside the Si bulk substrate. Moreover, by modeling the fabrication process using CAD tools, we were able to fine-tune the doping process to achieve optimum doping profile required for building miniaturized electronic components. The technique was demonstrated by fabricating metal oxide field effect transistors (MOSFETs) devices with outstanding performance. From the I-V characteristics, the devices showed an effective mobility (μeff) of ~320 cm^2/V.s in the linear regime, and 300 cm^2 /V.s in the saturation regime. The transfer characteristics also revealed on/off ratio of ~ 10^4 for devices with 10 μm channel length. Moreover, the drain current was negligible at zero gate voltage, which confirms that the fabricated MOSFETs are operating in enhancement mode as desired, and was further confirmed by TOF-SIMS measurements. We believe that this novel doping technique will pave the way as an alternative cost-effective method to fabricate miniaturized electronic devices on a large scale for semiconductor industry.

PM02.10.12

Deposition of Metallic Casing Layers via Flash Lamp Sintering of an Inkjet Printable, Self-Reducible Nickel Metal-Organic Decomposition (MOD) Ink for Thermal and Chemical Protection of Copper Circuits

Sean Jackson; Oak Ridge Associated Universities, United States

Copper (Cu)-based conductive inks have been widely utilized for deposition of conductive electrodes with high economic value. While traditional thermal processing technologies of convection and conductive heating are sufficient to generate conductive copper traces, copper's relatively high chemical reactivity results in rapid oxidation during thermal processing in ambient conditions. Furthermore, while the relatively low thermal stability of metallic copper increases manufacturing compatibility, low thermal stability simultaneously hinders its durability for use in high-temperature applications.

These challenges hinder the development of miniaturized electronics that are deployable in thermally demanding and chemically unstable environments. To address these challenges, we introduce a two-part printing and processing strategy, whereby printable Cu metal-organic decomposition (MOD) inks are inkjet printed and thermally processed via flash lamp sintering.

Following, Nickel (Ni) MOD inks are inkjet printed and flash lamp sintered, functioning as a metallic barrier to increase both chemical and thermal resistance of underlying conductive copper traces. The optimization of inkjet printing parameters and flash lamp sinter processing is discussed, describing the iterative optimization methodologies used for 1) controlling deposition of nickel thin films of various thickness values alongside 2) modulating flash lamp irradiation of NiMOD films to control the microstructure of the deposited protective coating.

PM02.10.13

Additively Manufactured Rapid Prototype Circuits with Convertible Inks *Gavin Alexander, Daniel Bousquet, Morgan Michael, Andrew Luce, Guinevere Strack, Alkim Akyurtlu and Oshadha K. Ranasingha; University of Massachusetts Lowell, United States*

Flexible Hybrid Electronics (FHE) devices are primarily manufactured using printable inks, such as conductive/resistive and dielectric/insulative inks. Printable inks usually consist of metal nanoparticles or polymers/ceramics to produce conductive/resistive or dielectric/insulative patterns, respectively. However, various issues must be addressed when using multiple printable inks, such as solvent compatibilities and adhesion between multiple inks. The best solution is to develop one ink that can be used to fabricate both conductive/resistive and dielectrics/insulative parts. In order to fulfill this requirement, our group developed a first-generation convertible ink previously. In this project, a second-generation convertible ink was developed with superior performance compared to the first-generation convertible ink. The second-generation convertible ink was developed using silver nanoparticles combined with polyvinyl pyrrolidone and/or ceramic nanoparticles. After curing at 120 °C for 30 minutes, an insulating blanket film is left. Then, selective laser sintering can be used to create conductive/resistive patterns. The resistivity can be adjusted by varying laser sintering parameters. This convertible ink can be printed in aerosol jet printers and dispensing printers, and selective laser sintering can be performed with the inbuilt 830 nm laser in Optomec AJ5X aerosol jet printer. This technology can be used to fabricate FHE devices in remote locations where printing is not feasible. Insulating layers can be printed and can be sent to a remote location to fabricate FHE devices using a compact laser. This technology can be identified as potential FHE device fabrication technology at the International Space Station (ISS) without printing liquid inks under microgravity. Ink formulation, characterization, and fabricated FHE prototypes will be presented.

PM02.10.14

Wear Resistance of 3D Printed Composite Materials *Kamyar Pashayi and Tauris Germany; Siena College, United States*

This study investigates the fabrication of 3D printed composite materials using a Creality Ender 3D printer and studies wear properties of the resulting composites. Within 3D printing, composites are typically a combination of a polymer material (a matrix) and a reinforcing element. In this work we used PLA as a thermoplastic polymer matrix and applied the following reinforcing materials: Titanium Carbide microparticles & nanoparticles, Graphene, Iron Oxide, and NANO Gloop adhesive. The reinforcing materials were applied utilizing manual brushing with q-tips to each layer of the sample while the 3D printer was injecting PLA filament on the print bed. The samples were dimensionally accurate (within ± 2.5%) and exhibited less than three visible voids when observed under an optical microscope. The last objective of this research is to test the wear resistance of the composite samples in accordance with ASTM G-99 using a pin-on-disc setup.

PM02.10.15

Negative Curvature Hollow Core Fibers for Terahertz Wave Guidance via 3D Polymer Printing *Muhammad Z. Siddiqui[1], Taiyu Okatani[2], Yoshiaki Kanamori[2] and Mustafa Ordu[1]; [1]Bilkent University, Turkey; [2]Tohoku University, Japan*

Utilizing 3D printing to fabricate optical waveguides is a versatile approach for developing sophisticated structures to efficiently guide the light. The terahertz (THz) region is significant for telecommunication, imaging, and sensing applications, and developing high-performance THz waveguides is critical to successfully demonstrating its importance for the applications mentioned above. This study introduces the design, optimization, and fabrication of a THz guiding negative curvature hollow-core fiber (NCF) realized via the 3D printing technique. The fiber is *designed as a hollow-core structure surrounded by four sets of tubular elements with bars as nest elements at the center of the tubes. The fibers are modeled using cyclic olefin copolymer (COC, or commercially known as TOPAS), which has low absorption losses in the THz region. The fiber's geometry is systematically optimized for outstanding optical performance, and iterative simulations are performed to define the design parameters. The calculated confinement and total losses are found below 1 dB/m across a wide THz frequency region with periodic high absorption peaks occurring naturally in every NCF structure. The optimized 4-tube design is later fabricated using the fused deposition modeling (FDM) 3D printing technique and commercially available COC filaments. Fibers with a 3 mm core diameter, an 11.6 mm outer diameter and 150 mm length are realized with a minimum feature size of 400 µm. The optical performance of the fibers will be investigated using a THZ frequency domain spectroscopy (FDS) device in the frequency region ranging from 0.1 to 1 THz. This innovative approach opens up possibilities for developing customized and sophisticated NCFs tailored for various THz applications, thereby accelerating advancements in this rapidly evolving field.*

PM02.10.16

3D Printable One-Part Carbon Nanotube Elastomer and Flexible Frequency Tunable Tactors for Sensing-Actuation Platform *Phillip D. Glass[1], Sung Hyun Park[2] and Daeha Joung[1]; [1]Virginia Commonwealth University, United States; [2]Korea Institute of Industrial Technology, Korea (the Republic of)*

Flexible electronics which generate proprioceptive feedback loops are a promising field for those with prosthetic limbs or degenerative nervous system conditions like Parkinson's disease. A platform which combines the sensing of pressure and stretching in the limbs and sends feedback through an actuator is desirable for those who have difficulty or inability in both sensing and in sending sensory feedback to the brain. To this end, custom mechanical sensors should be designed for facile fabrication, customization for patient specific application, wearability, flexibility, and with consideration for connection to wearable actuators. The connected vibrotactile actuators, similarly, should be designed with high flexibility, custom manufacturing of size, and tunable resonant vibration frequency. First a novel one-part, highly conductive, flexible, stretchable, 3D printable carbon nanotube (CNT)-silicone composite is developed and thoroughly characterized. The one- part ink is an excellent candidate for easily customizable 3D printed sensors since it cures from ambient moisture without mixing, additives, needs no additional post processing, and can be printed at 100 µm resolution. In combination, a novel flexible tactile actuator is fabricated with advanced manufacturing with customizable size (4- and 10-mm diameters demonstrated), high flexibility, customizable vibration resonant frequency, and strong penetrative vibration. A platform which utilizes these 3D printed sensors and actuators are connected mechanically by 3D printed flexible wearable substrates and electrically by 3D printed flexible silver pathing. The event cue feedback loop formed by the mechanical sensing of custom CNT elastomers and the actuation of custom flexible actuators forms advanced e-skin platforms for treatment of freeze of gait, in grip control, prosthetic socket wearability, and beyond towards personalized health monitoring and proprioceptive feedback control for those with limited nervous system function.

PM02.10.17

Green Synthesis in Ambient of Photothermally Activatable Copper Nanoparticles for Additive Manufacturable 3D Electronics *Sanghyeok Bae, Yeongje Lee, Beomjung Baek, Dongyoung Kim and Sunho Jeong; Kyung Hee University, Korea (the Republic of)*

Recently, three-dimensional (3D) printed electronics has gained a tremendous interest as a technology that can potentially address a critical economical issue in patterning designated functional materials in three-axis directions. A development of 3D printable conductive ink is highly prerequisite to ensure a realization of 3D printed electronics. The conventional silver nanoparticle-based conductive inks can be an excellent candidate in terms of *electrical conductance and environmental stability, but they are limited in widespread use due to critical issues in cost and susceptibility to electromigration. The cost-effective copper nanoparticles have been recognized as a viable alternative owing to their capability of offering a high conductivity comparable that of silver nanoparticles. Herein, we introduce a green technique of synthesizing surface oxidation-suppressed copper nanoparticles in air. The copper nanoparticles with an ultrathin surface oxide layer are designed to be sintered by 3D surface-conformal green laser irradiation process to address the limitations of conventional heat treatment process. More importantly, we also suggest a surface modification technique of removing photothermally the ultrathin surface oxide layer upon a completion of green laser irradiation process. We demonstrate that a combinatorial strategy of combining the 3D green laser activation process and the surface modification technique enables effectively to achieve the widen processing window, long-term storage of copper nanoparticles (for over 30 days in air), and high electrical conductivity of over 20,000 S/cm in 3D shaped circuitries.*

PM02.10.18

Design and 3D Printing of Heat-Dissipating Thermoelectric Architecture Utilizing Ternary Silver Chalcogenides *Keonkuk Kim, Seungjun Choo, Jungsoo Lee and Jae Sung Son; Pohang University of Science and Technology, Korea (the Republic of)*

Thermoelectric devices have garnered substantial attention due to their potential for sustainable energy recovery. Optimizing heat transfer and dissipation is essential for maximizing power output in these devices. Conventional approaches to heat dissipation often rely on external active or passive cooling systems, which suffer from heat loss and increased system weight. This research introduces a design of heat-sink integrated thermoelectric legs to improve heat dissipation without external cooling devices. This design is realized through finite element model simulations and 3D printing process of ternary silver chalcogenide-based thermoelectric materials. The synthesized $AgBiSe_2$ *(n-type) and* $AgSbTe_2$ *(p-type) particles exhibit self-induced surface charges, resulting in high viscoelasticity in the particle-based colloidal inks. This property enables the fabrication of complex heat-dissipation architectures through 3D printing. Thermoelectric generators constructed from these 3D-printed heat-dissipating legs achieve higher temperature differences and increased output power compared to traditional cuboidal thermoelectric generators. This strategy introduces a new way to enhance thermoelectric power generation*

PM02.10.19

Additive Manufacturing Protocol for Production of Complex and Oscillating POSS-Based 4D Structures

Nicole Gorohovsky[1], Ronen Verker[2,1] and Noa Lachman[1]; [1]Tel Aviv University, Israel; [2]Soreq Nuclear Research Center, Israel

Two-way shape memory polymers (2WSMPs) are a fascinating class of materials with the unique ability to revert between two distinct shapes in response to external stimuli. Upon exposure to a specific stimulus, such as heat or humidity, the polymer undergoes a reversible transition, enabling it to switch back and forth between the two shapes. This dynamic behavior of 2WSMPs opens up a wide range of potential applications in fields like medicine, aerospace, soft robotics, and smart textiles.

In this study, complex and high-performance 2WSMPs actuators were manufactured for the first time via direct ink writing (DIW) additive manufacturing (AM) technique of crosslinked poly Oligomeric Silsesquioxanes (PolyPOSS) thermoset applied on a Kapton film. For this purpose, a fused filament fabrication (FFF) 3D printer was converted into a DIW 3D printer.

Initially, physical parameters such as PolyPOSS gelation time at various temperatures, as well as its wetting ability on Kapton substrates were investigated. Then, PolyPOSS printing parameters were meticulously investigated, and ideal printing parameters were identified while establishing a unique printing protocol for thermoset polymers.

Parameters such as printing speed, volumetric flow rate, layer height, and layer width were investigated, and the results were confined and evaluated according to a single printing index developed uniquely for this purpose. A set of printing parameters that yields the lowest printing index, i.e., the most unified printed lines, was identified. The optimal line distance to print a uniform layer was then tested. After obtaining a satisfactory first layer, an additional set of printing parameters, this time for a second layer, was established.
Finally, various complex 2WSMP actuators were printed. The actuators' response to various temperatures, gripping abilities, and unique as well as oscillating shape memory behaviors was recorded.
We thus showed that using AM allows complex 2WSMP structures to be produced in a manner that would be nearly impossible with conventional casting manufacturing methods.

PM02.10.20

Selective Electrodeposition of Graphitic Materials for Additve Manufacturing of Printed Circuit Boards (PCBs)

Wedyan Babatain, Christine Park, Hiorshi Ishii and Neil Gershenfeld; Massachusetts Institute of Technology, United States

The rise of flexible electronics, particularly for wearable applications, has increased the demand for additive manufacturing approaches for printed circuit boards (PCBs). These techniques leverage innovation at both material and fabrication process levels to reduce cost and streamline production. Among various techniques, printed electronics enabled by laser processing are advantageous due to their accessibility, precision, scalability, and cost-effectiveness. Recently, laser-induced graphene (LIG) has emerged as a versatile functional material used in several devices and applications including sensors, actuators, batteries and energy harvesters. In this work, we introduce a novel laser-enabled technique for manufacturing of single- and double-sided printed circuit boards using LIG as a seed layer for selective copper plating. This new utilization of LIG offers an additive, low-cost, maskless approach that not only minimizes material waste but also reduces the need for subtractive processes typically used in the electronics industry. We developed a comprehensive process flow that includes direct writing of PCB layouts, VIA formation, assembly of surface mount components, and protective coating, resulting in the production of flexible PCBs on polyimide substrates. These PCBs can be readily transferred to transparent and stretchable substrates, owing to the unique 3D porous structure of LIG. Our approach effectively resolves PCB traces as small as 50 µm with various lengths and patterns. A key feature presented in our work is the streamlined two-step process for VIA formation. Optimizing the laser parameters enabled the formation of graphitized 250 µm holes across the polyimide substrate that serves as conductive VIAs upon copper electrodeposition. This approach reduces traditional multi-step VIA fabrication methods and results in efficient production of double-sided PCBs, allowing for the integration of electronic circuits on one side with functional graphene devices on the other, enhancing both functionality and device integration. Characterization using scanning electron microscope (SEM) and Raman spectroscopy was performed to confirm the presence of a graphitic 3D porous structure in the generated LIG. Extensive optimization of laser parameters and copper plating conditions was performed, significantly reducing LIG trace resistance from 900 Ω to 0.2 Ω, making them highly conductive and suitable for conventional circuit applications. The practical utility of the developed technique was demonstrated by fabricating PCBs integrated with functional LIG devices, including a strain sensor, temperature sensor, thin film heater, and soft electrothermal actuators, all powered and controlled via PCBs fabricated using our method. This addresses the existing challenge of establishing homogeneous electrical contacts to LIG devices while providing seamless integration of circuit boards and functional devices on a single substrate. In future, we plan to develop a tabletop machine that integrates LIG processing with a streamlined plating process, providing an all-in-one digital fabrication solution. Additionally, this approach can be extended for the fabrication of PCBs on 3D geometries and curved surfaces, demonstrating the potential of multifunctional materials and hybrid manufacturing techniques in contributing to the electronics industry.

PM02.10.21

Laser Fabricated Digital Dewetting Patterns for Self-Alignment of Inkjet-Printed Materials for Organic Field Effect Transistors (OFETs) *Christian Rainer, Ali Tunc, Orlando Torres Perales, Gerardo Hernandez-Sosa and Uli Lemmer; Karlsruhe Institute of Technology, Germany*

Inkjet printing is a versatile technology that enables industry scale production of electronic devices with minimal loss of material, since it's a digital process using drop-on-demand processing. It is compatible with a wide range of both organic and inorganic materials, can support flexible substrates and even be used for biodegradable devices. Applications include solar cells, photodetectors and medical sensors.

Of particular interest in our group are field effect transistors based on organic materials. It is beneficial to reduce the feature size of printed transistors to reduce operating voltages, power consumption and enable fast switching frequencies. One fundamental limit of inkjet printing is the lateral achievable feature size, that is heavily influenced by the volume of individual ink drops and their interactions with the surface of the substrate. Typically, resolution is restricted to several tenths of µms. We propose the combination of additive as well as subtractive laser-based processing techniques to enhance inkjet-printed devices and achieve resolutions of 10 µm or lower, while at the same time confining the process to one machine, reducing the complexity of processing and alignment. In the past, we already investigated similar ideas using aerosoljet printed structures[1].

One approach relies on the controlled modification of surface free energy (SFE) using laser-based crosslinking of the photoresist material SU-8 with a resolution of 10 µm in the focal spot of a UV fs-laser (additive). The process is fully digital in 2D, allowing for design freedom and flexibility. After crosslinking and washing of residual materials, SU-8 and substrate show contrasts in surface energies. Subsequent deposition of functional silver ink for electrode structures leads to de-wetting and self-alignment along the pre-defined patterns, resulting in the formation of channels that are in the order of 10 µm and only limited by the laser resolution.
Subsequent layers are inkjet-printed on top, forming the field effect transistor. Compared to fully printed field effect transistors, the channel length is reduced by a factor of at least 3.

Another approach relies on the idea of utilizing high power fs-laser ablation to cut transistor channels into previously printed thin film electrode structures (subtractive process). By fine-tuning the laser output power and carfully optimizing the processing, channel lengths below 10 µm can be realised.

Apart from utilizing 1-photon polymerization with a UV-laser as the main crosslinking mechanism in our additive approach, further investigations are intended to be performed using two photon polymerization processes, which would allow to push dimensions to the sub 1 µm regime.

PM02.10.22

Polyvinyl Fluoride/Ionic Liquid Blend-Based Sensors for Volatile Organic Compounds Detection *Bruna F. Gonçalves[1], Eduardo Fernández[1], Nikola Perinka[1], Mattia Gaboardi[2], Viktor Petrenko[1,3], Jose Porro[1,3], Daniela Correia[4], Felix Fernández[2,3,5], Roberto Fernández de Luis[1] and Senentxu Lanceros-Mendez[1,3]; [1]BCMaterials, Spain; [2]University of the Basque Country, Spain; [3]IKERBASQUE, Basque Foundation for Science, Spain; [4]Chemistry Centre of Minho and Porto Universities, Portugal; [5]Donostia International Physics Center (DIPC), Spain*

Indoor air pollution is a serious health threat, linked to over 3 million deaths per year. Therefore, monitoring indoor *pollutants, in particular volatile organic compounds (VOCs) arising from building materials, is essential to take proper health measures in due time. Among the existing gas sensor technologies, metal oxide semiconductors are at the forefront due to their low operating temperature, high sensitivity and affordability, but still their selectivity and processability continue to be their main drawback, especially when comparing to polymers.[1] On the other hand, the performance of polymers for gas sensing is undoubtedly far from being competitive, in particular due to their highly resistive nature.*

The use of ionic liquids (ILs) can overcome this technological barrier, as ILs display high ionic conductivity, low volatility and high chemical/thermal stability. In addition, the combination of different IL's cations and anions enables precise adjustment of their physical-chemical properties for selective gas interaction and improved electrical output.[2] Nevertheless, most ILs remain liquid at room temperature, challenging their processability. The encapsulation of ILs into polymer matrices can create robust, versatile, and easily manufacturable materials. Among the different polymers, polyvinylidene fluoride (PVDF), an electroactive polymer with high thermal, chemical and radiation resistance, offers a suitable dipolar-ion interaction with IL ions, enabling a high magnitude of response. The combination of PVDF and ILs allows their processing via printing technologies, giving rise to miniaturized and flexible devices at a low cost. Further, these particle-free inks offer several advantages, as they can be easily formulated and printed, preventing clogging issues. Overall, the process provides a platform to develop transparent and cost-effective sensors which can be printed on flexible substrates.[3]

This study reports on a novel platform for printed robust and flexible gas sensors by exploring the performance of PVDF/ILs sensors and by investigating the physical-chemical interactions between PVDF and ILs. Accordingly, the wettability, structural, thermal, morphological, and electrical properties of the PVDF/IL films were evaluated to investigate the effects of incorporating various loadings of ILs with different anions (TFSI, $N(CN)_2$, SCN, $FeCl_4$, $NiCl_4$, $Co(SCN)_4$) and similar cations (Bmim, Emim) into the PVDF matrix. In addition, the sensor's sensitivity and selectivity to humidity and VOCs including ethanol, acetone and isopropanol (IPA) were evaluated.

The variation in capacitance (ΔCp) revealed that the response of the IL alone differs from the response of the same IL when encapsulated in PVDF, indicating that PVDF not only serves as a host but also influences the sensor's sensitivity and selectivity. Additionally, it was found that the key factors affecting the sensor's ΔCp are the film's ionic conductivity, wettability, and the ILs' polarity and volume, rather than the film's morphology. The PVDF/IL sensors' response yielded maximum sensitivities of 6×10^{-3}, 3×10^{-4}, 9×10^{-5} and 9×10^{-5} pF/ppm for humidity, ethanol, acetone, and IPA, respectively. The minimum detection limits for these substances were ~200, ~850, ~2.8k and ~650 ppm for humidity, ethanol, acetone and IPA. Thus, our experimental setup can effectively detect IPA and ethanol at relevant concentrations, as IPA becomes harmful above 3k ppm and ethanol begins to irritate the eyes above 1k ppm. Given the promising results of the individual sensors, a cross-selectivity system was implemented to enhance selectivity and provide a fast and accurate sensor capable of promptly detect indoor excessive VOC concentrations, safeguarding human health.

Mechanical Reinforcement of Additively Manufactured Ceramics with Boron Nitride Nanotubes

Dingli Wang, Nasim Anjum and Changhong Ke; Binghamton University, The State University of New York, United States

Ceramic materials face significant challenges in industrial applications due to their inherent fragility and limited manufacturability. These limitations can potentially be overcome through the use of reinforcements and additive manufacturing (AM) techniques. Boron nitride nanotubes (BNNTs) possess exceptional structural and physical properties, making them promising candidates for reinforcing ceramics to create lightweight, strong, and durable ceramic materials. These characteristics are attractive to a number of industries, such as aerospace, automotive, *and biomedical sectors. The reinforcement potential of BNNTs for ceramic composites is supported by our recent findings of efficient interfacial load transfer in BNNT-ceramic nanocomposites, which is attributed to the partially ionic B-N bonding and the resulting rugged anisotropic energy landscape. Here, we investigate the bulk mechanical properties of AM-produced BNNT-reinforced silica (SiO2) nanocomposites. Our study aims to elucidate how the superior interfacial load transfer characteristics observed at the nanoscale translate into enhancements in the bulk mechanical properties of these nanocomposites. The BNNT-silica nanocomposites employed in our study are additively manufactured using digital light processing (DLP) techniques. Our findings demonstrate that the incorporation of a small quantity of BNNTs can significantly improve the bulk mechanical properties (flexural modulus, strength, and fracture toughness) of AM-produced ceramic nanocomposites. We further analyze the local interfacial load transfer within the AM nanocomposite through in situ Raman micromechanical measurements. The findings provide valuable insights into the role of nanotube-ceramic interfacial strength in enhancing the mechanical properties of the nanocomposite. Our research contributes to a better understanding of the relationship between process, structure, and properties in AM-produced ceramic nanocomposites and the development of durable and reliable ceramics technology.*

PM02.10.24

Aerosol Jet Printing of Dielectric Polymer-Based Nanocomposites with Improved Thermal Conductivity for Electronic Applications *Simone Bagatella[1], Giacomo Scagnetti[1], Marco Salina[2], Laura Castoldi[2], Marco Cavallaro[1], Raffaella Suriano[1] and Marinella Levi[1]; [1]Politecnico di Milano, Italy; [2]STMicroelectronics, Italy*

Aerosol Jet Printing (AJP) is an advanced additive manufacturing technology emerging for its ability to produce high-resolution, cost-effective, and energy-efficient electronic devices. It enables the deposition of a diverse range of materials, including metals, ceramics, and polymers, which is crucial for creating miniaturized, high-performance devices for industrial applications. In the electronics industry, AJP could offer significant advantages over traditional lithographic and screen-printing methods. Its maskless, computer-aided design (CAD) approach allows for rapid prototyping and customization without the need for costly and time-consuming mask production.
As technology advances, electronic devices require higher frequencies, increased integration levels, and miniaturization, bringing increasingly demanding requirements and challenges. The need for low delay times, crucial for high frequencies, has driven attention to low dielectric constant materials. Additionally, densely packed components in miniaturized electronics generate more heat, making efficient heat dissipation fundamental. Thus, materials combining dielectric properties with high thermal conductivity and stability are urgently required to improve heat dissipation and device reliability. Moreover, precision in manufacturing processes is necessary for complex pattern production. Therefore, designing materials with low dielectric constant, improved thermal conductivity, and high thermal stability, and studying their processability with AJP, is a current challenge for fabricating efficient and reliable miniaturized electronics meeting the latest requirements.

In this study, multifunctional polymer-based nanocomposites with a benzocyclobutadiene (BCB) matrix and boron nitride nanosheets (BNNS) as filler, varying from 0 to 20 wt%, were designed and processed by AJP for potential electronics applications. A comprehensive investigation of these nanocomposites' processability with AJP was carried out, and the effects of BNNS in the polymer matrix were investigated in terms of rheological, dielectric, and thermal properties.
The rheological properties of the inks were optimized to ensure viscosity requirements for pneumatic AJP, typically between 1 and 1000 mPa·s for high-quality prints. The optimized ink formulations facilitated the generation and transport of stable inks. The printability of the inks was investigated by managing various printing parameters, such as atomizer gas flow rate, driving gas flow rate, sheath gas flow rate, and printing speed, unraveling their complex interplay. This analysis followed a design of experiment (DOE) approach, allowing the identification of optimized parameter combinations according to the filler content and, thus, printing patterns with complex geometries,

featuring resolutions around 50 µm, demonstrating AJP's applicability in electronics.
The addition of BNNS positively affected the polymer properties. The nanocomposites showed a low dielectric constant even with 20 wt% BNNS, ranging from 2.30 to 2.55, with low dielectric loss values. The heat dissipation ability increased, with a 232% enhancement in thermal conductivity compared to the plain matrix with 20 wt% BNNS incorporation. Furthermore, the nanocomposites were found to be highly thermally stable, with degradation temperatures above 440 °C.

In conclusion, the successful design and printing of nanocomposite dielectric and thermally stable inks with enhanced thermal conductivity demonstrate AJP's capability to process complex formulations with high quality. These findings support the broader adoption of AJP in the electronics industry, especially for multifunctional polymer-based materials with potential applications as passive components like microelectronic packaging, thermal interface materials, and adhesives in high-temperature electronics.

PM02.10.25
Programming Mechanoresponse Behavior in Spiropyran-Incorporating Liquid Crystal Elastomers via Direct-Ink-Writing *Kyeong-wan Kim[1], Tae Ann Kim[2] and Suk-kyun Ahn[1]; [1]Pusan National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)*

Mechanoresponsive polymers have received significant attention, due to their potential application in stress and/or strain sensing and damage warning. Among them, spiropyran (SP)-based mechanoresponsive polymers, which can undergo ring-opening to the merocyanine form under mechanical stress, is the most established. The majority of SP-containing mechanoresponsive polymers investigated so far uses the isotropic polymer matrices such as silicone, polyurethane and poly(methyl methacrylate). In this work, we introduce SP into the anisotropic liquid crystal elastomer (LCE) matrix (SP-LCE) to investigate the linkage between LC alignment and mechanochromic behavior. In particular, the nematic director of SP-LCE can be efficiently controlled by direct-ink-writing method. Most interestingly, the mechanochromic responses of SP-LCEs can be significantly altered depending on the stretching direction with respect to the nematic director unlike conventional SP-based mechanoresponsive polymers. The ability to spatially program the mechanoresponse behavior in the SP-LCE monolith can offer the opportunity to develop a new class of strain sensors and anti-counterfeiting materials.

PM02.10.26
Effects of Nanoparticles on Laser Sintering of Metal and Ceramic Powders *Ka'Tra Winchester, Uchechukwu Alih, Noble Agyeman-Bobie, Zie Nia Rice, Enoch Owoade, Jovana Latinovic, Stecy Chirinda and Haeyeon Yang; Grambling State University, United States*

Continuous wave (CW) laser was used to melt micrometer sized powders mixed with various nanoparticles including copper and titanium. To create "nano-liquid" during the laser melting of powders, nanoparticles of high melting point are mixed with powders so that the NPs are kept in solid phase while the lower melting point powder elements become liquid. During this short period time, the laser melted liquid can be viewed as nanoliquids. Nanoliquids have been known as medium of excellent heat transfer so that commercial nanoliquids are available such as engine coolant and liquid for drilling oil wells. In this presentation, the laser melting of powders such as SmCo5 and lunar regolith with various nanoparticles will be discussed including their crystalline structure, hardness, and magnetic properties.

PM02.10.27
Fabrication of Multi-Height Microlens Arrays Using Maskless Grayscale Photolithography *Sebeen Lee, Eunsol Lee, Jewoong Lee, Changsoon Kim and In-Suk Choi; Seoul National University, Korea (the Republic of)*

A microlens array (MLA) consists of micro-scale lenses arranged in a regular pattern. Traditionally, MLAs have been fabricated using methods such as thermal reflow, inkjet printing, and photolithography, finding applications in displays and cameras. Single-height MLAs, however, are limited by their narrow depth of field, necessitating for multi-height MLAs which offer multiple focal lengths.
In this study, we addressed these challenges by employing a maskless grayscale photolithography system to efficiently implement multi-height MLAs. The process involved fabricating MLA molds using photoresist and then producing replica lenses with PDMS. To ensure reproducibility, multiple samples of multi-height MLAs were created. The fabrication results were validated by measuring the heights using a surface profiler and comparing the visibility of light patterns, confirming the satisfactory quality of the produced lenses.
This study achieved a simplified and efficient production of multi-height MLAs using a single photolithographic step with the grayscale photolithography system, circumventing the complexities associated with traditional methods. Moreover, the use of a maskless approach maximized the fill-factor, enhancing area efficiency. The versatility of these multi-height MLAs promises significant expansions in applications such as 3D imaging, holography, and camera.

PM02.10.28

Highly Stretchable Anti-Chiral Auxetic Structure Having Tunable Poisson's Ratio *Jaeyoung Choi[1], Yu-Ki Lee[2], Jinhee Kim[3], Changsoon Kim[1] and In-Suk Choi[1]; [1]Seoul National University, Korea (the Republic of); [2]SK Hynix, Korea (the Republic of); [3]Seoul National University Soft Foundary Institute, Korea (the Republic of)*

In this study, we present an innovative anti-chiral auxetic structure designed for exceptional stretchability and unique auxetic properties. Our design integrates circular elements with spiral interconnections, resulting in superior stretchability and auxetic characteristics compared to conventional auxetic structures.
Through Finite Element (FE) simulations, we identified two key design features. First, our design allows for precise control of the Poisson's ratio through careful geometric adjustments. Second, the circular components maintain their alignment even when stretched, indicating the potential for distortion-free stretchable displays.
Building on these insights, we developed a conceptual stretchable auxetic display capable of adjusting its Poisson's ratio before and after stretching, thereby altering its aspect ratio as needed. To demonstrate practical applications, we fabricated a preliminary prototype of an auxetic display using 3D printing combined with mini LEDs. This prototype serves as a proof of concept, achieving remarkable stretchability while maintaining a Poisson's ratio of negative one, ensuring the LED display remains undistorted under stress.
In conclusion, our advanced anti-chiral auxetic design holds significant promise for a range of applications, including stretchable displays, wearable electronics, skin-affixed sensors, and adaptable devices.

PM02.10.29

Analytical Modeling of Materials Properties in Metal Additive Manufacturing *Wei Huang; Georgia Institute of Technology, United States*

The emerging technology of additive manufacturing (AM) offers a sustainable and eco-friendly approach to manufacturing, which contrasts with traditional methods and supports global decarbonization efforts. However, AM still faces numerous challenges due to its complex processes across different materials and applications. The main focus of this investigation is to examine how microstructural changes impact material properties such as elastic modulus and Poisson's ratio, affecting performance factors like residual stress and fractures. This involves studying the material's microstructure, including its surface textures, grain size, and any defects. In this study, simulations of texture and grain size for multi-phase materials are performed based on accurate modeling of the processing conditions. The research also characterizes how microstructural changes in metal additive *manufacturing affect material properties. Various models have been developed to predict manufacturing processes using physics-based frameworks, and experimental results have been used to validate these models. It has been observed that the computer-simulated effective elastic modulus, using the same experimental processing parameters, remains stable at around 109-117 GPa and is not significantly influenced by specific settings. Moreover, the simulated derivatives under the same settings are stable at around 850-900 MPa, which aligns closely with the experimental data. This research aims to bridge the gap between the micro- and macrostructures of AM and to transform the sector by providing a new perspective on science.*

PM02.10.30

Aluminum-Based Multiscale 3D Structures for Customizable Flexible Sensing

Lang Wang, Hangtong Li, Sergio Andres Galindo Torres and Liaoyong Wen; Westlake University, China

Over millions of years, biological systems have evolved optimized functions based on the beneficial size and material effects of their unit cells, which contribute to favourable mechanical and physical properties. For example, micro- and nanoscale two-tier structures play a crucial role in enabling lotus leaves to achieve both high apparent contact angles and low adhesion. Inspired by these natural systems, researchers have employed various trial-and-error reverse-engineering and computational methods to mimic these complex structures for a wide range of applications, such as light management, flexible sensing, wetting control, adhesion, and electrocatalysis. However, manufacturing man-made structures with controllable features across multiple length scales, particularly down to the nanoscale, remains a significant challenge, which can adversely affect their collective properties.

In this work, we introduce an aluminum-based 3D lithography (AL-3DLitho) technique that combines sequential nano-micro-macro-imprinting and anodization of multiscale anodic aluminum oxide templates to fabricate well-defined multiscale structures using various materials. The high-fidelity nano- and micropatterns are achieved through the surface work hardening phenomenon, with nanopatterns further refined by anodization to obtain high aspect ratios and tunable nanoholes. Using AL-3DLitho, we successfully fabricated multiscale materials across at least 10^7 length scales, including carbon, semiconductors, and metals. As a proof-of-concept, we developed homogeneous multiscale carbon network-based pressure sensors by integrating arrayed nanofibers, micropyramids, and macrodomes. These sensors demonstrate a low detection limit (0.09 Pa), a wide linearity range (0-150 kPa), and excellent stability (over 10^5 cycles). Furthermore, we integrated two multiscale carbon networks back-to-back to create “on-chip” pressure and biosensors with customizable performance, fully utilizing the strengths of multiscale carbon networks across different length scales. This work provides a versatile technique for prototyping on-demand multiscale structures and materials, enabling the exploration of desirable mechanical and physical properties.

PM02.10.31

Closed-Loop Two-Photon Lithography for Improved Precision and Repeatability

Qi Shao and Shih-Chi Chen; Chinese University of Hong Kong, Hong Kong

We present a closed-loop two-photon lithography (TPL) system based on optical diffraction tomography (ODT) and digital micromirror device (DMD)-based multi-focus ultrafast 3D scanning. Traditionally, micro- nanostructures fabricated by TPL can only be observed by scanning electron microscopy (SEM) and atomic force microscopy (AFM) with special sample treatments, such as metal coating. On the other hand, focus-ion beam is typically the option to investigate the internal structure quality of a printed structure, which is destructive. Overall, these complex and expensive approaches are post-fabrication observation methods and cannot provide immediate feedback during the printing process, leading to low reproducibility and loose dimensional accuracy when writing sub-diffraction limit features (i.e., < 400 nm).

To address these challenges, we have developed a closed-loop TPL system, where an ODT module is integrated with a parallel TPL system based on a DMD. A 1-kHz regenerative femtosecond laser amplifier is the TPL light source to provide sufficient power to command up to 2,000 individually programmable laser foci for parallel nanofabrication. The ODT module uses a DMD to scan a 532-nm metrology laser at 22.7 kHz via 10 – 50 different angles to construct 3D tomograms of the work volume at a rate of 400 – 1000 Hz. The tomogram gives a 3D refractive index (RI) map of the work volume. As RI is directly related to the laser doses, fast RI monitoring enables closed-loop TPL for the first time.

To characterize the closed-loop TPL system, we designed and fabricated different 3D micro-structures. The results, for the first time, show that in conventional TPL processes, polymerized structures can have an ± 0.01 RI variation due to varying laser doses; in other words, fine structures, e.g., nanowires or bridges, written by thresholding the laser energy will each have different RIs. Microlenses written by different scanning strategies (e.g., fine-scanning on the surface and fast exposure for the interior) will have non-uniform RI distribution. Based on closed-loop TPL, we show micro-structures can be printed with uniform RI distribution. In the experiments, we further demonstrated that closed-loop TPL presents improved dimensional accuracy, i.e., 200 nm ± 30 nm vs. 200 nm ± 100 nm (conventional open-loop TPL printing) and reproducibility.

In summary, we will present the design and characterization of a closed-loop TPL system based on ODT, which addresses the long-standing low reproducibility challenge of TPL, making it now suitable for industrial applications (i.e., high-resolution, high-speed, low-cost, and high yield). As the ODT technology rapidly monitors RI distribution, the impact can be extended beyond TPL; for example, UV stereolithography or label-free imaging.

PM02.10.32

Inkjet-Printed Nanocomposite Quasi-1D Gold PVA Hydrogels for the Catalytic Degradation of Phenolic Compounds

Nizzy James and Stephen Evans; University of Leeds, United Kingdom

In a recent study, Ye et al. introduced a novel wet-chemical synthesis method for producing freestanding, atomically thin (0.47 nm) gold nanosheets (AuNS).[1] The thickness was measured by AFM and morphology by TEM. These nanosheets showed tenfold greater catalytic efficiency in reducing 4-nitrophenol compared to colloidal gold nanoparticles. Along with enhanced catalytic ability, they demonstrated peroxidase-mimicking activity by oxidizing TMB and DAB. The synthesis route was changed to produce various gold nanostructures, including 1D nano-tapes (AuNT) and nano-pinecones (AuNPC).[2] Among 3D (AuNPC), 2D (AuNS), and 1D (AuNT) structures, AuNTs showed the highest catalytic efficiency.[3]

The concept of "green chemistry" within catalytic chemistry highlights the importance of conducting reactions under mild conditions, including in aqueous solutions, at atmospheric pressure, at room temperature, and with easy separation of products from catalysts.[4] Incorporating Au nanomaterials into PVA hydrogels preserves catalytic properties, making them effective heterogeneous catalysts. PVA hydrogels, known for versatility and easy processing, are ideal for enhancing performance, though common deposition methods lead to material waste and design limitations. [5]

This study uses inkjet printing (Dimatix materials printer - 2850) to deposit AuNT/AuNP-based PVA hydrogels to create thin gel structures.[6] Inkjet printing facilitates the creation of customised patterns, allowing for selecting a mesh structure which facilitates easy diffusion of reactants to the catalytic sites, optimising reactions within the porous hydrogel. Specifically, inkjet printing offered precise control over gel thickness, ensuring efficient diffusion and interaction with nanoparticles immobilised within the polymer matrix. Despite limited research on inkjet printing of PVA hydrogels, the resulting micrometer-thin hydrogel mesh shows potential for catalytic applications. Its thickness was measured using a Dektak surface profilometer. Furthermore, this study evaluated the potential *of AuNT- PVA meshes in degrading phenolic compounds such as 4-nitrophenol and phenol. Phenol and phenolic compounds are widespread pollutants in various industries, posing significant environmental and health risks due to their high toxicity and low biodegradability.*[7] *The newly developed AuNT shows promising catalytic activity compared to spherical gold nanoparticles and HRP enzymes. Additionally, the incorporation of AuNT into PVA gels improves catalyst reuse and recyclability, which was confirmed through experimental validation.*

Computational Modeling of Microstructure Formation During Laser Powder Bed Fusion of Bulk Thermoelectric Materials

Bengisu Sisik[1]*, Ryan Welch*[1]*, Theron Rodgers*[2] *and Saniya LeBlanc*[1]*;* [1]*The George Washington University, United States;* [2]*Sandia National Laboratories, United States*

Additive manufacturing has enabled the production of complex geometries with enhanced functionalities. The advancements in additive manufacturing, particularly in laser powder bed fusion (PBF-LB), underscore the need for computational simulation efforts to better understand grain formation in laser-processed thermoelectric (TE) materials. Accurately predicting the process-structure relationship is essential for extending the capabilities of PBF-LB in additively manufacturing multifunctional materials. PBF-LB works by scanning a laser upon powder layers, melting and fusing the material into hierarchically structured shapes. Processing parameters such as laser power, laser scan speed, laser spot size, hatch distance, scanning strategy as well as the setup parameters such as powder layer thickness influence the melt pool solidification behavior, which directly affects the resulting microstructure in bulk parts. This study focuses on two well-known thermoelectric materials: bismuth telluride, a low-temperature thermoelectric material, and silicon germanium, a high-temperature thermoelectric material. The microstructure formation of bulk bismuth telluride and silicon germanium parts are computationally predicted using the finite difference Monte Carlo (FDMC) method used in the Stochastic Parallel PARticle Kinetic Simulator (SPPARKS) code developed by Sandia National Laboratories. The model achieves experimental bulk dimensions on the millimeter scale. Simulations of uni-directional and bi-directional laser scan strategies, including the 90-degree rotation between layers, are compared to experimental results. This work represents the first computational study of grain structure formation in thermoelectric bulk parts produced via PBF-LB. The findings indicate that microstructure formation can be controlled by adjusting scan strategies, which influence grain orientation, and by modifying laser processing parameters such as laser scan speed and laser power, which affect grain size. This approach offers a pathway to optimize the process-microstructure-property relationship in additively manufactured multifunctional materials.

PM02.10.34

Towards Industrialization of Organic Photovoltaic Cells and Modules for Indoor Applications *Sadok B. Dkhil; Dracula Technologies, France*

The need of scalable fabrication of high-efficiency organic photovoltaic cells and modules has gradually emerged. In particular, indoor organic photovoltaics (IOPV) constitutes an attractive energy harvesting solution to power IoT devices, given its deployability, reliability, and power density. A substantial portion of the billions of new IoT devices that will be installed in the coming years are expected to be located inside buildings. Such devices like environmental sensors, can have several shapes and sizes, hence the need to develop custom-made conformable photovoltaic devices to facilitate their integration into the final product. In this context, inkjet printing has become a very attracted printing technology for large-scale printed flexible cells and modules with freedom of shapes and designs.

Herein we demonstrate the challenge to go from lab-scale to industrial scale to achieve highly efficient fully inkjet printed IOPV cells and module. To prove the great advantage of inkjet printing as a digital technology allowing freedom of forms and designs, particular OPV modules with different shapes are demonstrated and integrated into different IoT devices to operate autonomously without using batteries or connections to the grid to ensure sufficient flexibility in their placement.

PM02.10.35

Optimizing Process Parameters for 3D Nanomaterials Printing—A Machine Learning-Guided Approach *Anita Ghandehari, Jorge Alfonso Tavares Negrete, Jerome Rajendran, Xiaochang Pei, Shingirirai Chakoma and Rahim Esfandyarpour; University of California, Irvine, United States*

Pneumatic 3D-nanomaterial printing stands out as a significant additive manufacturing method, particularly effective for handling advanced materials. Among these advanced materials, MXene, a two-dimensional (2D) transition nanomaterial distinguished by its triboelectric, conductive, and flexibility properties, has successfully been used in extrusion-based 3D nanomaterial printing processes. MXene's highly reactive surface, similar to that of transition metal oxides and adorned with functional groups (F, O, OH) that act as bonding sites, positions it as a highly advantageous material for applications in nano-energy, flexible electronics, and wearable sensors. The printing of MXene through 3D nanomaterial methods necessitates maintaining uniform and high-quality outputs with exact control over the filament diameter, which is essential for creating precise, conductive, and flexible microscale sensors and circuits. Optimizing key process parameters like applied pressure, ink concentration, nozzle diameter, and printing speed remains a critical challenge to ensure uniformly high-quality prints with precise filament diameters. Conventional methods based on trial and error are not only time-intensive but also lead to considerable material wastage. In response, our research introduces a detailed pipeline that first verifies the ability of chosen parameters to produce consistent, high-quality MXene prints. Following this, we employ a Physics-Guided Artificial Neural Network (PGANN) to forecast the filament diameter, merging basic physical laws of the printing process with empirical data. Our results reveal that with an XGBoost classifier, we can determine the quality of printed filaments with 90.44% accuracy. Additionally, the PGANN model excels in predicting the filament diameter, demonstrated by a Pearson Correlation Coefficient (PCC) of 0.9488, and a Mean Absolute Error (MAE) of 0.00711 mm. This pipeline significantly streamlines the process for researchers, facilitating the selection of optimal printing parameters to consistently achieve high-quality prints and accurately produce the desired filament diameter tailored to specific applications.

3D Printing of Optofluidic Devices and Systems with Femtosecond Laser Qiying Chen; *Memorial University of Newfoundland, Canada*

Femtosecond laser micro-/nano-fabrication has been recognized as an enabling technology with unprecedented high precision and quality, which achieves the fabrication of various optoelectronic devices, including optofluidic devices for chemical and biomedical diagnostics with merits of versatile functionalities, compactness, high degree of integration, minimized waste, and low cost. Starting from the study on the fabrication of three-dimensional structures in dielectrics with the fundamental output of a femtosecond laser (wavelength at 800 nm, repetition rate of 1 kHz, and pulse energy up to 1 mJ), we report either a chemical etching-assisted femtosecond laser microfabrication technique or femtosecond laser induced multiphoton absorption technique to realize optofluidic devices. In this study, effects of fabrication parameters, such as laser energy, polarization of laser, and writing speed, have been investigated in order to identify optimal parameters for the realization of microstructures of different designs and specifications. Complex features, such as waveguides and ring-resonators, have been designed and achieved to implement different functionalities. Fluidic movement in the optofluidic devices of different configurations, such as laminar flow and diffusion, has been explored for particle sorting. The applications of the femtosecond laser printed optofluidic devices and systems in sensing different environmental parameters, such as temperature, refractive index, pressure, and concentration, will be discussed, together with the revelation of different sensing mechanisms and the possibility of multiparameter sensing.

PM02.10.37

Volumetric Additive Manufacturing of Composites Via Hydrogel Infusion Enze Su, Yiming Ji and Daryl W. Yee; *École Polytechnique Fédérale de Lausanne, Switzerland*

Volumetric additive manufacturing (VAM) is an emerging polymer additive manufacturing (AM) technique that offers significant advantages over traditional layer-by-layer AM methods. VAM boasts faster print speeds, improved surface finishes, and support-free fabrication of complex structures.

However, one of the current limitations of VAM is that it is only compatible with photoresins that are highly transparent. As such, the use of particle-filled photoresins for the VAM of polymer composites is currently impossible due to extensive particle-induced light scattering and absorption.

In this work, we demonstrate that the post-fabrication in-situ synthesis of nanoparticles can circumvent the transparency limitations in VAM and enable the fabrication of polymer composites. VAM-printed hydrogels are first infused with metals precursor solutions, followed by a precipitation step to form inorganic particles in-situ. By applying multiple post-processing steps, the hydrogel composite can be imbued with enhanced and/or multi-functional properties. We anticipate that our polymer composite fabrication approach can be extended to other AM methods that require high-transparency resins, and thus vastly expand the types of functional materials that can be made.

PM02.10.38

3D-Printed Epidermal Wearable Microfluidic Platforms for Accurate Spectroscopic and Fluorometric Sweat Analysis Da Som Yang[1,2] and John A. Rogers[2]; *[1]Chung-Ang University, Korea (the Republic of); [2]Northwestern University, United States*

Wearable technologies for sweat capture and biochemical analysis offer a non-invasive, real-time window into physiological health, enabling the continuous monitoring of hydration levels, electrolyte balance, metabolic function, and exposure to harmful environmental agents or illicit substances. These devices are particularly valuable for preventive health, fitness monitoring, and early-stage disease diagnostics. Despite recent advancements in skin-compatible, flexible microfluidic systems, current platforms face limitations in achieving *reliable, artifact-free measurements during on-body testing due to mechanical deformation and inaccuracies inherent to digital imaging in colorimetric assays.*

In this study, we introduce a novel 3D-printed microfluidic platform featuring integrated microscale optical cuvettes and valves, fabricated from hard/soft hybrid materials. This innovative system enables highly accurate and sensitive spectroscopic and fluorometric assays of sweat biomarkers, overcoming the limitations of conventional wearable sensors. By utilizing 3D printing techniques, we achieve precise control over microfluidic architectures, allowing for optimized fluid handling, enhanced mechanical stability, and improved analyte isolation. The hybrid material design combines rigid structural components for stability with soft, skin-compatible elements, ensuring both robustness and user comfort during continuous wear.

Comprehensive experimental evaluations demonstrate the platform's capability to accurately quantify concentrations of copper, chloride, and glucose in sweat, as well as monitor pH levels, with laboratory-grade precision under diverse physiological and environmental conditions. The system is designed to mitigate common sources of error in on-body sweat analysis, such as evaporation and contamination, thus ensuring high data fidelity in real-time monitoring scenarios. Furthermore, the platform offers dual functionality: in situ analysis for immediate feedback and compatibility with benchtop spectrometers for high-resolution data acquisition in laboratory settings.

This work also explores a range of polymeric materials for the fabrication of the platform's hard and soft components. Quantitative investigations of their optical, chemical, and mechanical properties, coupled with computational modeling, inform the design of microfluidic networks and cuvette geometries optimized for efficient fluid management and minimized cross-contamination. Field studies conducted in a variety of settings further validate the system's robustness and accuracy during physical activity, underscoring its potential for wide-ranging applications in health diagnostics, fitness monitoring, and environmental assessment.

The integration of 3D-printed microscale optical cuvettes within a hard/soft hybrid material system represents a significant advancement in wearable sweat sensing technology. This approach not only enhances the precision and sensitivity of biomarker detection but also addresses critical challenges associated with mechanical deformation and imaging artifacts in on-body measurements. As a result, this platform establishes a new standard for reliable, field-deployable biochemical sensing systems, with broad implications for clinical diagnostics and health monitoring in everyday life.

Intelligent Waveform Control for Optimizing the Jetting Behavior by Reinforcement Learning *Seongju Kim and Sungjune Jung; Pohang University of Science and Technology, Korea (the Republic of)*

Jetting behavior plays a critical role in the quality of inkjet printing patterning. The ideal jetting behavior is achieved by optimally designing the waveform to match the ink characteristics. Even after the optimal waveform has been *found, the jetting behavior must be optimally maintained during printing. This study proposes the strategy of not only optimal waveform design, but also adaptive waveform control to improve the jetting reliability through the machine learning technique. We built the jetting prediction model of the complex ink, which has the complicated viscoelastic properties, based on supervised learning. The jetting image data at different waveforms was collected from the drop watching system. The learning model predicts the drop velocity and jetting morphology from the rheological parameters and the waveform. The prediction model shows reasonable accuracy of the characteristics of the jetting behavior. Reinforcement learning was used to build the algorithm to design the optimal waveform that generates a single drop at 3 ms^{-1} using the prediction model. The trained agent successfully recommends the optimal waveform from a random initial waveform within 30 steps. We transfer the trained agent to the drop watching system for adaptive waveform control. The trained agent automatically manipulated the waveform to achieve the optimal jetting behavior, even though the jetting temperature is increased.*

8:45 AM PM02.11.02

Architected Materials Informatics for Designing Cellular-Structured Heat Sinks Fabricated by Additive Manufacturing *Asuka Suzuki, Hideto Nakatani, Soya Nakagawa, Makoto Kobashi and Yoshiyuki Tsuji; Nagoya University, Japan*

With the increasing integration of electronic devices, there is a need for higher-performance heat sinks to dissipate heat efficiently. Heat sinks usually have fin or pin shapes and enhance the heat transfer at the solid/fluid interface by expanding the surface area. The conventional manufacturing techniques for heat sinks including extrusion, forging, and machining have limited their manufacturable shapes. Recent developments in additive manufacturing (AM) have expanded the freedom of manufacturable shapes and enabled the fabrication of complex-shaped architected materials including lattice or cellular structures. The cellular structures have a larger surface area than fin or pin structures, and more efficient heat transfer will be expected. When heat sinks are used under forced convection, a fluid is supplied to heat sinks by using a fan or rotating heat sinks. The pressure loss needs to be suppressed to supply a fluid with a high velocity efficiently. It is known that high-heat transfer rate and low-pressure loss have a trade-off relationship under a constant fluid velocity because a large surface area increases the resistance of fluid flow. Therefore, it is necessary to develop a methodology for optimizing cellular-structured heat sinks with a good balance of high-heat transfer rate and low-pressure loss according to the high manufacturing freedom of AM processes.

Computational fluid dynamics (CFD) simulations are usually used for evaluating the heat transfer rate and pressure loss of cellular-structured heat sinks. However, the CFD has a high computational cost, and a huge amount of time will be required to repeat the simulations until the heat sink structure is optimized. To reduce the calculation cost, machine-learning surrogate models have been developed and inversely analyzed by optimization algorithms. However, to input structural information into a surrogate model, the structure needs to be converted into numerical data. Therefore, only the dimensions of cellular structures (size of basic structure, thickness of struts, space between adjacent basic structures) have been optimized while the basic structure has been fixed.

In this study, an attempt was made to optimize the basic structures by combining a machine-learning surrogate model and Voronoi tessellation. The Voronoi tessellation divides planes or spaces by arranging seed points and drawing perpendicular bisecting lines or planes between adjacent seed points. When the edges of the perpendicular bisecting planes drawn on the spaces are replaced by solid struts, various cellular structures can be designed by changing the number and coordinates of seed points. In addition, the Voronoi tessellation is compatible with machine learning because the number and coordinates of seed points (numerical data) are uniquely linked to the cellular structures.

800 cellular structures are designed by randomly changing the coordinates of 9 seed points and the thickness of solid struts. The heat transfer rate and pressure loss of the structures were evaluated by CFD simulations under forced convection with a fluid velocity of 1 m/s. The data set of the coordinates of seed points, the thickness of *solid struts, heat transfer rate, and pressure loss was trained to a neural network model. The neural network was inversely analyzed by a genetic algorithm (NSGA-II) to obtain a Pareto front of high-heat transfer rate and low-pressure loss. The properties of an optimized structure and a counterpart with a lower heat transfer rate and almost the same pressure loss compared to the optimized structure were evaluated by the CFD simulations and experiments using small-sized wind channel equipment. It was validated in the CFD simulations and experiments that the optimized structure exhibited a higher heat transfer rate and almost the same pressure loss compared to the counterpart. This study constructed a base of a novel methodology for designing cellular-structured heat sinks.*

9:00 AM PM02.11.03

Inverse Design of 3D Chiral Mechanical Metamaterials with Static and Dynamic Behaviors via Generative Models *Jeonghoon Park[1], Jaebum Noh[1], Jehyeon Shin[1], Grace Gu[2] and Junsuk Rho[1,1,1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]University of California, Berkeley, United States*

Recent advancements in 3D printing have facilitated the fabrication of complex 3D mechanical structures, including metamaterials with unique properties such as negative effective bulk modulus and band gaps. While chiral mechanical metamaterials have demonstrated complete band gaps to block elastic waves of all polarizations, previous research often overlooked structural stability. Designing stable metamaterials requires simultaneous consideration of both dynamic properties (e.g., bandgaps) and static properties (e.g., stress distribution), presenting challenges for traditional heuristic-based design approaches.

We propose a novel artificial intelligence-driven method for the inverse design of 3D chiral mechanical metamaterials with desired static and dynamic characteristics. Our approach utilizes a generative neural network pipeline comprising a conditional GAN, an encoder, and a regressor module. This framework allows for the simultaneous optimization of dynamic and static properties, resulting in mechanical metamaterial designs that enhance stability while preserving desired physical characteristics. The conditional GAN generates design parameters based on input band gap frequencies, while the encoder transforms these parameters into embeddings, facilitating easier training. The regressor module addresses the non-uniqueness issue in inverse design. Through numerical simulations, we confirm that the produced structures exhibit the intended bandgap frequencies and low stress distributions. Experiments on the structures fabricated through 3D printing excellently corroborate the numerical analysis results.

Our research demonstrates the potential of AI-driven inverse design in developing complex 3D chiral mechanical metamaterials with optimized static and dynamic properties, overcoming limitations of conventional design methods. This approach opens new possibilities for creating 3D-printed mechanical metamaterials with tailored properties for various applications in vibration control, acoustics, and structural engineering.

9:15 AM PM02.11.04

Inverse-Designed Architected Materials for Tailored Piezoelectric Response *Saurav Sharma, Satya K. Ammu, Prakash Thakolkaran, Jovana Jovanova, Kunal Masania and Siddhant Kumar; Delft University of Technology, Netherlands*

Mechanical metamaterials enable a variety of tailored physical characteristics such as negative Poisson's ratio, selective energy dissipation, non-reciprocity, shape morphing, and elastic waveguiding. Incorporating the concept of metamaterials with active materials leads to the development of smart metamaterials, which opens the possibility of having unique characteristics in multiphysics-coupled phenomena. Though mechanical metamaterials have been designed to achieve tuneable anisotropy of mechanical response through inverse design, there is an unexplored potential for metamaterial design and fabrication for tailored piezoelectricity. Here, we design novel piezoelectric truss metamaterials using machine learning to efficiently harness the full design space of tuneable electromechanical response. An electromechanically coupled computational framework based *on the finite element method and deep learning is developed to surrogate the effective elastic, electrical, and electromechanical response of a unit cell. Based on this computational framework, an inverse model is trained to efficiently and systematically reverse engineer the geometry and topology of the metamaterial unit cell with the tailored, effective piezoelectric response of the metamaterial. We explore auxetic piezoelectricity, negative piezoelectricity, and arbitrary ratios of shear and normal piezoelectric coefficients through the architectures designed with the inverse-design framework. As a proof of concept, lattices with exotic properties are additively manufactured, and their effective piezoelectric response is characterized.*

Superlative Mechanical Energy Absorbing Efficiency Discovered Through Self-Driving Lab-Human Partnership *Kelsey Snapp[1], Benjamin Verdier[1], Aldair E. Gongora[1], Samuel Silverman[1], Adedire Adesiji[1], Elise Morgan[1], Tim Lawton[2], Emily Whiting[1] and Keith A. Brown[1]; [1]Boston University, United States; [2]U.S. Army, United States*

Energy absorbing efficiency is a key determinant of a structure's ability to provide mechanical protection and is defined by the amount of energy that can be absorbed prior to stresses increasing to a level that damages the system to be protected. Here, we explore the energy absorbing efficiency of additively manufactured polymer structures by using a self-driving lab (SDL) to perform >25,000 physical experiments on generalized cylindrical shells. We use a human-SDL collaborative approach where experiments are selected from over trillions of candidates in an 11-dimensional parameter space using Bayesian optimization and then automatically performed while the human team monitors progress to periodically modify aspects of the system. The result of this human-SDL campaign is the discovery of a structure with a 75.2% energy absorbing efficiency and a library of experimental data that reveals transferable principles for designing tough structures.

10:30 AM PM02.11.06

Microstructure, Property and Process Optimization for Powder-Bed Fusion Additive Manufacturing Using Small Dataset Deep Learning *Xipeng Tan; National University of Singapore, Singapore*

The dataset size in machine learning may directly influence the model's accuracy, robustness, and ability to uncover nuanced patterns critical for enhancing efficiency and reducing costs. This work presents recent advancements in optimization of metal additive manufacturing, particularly powder-bed fusion 3D printing process, through the application of deep learning techniques with limited datasets. Focusing on microstructure, property, and process optimization, we address challenges in achieving full-spectrum yet precise control. By leveraging small dataset deep learning techniques, the research explores efficient strategies for predicting material behavior and optimizing 3D printing parameters by making use of titanium alloy and stainless steel as model materials. Key findings demonstrate significant improvements in understanding microstructural evolution and mechanical properties, enhancing the feasibility and scalability of additive manufacturing processes. This work underscores the potential of tailored deep learning approaches to revolutionize manufacturing paradigms, fostering innovation in materials science and engineering.

10:45 AM PM02.11.07

Irregular Networks Reinforced Composites—From Bioinspired Design to Mechanical Performance *Tommaso Magrini[1,2]; [1]Technische Universiteit Eindhoven, Netherlands; [2]California Institute of Technology, United States*

Composites with high strength and high fracture resistance are desirable for structural and protective *applications. Most composites, however, suffer from poor damage tolerance and are prone to unpredictable fractures. In my talk, I will report an approach to design architected polymer composites reinforced by a continuous irregular network generated through a virtual growth algorithm. [1] The algorithm stochastically assembles a selection of simple tiles relying on predefined adjacency rules that control independently the topology and the local geometry of the microstructure, achieving mechanical reinforcement across multiple length scales. [1] Using quasi-static and dynamic mechanical testing, I will highlight how the reinforcing architecture of the composites influences the strength, the stiffness, and the energy dissipated during fracture. Using 2D-Digital Image Correlation, I will showcase the local mechanisms that influence the initiation and the propagation of fractures in the composites. With these findings, I will finally demonstrate how the temporal and spatial propagation of fractures in architected composites can be designed and controlled a priori, combining different reinforcing networks into a spatially determined meso-scale assemblies. [1]*

A Unified Approach for the Finite Element Analysis of Auxetic Materials with Periodic and Multifaceted Symmetric Microstructures *Yunfa Zhang; National Research Council Canada, Canada*

Advanced computational material modeling tools enhanced with artificial intelligence algorithms and manufacturing approaches such as additive manufacturing have resulted in the successful development of many novel metamaterials such as materials with negative Poisson's ratio (auxetic) or negative coefficient of thermal expansion, which are very promising to be used in extreme environments such as high strain-rate impact and abrupt temperature changes. In the design analysis and optimization of metamaterials, computational homogenization approaches based on the finite element method are commonly employed to predict the macro effective thermoelastic properties using unit cells exhibiting periodic topologies and multifaceted symmetries depending on the microstructures. In the micromechanical analysis of the unit cells, appropriate periodic boundary conditions should be specified as multiple point constraints and symmetric conditions are exploited to reduce the size of the problem and computation time. However, in previous analyses of metamaterials with multifaceted symmetries, mostly a full unit cell or a quarter cell is employed which accounts for the reflection symmetry only. In this study, an approach for the finite element analysis of unit cells with multifaceted symmetries is proposed and illustrated. For a novel auxetic configuration, boundary conditions accounting for the mirror reflection, 0° rotation, 180° rotation, and skew symmetries are determined and the size of the unit cell is reduced up to 1/16th of the full size. Moreover, analysis approaches for both normal and shear loadings are illustrated and the results are validated by comparing with available numerical and test results. Finally, using the proposed approach, an analysis is conducted for a hybrid microstructure manifesting a negative coefficient of thermal expansion. It is demonstrated that a 1/8th model is suffice for the thermal stress analysis under temperature changes.

Buckling-Stretch-Buckling Dominated Hybrid Mechanical Metamaterials for Improving Mechanical Properties *Kashif Azhar and Aamer Nazir; King Fahd University of Petroleum and Minerals, Saudi Arabia*

Lattice structures have undergone significant changes due to the advancement of additive manufacturing, and more recently, hybrid lattice structures have provided opportunities for numerous future applications. The goal of this study is to introduce a novel method for conceptualizing and designing hybrid lattice structures that specifically addresses the issue of global buckling in lattice frameworks. The present methodology effectively *integrates the unique mechanical characteristics of lattice structures dominated by stretch and bending. Here, we partition the structures into three layers, positioning the bending dominant structures at the upper and lower ends, and the stretch dominant structures in the middle layer to mitigate the impact of global buckling at the center. The BCC, FCC, and Kelvin lattices are employed as uniform lattice structures, and the Octet, Iso-Truss, and Truncated Cube lattices as intermediate layers in hybrid laminate structures. The stereolithography process fabricates three homogeneous and hybrid lattice structures, using epoxy resin as material. The peak load, force-displacement response, compressive strength, and energy absorption of all lattice structures have been studied. It is observed that the hybrid structure combining FCC and Truncated Cube (HS-FTF) outperforms both uniform and hybrid lattice structures and exhibits superior peak load, compressive strength, and energy absorption properties. The hybrid structure combining Kelvin and Iso-truss structure (HS-KIK) exhibits superior performance in terms of load-bearing capacity when compared to its Kelvin uniform lattice topology. The hybrid structure of BCC and Truncated Cube (HS-BTB) exhibits superior energy absorption and compressive strength in comparison to the BCC uniform structure. All structures fall within the range recommended by the Gibson-Ashby model, and HS-FTF has surpassed the maximum compressive modulus limit.*

Plasma-Surface Interaction During Plasma-Enhanced ALD and ALE—From 2D Materials to Quantum Devices
Erwin Kessels; Eindhoven University of Technology, Netherlands

Atomic layer deposition (ALD) and atomic layer etching (ALE) have become critical techniques in the *semiconductor industry, providing the precision and control required for the fabrication of next-generation devices. As technology nodes continue to shrink, the demand for ultra-thin films and atomic-level etching processes has surged, making ALD and ALE indispensable for achieving the necessary material properties and dimensional accuracy. These methods offer unparalleled advantages in conformality, uniformity, atomic-scale precision, and selectivity, enabling the development of advanced semiconductor components. In many cases, plasma-enhanced processes are required to achieve the desired film properties and etching profiles, offering additional benefits such as improved reactivity and lower process temperatures. Consequently, the importance of plasma-enhanced ALD and ALE will grow significantly as the semiconductor industry continues to push the boundaries of miniaturization and performance in upcoming technology nodes. This evolution necessitates a deeper comprehension of plasma-surface interactions during these processes, a focus that has been central to our research for many years. In this presentation, we will highlight recent insights into the plasma-surface interaction during ALD and ALE, drawing examples from 2D materials processing and quantum technology applications. We will discuss fundamental aspects, such as the role of surface ion bombardment and surface radical recombination, based on advanced experimental studies.*

9:15 AM PM03.01.02

Bias-Pulsed Atomic Layer Etching for Rapid Material Processing *Julian Michaels[1], Nazar Delegan[2,3], Yeghishe Tsaturyan[3], Russ J. Renzas[4], James G. Eden[1], David Awschalom[3,2] and F. J. Heremans[2,3]; [1]University of Illinois at Urbana-Champaign, United States; [2]Argonne National Laboratory, United States; [3]The University of Chicago, United States; [4]University of Nevada, Reno, United States*

Atomic layer etching (ALE) is a binary cyclical process renowned for its precise removal of atomic monolayers, making it ideal for fabricating nanotechnological devices; However, its slow effective etch rate, often less than a monolayer per minute (tenths or hundredths of an angstrom per second), limits its widespread use to niche applications requiring unparalleled precision. If the process were faster, semiconductor, optical, and quantum devices could regularly employ ALE, benefiting from its ability to achieve consistent critical dimensions and smoother post-etch surfaces, thereby enhancing overall device performance.

The slow pace of ALE is primarily due to the time-consuming purge steps required to fully separate the chemical and physical phases of the cycle. Therefore, minimizing the duration of these purge steps is a logical strategy for speeding up the process. Bias-pulsed atomic layer etching (BP-ALE) addresses this challenge by using plasma etching in a simplified manner. Unlike traditional plasma ALE, which pulses multiple parameters such as gas flows, plasma DC bias, chamber pressure, and substrate temperature, BP-ALE achieves atomic precision by pulsing only the plasma DC bias. This method eliminates the need for gas purging, significantly reducing cycle time.

BP-ALE has been successfully demonstrated on materials like 4H-SiC and diamond, achieving cycle durations of just 6 seconds compared to the minute-long cycles of conventional ALE, while also producing subangstrom RMS surface roughness. This presentation will detail the execution and potential applications of BP-ALE, outline the material and chemical characteristics necessary for its implementation, and predict material/chemistry systems suitable for BP-ALE processing.

9:30 AM PM03.01.03

Remote Plasma-Generated Oxygen for Interstitial Atom Injection from a TiO_2 Surface *Nicholas Connolly, David Ruzic and Edmund Seebauer; University of Illinois at Urbana-Champaign, United States*

Using surfaces for rapid, controllable injection of interstitial atoms represents a new and versatile tool for tuning material properties after initial synthesis. Lowered chemical coordination at clean metal oxide surfaces facilitates the creation of interstitial atoms. An example is generation of oxygen interstitials (O_i) from adsorbed O atoms with *energy barriers near or below roughly 1 eV.[1] The atomic configurations for interstitial injection resemble those for site hopping in the bulk, with barriers only slightly higher. The modest hopping barriers of O_i in oxides, coupled with those for injection, make clean surfaces effective pathways for populating the nearby bulk with O_i near room temperature. Surfaces of several different oxides have proven capable of generating the requisite adsorbed O when submerged in liquid water,[1] with possible applications in defect engineering and isotopic purification[2] – both done post-synthesis near room temperature. For oxides, however, generating adsorbed O atoms directly from O_2 gas requires high temperatures. Generation from water requires removal of two H atoms, which can be rather slow even with electrochemical augmentation. However, generation of O atoms from a remote O_2 plasma should overcome these difficulties and avoid lattice damage from ions impacting the surface. Here we confirm this hypothesis using isotopic self-diffusion measurements of O in rutile TiO_2 single crystals exposed to a remote plasma containing $^{18}O_2$. Injected O_i fluxes exceed those from comparable electrochemical methods. Temperatures are not limited to 100°C as with liquid water methods, and injection is less susceptible to surface poisoning. However, to minimize solid-state trapping of O_i that limits diffusional penetration, we show it is important to suppress injection of interstitial H originating from stimulated desorption of H_2O from the chamber walls.*

Plasma Etched Omniphobic Hydrophobic Porous Membranes for Application in Pressure-Driven Distillation

Elizabeth A. Hjelvik, Kian Lopez, Hannah Cairney, Martin Nguyen, Samuel Marks, Michael F. Toney and Anthony Straub; University of Colorado Boulder, United States

There is an increased interest in implementing hydrophobic membranes in desalination technologies due to their potential for high chemical resistance and ability to reject nonvolatile contaminants. When hydrophobic membranes are submerged into a wastewater stream, an air liquid interface is formed and driving forces such as heat, pressure or concentration cause the water to evaporate at the interface and transport through the membranes as vapor water. This mechanism allows for full rejection of nonvolatile contaminants from the feed stream. However, hydrophobic membranes are susceptible to water penetrating through the airgap in the presence of low surface tension liquids leading to pore wetting and the eventual loss of the highly selective nature of these membranes. As a result, the ability to create membranes with reentrant structures on the surface, otherwise known as omniphobic membranes, has been increasingly sought out to address these unfavorable interactions. Current methods to create these surfaces are multistep and complicated procedures that would be difficult to scale up. Much research has been done to find simpler methods to create nanotextures, and plasma etching has recently been found to create uniform textures on polymer surfaces. In this work, we created an omniphobic polymer membrane by treating PTFE membranes with a brief low power oxygen plasma and found that not only does the plasma treatment create uniform nanotextures on the surface, but also enhances the hydrophobicity. We found that the treated membranes have enhanced wetting behavior in the presence of low surface tension liquids in addition to enhanced flux values in pressure driven distillation. We also probed the polymer texturing mechanism with x-ray photoelectron spectroscopy, scanning electron microscopy and x-ray diffraction to provide further insights on how plasma processes can be used to design hydrophobic membranes for use in desalination.

Challenges in Plasma Etching for Microelectronics Nanofabrication *Gottlieb S. Oehrlein; University of Maryland, United States*

Plasma-based etching methods along with photolithographic methods and thin film deposition have enabled the exponential progress in semiconductor technology referred to as Moore's Law. This has been possible because of a continuous evolution of plasma-based etching approaches that could meet the growing requirements of advanced microelectronics manufacturing. A review of the current challenges of plasma etching has recently been published,[1] and in this presentation we will focus on a subset of the topics reviewed there. We will discuss several examples of the recent evolution of challenges on plasma surface interaction control, including plasma etching of high aspect ratio (HAR) features required for 3D fabrication, and advances in cryogenic etching that has led to significant advances in this area. Atomic scale processing and ultra-high materials selectivity, including area selective deposition and etching, is another area that has seen significant development and will be discussed. One area that will play an increasing role in plasma etching development is the introduction of more sustainable practices enforced by legislative environmental regulations, e.g. the American Innovation and Manufacturing (AIM) Act of 2020 which directs a phase down of the production and use of hydrofluorocarbons which have been very important precursor gases for plasma etching of dielectric materials.

Metal-Ion Synchronized HiPIMS of AlN and AlScN for Piezoelectric Applications *Sebastian Siol; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland*

Ionized physical vapor deposition (PVD) techniques, such as High Power Impulse Magnetron Sputtering (HiPIMS), offer unique opportunities to control the microstructure of thin film materials by accelerating ions onto the growing film using substrate-bias potentials. At moderate acceleration potentials, the increase in ad-atom mobility often leads to improved crystalline quality and texture. This, in turn, enables the deposition of high-quality thin films at low deposition temperatures. However, gas-ion incorporation can limit the feasibility of such synthesis approaches for defect-sensitive materials. In recent years, HiPIMS processes with a synchronized pulsed substrate bias have been developed with the goal to selectively manipulate the kinetic energy and momentum transfer of the film-forming species, particularly the metal ions. These processes hold remarkable potential to significantly reduce the defect concentration and stress in HiPIMS-deposited films, potentially unlocking a host of new applications for the technique.

In this presentation, I will showcase our latest work on the development of reactive metal-ion synchronized HiPIMS processes for the growth of piezoelectric AlN and AlScN thin films. It will be shown how highly textured, c-axis oriented AlN and AlScN films can be grown using reactive metal-ion synchronized HiPIMS. Here, even unconventionally moderate substrate bias potentials of up to only -30 V already lead to significant improvements in the films' properties.[1] Most strikingly, the application of a substrate bias facilitates the deposition at oblique deposition angles and on structured substrates, while also significantly reducing the fraction of undesirable misoriented grains. A detailed characterization of the piezoelectric coefficients of the materials show values comparable to the current state-of-the-art. In addition, for AlScN in particular, the phase formation and stress state can be tailored by applying different biasing schemes and combinations of different sputter modes (i.e., HiPIMS or DCMS, or hybrid).[2] Importantly, it will be shown that the applicability of these types of processes can

be significantly extended, even on insulating substrate materials.
The goal of this presentation is to demonstrate the tremendous potential of synchronized HiPIMS processes for the deposition of defect-sensitive materials, especially in applications where tailoring microstructure and texture of the thin film materials is important.

HiPIMS Deposition of Protective Tungsten-Based Coatings on Metallic Substrates *Luigi Bana[1], Davide Vavassori[1], Marco Bugatti[1,2], Matteo Iafrati[2], David Dellasega[1,3] and Matteo Passoni[1,3]; [1]Politecnico di Milano, Italy; [2]ENEA, Italy; [3]CNR, Italy*

Plasma processing of thin films provides unique opportunities to tailor their properties and performances. In the context of Physical Vapor Deposition techniques, High Power Impulse Magnetron Sputtering (HiPIMS) is steadily growing in popularity. Relying on the working principles of magnetron sputtering, HiPIMS applies high voltage cathode pulses at a low duty cycle to enhance plasma density and the ionization of sputtered species [1]. The application of appropriate substrate bias voltages allows to energize the plasma ions and perform substrate treatments to increase coating adhesion. Additionally, the ability to engineer interfaces at the atomic level with HiPIMS contributes to enhanced mechanical properties and thermal stability of the coatings [2].
Thanks to the improved characteristics that can be achieved with HiPIMS, this technique finds one notable application in the production of protective layers for harsh conditions. In the field of innovative nuclear reactors, the proposed concepts rely on fluids with improved thermophysical properties such as liquid metals and molten salts [3,4]. However, compatiblity in these extreme environments remains a concern, particularly because nuclear conditions constrain the choice of materials. The identification of strategies to limit component degradation is therefore an active and multidisciplinary research area, with the deposition of protective coatings emerging as a promising approach.
The use of liquid tin (Sn) as plasma facing material in the context of nuclear fusion experiments is a significant example. [5]. Indeed, solid copper-based materials, chosen to comply with thermomechanical constraints, suffer from liquid tin corrosion under the prospected operating conditions [6]. Concerning the choice of coating material, tungsten and its alloys emerged as reference candidates thanks to their exceptional thermomechanical properties, compatibility with harsh environments and extensive characterization in nuclear fusion conditions [7].
Here we report on the HiPIMS production of tungsten-based coatings on copper substrates and the characterization of their properties and protective performances in the harsh liquid tin environment. Compact pure tungsten and multielemental layers were deposited by HiPIMS on fusion-relevant copper substrates. The morphological and structural properties were characterized by Scanning Electron Microscopy and X-Ray Diffraction, before and after exposure to liquid tin at fusion-relevant temperatures for ten hours.
Our findings indicate that HiPIMS-deposited tungsten-based coatings exhibit enhanced protective properties compared to those obtained by conventional methods. While tungsten confirms its inertness in liquid Sn, the protective layer performance depend on film morphology, structure, and intrinsic stress state. Multi-elemental depositions and plasma processing allows to tune these properties, highlighting the potential of HiPIMS in advancing the field of protective coatings for energy and nuclear fusion applications.

Plasma Etch in the Nanosheet FET Era and Beyond *Sonam Sherpa; Georgia Institute of Technology, United States*

Plasma etch is a critical technology for the fabrication of integrated circuits. As the transistor architecture has evolved from planar FET to finFET to nanosheet FET to complimentary FET, plasma etch has also continually evolved to meet the ever-tightening process specifications. In this talk, we will review the seminal innovations in plasma etch that will enable these technology inflections. The focus of this talk will be on pulsed plasma, atomic layer etch, and cryogenic etch that offer a pathway to escape the fundamental limits of thermodynamics and mass transfer during the plasma etch.

SESSION PM03.02: Plasmas for Functional Materials I

1:30 PM *PM03.02.01
Plasma Synthesis of 2D Materials and Their Applications to Next Generation Devices *Taesung Kim; Sungkyunkwan University, Korea (the Republic of)*

The discovery of graphene in 2004 rapidly evolves numerous fields related to layered two dimensional (2D) materials. Especially, transition metal dichalcogenides (TMDCs), one of 2D material group, have been taken significant attention owing to their unique characteristics, which enable to use various applications in electric devices, electrochemical catalysts, and sensing technology. However, the usage of 2D TMDCs still faces critical issues and problems such as high temperatures, poor controllability, and low product. In order to overcome the limitations, our research group is focusing on a plasma-enhanced chemical vapor deposition (PECVD) process to develop a simple and effective 2D materials synthesis. Since we successfully demonstrated that a wafer scale MoS_2 *thin film on a 4-inch* SiO_2 *substrate was synthesized using PECVD, the fabrication of homogeneous and heterogeneous 2D TMDCs was also accomplished at much lower temperature compared to other reports. Moreover, nano crystallinity in these 2D TMDCs contributes to peculiar electrical properties, allowing them to be utilized to next-generation device applications like negative differential resistance devices, non-volatile memristors, neuromorphic devices. The introduced PECVD-assisted fabrication method not only provides new insight for 2D materials synthesis and processing but pave a way for the realization of advanced electronic devices.*

2:00 PM PM03.02.02
Reinforcing Band-to-Band Tunneling via Temperature Dependent Phase Transition in WS_2 *Jinill Cho, Gunhoo Woo, Jinhyoung Lee, Chanho Park, Jeongryul Yoo, Jinsoo Yoon, Jongwoo Kwon and Taesung Kim; Sungkyunkwan*

University, Korea (the Republic of)

Negative differential resistance (NDR) phenomenon is non-linear relationship that the current suddenly drops at a specific voltage range, showing a N-shaped current-voltage curve. The unique electrical property has been taken significant attention because of the potential applications in multi-logic devices, non-volatile memory, oscillator systems. Layered 2D materials is suitable to easily construct broken band alignment that is required to drive NDR performance such as boron nitride and black phosphorus. However, their unstable structure and additional processes to prevent degradation are still big challenges for improving the electron tunneling performance and feasibility. To overcome these limitations, we fabricated multiple-phased tungsten disulfide (MP-WS_2) thin film consisting of distorted 1T (D-1T) and 2H phase via plasma-assisted chemical vapor deposition (PECVD). As numerous ions in the plasma made high density of crystal seeds on the metal thin film, concomitant tensile stress led to the generation of multi-phases. It was possible that the outstanding stability and electric properties of D-1T phase attributed to long term endurance and high tunnelling efficiency. Additionally, the ratio of D-1T phase to 2H phase could be controlled with synthesis temperatures during the plasma treatment, resulting in the modification of NDR intensity. Finally, such phase engineering process during PECVD provides new insight for enhancing the sophisticated functionality of NDR devices.

2:15 PM PM03.02.03

Advanced Nitrides and MXene-Like Coatings Applied as Sensing Units in an Impedimetric E-Tongue Setup

Leonardo M. Leidens[1], Carla D. Boeira[1], Endel E. Costa[1], Maria H. de Souza[1], Antonio R. Zanatta[2], Fernando Alvarez[1] and Antonio Riul Jr.[1]; [1]Universidade Estadual de Campinas, Brazil; [2]Universidade de São Paulo, Brazil

MXenes exhibit unique properties that may catalyze significant scientific and technological advancements [1,2] due to their uncommon characteristic among similar materials. The versatility of combining transition metals enlarges promising features; however, the traditional MXene synthesis relies on harsh chemical methods, particularly hydrofluoric acid (HF) etching, which constrains further application. Plasma processes may be an interesting tool to change this paradigm, allowing very precise control of properties and a wide range of possibilities to be explored, including materials' composition and system parameters. Based on that, our work aims to develop and validate a groundbreaking physical synthesis route for MXenes, eliminating the need for strong acids. This innovative method integrates multi-component targets with physical vapor deposition (PVD) and dynamic substrate angle control, providing enhanced control over thin film properties. Initial evaluations focus on CrN and TiN-based materials, with intentional surface terminations formed in situ to prevent undesired bonds and circumvent the traditional etching step. As we progress towards establishing a physical synthesis route for MXenes, we anticipate the emergence of intermediate materials, potentially free-standing nitrides and carbides. These MXene-like structures will be thoroughly characterized and explored to verify their properties and potential applications. As a proof of principle, preliminary results on using the developed materials to enhance impedimetric e-tongue sensing units will be presented. Achieving a physical synthesis route for MXenes has the potential to revolutionize the field, offering an environmentally friendly and versatile approach to material synthesis. This advancement could significantly enhance the applicability of MXenes in various domains, including sensing technologies, environmental monitoring, and beyond. Despite the promising outlook, numerous challenges remain, and continued research is essential to realize the full potential of this innovative green synthesis route.

Plasma-Engineered Plastics-Derived Nanographene-Based Single-Atom Catalysts *Chia-Hung Lin and Wei-Hung Chiang; National Taiwan University of Science and Technology, Taiwan*

Plastic waste is a prevalent material found in plastic bottles and optical discs, contributing significantly to annual production volumes and posing a pressing need for efficient recycling methods to safeguard the environment. The development of recycling method for plastic waste under ambient conditions is demanded. Single atom catalysts (SACs) represent a revolutionary advancement in the field of catalysis, offering unparalleled efficiency and selectivity in chemical reactions. Unlike traditional heterogeneous catalysts, which consist of clusters or nanoparticles, SACs feature isolated metal atoms dispersed on a support material. This unique atomic-scale architecture maximizes the utilization of active sites, leading to exceptional catalytic performance. SACs have garnered significant attention across various industries due to their potential to catalyze a wide range of reactions with high activity and selectivity, while also minimizing the use of precious metal resources. In recent years, SACs have emerged as promising candidates for addressing key challenges in energy conversion, environmental remediation, and chemical synthesis, positioning them as transformative catalysts for future sustainable technologies.

Here we report a novel recycling method whereby plastic waste is converted into graphene quantum dot (GQD)-based SACs using atmospheric-pressure microplasma under ambient conditions. The synthesized GQD-based SACs demonstrate remarkable catalytic activity, particularly in the rapid reduction of carcinogenic 4-nitrophenol (4-NP) to the essential pharmaceutical intermediate 4-aminophenol (4-AP). Furthermore, the fact that H2O2 is involved in the production of luminous materials implies that using a peroxidase might potentially speed up the reaction. Furthermore, these SACs exhibit nanozyme-like activities, enabling organic dye photodegradation. Notably, our catalysts display exceptional catalytic performance with a Km value of 0.01653 for peroxide-like (POD) activity applications, highlighting their versatility. This work provides an approach to recycling, transforming plastic waste into a useful nanocatalysts for carbon neutral society.

Plasma-Synthesized Few-Layer Graphene—From Fundamentals to Applications *Claudia-F. Lopez Camara; Eindhoven University of Technology, Netherlands*

Substrate- and catalyst-free gas-phase microwave-plasma synthesis of freestanding few-layer graphene (FLG) flakes leads to crumpled FLG structures. Yet, the mechanism that produces such structures, as well as the role of *some other synthesis parameters—e.g., C/O ratio and precursor—was unclear until recently. During this talk, an overview of the importance of these process parameters and the evolution of FLG morphology during synthesis will be presented. Moreover, a folding-based mechanism for FLG and a structure-formation process that explains the final crumpled structures obtained will be proposed. Lastly, some applications based on or enhanced by FLG will be discussed.*

3:45 PM PM03.03.02

Selective Optimized-Plasma Synthesis of Bio-Resource-Derived Nanographene and Nanodiamonds

Muhammad Hussnain Akmal, Neha Sharma, Darwin Kurniawan and Wei-Hung Chiang; National Taiwan University of Science and Technology, Taiwan

Carbon quantum materials such as graphene quantum dots and nanodiamonds have promising applications in bio-imaging, energy conversion, storage, optoelectronics, and nanocatalysis because of their unique properties, including tunable photoluminescence, quantum confinement, and biocompatibility. However, their precise nanoscale engineering is challenging due to inefficient synthesis methods and a limited understanding of their growth mechanisms. To overcome these obstacles, we have developed a DC atmospheric-pressure microplasma-assisted electrochemical method, enabling catalyst-free reactions through higher electron density at the plasma-liquid interface and allowing for precise tuning of graphene quantum dots' structures and optical properties. This method demonstrates that sustainable bio-resources can serve as carbon sources without requiring high temperatures or vacuum conditions. We have employed non-intrusive in-situ optical emission and absorbance spectroscopy as a diagnostic tool to understand the underlying growth mechanisms of these materials.
We have unveiled a significant correlation between the production, emission properties, and chemical phases of graphene quantum dots (GQDs) and the concentration of OH radicals in the plasma, which the discharge parameters can control. Notably, we have observed that higher OH radical concentrations enhance the dissociation of the precursor molecule, leading to an increased production of GQDs. Our studies using TEM and Raman techniques have yielded valuable insights into the composition of graphene quantum dots produced from fructose. We found a combination of graphene and diamond structures and observed that the sp^3-to-sp^2 ratio can be adjusted through plasma energy. By increasing the precursor concentration and discharge current and optimizing discharge parameters, we can enhance emission intensity, leading to faster growth rates and improved optical properties. It was also observed that plasma conditions can influence the carbon phases, with longer plasma treatment times causing a shift from sp^2 to sp^3. Furthermore, our research indicates that higher plasma currents enhance plasma emission, resulting in increased production of graphene quantum dots by generating more OH radicals. This research contributes to the advancement of plasma-assisted synthesis methods and provides a basis for the scalable and controlled manufacturing of high-quality CQMs. These insights are crucial for designing customized nanomaterials for integration into a wide range of advanced technological applications.

Synthesis of Nanomaterials—From Nanoparticles to Low-Dimensional Structures Using Thermal Plasma

Tae-Hee Kim, Seong-Pyo Kang, Han Jun Lee and Se Jin Oh; Wonkwang University, Korea (the Republic of)

Thermal plasma is an extremely high-temperature fluid exceeding 10,000K, consisting of electrons and heavy particles such as ions and neutral atoms. Approximately 5-10% of the plasma-forming gas molecules are ionized, producing highly reactive chemical species such as radicals. In addition, due to the steep temperature gradient from the core of the highest temperature region to the tail of the plasma jet, it provides a high-enthalpy medium with a quenching rate of 10^4-10^6 K/s. It allows to occur for thermodynamically non-equilibrium or high activation energy chemical reactions. These extreme conditions enable the synthesis of unique nanomaterials that cannot be produced in typical low-temperature or slow-reaction environments.

Among various nanomaterials, thermal plasma is particularly advantageous for synthesizing nitrides, borides, carbides, and their composites. Not only can they have unique chemical compositions, but they can also form unique structures, such as nanotubes(e.g. Carbon nanotubes and Boron nitride nanotubes) as low-dimensional nanomaterials and nanocomposites with dispersed cores that are completely different from traditional core-shell structures. Thermal plasma is generally categorized by power sources, DC(Direct current) and RF(Radio frequency). We primarily utilize thermal plasma with a DC power source to maximize the quenching rate and miniaturize the synthesis volume. This presentation aims to review the current state of nanomaterial synthesis and production using thermal plasma by sharing research results in synthesizing various nanomaterials. Additionally, it will suggest the limitations required to be overcome for further commercialization or improved TRL.

Producing Nanoparticles and Complex Interfaces for Energy Storage at an Industrial Scale by a Supersonic Dusty Cold Plasma Jet *Fabio Di Fonzo[1,2]; [1]X-Nano, Italy; [2]Istituto Italiano di Tecnologia, Italy*

The production of nanomaterials at an industrial scale is still a challenge. Even more so, it is for all those applications which require precise engineering of the nanoparticle assembly over multiple length scales, like energy storage and electrolysis.
Here we share with the plasma community our efforts to scale-up and industrialize the production of hierarchical mesoporous nanomaterials by a proprietary technique based on a supersonic dusty cold plasma jet technique name NanoJeD.
NanoJeD consists in two chambers separated by a high aspect ratio slit. A precursor gas is injected through a porous plug from the top and a vacuum system is connected from the bottom. The slit allows the establishment of a high-pressure ratio between the two chambers and hence the formation of a supersonic jet. The precursor gas, flows between two electrodes where a radio frequency (RF) signal is fed (13.56 MHz). The RF ignites a non-thermal plasma, operating in dusty-mode, in which the precursor molecules are ionized and dissociated into radicals, which polymerize forming clusters and nanoparticles (NPs) of different sizes. Thanks to the in-flight polymerization, in order to minimize the surface energy the formed nanoparticles are perfectly spherical in shape. Once formed, NPs are dragged through the slit by the gas stream and finally eject on the lower chamber. The abrupt pressure drop among the two chamber decrease the gas temperature, quenching the nanoparticles and fixing their shape. The control on the film properties/morphology is set by the aerodynamic filter: adjusting the substrate-slit distance is possible to cut from the deposition all the nanoparticles that does not have enough kinetic energy to decouple from the supersonic gas stream. Moreover, is possible to adjust the NPs impact energy and hence the coating density, passing from a thick dense coating to a hierarchical porous low-denisty coating.
We discuss the application of this technology for the production of electrodes for vanadium redox flow batteries (VRFB) and lithium ion batteries (LIB).
In the case of electrodes for VRFB, the precursor gas used is an argon-acetylene mixture, while the substrate is a carbon fiber mat in the form of paper or cloth. The NanoJeD source produces C nanoparticles, pure or doped, which are first impacted over the C-fibers of the substrate and then processed to be converted in a hierarchical mesoporous assembly of Carbon Nano-Onions (CNO) over carbon fibers. The precise control over this processes

allows the fabrication of high performance electrodes for VRFB which combine high surface area and high catalytic activity. A typical current density of 400 mAcm^{-2} with round trip energy efficiency of 81% and an electrolyte utilization of 70% is obtained. Stability tests showed a low degradation rate, losing less than a 0.004% energy efficiency per cycle in over 1000 cycles.
When compared to the typical current density of around 100 mA/cm^{2} obtained with ordinary carbon felt electrodes, it is evident the huge impact that these electrodes may have to slash the capital cost of the VRFB stack, dramatically increasing their competiveness for long duration energy storage. Switching the precursor gas in the nucleation chamber to a mixture of Argon and Silane, the non-thermal plasma leads to the formation of silicon nanoparticles (SiNPs). In this case, the SiNPs are collected in a copper current collector. Such a system allows the deposition of film thicknesses up to hundreds of microns, with a porosity of about 80%. By tuning the RF-plasma power in the nucleation chamber particles of different dimensions are obtained, as well as different crystalline percentages, ranging from completely amorphous materials up to nanocrystalline. Further processing transforms the Si NPs in an mesoporous silicon-dominant anode for Li-ion batteries characterized by a specific capacity above 1200 mAh g^{-1} (based on whole anode weight) and excellent stability over more than 300 cycles.

9:15 AM PM03.04.02
Plasma-Electrified Synthesis for Zero-Dimensional Semiconductor and Metal Nanostructures *Wei-Hung Chiang, Darwin Kurniawan and Ren-Jie Weng; National Taiwan University of Science and Technology, Taiwan*

Nanomaterials with tunable properties are the forefront of materials research owing to their significance in numerous application fields, including biomedical, optoelectronics, nanocatalysis and energy conversion and storage. However, achieving this in a catalyst-free, low-temperature, rapid, and environmentally friendly manner is challenging. Here we utilize non-equilibrium and low-temperature microplasmas to synthesize zero-dimensional (0D) structure-controlled semiconductor and metal quantum dots (QDs) at ambient conditions without any additional toxic chemicals, expensive catalysts, and sophisticated vacuum technologies. The reactive species generated by the plasma enable not only rapid disassembly of precursors into small moieties, but also simultaneous reconstruction of crystalline cluster domains and nucleation into QDs. Among various QDs, polyethylene terephthalate-derived GQDs (PET-GQDs) exhibit stable white emission under 365 nm UV irradiation with a Commission Internationale de l'Eclairage 1931 of (0.29, 0.35). The colloidal PET-GQDs can be applied for heavy metal ions detection with a low limit of detection of 8.4 nM, while the composite film state can be utilized as a sensitive temperature tag from 10 – 80 °C and a high-brightness white LED panel. This work provides new insights into the effective mechanisms for QD growth in a renewable electricity-driven, scalable, and environmentally sustainable way.

9:30 AM PM03.04.03
Gas-Phase Synthesis of Graphene Nanoflakes in a Microwave Plasma Reactor on the Pilot Plant Scale
Frederik Kunze[1], Martin Underberg[1], Ivan Radev[2], Edward Nürenberg[2], Tim Huelser[1] and Sophie M. Schnurre[1]; [1]Institut für Umwelt & Energie, Technik & Analytik e.V., Germany; [2]The Hydrogen and Fuel Cell Center ZBT GmbH, Germany

Research on graphene has increased significantly due to the exceptional electrical, mechanical and optical properties of this 2D material. These specific properties of graphene hold great potential in a wide range of applications. However, the successes achieved so far in practical applications have fallen short of expectations. One of the reasons for this is that the exceptional properties of high-quality graphene often cannot be successfully transferred to industrial applications. In addition, the synthesis process is a major challenge. A successful combination of high production rates of graphene with high quality (high purity, reduced number of layers, low concentration of defects and functional groups interrupting π electronic conjunction within the honeycomb

structure of graphene) of such a sophisticated material has not yet been achieved. To address this challenge, we performed gas-phase synthesis of graphene on a pilot plant scale.
A 50 kW pilot-scale microwave plasma reactor with a frequency of 915 MHz is employed to convert ethanol into few-layer graphene. Initially, ethanol is evaporated and continuously fed through an argon-hydrogen plasma generated by microwave radiation. The graphene powder is collected on filter membranes and ex-situ analyzed by electron microscopy as well as Raman spectroscopy. Furthermore, the electrical conductivity σ and the apparent density ρ of the graphene powders were investigated as a function of compression force in a specially designed powder conductivity test cell by a quasi-four electrode test principle.
The influence of the precursor feeding rate, applied microwave power and residence time in the plasma on the product properties is investigated. The highest specific conductivity is observed for graphene produced with an ethanol feeding rate of 200 g/h, microwave power of 2.85 kW and a long residence time (σ = 3.19 S/cm; ρ = 0.23 g/cm^3 at 100 N/cm^2). The conductivity of the synthesized graphene is 8.6 times higher than that of the commercial graphene platelets CP-0080-HP-0010 (IoLiTec Ionic Liquids Technologies GmbH, thickness 1-10ML; size 0.5-3 µm; 270 USD/g), which exhibits a specific conductivity of 0.37 S/cm and the corresponding apparent density of 0.12 g/cm^3 at 100 N/cm^2.
This work demonstrates that the synthesis of graphene, using ethanol as a precursor, has the potential to be scaled up into s continuous graphene synthesis process. The graphene could be employed in the production of functional materials, for instance as catalyst carriers in electrolyzers and fuel cells.

10:15 AM *PM03.04.04

Fabrication and Engineering of Janus Transition Metal Dichalcogenides as Novel 1D and 2D Materials

Toshiaki Kato; Tohoku University, Japan

Atomic layer materials composed of two-dimensional sheets with atomic thickness have been a significant research focus due to their unique shapes and excellent properties. We have conducted extensive research on the synthesis of carbon nanotubes [1,2] and graphene nanoribbons [3-8] with advanced plasma CVD. More recently, our research has expanded to include new atomic layer materials [9-17]. Transition metal dichalcogenides (TMDs), which are two-dimensional sheet structures where transition metals are sandwiched between chalcogen atoms, have recently garnered significant attention as two-dimensional materials with various functionalities such as semiconductors, metals, superconductors, and topological insulators. While conventional TMDs consist of chalcogen atoms of the same type on both the top and bottom layers, a new material called Janus TMDs has been discovered, in which the chalcogen atoms on the top layer are replaced with different chalcogen atoms. This unique material, possessing polarization in the out-of-plane direction despite being monolayered, has been the subject of extensive theoretical research. However, experimental studies have not progressed significantly due to the difficulty of synthesizing high-quality samples.
In response to this challenge, we have recently developed an in-situ observation apparatus that allows direct observation of the optical spectra of TMDs during the Janusization reaction. Our in-situ monitoring system allows us to measure Raman and photoluminescence spectra during the formation of Janus TMDs using a mild H_2 plasma reaction. By utilizing this in-situ monitoring system for Janus TMD formation, we have successfully created novel 1D Janus TMDs. When Janus formation was carried out using TMD nanotubes as the initial material, it was confirmed that the sulfur on the outermost surface was replaced with selenium while maintaining the tube structure, marking the first successful creation of Janus TMD nanotubes [15]. Additionally, it was discovered that after forming conventional 2D Janus TMDs, the introduction of a liquid followed by drying led to a transformation into a scroll structure due to inherent strain effects. Atomic structure analysis revealed that the Janus structure was maintained in each layer of the scroll, also marking the successful creation of a novel 1D material, the Janus

TMD nanoscroll [16]. Additionally, we have demonstrated that a unique moiré potential structure can be observed in the heterostructure composed of 2D Janus TMD and conventional TMD layers [17]. These 1D and 2D Janus TMDs are expected to exhibit various exotic physical properties in the future.

10:45 AM PM03.04.05

Rectification of Plasma Flow for Homogeneous Formation of Si Nanoparticles and Its Effect on Lithium-Ion Battery Performance

Makoto Kambara[1], Mizuki Yamanaka[1], Toshimi Tanaka[2], Masashi Dougakiuchi[3] and Kenichi Fukuda[3]; [1]Osaka University, Japan; [2]Takeuchi Electric Co. Ltd., Japan; [3]Shimane Institute for Industrial Technology, Japan

Next generation lithium-ion batteries (LiBs) are anticipated ideally to carry nearly 10 times higher electric capacity than the conventional LiB, by employing silicon as negative electrode active material replacing the graphite. Practically to make use the high potential of silicon, this material has to be processed smaller than 150nm and in a functional composite structure. This is because silicon changes its volume up to 400% during charge/discharge reaction cycles and tends to fracture in several cycles, casing a loss of electric and ionic conducting paths within the electrode and appreciable capacity decay in the end. From the engineering point view, these nanocomposite structures are to be produced at low cost and at high-process throughput to meet the ever-growing large LiB market demands. In this respect, plasma spray with which nanoparticles are produced from $2-3 powder feedstock and at a speed faster than 1kg/h is recognized as one potential candidate for the industrial method for the silicon electrode production. We have successfully produced silicon nanoparticles with various functionalities by plasma spray and demonstrated their high potentials for liquid-electrolyte LiB as well as for all-solid-state LiB. However, due to the presence of various distributions involved in the plasma spray process, the structural characteristics of nanoparticles have also a distribution which leads to unstable yield and battery performances. To tackle this issue, we have attempted to homogenize the condensation process for nanoparticle formation by rectifying the thermal history of high silicon vapor i.e. plasma gas [1]. In the present work, we have equipped the inline axial cyclone underneath the ICP plasma torch within the plasma spray reactor. This cyclone has no mobile turbine so that the plasma flow is rectified spontaneously with no additional energy by its design. The fluid dynamics simulation have indicated that the recirculation flow within the plasma reactor that is commonly observed without cyclone disappears. That is, the total plasma gas flow time from the ICP torch exit to the particle

collection filter is significantly shortened and the temperature of any gas streamline reduces monotonously, i.e. rapid and straightforward cooling. The estimated transport entropy of these streamlines suggests that the distribution of the gas thermal history is significantly reduced by an introduction of the cyclone. The nanoparticles so produced has also rather sharp particle size distribution and the resultant LiB cycle capacity is found to be improved appreciably.

11:00 AM PM03.04.06

Next-Generation Anode Materials from Plasma-Produced Nanoparticles *Lorenzo Mangolini; University of California, Riverside, United States*

Despite being heralded as the next high-capacity lithium-ion anode material, silicon remains barely utilized by the battery industry. This is mainly due to the poor stability of the material, which typically shows a high rate of capacity loss. Here we show that exceptionally stable lithium-ion anodes can be realized by utilizing plasma-produced silicon nanoparticles. Ultra-fine particles, with size below 20 nm, have been produced using silane as a precursor. Extensive material and battery characterization suggest that the improved capacity retention is largely due to the narrow particle size distribution, which is uniquely accessible by this class of plasma-based processes. When tested in a pouch cell using real-life components such as a NMC cathode, we observe 80% capacity retention after 400 charge-discharge cycles, well on track to meet the demanding requirements of the electric-vehicle industry. We also compare the performance of plasma-produced nanoparticles with commercially available silicon nanopowders, and find that the plasma-produced ones are largely superior in terms of cycle life. This presentation will also discuss a preliminary life-cycle analysis, further underscoring the potential of this technology to provide a cost-effective and sustainable next-generation anode material.

Plasma Interactions at Complex Interfaces—From Catalytic Reactions to In Situ Probing Nanomaterial Modifications *Peter Bruggeman; University of Minnesota, United States*

Non-equilibrium atmospheric pressure plasmas are increasingly used as an enabler of nanomaterial synthesis, functionalization and selective chemical reactions. Despite the growing success of these plasmas in these applications, the mechanistic understanding of these interactions is lagging mainly due to a lack of in situ diagnostic capabilities.

We will present an experimental approach that allows us to quantitatively characterize plasma-catalytic reactions. Key outcomes we will highlight are the dominant effect of transport limitations and the competitive nature between bulk gas phase and surface reactions. Furthermore, we highlight a newly developed diagnostic capability: operando environmental Transmission Electron Microscopy (TEM) in a plasma environment. As an example, we will report the ability to probe morphological changes of nanoparticles during plasma-nanoparticle interactions.

Improvement Long-Term Corrosion Resistance by Plasma Enhanced Chemical Vapor Deposition of Hexamethyldisilazane *Meng-Jiy Wang and Danang Tri Hartanto; National Taiwan University of Science and Technology, Taiwan*

Titanium (Ti) and stainless-steel (SS) are the commonly applied metallic biomaterials because of the excellent biocompatibility, mechanical strength, and durability. Ti was applied for joint replacements and dental implants with advantageous biocompatible and mechanical properties. On the other hand, SS, with its superior biomechanical properties, provides stiffness and ease to fabricate which is suitable for orthopedic and cardiovascular applications. However, long term corrosion of Ti and SS remains an issue for the applications in biomedical devices. The occurrence of corrosion results in not only the mismatch of mechanical properties but also the release of metallic ions which might cause allergic reactions or inflammatory responses.

Different methods were employed to modify Ti and SS to prevent corrosion including sol-gel dip coating, electrodeposition, and plasma enhance chemical vapor deposition (PECVD). To coat a sol-gel bioactive glass on 316L SS improves the corrosion resistance in simulated body fluid. In addition, to employ electrodeposition of chitosan on 316L SS reduced corrosion current density from 172.7 $\mu A/cm^2$ to 6.011 $\mu A/cm^2$ at a 0.6 mm thickness. The corrosion resistance can also be improved by depositing hydroxyapatite (HA) on Ti6Al4V using PECVD. Organosilicon compounds are extensively utilized in medical and biomaterial applications thank to the excellent biocompatibility.

In this study, plasma polymerization of hexamethyldisilazane (ppHMDSZ) was applied to modify Ti and SS to evaluate the long-term corrosion resistance via a set of accelerating experiments. The anti-corrosion performance of ppHMDSZ on Ti and SS substrates was investigated at different temperature to identify the reliability of the thermal accelerating aging phenomena. The validation of the results are confirmed by chemical composition, characterization of functionalities, electrochemical analyses, and cytocompatibility. The results showed that plasma polymerization to deposit ppHMDSZ on Ti and SS significantly reduced the corrosion current up to 80% with long term stability, providing great potential for surface modification on metallic biomaterials.

2:00 PM PM03.05.02

Controlling the Composition of $MeB_{2\pm\delta}$ (Me = Al, Ti, Cr, W) Thin Films Grown by DC Magnetron Sputtering and HiPIMS *Niklas Hellgren[1], Katherine Anthony[1], Wiliam Griffith[1], Mauricio Sortica[2], Teodor Hellgren[3] and Johanna Rosen[4]; [1]Messiah University, United States; [2]Uppsala University, Sweden; [3]Worcester Polytechnic Institute, United States; [4]Linköping University, Sweden*

Controlling film composition is essential for engineering the properties of thin films. One system that has proven particularly sensitive to deposition process parameters is titanium boride, TiB_x; films grown by direct current magnetron sputtering (DCMS) from a TiB_2 target are usually over-stoichiometric ($2.0 \leq x \leq 3.0$), due to different angular distribution of the Ti and B deposition flux. On the other hand, films grown by high power impulse magnetron sputtering (HiPIMS), tend to be under-stoichiometric ($1.4 \leq x \leq 2.0$), due to the much higher degree of ionization, especially of Ti, which leads more Ti^+ ions to be guided by the magnetic field toward the substrate, and hence reducing the B/Ti ratio. Other transition metal borides have been reported to show none, or only little, of this effect, for reasons not well understood.

In this work, we deposit four different metal-diborides; AlB_2, TiB_2, CrB_2 and WB_2, by DCMS and HiPIMS, and compare compositions, measured by RBS, ERDS and EDS, of samples mounted at 0°, 30° and 60° relative to the surface normal of the 3-inch-diameter targets. This allows us to study the effect of the distinctly different atomic masses, and ionization potentials, on the angular distribution of the deposition flux. All films are grown in an Ar

atmosphere at a pressure of 5 mTorr (0.67 Pa), with no substrate heating.
The resulting film boron-to-metal ratios vary between ~1.3 and 3.0, depending on deposition condition and sample position, with different trends for the different elements, in a seemingly inconsistent way. Thus, in order to understand the experimental results, the sputtering and re-sputtering effects due to energetic particle bombardment at the target and substrate, respectively, were simulated by the SRIM, TRIDYN and IMSIL software. The calculated angular and energy distributions of the sputtered species from the target were then used to estimate the trajectories of ions through the magnetic field from the magnetron due to the Lorentz force. Even though the effects of plasma interactions, gas rarefaction, and the "sputtering wind" cannot easily be simulated, this does give insight into how the ion flux distribution will differ from the neutral flux, which, in turn, can explain differences between films grown by DCMS vs. HiPIMS.
The combined experimental and simulated results provide us with an improved understanding of how the film composition depends on preferential emission angle, ionization potential, atomic mass, and gas phase transport of the different elements.

2:15 PM PM03.05.03

Forecasting Active Species in Radio Frequency Nitrogen Plasma with Quantum and Conventional Machine Learning Algorithms *Andrew S. Messecar[1], Clifford Aidoo-Mensah[1], Steven M. Durbin[2] and Robert A. Makin[1]; [1]Western Michigan University, United States; [2]University of Hawaii at Mānoa, United States*

Radio frequency (RF) nitrogen plasma sources are of great importance for the epitaxial synthesis of nitride materials. The energetics and relative concentrations of the various active species within the plasma have a significant impact on the quality and structure of the grown sample. Thus, controlling the populations of these active species is critical to refining nitride material growth processes and producing high quality samples in both manufacturing and research and development contexts. Furthermore, enhancing control over the relative concentrations of active nitrogen species that are found in RF plasma can lead to an improved understanding of the influence that the various species have on the growth and processing of thin film material samples and devices.

RF plasma source operating parameters are traditionally optimized through Edisonian trial–and–error. This iterative approach to process refinement can be expensive in terms of both material resources and the time spent developing and implementing experiments. Previous work towards a more informed selection of operating parameters for RF nitrogen plasmas has involved calculating the ratio of active molecular to active atomic nitrogen species under various combinations of operating parameters and interpolating between the recorded data points; this approach yields plotted processing spaces from which operating parameters can be selected, but it is limited by the range of operating parameters spanned by the data points. Machine learning algorithms present a useful strategy for recognizing complex patterns and generalizing beyond recorded data points to forecast novel, unobserved information. To date, machine learning technologies have been successfully implemented to predict both electron density and electron temperature in RF nitrogen plasma from optical emission spectroscopy data. In the present work, we use supervised machine learning models, including those which incorporate quantum computation, to study the relationships between RF nitrogen plasma operating parameters and optical emission spectra features that are of interest for thin film deposition applications, including the ratio of active molecular to active atomic nitrogen species.

For a RF plasma source operated within a molecular beam epitaxy chamber, we have acquired optical emission spectroscopy data and measured the relative concentrations of the active nitrogen species for nearly 2000 different combinations of RF plasma source operating parameters spanning large portions of the parameter space that have not been previously studied. Each data point includes the full set of operating parameters as well as the *resulting chamber pressure and the ratio of molecular to atomic active nitrogen species as measured from optical emission spectra. The relationships between these variables were first investigated by calculating matrices of both Pearson's correlation coefficients and p–values for all possible pairings of the variables within the data set. These analyses were corroborative in describing the RF nitrogen plasma processing space as one defined by coupled variables that are highly interdependent upon one another. The splitting rules of regression tree models fit to the data further corroborated this assessment. Quantum and classical supervised learning models, including tree–based algorithms, quantum support vector regressors, and artificial neural networks, were trained upon the data and compared for generalization performance. The trained and tuned algorithms exhibiting superior generalization performance metrics were used to predict features such as the ratio of molecular to atomic active nitrogen for combinations of RF plasma operating parameters not contained within the recorded training data. This mapping displays trends that agree with conventional wisdom established through prior studies while also describing areas of the RF nitrogen plasma processing space that have not been previously investigated.*

Boron-Doped Diamond and the Discovery of New Properties in an Old Material *R. Mohan Sankaran; University of Illinois at Urbana-Champaign, United States*

Doped semiconductors can possess metallic-like properties such as superconductivity and localized surface plasmon resonances. Among semiconductors, diamond stands apart because of its extraordinary mechanical, thermal, electronic, and optical properties. While diamond has been studied for many decades now, new properties continue to be unearthed because of the following: 1) synthetic challenges related to the thermodynamic equilibrium which can only be overcome under near ambient conditions by a handful of techniques including plasma-based chemical vapor deposition; 2) a limited number of impurity dopants that can produce electronic effects; and 3) the lack of measurement tools that can probe the relevant energy transitions.

In this talk, I will present our recent discovery of a yet another property in boron-doped diamond. Specifically, we report on intervalence band plasmons, defined as the collective electronic excitations between the valence subbands. To probe these low-energy (<0.5 eV) transitions, we applied two relatively advanced techniques, scanning transmission electron microscopy-valence electron energy loss spectroscopy and photoinduced force infrared spectroscopy. The measured loss and absorbance spectra, respectively, are found to exhibit an intense signal at an energy of ~0.15 eV for boron-doped diamond, which is completely absent in undoped diamond. We carried out first-principle calculations and were able to reproduce the measured spectra based on the contributions of intervalence band transitions to the dielectric function. The calculations are then used to reveal that the real part of the dielectric function contains a resonance and a zero-crossing that energetically increases with carrier density, which are characteristic of metal-like collective excitations of a plasmon. While plasmonic behavior in doped semiconductors is well-documented, it has typically been attributed to Drude excitation of free charge carriers (e.g., holes). Our study shows the possibility of other mechanisms for the measured plasmonic *response. In addition, the introduction of plasmonic properties in diamond may lead to applications that take advantage of its ability to host emissive and spin-active defects.*

4:00 PM PM03.06.02

Shape-Transformable Long-Lasting Superhydrophilic Carbon Cloth for Sustainable Solar Vapor Generation

Do Van Lam[1], Uyen Nhat Trieu Nguyen[2], Dao Thi Dung[2], Mikyung Lim[2], Jae-Hyun Kim[2] and Seung-Mo Lee[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Machinery & Materials, Korea (the Republic of)

Global water scarcity has spurred the quest for eco-friendly, cost-effective solar-based water desalination and purification methods. However, creating an efficient and durable solar evaporator still remains a formidable challenge. Here, we demonstrated that a rapid and straightforward air plasma activation process can transform a commercially available hydrophobic carbon cloth into a shape-transformable superhydrophilic solar evaporator enriched with nitrogen and oxygen dopants. The activated carbon cloth preserved the merits of the original material. It exhibited long-term wettability and salt-rejection properties which are critical for the realization of stable solar vapor generation. Notably, the resulting activated carbon cloth achieved a remarkable vapor evaporation rate of 1.78 kg/m^{2}h under one-sun irradiation, likely thanks to the abundance of surface intermediate waters that reduce the enthalpy required for evaporation. Furthermore, the constructed column-like solar evaporator with a 5-cm height exhibited an impressive evaporation rate of 3.82 kg/m^{2}h under one-sun irradiation.

4:15 PM *PM03.06.03

Deposition of Durable Antireflection, Anti-Fog and Anti-Soiling Coatings from a Rough-Vacuum Non-Thermal Plasma Source *Zachary Holman[1,2]; [1]Arizona State University, United States; [2]Swift Coat, United States*

A persistent challenge in forming functional thin films on glass and transparent plastics is the independent control of film refractive index and surface energy while maintaining durability suitable for high-touch and outdoor environments. This talk will introduce aerosol impact-driven assembly (AIDA), a rough-vacuum deposition process in which gaseous precusors are nucleated into particulate material in a non-thermal plasma, and that particulate material is subsequently accelerated through a slit-shaped nozzle towards a translated substrate, where it is deposited. By tuning deposition parameters, AIDA can yield coatings of metal oxides that have refractive indices and surface energies that are tunable over a wide range of values by adjusting porosity and surface roughness. And, below a porosity threshold, these coatings are robust against abrasion and chemical attack. This talk will demonstrate example coatings that have antireflection, anti-fog, and anti-soiling behavior, and highlight ongoing efforts to scale the AIDA deposition technology to multi-meter-wide substrates.

Plasma-Assisted Enhancement of Photoresponsivity in CdTe Thin Films for Photovoltaic Applications *Alaa Elwehishy, Mohammad F. Al-Kuhaili and Kion Norrman; King Fahd University of Petroleum and Minerals, Saudi*

Arabia

Photovoltaic (PV) technology presents the most effective answer to the challenges of energy shortages and the need for cleaner energy sources. Thin film semiconductors hold significant promise for the development of optoelectronic semiconductors and photovoltaic devices. Among the A^{II}-B^{VI} binary semiconducting compounds, CdTe stands out as one of the most promising PV materials, particularly for use in thin-film solar cells. It has achieved notable conversion efficiencies of over 22% and is regarded as the second-lowest-cost material after silicon in the photovoltaic market. post-deposition plasma treatment of the films has a significant effect on their properties. in plasma etching, a reactive gas such as O2, Ar, N2, SF6, CF4, C2H5OH, etc., or their mixture is used as an etchant gas. In this work, CdTe thin films were prepared by thermal evaporation and subsequently subjected to Ar plasma treatment for one hour with an argon flow rate of 20 sccm at different plasma powers 20,30, and 40-watt. The structural properties were investigated using XRD and it is clear that at higher plasma power there is an increase in the polycrystallinity also the texture along the (220) direction was improved upon increasing the plasma power to 50 watts. However, increasing the plasma power resulted in a reduction in the degree of orientation of the films along that direction. Moreover, the morphological properties were studied using AFM and it has been found that the roughness of the films increased slightly. The band gap was reduced by 0.01 eV and the films became more conductors as the resistivity decreased from 104 to 102. Then the I−V curves were obtained using longitudinal configuration by seeping the voltage from 0 to 10 V and measuring the corresponding current. All measurements were conducted in no-light conditions and with illumination provided by a 150-W xenon lamp. It was found that both the dark and photocurrent were increased Upon treatment by plasma at higher power.

PM03.07.02

Edge Plasma Control Through the Modification of Electrode Protective Materials in a DC Power Bias Environment *Chanho Park[1], Jeongryul Yoo[1], Jinsoo Yoon[1], Jongwoo Kwon[1], Jinill Cho[1], Gunhoo Woo[2], Jinhyoung Lee[1] and Taesung Kim[2,1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)*

As a pitch continues to shrink, dry etching process has become necessary to obtain high aspect ratio in semiconductor industry. However, it is still challenged to form a suitable plasma density and sheath at the edge due to lack of proper rings of a chuck. Rings at the edge of chuck play an important role of controlling a bias using DC power in RF system to make rectangular waveform. A quartz has been widely used as a ring, but it is too weak to protect the edge of plasma, resulting in low yield and unstable plasma. In this work, we achieved the uniform plasma by replacing the quartz with silicon and altering its shape based on an impedance ratio of 1.2. We monitored and evaluated variations in the impedance ratio according to changes in the ring's thickness and shape. Furthermore, concomitant plasma properties were confirmed through numerical simulation. As a result, the impedance ratio between the center and edge in the plasma varied from 1 to 1.4. It was also verified that ions in the plasma had the enhanced unidirectionality flux as a main factor to fabricate high aspect ratio. This research will contribute to extending the lifespan and improving the yield of semiconductor manufacturing processes in new bias power technology of Rectangular waveform.

PM03.07.03

Control of Carbon Layer Coating on Y_2O_3 Through Plasma Sources *Jeongyeol Yu[1,2], Chanho Park[1,2], Jongwoo Kwon[1,2], Jinsoo Yoon[1,2], Jinill Cho[1], Gunhoo Woo[1], Jinhyoung Lee[1] and Taesung Kim[1,1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of)*

In semiconductor industry, many components should be coated with Y_2O_3 to prevent them from undesirable plasma damages. However, with continuously development of chemical reactants, carbon polymers or *contaminant generated from the interaction of new gas plasma with Y_2O_3-coated components acts as particles or passivation elements, leading to various etching defects. Therefore, it is required to verify the interactions between the new source in a plasma and Y_2O_3. In this work, we modified the de-chuck gas conditions in a chamber equipped with newly coated Y_2O_3 components. By changing the source gas for plasma activation under de-chuck conditions, we measured the optical intensity and estimated etch rate. When the de-chuck process was conducted by switching from N_2 plasma to Ar plasma with the new Y_2O_3-coated components, CO-related EPD intensity increased 3 times and etch rate decreased. These results are attributed to the formation of the coating film caused by the interaction between C_xF_y gases and the coating material depending on the gas. This research will contribute to yield improvement in semiconductor manufacturing with the differences in coating material stabilization with the introduction of new gases.*

PM03.07.04

Enhancing Ohmic Contacts in β-Ga_2O_3 via N_2 Plasma Treatment

Junghun Kim[1], Dongryul Lee[2] and Jihyun Kim[3]; [1]Korea Electrotechnology Research Institute, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

β-Ga_2O_3 has emerged as a highly promising material for next-generation power semiconductors due to its exceptional properties such as high theoretical breakdown field and Baliga's figure-of-merit. However, the performance of β-Ga_2O_3-based devices, including SBDs and MOSFETs, is often hindered by the presence of high contact resistance between the Ga_2O_3 and metal contacts. This resistance limits device efficiency by increasing switching and conduction losses.

Conventional methods for reducing contact resistance include: 1) rapid thermal annealing (RTA) to enhance interface defects between metal and semiconductor, and 2) ion implantation to increase doping concentration beneath metal contacts. However, post-metallization annealing (400–500°C) may lead to interfacial degradation, potentially restricting the front-end-of-line process for Ga_2O_3. Moreover, ion implantation for doping can cause damage to the semiconductor lattice.

In this study, a novel annealing-free N_2 plasma treatment for achieving Ohmic contacts was demonstrated. This simple treatment successfully reduced the contact resistance to 13.1 kΩμm through a defect-compensating effect. X-ray photoelectron spectroscopy (XPS) was employed to verify the impact of N_2 plasma treatment on Ga_2O_3 bonds, while Raman spectroscopy assessed the crystalline quality of the plasma-treated region. β-Ga_2O_3 nanosheet FETs treated with N_2 plasma exhibited an impressive on/off ratio of $\sim 10^{10}$ and a field-effect mobility of 103.7 cm^2/Vs. To validate the air-stability of the N_2 plasma-treated devices, electrical measurements were conducted seven days after fabrication. This work presents a robust method to reduce contact resistance using a simple process, pushing the boundaries of β-Ga_2O_3 device performance.

This research was financially supported by the Korea Research Institute for Defense Technology Planning and Advancement (KRIT) grant funded by the Defense Acquisition Program Administration (DAPA) (KRIT-CT-22-046)

PM03.07.05

Surface Modification to Control Wettability of Paper Using Argon-Carbon Plasma Treatment

Hong Tak Kim and Sung-Youp Lee; Kyungpook National University, Korea (the Republic of)

Paper is an abundant, eco-friendly, and inexpensive material widely applied in fields such as printing, packaging, paper-based devices, and sensors. Paper has hydrophilic properties and can absorb large amounts of water because the bonds between cellulose molecules in the paper structure are primarily composed of hydrogen bonds involving hydroxyl groups. These hydroxyl groups of the cellulose structure cause the polarity of the paper *surface so that the paper is hydrophilic. It is complicated to make paper have water-resistant properties, but a process of controlling water-resistance properties is essential for applications in various fields.*

This study introduces a straightforward method to transform ordinary paper into water-resistant paper using argon-carbon (Ar-C) plasma generated by a direct current pulsed sputtering device equipped with parallelly arranged magnets. Argon gas was used as a sputtering gas, and the carbon element was supplied from the graphite target. Plasma was generated using a negative pulse power source with a square pulse and a frequency of 60 kHz. The plasma treatments were performed at powers of 80 W (plasma current: 300 mA), 135 W (500 mA), and 200 W (700 mA) with an exposure time of 20 seconds. All processes were conducted at room temperature.

Damage from energetic plasma ions bombarding the paper surface after plasma treatment was minimal. This result could be explained by the fact that the paper was exposed to plasma for a short time, and the pulsed power reduced damage. Analysis in the C 1s region revealed an inverse relationship between C-C and C-OH bonds, while C=O and O-C=O bonds showed little variation. The variation ratio of the C-C bond increased from approximately 5% to 11% with the increase in plasma current. These results meant that the Ar-C plasma removed the hydroxyl groups on the paper surface, and the C elements were substituted at the site of the removed hydroxyl groups. The replacement of C elements led to hydrophobic properties on the paper surface. Therefore, the degree of substitution of the hydroxyl group can be controlled using Ar-C plasma, which leads to the control of the paper's wettability degree.

The contact angle decreased gradually with time due to the water absorption of the paper. The reduction ratio of the contact angle was linear with time, decreasing from 0.945 to 0.182 (°/s) with plasma current increasing from 300 to 700 mA. The water droplet on the ordinary paper surface was absorbed immediately and spread widely. As the plasma current increased, the water droplet did not spread and was absorbed under the droplet. Notably, the contact angle of the paper plasma-treated at 700 mA remained unchanged for 20 seconds.

In conclusion, the water-resistant properties of the paper surface were successfully achieved and controlled through Ar-C plasma treatment. The wettability of the paper was controlled by adjusting the substitution ratio of hydroxyl groups with carbon components through Ar-C plasma treatment according to the plasma current. This substitution neutralized the polarity originating from hydroxyl groups on the paper surface, thereby imparting hydrophobic properties. Since Ar-C plasma-treated paper does not contain polymers or harmful substances, it can be easily recycled after use. The Ar-C plasma process is a simple, easy, and inexpensive method that can be applied to mass production. It is also an eco-friendly method that does not use harmful gases. In addition, this technique is effective for treating weak sheets, including paper and polymer sheets.

PM03.07.06

Surface Modification of Polydimethylsiloxane Flat Films by Plasma Metal Induced Patterning

Sudipta Mukherjee, Sumantra Mandal and Rahul Mitra; Indian Institute of Technology Kharagpur, India

Self-organized wrinkles are known to form when a metal thin film is deposited over a thin cross linked Poly-dimethyl-siloxane (PDMS) film. In this work we have performed chemical modification for surface modification of the PDMS thin films by exposing them to plasma with oxygen as the active gas, before deposition of the metal layer. We show that wrinkles of different wavelengths and amplitude can be obtained over plasma films exposed for different durations, while keeping the curing time (~120°C, 12 hours) and thickness of the bottom PDMS layer same. After deposition and as a consequence of the significantly different thermal expansion coefficient of the metal and the polymer plasma bilayer, compressive stress would be generated. When the latter gets relieved, surface undulation spontaneously takes place. The metal thickness was kept same between 50-60 nm. Variation in plasma exposure time (t_P) with oxygen lead to decrease in hydrophobicity and variation in wavelength and amplitude of the wrinkles in micron and nanoscale range. Secondary Ion mass spectrometry(SIMS) has provided information regarding the mechanism of oxidation of the PDMS surface while contact angle goniometry provided information for the surface energy. The results provide new insights in tailoring surface properties in many *applications in microfluidics, cell engineering, hydrophilic inks or direct stamping of proteins.*

PM03.07.07

Effects of Gate Dielectric Process on Electrical Characteristics of InGaZnO Vertical TFT *Sein Lee, Jeong-Min Park, Junseo Lee, Woochan Bae and Jang-Yeon Kwon; Yonsei University, Korea (the Republic of)*

The importance of backplane thin-film transistor (TFT) for ultrahigh-resolution (UHR) displays has grown with the recent advancements in augmented reality (AR) and virtual reality (VR) technology. To minimize screen effects caused by low resolution of displays, AR/VR panels with thousands of pixels per inch are required. As a result, there is an increasing need for TFTs with vertical channels rather than conventional planar structures to reduce the device footprint. [1]

All planar structures used in the current display industry require more area compared to vertical TFTs. In active-matrix organic light-emitting diode (AMOLED) displays, the self-aligned top gate (SATG) TFT is commonly employed as a planar backplane device structure due to its low parasitic capacitance and resistance to illumination degradation from the emitting layer. However, SATG TFTs face inherent limitations for device miniaturization because they require a significant metallization area to reduce contact resistance and have a scaling limit of the channel caused by carrier diffusion, which reduces the effective channel length.

In contrast, Vertical TFT (VTFT), while inherently possessing parasitic capacitance and being susceptible to degradation from backchannel effects, offer the advantage of scaling the channel dimension to below 1 μm by adjusting the thickness of the spacer layer and gate width. Additionally, since the source and drain electrodes are formed on different layers, it is easier to adjust the position of metal line, making it a structure suitable for increasing integration density. Therefore, VTFT are an appropriate structure for transistors in ultrahigh-resolution displays.

However, unlike the extensively studied planar TFTs, VTFTs have not been widely researched concerning the impact of gate dielectric processes, despite its significant sensitivity to backchannel effects. Therefore, we investigated the changes in VTFT characteristics with respect to the temperature and power of the PECVD SiO_2 dielectric process and optimized the process accordingly.

Novel Growth and Wafer-Scale Integration of Q-Carbon Thin Films *Naveen Narasimhachar Joshi, Pranay B. Kalakonda, Roger Narayan and Jagdish Narayan; North Carolina State University, United States*

We report the single-step, wafer-scale growth of highly uniform quenched-in carbon (Q-carbon) thin films of two different thicknesses (10 nm and 20 nm) via the plasma-enhanced chemical vapor deposition (PECVD) process. A mixture of 25 SCCM hydrogen and 2 SCCM methane were used as precursor gases for the formation of Q-carbon layers. Through this method, we show that the amorphous carbon layers can be effectively converted into Q-carbon by bombarding the surface with 250 eV Ar^+ ions via negative biasing. The surface topography, structure, *morphology, chemical composition, and bonding characteristics in the as-deposited thin films were thoroughly investigated by AFM, Raman, XPS, TEM-EDS, and EELS studies. High-resolution TEM imaging and AFM analysis reveal the formation of highly uniform Q-carbon thin films with negligible surface roughness. EELS, XPS, and Raman analysis consistently indicate higher sp^3 content (> 75%) in films, a characteristic feature of Q-carbon structures. Further, sp^3 content was shown to decrease with the increase in the thickness of the film as the conversion of amorphous carbon into Q-carbon is incomplete in films thicker than 10 nm. We propose a detailed mechanism to describe the formation of Q-carbon thin films via the low-energy ion bombardment in the PECVD process. The energy of these ions is just adequate to generate a Frenkel pair, that facilitates the conversion of three-fold coordinated sp^2 carbon units in the as-deposited carbon layer to five-hold sp^3-bonded tetrahedral carbon units in Q-carbon but does not induce damage to the formed structure. This enhances the sp^3 content and the atomic number density due to the random packing of tetrahedral units in the Q-carbon structure, providing easy nucleation sites for diamond growth. If the underlying substrate facilitates the epitaxial growth of diamond films via domain matching epitaxy, the wafer scale integration of Q-carbon opens up new avenues in the development of diamond-based novel devices and systems.*

PM03.07.09

A Soft Solution Route for Direct Patterning of Titanium Oxide Nanostructures onto The Silicon Substrate in Ambient Condition by In Situ Plasma Discharge Technique *Sumanta Sahoo[1,2], Kripasindhu Sardar[3,2], Satoru Kaneko[4,5,2], Kao-Shuo Chang[2], Akifumi Matsuda[5], Masahito Kurauchi[4] and Masahiro Yoshimura[2,4,5]; [1]Radhakrishna Institute of Technology and Engineering, India; [2]National Cheng Kung University, Taiwan; [3]Tohoku University, Japan; [4]KISTEC, Japan; [5]Tokyo Institute of Technology, Japan*

Patterning of functional oxides and various carbon are emergent subject of research. At present, these patterning process have been multi-step batch process: i.e., (1) thin film formation by PVD or CVD technique, (2) masking, (3) etching, and (4) post-heating. These multi-step processing in semiconductor fabrication technique is not environmental-friendly, as it require huge amount of energy, materials losses, rigid selective process, and more time. However, we have challenged "direct patterning in solution" as a one-step patterning of various advanced functional nanomaterials onto a semiconducting substrate
We have proposed in establishing a novel direct patterning of functional oxides by plasma discharge in solution onto a semiconducting substrate. Herein, titanium dioxide micropatterning has been established. An electrochemically etched tungsten tip has been used as probe electrode for the plasma discharge, and acts as a pattern forming tip. At an applied cathodic bias of ~1-2 kV, a localized activated plasma has been generated. Titanium species containing electrolyte complex has been used at ambient temperature and pressure. The micro-patterned titanium dioxides structures have been analysed by optical microscopy, scanning electron microscopy, and Raman spectroscopy.

Study of Plasma Treatment Effects on β-Gallium Oxide Metal Contacts *Sahyadri Patil and Mengbing Huang; University at Albany, State University of New York, United States*

Gallium Oxide (Ga_2O_3) has been considered a promising material for next-generation power electronics due to its ultra-wide bandgap of 4.6-4.9 eV. With its remarkable properties, including an 8 MV/cm high breakdown electric field, tremendous Baliga's figure of merit (BFOM), and excellent chemical and thermal stability, it is a potential material for high-power and high-frequency applications. Nevertheless, the formation of reliable and thermally stable ohmic contacts to this material is still a daunting task, derived from its peculiar material properties that result in difficulties in lowering the contact resistance and enhancing the thermal stability at metal/Ga2O3 interfaces.

Here, we study the effects of plasma processing of β-Ga_2O_3 surfaces on Ti/Ga_2O_3 interfacial properties with the aim of improving the ohmic contact performance. The surface of a commercially available β-Ga_2O_3 crystal substrate was plasma treated in varied conditions, and Ti thin films of nanometer thickness were e-beam deposited on samples both with and without the plasma treatments. These samples were characterized with x-ray photoelectron spectroscopy (XPS) to understand the metal-Ga_2O_3 interactions at the interface. The XPS features, such as the binding energy position and peak intensity of each chemical state component for three major elements, including Ga, O, and Ti, were found to be different between the samples with and without the plasma treatments. A detailed analysis of the XPS data suggests a Fermi level shift in the plasma-treated samples, possibly related to the plasma effects on carrier density and defect passivation at the Ti/Ga$_2$O3 interface. In addition, transmission line model (TLM) measurements were performed to determine the contact resistance to determine the plasma effects on metal-semiconductor barrier height. The electrical properties and thermal stability of Ti/Ga_2O_3 contacts are correlated with the structural information at the interface. These findings provide valuable insights to develop effective surface-engineering approaches for optimizing the electronic performance of β-Ga_2O_3-based devices

PM03.07.11

***Plasma-Assisted Deposition and Pattering of Chitosan/Silk Fibroin Interfaces** Artem Arkhangelskiy[1], Alberto Quaranta[1], Antonella Motta[1], Yuejiao Yang[1], Vamsi K. Yadavalli[2] and Devid Maniglio[1]; [1]Università di Trento, Italy; [2]Virginia Commonwealth University, United States*

Natural polymers are largely proposed as bioactive coatings but their application to surfaces are limited by several factors, such as limited control of the mechanical and chemical stability and weak adhesion to the underlying surface. [1]

Plasma processes provide unique features, such as surface activation, functionalization or assisted polymerization, all of which can be obtained using mild conditions. Plasma modification can enhance the adhesion via covalent bonding between the functional groups formed at the interface between the substrate and the coating. On the other side, commonly adopted cold plasma processes provide limited coating thickness and topography control. In this research, we present a new methodology to obtain spatially controlled deposition of natural biopolymers (silk fibroin and chitosan) using an atmospheric plasma torch fed by an aerosol aqueous solution containing the polymers to be deposited [2].

The resulting coatings were characterized by electron and atomic force microscopy and ATR-FTIR. The stability of the films was tested in phosphate-buffered saline (PBS) solution (pH 7.4) for 2 weeks at 37 °C, followed by treatment in sonication bath for 10 min. Adhesion strength was evaluated by a peeling test.

The presented plasma process provides unique features in a single step, such as surface activation, functionalization and assisted polymerization. Coatings can be obtained using low power (10 W) and at room temperature, resulting in excellent adhesion and stability on a large variety of materials, even with complex shape geometries. Soda-lime glass, a metal alloy (Ti4Al6V), a thermoplastic polymer (polyethylene terephthalate), a silicone rubber (poly-dimethylsiloxane) were demonstrated as substrates without the need for any surface pretreatment. The developed method was also successfully optimized for multi-layer deposition of fibroin-on-chitosan and chitosan-on-fibroin, with the aim of realizing patterned surfaces. The biological response of these patterned surfaces was then tested by protein adsorption and cell culture studies, underlining their capacity to guide cell adhesion and control cell proliferation.

This plasma method demonstrated, allows the achievement of spatially controlled deposition, even on complex-shaped substrates, together with the deposition of different biomaterials under mild conditions. This versatility can therefore represent a powerful method for obtaining instructive biosubstrates with optimized cell interactions, suitable for application in biomedical implants and bioelectronics devices.

The Application of Plasma Technology in the Heterogeneous Adhesion of CFRTP *Hunsu Lee[1], Unseok Jung[1,2], Jihyeon Lim[1,3] and Jaewoo Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]GIST, Korea (the Republic of)*

Carbon fiber-reinforced composites, such as carbon fiber-reinforced thermosetting polymer (CFRP) and carbon fiber-reinforced thermoplastic polymer (CFRTP), have been widely applied in various fields due to their excellent strength, light weight, and chemical resistance. CFRTPs, with their ability to melt under heat and be molded quickly, are gaining attention for their productivity and recyclability benefits.

The integration of dissimilar materials, specifically metal and fiber-reinforced polymer (FRP), has become an indispensable practice across diverse industries, spanning from aerospace and automotive to infrastructure and marine applications and beyond. Among the various methods (e.g., screws, welds, rivets, adhesive, etc.) employed to achieve this integration, adhesive bonding has emerged as a promising approach due to its ability to address concerns related to corrosion, bonding compatibility, and design flexibility.

In applications where CFRTPs are combined with metal components, their joining technology has become a key research topic. While mechanical fastening and thermal welding have been traditional methods for hetero-joining, adhesive bonding offers advantages such as simplicity in processing, no substrate damage, and suitability for complex-shaped surfaces.

Surface modification techniques such as mechanical, chemical, and plasma treatments play a crucial role in maximizing the interfacial stability of bonded joints. These treatments enhance adhesion between materials like aluminum (Al) and CFRP, improving lap shear strength and interlaminar shear strength. Plasma treatment, in particular, offers environmental benefits and is effective for complex irregular surfaces, making it favorable for industrial applications.

In this study, we investigate three plasma treatment methods for enhancing adhesion strength in carbon fiber reinforced thermoplastic (CFRTP) composites.

The first method employs inductively coupled plasma (ICP), a low-pressure plasma technique widely used in industry due to its high plasma density and temperature, which facilitates rapid and effective treatments. The vacuum-based apparatus allows for precise control of gas conditions and pressure, optimizing treatment outcomes. Our results indicate that ICP plasma treatment yielded the highest adhesion strength among reported studies for CFRTP composites.

The second method utilizes dielectric barrier discharge (DBD), an atmospheric pressure plasma technique. DBD enables large-area treatments without the need for vacuum conditions, minimizing electrical and thermal damage to the substrate. This approach eliminates the time-consuming vacuum process and removes size constraints associated with vacuum chambers, potentially reducing processing time and costs. While DBD treatment increased adhesion strength, it did not match the performance of ICP-treated joints. Consequently, additional wet treatment using silane coupling agents may be necessary to further enhance bond strength.

To address the limitations of both atmospheric pressure and vacuum plasma techniques, we propose a third method: a localized low-pressure plasma applicator system. By reducing the chamber size, vacuuming times can be decreased to less than one second and the size restrictions on treated parts could be eliminated. This novel *approach achieved adhesion strength close to that of the low-pressure plasma treatments while maintaining the benefits of atmospheric pressure plasma processing.*

PM03.07.13

Reactive Ion Etching of Silicon Dioxide Using Molybdenum as a Hard Mask *Habeeb Mousa, Saidjafarzoda Ilhom and Helena Silva; University of Connecticut, United States*

Various metals such as Aluminum (Al) and aluminum nitride (AlN) [1] have been used as hard masks for etching thick silicon oxide (SiO_2) layers. This study explores the efficacy of using Molybdenum (Mo) as a hard mask for Reactive Ion Etching (RIE) of SiO_2. Molybdenum offers the advantage of straightforward removal methods. In our experiments, a 30 nm thin film of Mo was employed as a hard mask to etch 300 nm of SiO_2 using a CHF_3 (60 sccm) and O_2 (3 sccm) gas mixture in an RIE system (30 mTorr and 100 W). The etch rate of SiO_2 was determined to be approximately 25 nm/min based on ellipsometry measurements. The etch rate of Molybdenum in the same process was estimated to be less than 0.5 nm/min based on electrical resistance measurements. SEM was used to analyze the surface morphology of the films after etching and revealed that the Mo thin film remains smooth and highly conductive after the etch, making it an attractive choice for microfabrication processes. Post-etching, the Mo layers were successfully removed either through wet etching with hydrogen peroxide (H_2O_2) or deionized (DI) water [2], or via a secondary RIE step using CF_4 and O_2 gases. Molybdenum can be used as a hard mask in CHF_3/O_2 RIE for applications requiring deep etching and clean removal processes.

PM03.07.14

Plasma-Induced Cryo-Oxidation of 4H-SiC *Gernot Fleckl; Technische Universität Wien, Austria*

Classical approaches for oxidation of silicon or silicon carbide are well investigated. Thermal oxidation is probably the best investigated oxidation process of semiconductor materials. The process is based on thermal diffusion and Fick's law. The resulting layer thickness can be well estimated by Deal-Grove model and Massoud model for the thin layer regime. Alternatively, the application of highly reactive oxygen ions can reduce the oxidation temperature. Especially for wide bandgap materials like 4H-SiC oxidation rates are rather low and demand high temperatures of 1000°C and above due to the materials strong bonds.

The aim of this work is to examine the boundaries of the reduction of the oxidation temperature during a plasma-driven oxidation process. The absence of external thermal energy during the experiment was driven to an extreme, limited by equipment conditions. The 4H-SiC substrate was cooled down to a temperature as low as -150°C. Consequently, the substrate was exposed to an oxygen plasma with an implantation dominated process character. Analytical investigations revealed the growth of an amorphous SiO_2-layer. But unlike originally expected, an unprecedented property of the fabricated SiO_2-layers occurred: the materials dielectric polarization characteristic strongly depends on its temperature. The effect is fully reversible after cooling down to room temperature with minor hysteresis effects. The materials new property appears to be related with a defect induction into the SiO_2-layer, caused by the novel, implantation dominated cryooxidation method. The materials behavior is highly functional with many possible applications but its most obvious in temperature sensing. The devices were calibrated by an allocation of extracted permittivities to temperatures in range between 300 K to 575 K. To gain information about the sensing accuracy, 30 randomly chosen temperatures within the calibration range

were approached and capacity-over-frequency spectra recorded. By an interpolation of the calibration curve, each from capacity-over frequency spectra extracted permittivity can be dedicated to a certain temperature. The strongly temperature-dependent effective dielectric properties are expected to be related to interface state defects placed deeply in the SiC's wide bandgap.
The method of cryo-oxidation is not limited to SiC but rather open to any oxidizable material. It is proofed that the strong Si-C bonds with a bond energy of 4.6 eV can be broken with a practical absence of thermal energy and related diffusion mechanism. Thus, the presented oxidation method is a highly promising process for multiple applications in semiconductor processing and material science in general. The process temperature has a strong impact on resulting dielectric properties and an adjustment of interface defect energies by this novel plasma fabrication technique.

The Digital Twin for Plasma Materials Processing for Microelectronics—Methods, Requirements and Progress *Mark J. Kushner; University of Michigan, United States*

Increasing microelectronics device performance is now relying on more complexity and new materials as limits are being reached in the ability to shrink devices. The transition to 3-dimensional devices (e.g., 3D-DRAM memory, GAA transistors) reflects the trend to improve performance by stacking devices as opposed to shrinking. The majority of manufacturing steps involve plasmas, which in turn creates challenges in developing new plasma processes to address this complexity that are sustainable and economic. An industry wide effort to address processing challenges is the digital twin – conceptually, a computational representation of the entire fabrication process, from delivery of blank wafers to packaging of completed devices. Digital twins for plasma processing would address equipment scale production of fluxes of reactive species (radical, ions, electrons, photons) delivered to the wafer and the nanoscale evolution of features in response to those fluxes; and so be tools used in process development. This is particularly relevant in the continuing effort of the industry to adopt sustainable processes. Digital twins would also track the state of the reactor predicting, for example, erosion of components or coatings on plasma facing surfaces, and recommending when preventative maintenance is necessary. In this talk, an overview of the digital twin for plasma processing will be provided, emphasizing process development and sustainability. The status of one aspect of the digital twin, computational models for plasma etching, will be discussed. The roles of fundamental physics-based modeling and those of surrogate models in the digital twin will be discussed.

Plasma-Activated Carbon Ore *Elijah Thimsen; Washington University in St. Louis, United States*

The United States is rich in carbon ore, also known as coal, but concerns about global warming have caused a decline of its use for electrical power generation. There is interest in finding alternative higher value uses for this natural research that do not require its combustion at a scale of hundreds of millions of tons per year. Innovations in material properties require innovations in material processing. In this talk, I will report our preliminary *experiments focused on understanding the material properties of coal exposed to nonequilibrium plasma, and compare that to coal that has been thermally processed under the same gas atmosphere. Preliminary experiments have revealed that processing the coal in a nonequilibrium nitrogen-hydrogen plasma produces a high specific surface area on the order 100 to 1000 m^2 per gram and this product is spontaneously combustible in an oxygen atmosphere, suggesting that the surface is highly active. Results from differential scanning calorimetry under an inert gas atmosphere will be presented to understand if the spontaneous combustion is related to an energetic metastable atomic configuration, for example on the surface, that is produced by plasma activation.*

Synergistic Thermal Activation and Plasma for Universal Low-Temperature Synthesis of Mesoporous Metal Oxides *Dongho Lee[1], Keon-Woo Kim[2], Hyunho Seok[3], Sihoon Son[3], Hongchul Moon[4], Taesung Kim[1,3] and Jinkon Kim[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of); [3]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); [4]University of Seoul, Korea (the Republic of)*

Mesoporous metal oxides (MMOs) with interconnected mesopores (2–50 nm) are critically important for applications in catalysis, energy storage, and sensing, owing to their substantial surface area and pore volume. This study introduces a novel and universal method for synthesizing MMOs through the co-assembly of block copolymers (BCPs) and metal oxide (MO) precursors, followed by their conversion to MMOs at reduced temperatures (150–200 °C) utilizing a synergistic thermal activation and oxygen plasma (TAP) process.

The BCPs serve dual roles as structure-directing agents for the self-assembly of sol-gel precursors into mesoscale architectures and as templates that sustain the resultant mesostructures. However, complete precursor condensation and BCP template removal typically require high temperatures (>350 °C), which are unsuitable for flexible substrates and can damage the mesoscale structure of certain MOs (e.g., V_2O_5 and MoO_3) with rapid crystallization kinetics. The TAP process circumvents these issues by enabling complete template removal and MO formation at significantly lower temperatures, thus making it compatible with flexible substrates. In this approach, BCPs function dually as structure-directing agents for the self-assembly of sol-gel precursors into mesoscale architectures and as templates that sustain the resultant mesostructures. However, complete precursor condensation and BCP template removal typically require high temperatures (>350 °C), which are unsuitable for flexible substrates and can damage the mesoscale structure of certain MOs (e.g., V_2O_5 and MoO_3) with rapid crystallization kinetics. The TAP process mitigates these issues by enabling complete template removal and MO formation at significantly lower temperatures, thereby making it compatible with flexible substrates.

Using vanadium pentoxide (V_2O_5) as a representative material, we successfully fabricated mesoporous V_2O_5 via the TAP process. This mesoporous V_2O_5, when utilized as an electrode material for a micro-supercapacitor (MSC), demonstrated superior electrochemical performance compared to V_2O_5 synthesized at higher temperatures (350 °C). This enhancement is attributed to its highly interconnected mesoporous structure, which provides a substantial surface area. Additionally, we achieved the direct synthesis of mesoporous V_2O_5 on indium-tin oxide (ITO) coated colorless polyimide (CPI) film, resulting in a flexible MSC that retained its energy storage performance under rigorous bending conditions (bending radius down to 1.5 cm and up to 3000 cycles). Remarkably, the TAP method was also successfully applied to synthesize a diverse array of MMOs, including V_6O_{13}, TiO_2, Nb_2O_5, WO_3, and MoO_3, at reduced temperatures. This underscores the versatility and potential of this approach for flexible device applications. This universal low-temperature synthesis technique represents a significant advancement in MMO synthesis, facilitating their direct application on flexible substrates and paving the way for the development of high-performance, flexible energy storage devices.

In-Flight Reduction of Iron Ore Particles in an Atmospheric Pressure Hydrogen Microwave Plasma *Sachin Kumar, Zichang Xiong, Julian Held, Peter Bruggeman and Uwe R. Kortshagen; University of Minnesota, United States*

CO_2 emission from the steel industry, which accounts for ~7-9% of the global anthropogenic CO2 emissions, is a key challenge for achieving a carbon-neutral future. To overcome this challenge, the steel industry must reduce its dependence on blast furnaces for iron ore reduction, i.e., the conversion of iron oxide to iron, and adopt new technologies that drastically lower carbon emissions. This contribution presents a plasma process for reducing iron ore particles with an atmospheric pressure hydrogen plasma. The plasma is maintained by coupling microwave power of 1.5 kW into an argon-hydrogen gas mixture. The iron ore particles with a size of about 50 µm are aerosolized and passed through the active plasma zone. After the treatment, the collected particles are observed to follow three distinct populations: i) unreduced particles with the shape and size of the original feedstock, ii) partially (15%) reduced spheres, larger than the feedstock, and iii) fully reduced nanoparticles. It is found that the nanoparticles are likely formed from previously evaporated material, and the reduction happens either on the surface of the particles before evaporation or in the gas phase after evaporation. The plasma temperature is estimated to be more than 2000 K, which enables the rapid evaporation and reduction of these particles within residence times of only a few 10 milliseconds. The technology has the potential to become a zero-carbon process. It overcomes some major problems encountered in competing technologies, such as the need for pelletizing, vacuum operation, and the lifetime of electrodes/plasma torches.

This work was supported by the University of Minnesota under the Ronald L. and Janet A. Christenson Chair in Renewable Energy and by the Minnesota Environment and Natural Resources Trust Fund under project 2023-171.

On the Determination of Energy and Particle Fluxes Towards Surfaces in Plasma Processing by "Non-Conventional" Probes *Holger Kersten, D. Zuhayra, P. Kropidlowski, T. Trottenberg and Viktor Schneider; Kiel University, Germany*

The diagnostics of electrons and ions in plasmas and the fluxes of charged and neutral species toward plasma-facing surfaces along with their energy and momentum transfer will be discussed. The focus is laid on the

fundamentals of "non-conventional" calorimetric (CP) and force probes (FP) [1] as well as their combination with common Langmuir probes (LP) and retarding field analyzers (RFA) for application to non-equilibrium plasmas and ion beams. These rather simple methods are useful tools for the measurement of overall, not species resolved, ions and neutral species and energy fluxes toward surfaces. Although the diagnostics have their roots in the beginnings of plasma research, they were gradually refined to match the requirements of plasma environments in industry, such as rf-discharges, reactive plasmas, dusty plasmas, and atmospheric pressure plasmas.

Of particular interest is the combination of different types of probes, e.g. retarding field analyzer (RFA) and passive thermal probe (PTP) [2]. The PTP serves as collector, in front of which three centrally aligned grids are operated as the retarding field system. In this setup the collector does not only measure the incoming ion current depending on the voltage applied to the grids of the RFA, but also the incoming energy flux density of the impinging ions or neutrals, respectively. The ion energy distribution (IED) is determined regarding the energy exchange of the neutral background gas with the ions extracted from the plasma source (charge exchange collisions) and the measured energy influx can even deliver information about fast neutrals and chemical reactions, recombination and secondary electrons.

The current trend in the miniaturization of sensors, adopted from the manufacturing of MEMS, will allow measurements with high spatial resolution in miniaturized plasma sources, like plasma jets or micro discharges [3], respectively.

Enhancing Osseointegration of Ti Grade 23 Alloy Using Dielectric Barrier Discharge Plasma Jet *Shayan Bayki, Komal A. Joshi, Jayesh Bellare and Soham Mujumdar; Indian Institute of Technology Bombay, India*

Several techniques are employed to improve the biocompatibility of implants and facilitate integration with surrounding bone tissue, thereby enhancing the success rates of implant surgeries. Although plasma treatment is notable for its ability to remove contamination and increase wettability, traditional plasma treatments often operate at low pressure, necessitating a treatment chamber and high working power. Atmospheric pressure dielectric barrier discharge (DBD) cold plasma has shown promise, particularly the DBD plasma jet, as it requires lower operational power, has a cost-effective setup, short processing times, and can function at atmospheric pressure. Furthermore, the DBD plasma jet setup facilitates the straightforward treatment of complex geometries, making it particularly suitable for implants. This research explores the application of a DBD plasma jet for surface treatment to improve the osseointegration of Titanium (Ti) Grade 23 in biomedical implants. The effects of plasma treatment are evaluated through a parametric study focusing on treatment time. The enhanced surface wettability of the plasma-treated Ti substrate is demonstrated by a decrease in the contact angle with simulated body fluid, attributed to alterations in surface chemistry. The size of the treated area is determined using a fog test. In vitro osseointegration experiments are being carried out with human osteoblast-like SaOS2 cells. The enhanced wettability of the Ti substrate achieved through plasma treatment is expected to improve the adhesion of Ti implants and promote osseointegration, which warrants further investigation through in-vivo studies

Advancing Understanding of New Materials Produced by Atmospheric Plasma Synthesis and Processing of Commercial Products Through Materials Characterization *Chi-Chin Wu[1], Scott D. Walck[2,1] and Lily Giri[2,1]; [1]U.S. Army Research Laboratory, United States; [2]Survice Engineering, United States*

By adding energy to matter, plasmas enable chemical reactions and interactions that are otherwise impossible or difficult to achieve with conventional techniques. Since 2017, the US Army Combat Capabilities Development Command Army Research Laboratory (DEVCOM ARL) has started to exploit the feasibility of advancing the frontier of novel materials through atmospheric pressure plasma synthesis and processing. Different materials, including organic deposits, nanodiamonds, and aluminum nanopowders have been fabricated or processed from commercial products by different prototype ARL dielectric barrier discharge reactors built in-house with different experimental conditions and commercial starting materials. This paper describes ARL's expertise in characterizing the effects of plasma synthesis and processing at the bulk and nanoscale levels by means of X-ray diffraction (XRD), Fourier-transform Infrared spectroscopy (FTIR), X-ray photoelectron spectroscopy (XPS), and transmission electron microscopy (TEM). As examples, we will show the unique nanoscale morphology and chemical compositions of the outermost surface for commercial core-shell nanoparticles (aluminum and diamond) in different TEM modes and how they correlate well with measurements from other techniques (XRD, XPS and FTIR). The goal is to advance understanding the complex plasma-induced mechanisms through interpreting the experimentally determined morphology and chemical composition at different length scales. This work also demonstrates DEVCOM ARL's ambition in pursuing new plasma synthesis and processing capabilities through continuous development of feasible methodologies as possible pathways to future new materials.

SESSION PM03.10: Plasmas for Functional Materials III

Advanced Characterization of Deposition Plasmas via Laser Scattering *Sedina Tsikata[1], Thibault Dubois[2], Tiberiu Minea[3] and Adrien Revel[3]; [1]Georgia Institute of Technology, United States; [2]ThrustMe, France; [3]Université Paris-Saclay, France*

Deposition plasmas, such as those created using planar magnetrons, exhibit many intriguing features, such as various types of instabilities and forms of self-organization. The connection between such features and deposition outcomes (such as the characteristics of thin films generated) remains unclear. Understanding the features of such plasmas has been hindered by certain key factors: the lack of mature simulations capable of fully describing a multiscale, three-dimensional, dense, and transient plasma and its dynamics, and inadequate diagnostics capabilities. In this talk, progress in the area of non-invasive diagnostics for such environments is discussed. Thomson scattering, in both coherent and incoherent regimes, has been applied to study highly-dynamic electron properties and drifts, and to identify electron density fluctuations associated with different instabilities. These results provide new insights into the phenomena underpinning the operation of crossed-field deposition devices and guidance for future simulation efforts.

2:00 PM PM03.10.02
De-Poisoning Catalysts for Sustainable Chemical Processing *Taylor G. Smith[1], Daniel R. Morphet[2], Zhifei Yan[2],*

Dongtao Cui[2], Kate Guerin[2], Ebubechi Nwaubani[2], Daniel G. Nocera[2] and Jane P. Chang[2,3,1]; [1]University of California, Los Angeles, United States; [2]Harvard University, United States; [3]Harvard Radcliffe Institute, United States

Metal catalyst enabled chemical processing produces the majority of products that we use in everyday life, from food, textiles, biodegradable plastics, pharmaceuticals, to environmentally safer fuels. Catalyst poisoning not only reduces the efficiency of these catalysts but also increases the demand for them. De-poisoning catalysts can not only improve the efficiency and sustainability of chemical processing but also address the lesser known yet serious fact that many catalysts are sourced from minerals mined in countries struggling with political instability, where the extraction of minerals is linked to environmental damage, violence, and human rights abuses.

Atomic layer etching (ALE) was developed in recent years to enable precision in patterning for integrating novel metal and metal alloys in nano-electronics, nano-photonics, spintronics, and sensors. Interestingly, many of the materials requiring nano-scale patterning have been used as catalysts. While a chemical reaction leading to the formation of a strongly chemisorbed species is considered poisoning in catalysis, it is a necessary step in initiating atomic layer etching of metals. The feasibility of utilizing ALE to reactivate catalysts relies on selective surface chemical reactions to remove just the poisoned layer. This presentation will focus on the intersection of two interdisciplinary research areas for nano-electronics and catalysis, leveraging what was achieved in ALE of metals to help de-poison/regenerate the catalysts. The specific example focuses on using Cu as a catalyst for CO_2 reduction, where sulfur and carbon (coking) poisoning through the use of model compounds served to deactivate the catalyst. Different plasma chemistries (e.g., Ar, O_2, N_2) are evaluated to assess the physical and chemical effects of the discharge on modifying the surface morphology, microstructure and composition. The Faradaic efficiency in the formation of main gases and liquid products (e.g., CH_4, formate, ethanol) is used to assess the efficacy of the plasma enhanced ALE processes in de-poisoning catalysts. The results demonstrated the feasibility of utilizing ALE to remedy catalyst poisoning, highlighting the effect of surface microstructure on catalytic selectivity, thereby making the catalytic processing more sustainable and effective.

2:15 PM PM03.10.03

Enhanced Electrochemical Performance of NiFe/Carbon Paper Electrocatalysts via Atmospheric-Pressure and Microwave Plasma Treatment for Anion Exchange Membrane Water Electrolysis *I-Chun Cheng[1], Shuo-En Yu[1], Meng-Jiy Wang[2] and Jian-Zhang Chen[1]; [1]National Taiwan University, Taiwan; [2]National Taiwan University of Science and Technology, Taiwan*

Plasma treatment offers a novel approach to modifying electrocatalysts by introducing vacancies and defects, thereby improving their performance in electrolytic processes. Building on our prior work, which demonstrated the efficacy of low-pressure plasma treatments in enhancing the electrocatalytic performance of various metalorganic frameworks (MOFs), such as RuCo-MOFs and NiRu-MOFs for hydrogen evolution reactions and NiCo-MOFs and NiFe-MOFs for oxygen evolution reactions, this study explores the application of atmospheric-pressure plasma jet and microwave plasma treatments. Specifically, we focus on the enhancement of electrochemically deposited nickel-iron on carbon paper (NiFe/CP) for use in anion exchange membrane water electrolyzer. Our results show that plasma-induced oxygen vacancies not only modify the oxidation states but also increase the number of active sites on NiFe/CP, significantly boosting the oxygen evolution reaction activity. The atmospheric-pressure plasma jet treatment for 60 s resulted in an appreciable reduction in specific energy consumption from 45.68 kWh/kg H_2 to 42.49 kWh/kg H_2, thus improving the energy efficiency from 79.68% to 85.66%. Additionally, a brief 15-s oxygen microwave plasma treatment notably decreased the overpotential from 320 mV to 230 mV at a current density of 10 mA/cm^2. This presentation will delve into the mechanistic insights and broader implications of these findings, highlighting their potential to enhance efficiency and reduce the costs associated with electrochemical energy *conversion technologies.*

***Navigating the Structure Zone Diagram for Precision-Engineered Films Using Next-Generation HiPIMS** Brian Jurczyk; Starfire Industries LLC, United States*

High-Power Impulse Magnetron Sputtering (HiPIMS) is a PVD technique that uses high current pulses to drive magnetron self-sputtering and achieve high ionization fraction. HiPIMS was initially marketed in the early 2000s as a middle ground between 'dirtier' ionic cathodic arc and 'cleaner' neutral dc sputtering albeit higher cost relative to both. This perception changed in 2017 with the introduction of next-generation pulse modules with IMPULSE® ultra-fast switching (dI/dt) and Positive Kick™ rapid voltage reversal (dV/dt) to electronically control and adjust the transient energy flux to the substrate (T) as well as the incident particle ion energy (E*). A materials engineer can more freely move around the Structure Zone Diagram (Thornton) to achieve desired properties, e.g. morphology, orientation, crystallinity, etc. Stress control and layering can readily be accomplished with electronic recipe control. The technique enables in-situ etching and implantation to control and grade interface properties. Further, the expanding dense plasma per pulse allows quasi-conformal deposition on 3D substrates so that PVD sputtering is no longer line-of-sight. Ultra-fast switching mitigates arcs and debris generation to improve film quality for semiconductor and anti-corrosion applications. This industrial invited talk will explore several industrial applications and the broad applicability for precision-engineered coatings at the nanoscale.*

3:30 PM PM03.11.02
***Metal Clusters and Cluster Doping with Atmospheric Pressure Microplasma?** Davide Mariotti; University of Strathclyde, United Kingdom*

Atmospheric pressure microplasma have demonstrated great opportunities to synthesize nanoparticles with diameters reaching values well below 5 nm, which are, for many materials, size ranges within the quantum confinement regime. The ability to synthesize and analyse clusters, e.g. with diameters below 1 nm, is scientifically intriguing but also important from many point of views. We have investigated cluster formation using an atmospheric pressure microplasma that uses a solid sacrificial metal wire and that has been very 'prolific' in the synthesis of metal and metal oxide nanoparticles. The formation of clusters is therefore an important step to understand the mechanisms leading to the nucleation and growth of larger particles. At the same time, metallic clusters have unique fundamental properties with relevance for many applications. Metal clusters also transcend accepted boundaries, for instance that between solid and liquid phases.
We report here our initial work to synthesize and understand metallic clusters, while providing some insights into the formation mechanisms of nanoparticles in atmospheric pressure plasmas. While our initial work was inspired by metallic tin clusters, we will also report our more recent work with bismuth. We report on the challenges to work with clusters, what we understand of their formation and some unexpected opportunities.

3:45 PM PM03.11.03

Development of Multilayered Coatings on Metal Plates with High Corrosion Resistance and Improved Electrical Conductivity by Plasma-Enhanced Chemical Vapor Deposition *Prawal P. Agarwal[1], Mruthunjaya Uddi[1], Chien-Hua Chen[1] and Benjamin Meekins[2]; [1]Advanced Cooling Technologies, Inc., United States; [2]University of South Carolina, United States*

The rapid growth of the proton exchange membrane fuel cell (PEMFC) market necessitates cost-effective and high-performance bipolar plates (BPs), which constitute a significant portion of the stack's weight and cost. While traditional graphite BPs are fragile and difficult to manufacture with precise flow channels, metallic BPs offer a promising alternative due to their superior mechanical properties and electrical conductivity. However, the corrosive operating environment of PEMFCs, characterized by high temperatures and acidic conditions, makes metallic BPs prone to corrosion, leading to performance degradation and reduced lifespan. Corrosion of BPs not only contaminates the catalyst layer but also impedes the electrical conductivity of the membrane electrode assembly. Various coating materials, including inert metals, transition metal nitrides, carbides, and carbon-based coatings, have been investigated to address this issue. However, the cost and performance limitations of these coatings necessitate further exploration of innovative solutions. This study focuses on the preliminary development of a novel approach utilizing plasma-enhanced chemical vapor deposition (PECVD) technology to deposit multilayered corrosion-resistant, electrically conductive, and durable coatings on metallic substrates. We report the successful development of an efficient PECVD reactor system and the optimization of deposition parameters for multilayered coatings comprising titanium (Ti), titanium carbide (TiCx), and amorphous carbon (a-C) on metal substrates. A safer and more environmentally friendly titanium precursor was identified and incorporated into the process, mitigating concerns about hazardous material (metal halides) during scaling. The resulting coatings were characterized using a variety of techniques, including Raman spectroscopy, X-ray diffraction (XRD), cross-sectional and surface scanning electron microscopy (SEM), as well as corrosion testing in acidic environments and thermal cycling tests. The coatings exhibited exceptional uniformity, high electrical conductivity, and promising corrosion resistance, meeting the demanding requirements for PEMFC applications. This innovative PECVD approach addresses critical performance bottlenecks in the fuel cell industry, enabling faster deposition rates and cost-effective fabrication of BPs that meet or exceed the performance targets of the US Department of Energy. The enhanced corrosion resistance, electrical conductivity, and durability offered by these multilayered coatings have the potential to revolutionize PEMFC technology, particularly in the rapidly expanding medium and heavy-duty vehicle sectors.

4:00 PM PM03.11.04

Temperature-Controlled Cold Plasma Synthesis of MoS_2–WS_2 (1T/1T, 2H/2H) Polymorphic Heterostructures for Hydrogen Evolution Reaction *Seowoo Son[1], Hyunho Seok[1], Jinill Cho[2], Sihoon Son[1], Dongho Lee[2], Hyunbin Choi[2], Geonwook Kim[2] and Taesung Kim[2,1,2]; [1]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)*

Transition metal dichalcogenides (TMDs) are attracting considerable interest due to their outstanding electrical and chemical properties, high carrier mobility, low power consumption, and exceptional flexibility and stretchability. Beyond these advantages, TMDs show great promise as catalysts for the hydrogen evolution reaction (HER). However, the practical application of two-dimensional (2D) materials has been hampered by inadequate phase control methods for TMDs. Current techniques, including post-treatment chemical processes, lattice deformation via ion collision, and strain-induced phase control, involve additional steps and yield low efficiency, limiting their practicality.

This research explores the design and characterization of polymorphic heterostructures of MoS_2 and WS_2, utilizing a novel temperature-regulated cold plasma-enhanced chemical vapor deposition (PECVD) method. By varying the substrate temperature while keeping plasma parameters constant (power, pressure, processing time, and gas ratio), this approach significantly enhances the versatility of TMDs.

The method facilitates the production of 1T-MoS_2/1T-WS_2 *(1T/1T-MWH) and* 2H-MoS_2/2H-WS_2 *(2H/2H-MWH) vertical heterostructures on a large 4-inch wafer scale. Cold plasma conditions, combined with ion bombardment, result in the formation of nanoscale grain boundaries and exposed edges that significantly boost catalytic activity. Techniques such as high-resolution transmission electron microscopy (HR-TEM) and X-ray photoelectron spectroscopy (XPS) confirm the successful creation and stability of these polymorphic forms.*

Electrochemical tests indicate that the 1T/1T-MWH displays superior HER performance, featuring a lower overpotential and enhanced stability compared to other polymorphic variants. This improved performance is attributed to the metallic properties of the 1T phase, which enable rapid charge transfer, and the alloy structures at the heterointerface, which lower reaction energy barriers.

Further analysis after HER cycles shows that 1T/1T-MWH retains its phase stability and catalytic efficiency even after 1000 cycles, proving its durability. This innovative synthesis approach offers a scalable and effective method for creating high-performance HER catalysts, underscoring the potential applications of TMD polymorphic heterostructures in renewable energy solutions.

SESSION QT01.01: Low-Dimensional Chiral Perovskites I
Session Chairs: Matthew Beard and Volker Blum
Monday Morning, December 2, 2024
Sheraton, Fifth Floor, Jamaica Pond

10:30 AM *QT01.01.01
Materials Theory of Halide Perovskites—Defect and Chirality *Shuxia Tao; Eindhoven University of Technology, Netherlands*

Halide perovskites have gained prominence in optoelectronics and quantum materials due to their chemical versatility, which allows for a broad range of interactions with light, electrons, spins, and lattice vibrations. My team employs first-principles methods like density functional theory, tight-binding models, and machine learning-accelerated ab-initio molecular dynamics to explore their complex structure-property relationships. We focus on defect chemistry to enhance PV solar cell efficiency and stability, identifying and mitigating defects that cause losses and degradation through compositional adjustments and surface treatments.
More recently, we explore the chirality of perovskites, using chiral ligands to introduce properties like chiral-induced spin selectivity and enhancing chiral optical activity. This exploration aims to harness these distinctive properties for pioneering applications in spin LEDs and chiral photodetectors, driven by a deep understanding of the relation between structural features and optoelectronic properties.

11:00 AM QT01.01.02
Control of Light and Spin with Chiral Metal Halide Perovskite Semiconductors *Mengxia Liu; Yale University, United States*

Chiral metal halide perovskites have attracted growing attention as promising candidates for spin- and polarization-resolved optoelectronic devices, thanks to their unique properties such as circular dichroism, circularly polarized photoluminescence, and chirality-induced spin selectivity. Despite their considerable potential for tunable spin and chiral light control, the underlying physical mechanisms remain elusive. In this presentation, I will introduce our recent studies on chirality-induced anisotropic absorption of spin currents in these materials. Through ferromagnetic resonance and time-resolved magneto-optical Kerr effect, we have identified strong anisotropic damping of magnetization precession in both chiral and racemic perovskites. Additionally, I will discuss how strategic manipulation of composition, dopants, and crystal orientation enables us to control the chiroptical activity of these perovskites, specifically targeting the circularly polarized absorption and emission.

11:15 AM *QT01.01.03
The Impact of Anisotropy and Anharmonicity on the Magneto-Optical Properties of Bulk 3D and 2D Lead Halide Perovskites *Shahar Zuri[1], Alyssa Kostadiniv-Mutzafi[1], Liang Z Tan[2], Leeor Kronik[3] and Efrat Lifshitz[1]; [1]Technion–Israel Institute of Technology, Israel; [2]Lawrence Berkeley National Laboratory, United States;*

[3]Weizmann Institute of Science, Israel

The renaissance of interest in halide perovskites, triggered by their unprecedented performance in optoelectronic applications, elicited worldwide efforts to uncover various intriguing physical properties, with a particular interest in spin-orbit effects. The current work presents magneto-optical experimental evidence for anisotropic electron-hole interactions in the 3D orthorhombic $MAPbBr_3$ *and the 2D* $(PEA)_2PbI_4$ *bulk single crystals. The evidence was seen in the magneto-photoluminescence spectra while monitoring several different crystallographic directions. The observations exposed a highly non-linear response to a magnetic field and asymmetry to the influence of the sign of the magnetic field. A theoretical model implementing anisotropy in the electron-hole interaction, Rashba effect, Landé g-factors, and a lesser contribution from an Overhauser effect corroborated the experimental results. A continuation of the work involved the investigation of the anharmonic ground-state of the* $(PEA)_2PbI_4$ *compound, using complementary information from low-temperature x-ray diffraction (XRD) to the photoluminescence spectroscopy, which was also supported by density functional theory (DFT) calculations. The study extrapolated four crystallographic configurations from the low-temperature XRD. These configurations imply that the ground state has an intrinsic disorder stemming from two coexisting chiral sub-lattices, each with a bi-oriented organic spacer molecule. We further show evidence that these chiral structures form unevenly populated ground states, portraying uneven anharmonicity, where surface effects may tune the state population. Our results uncover a disorder that may be associated with a dynamic Rashba effect. The current efforts include using a unique pump-probe experiment to follow a dynamic Rashba effect. Also, preliminary magneto-photoluminescence of* $(F\text{-}PEA)_2PbI_4$ *uncovered two opposing chiral structures alone through the entire temperature range under investigation. This result was already corroborated by XRD measurements, confirming the locking of the F-PEA degree of freedom. Further study is ongoing regarding the relation between anharmonicity, the Rashba effect, and the dependence on structure and composition.*

SESSION QT01.02: Chiral Light-Matter Interactions I
Session Chairs: Volker Blum, Paulina Plochocka and Shuxia Tao
Monday Afternoon, December 2, 2024
Sheraton, Fifth Floor, Jamaica Pond

1:30 PM *QT01.02.01
Chirality-Induced Spin-Orbit Coupling, Spin Transport and Natural Optical Activity in Hybrid Organic-Inorganic Perovskites *Zhi-Gang Yu[1,2]; [1]Sivananthan Laboratories, United States; [2]Washington State University, United States*

Hybrid organic-inorganic perovskites (HOIPs) have shown great promise in photovoltaics, light emitting, and radiation detection. While the conduction and valence bands in HOIPs are comprised primarily of orbitals in the inorganic PbX_6 *(X = I, Br, and Cl) octahedra,*
the organic ligands modulate interactions among these octahedra and influence the material's structural, electrical, and optical properties. When organic ligands are chiral, the resultant HOIPs possess chirality and exhibit strong natural optical activity (NOA) including circular dichroism (CD) and circularly polarized luminescence (CPL). Remarkably, the most pronounced CD and CPL peaks coincide with the HOIPs' exciton states but are far away from excited states associated with chiral organic ligands. Moreover, highly spin-selective transport is observed in chiral HOIP-based device structures. Since both excitons and carriers in HOIPs are extended Bloch waves with well-defined wave vectors, the observed NOA and spin transport indicate that the

organic ligands successfully extend their molecular chirality to the entire crystal. In this talk, I will discuss our attempt to develop a comprehensive and unified theory to understand spin transport and NOA in chiral HOIPs. These fascinating features can be traced to a chirality-induced spin-orbit coupling (SOC), $H_{so} = \alpha\tau k_z \sigma_z$*, which connects the carrier's spin* σ_z*, its wave vector* k_z*, and material's helicity* t *along the screw direction with strength* a *controlled by the geometry of the organic ligands. This SOC leads to a macroscopic spin polarization in the presence of an electrical current and is responsible for the observed chirality-induced spin selectivity (CISS). The combination of chirality-induced SOCs in the conduction and valence bands leads to a SOC between the exciton's center-of-mass wave vector* K_z *and its angular momentum, or equivalently, circular polarization,* j^{ex}_z*,* $H'_{so} = \alpha' \tau K_z j^{ex}_z$*, which is the key to understanding NOA in chiral HOIPs. Since spin transport and NOA in chiral HOIPs share a common origin -- the chirality-induced SOC, whose strength is determined essentially by the geometry of chiral organic ligands, designing suitable chiral organic ligands in HOIPs can systematically tailor their SOC strengths and help realize chiral HOIPs' promising potential in novel spintronic and optoelectronic applications. I will also briefly describe our recent effort to incorporate the chirality-induced SOC in the hopping-transport regime and understand inverse CISS observed in disordered chiral polymers.*

Highly Selective Room-Temperature Spin-Polarized Light-Emitting Diodes Enabled with Chiral Two-Dimensional Perovskties *Gyumin Jang, Chan Uk Lee, Wooyong Jeong, Jaehyun Son, Jeong Hyun Park and Jooho Moon; Yonsei University, Korea (the Republic of)*

Circularly polarized light (CPL) is an essential light source with a broad range of potential applications, including magnetic recording, three-dimensional displays, and information processing. In this work, we introduce core−shell heterostructured perovskite quantum dots (QDs) for room-temperature spin-polarized light-emitting diodes (spin-LEDs). Specifically, 2-dimensional (2D) chiral organic−inorganic hybrid perovskite shell was deposited onto the achiral 3D inorganic $CsPbBr_3$ *perovskite core. It is demonstrated that (R)- and (S)-1-(2-(naphthyl)ethylamine) chiral cations can enhance the degree of spin polarization due to their robust chiroptical properties. Owing to the chiral-induced spin selectivity (CISS) effect, the spin state of the injected charge carriers is biased when they are transmitted through the 2D chiral shell. Such spin-controlled carriers then undergo radiative recombination within the* $CsPbBr_3$ *core, resulting in the CPL emission. The spin-LEDs fabricated with core−shell QDs attained a maximum external quantum efficiency (EQE) of 5.47% and exhibited circularly polarized electroluminescence with an outstanding polarization degree (*$P_{CP\text{-}EL}$*) for both left- and right-handed 2D chiral perovskites at room temperature.*
Furthermore, blue spin-LEDs are demonstrated for the first time by inserting (R)- and (S)-2-fluoro-methylbenzylamine (R/S-2F-MBA) chiral cation into the surface of Br/Cl-mixed halide perovskite films. It was found that small ionic radii of bromide and chloride ions enable deeper penetration of ammonium functional groups inside chiral cations, enhancing circular dichroism of 2D chiral perovskites by ~4 fold. Due to the increased chiroptical properties as well as spin selectivity, resulting blue spin-LEDs exhibited remarkable circularly polarized electroluminescence dissymmetry factor. Also, halide vacancies inside perovskite films were effectively

passivated because of a high polarity of R/S-2F-MBA chiral cations, thereby achieving a notable EQE.

2:15 PM *QT01.02.04

Perovskite Metasurfaces for Chiral Light Emission and Topological Exciton Polaritons *Young Chul Jun; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Optical metasurfaces, which are structured thin films with subwavelength patterned elements, have been employed as a general platform for various nanophotonic studies. In perovskite metasurfaces, the metasurface itself can be defined by light-emitting perovskite materials. Therefore, perovskite metasurfaces can manifest various interesting features, such as chiral light emission and topological phenomena. In this talk, we discuss two related studies conducted in our group using perovskite metasurfaces. First, we present chiral emission with high levels of circular polarization, achieved using achiral perovskite materials. Second, we explore exciton polaritons and their topological features in perovskite metasurfaces.
Chiral optical objects exhibit different optical responses under left circularly polarized (LCP) and right circularly polarized (RCP) light incidences. Chiral metasurfaces can significantly enhance the chiral optical responses and provide unprecedented design flexibility. Particularly, chiral light sources utilizing perovskite materials are garnering significant interest for their outstanding optoelectronic properties. Here, we introduce two recent experiments from our group: chiral photoluminescence and chiral electroluminescence using chiral resonances in perovskite metasurfaces. Initially, maximally chiral emission from perovskite metasurfaces is demonstrated using chiral quasi-bound states in the continuum. Furthermore, chiral electroluminescence is achieved at room temperature with a substantial degree of circular polarization using thin-film-based chiral cavity structures.
Then, we discuss topological exciton polaritons realized at room temperature using perovskite metasurfaces. Exciton polaritons are hybrid light-matter quasi-particles that inherit the advantages of their photonic and excitonic components. Therefore, they can be an exceptional bridge between novel photonic structures and materials. Exciton polaritons constitute a highly multidisciplinary field and are attracting considerable attention across various fields. Recently, new materials have emerged for room-temperature exciton polaritons. Among these, perovskite materials have attracted significant attention because of their strong exciton responses at room temperature. We explain the formation of exciton polaritons in perovskite materials. We then delve into two topological features in our polaritonic perovskite metasurfaces: (i) topological defect in momentum space via bound state in the continuum and (ii) topological phase transition and interface state in a perovskite grating junction. Our results suggest a powerful platform for further extensive studies of room-temperature exciton polaritons and their device applications.

Mechanism of Circular Dichroism in Chiral 2D Halide Perovskites and Chiroptical Properties of Perovskite Nanocrystals *Peter C. Sercel; Center for Hybrid Organic Inorganic Semiconductors for Energy, United States*

A key motivator for research in hybrid organic-inorganic metal halide perovskites (HOIPs) is the potential to combine distinct characteristics of the inorganic and organic constituents to elicit desirable functional properties. For example, incorporation of chiral organic cations into layered 2D halide perovskites has been shown to result in structural chirality transfer to the inorganic layers, leading to Rashba/Dresselhaus-like spin-splitting while at the same time leading to the emergence of chiroptical effects such as circular dichroism (CD) [1,2].

In the first part of this talk, we address the following question: In chiral 2D perovskites, what connection exists, if any, between the spin textures that emerge by virtue of structural chirality transfer, and the emergence of chiroptical properties associated with the band edge exciton transitions? We explore this question utilizing an effective mass theory model parameterized by hybrid density functional theory calculations [3]. The model accounts for the mixed parity of the band edge states resulting from polar distortions and includes the effects of Rashba-like spin-splitting via an effective exchange interaction. We develop analytical expressions for the exciton fine structure, the electric and magnetic dipole transition matrix elements, and show a direct connection between particular spin textures and the emergence of CD in chiral 2D perovskites [3].

In the second part of the talk, we generalize the model and apply it to perovskite nanocrystals. We will discuss the mechanisms by which chiroptical properties can occur in perovskite nanocrystals, e.g., as reported in Ref. [4], with [5] or without polar distortions, and we will discuss the characteristics and magnitude of the chiroptical effects associated with the various mechanisms.

Rashba Spin Splitting in Non-Centrosymmetric Hybrid Metal Halide Perovskites Through Cation Tuning *Willa Mihalyi-Koch[1], Zhenbang Dai[2], Jonathan Schimmels[1], Andrew M. Rappe[2] and Song Jin[1]; [1]University of Wisconsin-Madison, United States; [2]University of Pennsylvania, United States*

Metal halide perovskites are a class of hybrid semiconductors that offer extraordinary structural tunability. Non-centrosymmetric low dimensional perovskites with strong spin-orbit coupling introduced by the heavy metal and halide atoms can exhibit useful properties such as Rashba and/or Dresselhaus spin splitting, ferroelectricity, and optical nonlinearity. Here, we discuss approaches to tune the structural symmetry of low-dimensional halide perovskites via the spacer, A-site, and metal cations and the consequence on spin splitting. Symmetry breaking in complex layered systems can occur across different length scales and local distortions do not always lead to bulk non-centrosymmetry. "Hidden" (monolayer) non-centrosymmetry is relatively common for $n > 1$ 2D perovskites –

including some phases with excellent excitonic properties – and can result in a hidden Rashba spin splitting along multiple paths in k-space that can be brought out in bulk via external perturbation such as applied pressure. Further cation engineering by modifying the metal site to increase stereochemical lone pair activity, increasing quantum well thickness (n), and incorporating an asymmetrically substituted spacer cation can break global (space group) centrosymmetry, but this doesn't always increase the magnitude of spin splitting and typically limits the splitting to one path in k-space. However, global C_{2v} polar symmetry leads to unidirectional spin splitting in k, i.e., persistent spin texture, which promises to increase spin relaxation time. We further show that the metal halide composition influences the type of structural distortion that results from incorporation of asymmetric spacer cations (e.g., tilting, octahedral distortion, and/or dimensional reduction). This work provides structural insights for designing new, low-dimensional non-centrosymmetric perovskites for spin-orbitronic and quantum applications.

4:15 PM QT01.03.03

Engineering Spin Textures in 2D Hybrid Perovskites *Rayan Chakraborty[1], Peter C. Sercel[2], Xixi Qin[1], David B. Mitzi[1,1] and Volker Blum[1,1]; [1]Duke University, United States; [2]Center for Hybrid Organic Inorganic Semiconductors for Energy, United States*

The crystalline symmetry plays a key role in determining the spin properties of charge carriers in solid-state structures that are required for realizing spin-optoelectronic effects.[1-4] In 2D organic-inorganic perovskites (2D-OIPs) with alternating layers of organic cations (A) and metal-halide octahedra ($[BX_6]^{4-}$; B = Pb, Sn and X = Cl, Br, I), the structural symmetry and optoelectronic properties can be tailored by the non-covalent interactions.[5-10] Here, we show how organic ammonium cations with restricted rotational motions can introduce asymmetric polar distortion modes in the B – X layers. The inherent polarization modifies the local effective magnetic fields through the spin-orbit coupling effect, driving the momentum-dependent spin polarizations (spin textures) at the frontier electronic bands of the 2D-OIPs. To rationalize these spin textures, we developed an analytical model that quantifies the effect of the inter-layer coupling on spin properties in multi-quantum-well structures. The obtained correlation between the spin textures (simulated through first-principles calculations) in a set of 2D-OIPs with different symmetry elements and the non-covalent interactions that are responsible for those symmetry elements (analyzed from single crystal X-ray diffraction measurements) directs us toward a design strategy for obtaining 2D-OIP semiconductors with tunable band gaps and measurable spin-properties (e.g., spin splitting, spin lifetime, and spin localization) that are suitable for room-temperature spin-optoelectronic applications.

Efficient Green Spin Light-Emitting Diodes Enabled by Ultrafast Energy- and Spin-Funneling in Chiral Perovskites *Haipeng Lu; The Hong Kong University of Science and Technology, Hong Kong*

Introducing molecular chirality into perovskite crystal structures has enabled the control of carrier spin states, *giving rise to circularly polarized luminescence (CPL) in thin films and circularly polarized electroluminescence (CPEL) in LEDs. Spin-LEDs can be fabricated either through a spin-filtering layer enabled by chiral-induced spin selectivity, or a chiral emissive layer. The former requires a high degree of spin polarization and a compatible spinterface for efficient spin injection, which might not be easily integrated into LEDs. Alternatively, a chiral emissive layer can also generate circularly polarized electroluminescence, but the efficiency remains low, and the fundamental mechanism is elusive. In this work, we report an efficient green LED based on quasi-two-dimensional (quasi-2D) chiral perovskites as the emitting layer (EML), where CPEL is directly produced without a separate carrier spin injection. The optimized chiral perovskite thin films exhibited strong CPL at 535 nm with a photoluminescence quantum yield (PLQY) of 91% and a photoluminescence dissymmetry factor (g_{lum}) of 8.6×10^{-2}. Efficient green spin-LEDs were successfully demonstrated, with a large EL dissymmetry factor (g_{EL}) of 7.8×10^{-2} and a maximum external quantum efficiency (EQE) of 13.5% at room temperature. Ultrafast transient absorption (TA) spectroscopic study shows that the CPEL is generated from a rapid energy transfer accompanied with spin transfer from 2D to 3D perovskites. Our study not only demonstrates a reliable approach to achieve high performance spin-LEDs, but also reveals the fundamental mechanism of CPEL with an emissive layer of chiral perovskites.*

SESSION QT01.04: Spin Control I

Using Chirality and Symmetry Breaking to Tailor Hybrid Metal Halide Perovskite Structures and Properties
David B. Mitzi; Duke University, United States

Hybrid organic-inorganic perovskite (HOIP) semiconductors offer unprecedented opportunity to control structure and properties using both inorganic and organic realms of chemistry and materials science,[1] and such tunability offers wide-ranging potential for applications including solar cells, light-emitting devices, detectors, transistors, spintronics, and advanced computing devices. This talk will focus on the impact of the organic cation (including use of chirality and cation mixing) on distortion and symmetry, and on how such structural control impacts properties. Exemplary topics will include recent studies exploring homochiral vs heterochiral cation mixing to impact spin splitting[2] and considering how isomer cation choice impacts melting and glass crystallization kinetics.[3] Detailed X-ray/neutron examination of structure through crystal-crystal and glass-crystal transitions also provides opportunity for better understanding the role played by hydrogen bonding in shaping local and long-range order. The discussed symmetry-related tunability highlights the promise of using the organic component to control light, charge and spin within the wide-ranging HOIP family.

***Halide Double Perovskites with a Spin—Identifying Semiconductors with Spin-Polarized Band Structures** Luc*

Walterbos[1], Kostas Fykouras[1], Huygen J. Jöbsis[2], Eline M. Hutter[2] and Linn Leppert[1]; [1]University of Twente, Netherlands; [2]University of Utrecht, Netherlands

Enhancing the performance of photoconversion devices necessitates slowing down the recombination rate of electrons and holes in semiconductors, to facilitate their diffusion to charge-extraction interfaces. Semiconductors with advantageous light absorption properties and slow charge-carrier recombination could be obtained in semiconductors with suitably aligned spin-polarized band structures. Halide double perovskites with the chemical formula $A_2BB'X_6$ offer significant chemical flexibility [1, 2], enabling the substitution of the B and B' sites with various combinations of similarly sized open-shell cations. This potentially results in spin-polarized band structures and robust exchange interactions, making double perovskites an interesting platform for controlling charge-carrier recombination via spin.

Our recent research demonstrates that Fe-based double perovskites exhibit low bandgaps and significant spin polarization and can be efficiently synthesized via mechanochemical synthesis [3]. However, while the incorporation of Fe^{3+} leads to a spin-forbidden recombination pathway, it also compromises electron mobility. Here, I will present a systematic high-throughput computational approach for exploring the opto-spintronic properties of halide double perovskites with robust opto-spintronic properties.

I will present our workflow for establishing a comprehensive database of double perovskites, including computationally determined structural parameters, energetically favorable spin states, and spin-polarized density of states, calculated using first-principles density functional theory with the HSE06 hybrid functional. Expanding on previous work [4], we included 3d, 4d, and 5d transition metals, as well as actinides and lanthanides in our high-throughput workflow, resulting in approximately 12,000 compounds predicted to crystallize in the perovskite structure. Additionally, I will discuss how machine-learning aided characterization of this dataset enables us to identify predictors of favorable opto-spintronic properties, paving the way for the rational design of spin-regulated semiconductors with enhanced photoconversion performance.

Homochiral and Heterochiral Cation Mixing in 2D Perovskites for Enhanced Structural Asymmetry and Spin Splitting

Yi Xie[1], Heshan Hewa-Walpitage[2], Jack Morgenstein[1], Volker Blum[1], Zeev Valentine Vardeny[2] and David B. Mitzi[1]; [1]Duke University, United States; [2]The University of Utah, United States

Overcoming the constraints of single-cation phases and further enhancing structural asymmetry emerges as a critical objective for optimizing emergent optoelectronic and spin-related properties in two-dimensional (2D) hybrid organic-inorganic perovskites (HOIPs). Mixing two different chiral cations within the 2D HOIP framework provides a particularly interesting opportunity to tailor the inorganic lattice through varied chirality mixing (with the same overall HOIP elemental composition), as one can envision two distinct pathways—i.e., homochiral (S/S) or *heterochiral (R/S) cation mixing.[1] Here, we demonstrate the homo- and heterochiral mixing in PbI_4^{2-}-based 2D HOIPs via a 1:1 mixing of S- and R-4-bromo-α-methylbenzylammonium with S-1-methylhexyammonium. Two types of arrangements of the cations induced by varied chirality mixing facilitate the accommodation of altered degrees of lattice strain, further tailoring the structural symmetry and distortions compared with their single-cation counterparts. Remarkably, the R/S system achieves an enhanced structural asymmetry, marked by a significant Pb-I-Pb bond angle disparity Δβ of 9.24°, attributed to the distinctive asymmetric templating effects from mixed cations with distinct molecular structures and opposite absolute configurations. Consequently, density functional theory (DFT) calculations indicate a substantial spin splitting (ΔE = 78.5 meV), among the largest reported for PbI_4^{2-}-based 2D HOIPs. The non-equivalent chiral information delivered by homo- and heterochiral mixing further diversifies and modulates the Cotton effect, as evidenced by the non-mirror-symmetric circular dichroism spectra, despite maintaining the same elemental composition. Our study demonstrates a novel material design strategy to overcome the limitations of current single-cation and single-enantiomer phases and to enhance chirality transfer and structural asymmetry within the 2D inorganic lattice for optimizing various distortion- and symmetry-dependent properties.*

***Lone-Pair Induced Ferroelectric Distortion and Rashba Effect in the Halide Perovskites** Michael W. Swift and John L. Lyons; U.S. Naval Research Laboratory, United States*

The lone-pair s states of germanium, tin, and lead endow the inorganic metal halide perovskites with many unconventional properties. Previously, only the germanium perovskites were thought to exhibit crystallographic expression of their lone pairs, but dynamic stereochemical expression of the lone pairs is well established for perovskites based on all three metals. Here we use first-principles calculations, namely hybrid density functional theory together with spin–orbit coupling, to study the effects of lone pairs on the electronic and crystal structures of halide perovskites. Using these calculations, we predict stable monoclinic polar phases for both $CsSnI_3$ and $CsSnBr_3$, which exhibit ferroelectric distortions that are driven by stereochemical expression of tin lone pairs [1]. Similar metastable ferroelectric phases are predicted to occur for $CsPbI_3$ and $CsPbBr_3$. Together with ferroelectricity, these phases also exhibit the Rashba effect, which has recently been shown to be crucial for controlling exciton fine structure in nanostructured halide perovskites. Spin splitting occurs in both the conduction and valence bands for the polar-ferroelectric phases, suggesting that nanostructures based on these compounds could host bright ground-state excitons if the correct phase is achieved. Finally, we how electric fields and tensile strain might aid in the experimental realization of these phases.

***Uncovering Multiple Intrinsic Chiral Phases with Unexpected Properties in $(PEA)_2PbI_4$** Shahar Zuri[1], Leeor Kronik[2] and Efrat Lifshitz[1]; [1]Technion–Israel Institute of Technology, Israel; [2]Weizmann Institute of Science, Israel*

We investigate the ground state of the benchmark $(PEA)_2PbI_4$ compound, using complementary information from *low-temperature x-ray diffraction (XRD) and photoluminescence spectroscopy, combined with density functional theory calculations. We find four crystallographic configurations from low-temperature XRD, indicating a ground state with an intrinsic disorder stemming from two coexisting chiral sublattices, each with a bi-oriented organic spacer molecule. We further show evidence that these chiral structures form unevenly populated ground states, portraying uneven anharmonicity, where the state population may be tuned by surface effects. Importantly, our computational studies further reveal the presence of an intrinsic Rashba effect within some of the ground state phases, suggesting its overall existence despite the nominally centrosymmetric nature of the structure.*

11:00 AM QT01.04.06

Enhancing the Chiroptical Property of a 2D Lead Halide Perovskite via a Pseudo-Triple Cation Approach

Adewale J. Babatunde[1], Pranab Sarker[2], Xiaoyu Zhang[1], Shripathi Ramakrishnan[1], Yuanze Xu[1] and Qiuming Yu[1]; [1]Cornell University, United States; [2]University of South Carolina, United States

Low-dimensional chiral perovskites have emerged as an interesting class of semiconductor materials with unique properties which hold promise for a range of applications including optoelectronics and spintronics. The insertion of chiral organic cations into the lattice of metal halide perovskites leads to the formation of 2D, 1D, and 0D perovskite structures with observed transfer of chirality to the inorganic framework. Despite the superior carrier mobility characteristic of chiral 2D perovskites relative to the 1D and 0D counterparts, they have so far been reported to possess the lowest degree of chirality – as assessed by the anisotropy factor of absorption (g_{CD}) and photoluminescence (g_{PL}) of circularly polarized light (CPL). This limits the utility and performance of chiral 2D perovskites in device applications such as in CPL photodetectors. Organic spacer cation mixing has proven a useful strategy to both modulate and enhance the chiroptical property of these 2D perovskites, but their corresponding g_{CD} values have yet to exceed the threshold of 10^{-3} order of magnitude.

In this work, we rationalize a pseudo-triple cation approach which resulted in a record g_{CD} on the order of 10^{-2} in a 2D metal halide perovskite, devoid of antisymmetric linear dichroism and linear birefringence (LDLB) contributions. By incorporating chiral enantiomers of 1-(1-Naphthyl)ethylamine (1NEA) and α-Methylbenzylamine (MBA) as spacer cations into the lattice of a lead bromide perovskite, we instigate the removal of mirror and inversion symmetries at both sub-lattice and local scales, induced by varied and asymmetric hydrogen bonding interactions, resulting in Rashba/Dresselhaus splitting of the electronic sub-bands - as revealed by Density Functional Theory (DFT) calculations.

Detailed characterization of the 2D mixed cation chiral perovskite revealed a strong preference for horizontal orientation via Grazing Incidence Wide-Angle X-ray Scattering (GIWAXS) measurements, large exciton confinement via absorption spectroscopy, and enhanced chirality with circular dichroism (CD) of ~2000 mDeg – yielding a g_{CD} value of ~0.03. Temperature-dependent circularly polarized transient absorption spectroscopy also unveiled picosecond spin depolarization kinetics of the perovskite system. The impact of temperature, composition, and solvent engineering on the resulting chiroptical properties of the perovskite system is also explored. These preliminary results showcase this material as a promising candidate for chiral optoelectronic and spintronic applications.

The unprecedented approach of employing pseudo-triple chiral cations provides a pathway to enhance the chiroptical properties of low-dimensional chiral perovskites and advances the ongoing efforts to elucidate the origin of these properties.

Electrically Switchable Chiral Second-Harmonic Generation in an Achiral Ferroelectric 2D Halide Perovskite

Up-to-date as of November 14, 2024

Go Yumoto[1,2], Fuyuki Harata[1], Tomoya Nakamura[1], Atsushi Wakamiya[1] and Yoshihiko Kanemitsu[1]; [1]Kyoto University, Japan; [2]The Institute for Solid State Physics, The University of Tokyo, Japan

Two-dimensional (2D) van der Waals (vdW) semiconductors are attracting attention as promising materials for efficient nanoscale nonlinear optical devices. Because the second-order nonlinearity allowed by broken inversion symmetry plays a key role in nonlinear optics, 2D vdW semiconductors lacking inversion symmetry are of great scientific and technological importance for nonlinear nanophotonics. 2D Ruddlesden-Popper lead halide perovskites (RPPs) are an emerging class of 2D vdW semiconductors with excellent photonic [1,2], optoelectronic [3,4], and spintronic [5,6] properties. In addition, 2D RPPs possess high structural flexibility and tunability [7,8]. Due to the high structural flexibility, ferroelectricity and chirality emerge and lead to unique second-order nonlinear optical responses: ferroelectricity enables electrical switching of the second-order optical nonlinearity and chirality leads to chiral second-order nonlinear responses. Along with the efficient and unique nonlinear optical properties of lead halide perovskites [9-11], these properties show that 2D RPPs can expand the potential of using 2D vdW semiconductors in nonlinear optical applications.

In particular, if ferroelectricity and chirality coexist and electrically switchable chiral nonlinear optics can be realized, it would offer a new paradigm for nonlinear nanophotonics based on 2D vdW semiconductors. However, so far, this has not been possible in 2D vdW semiconductors because it is difficult to electrically manipulate chiral structures in solid-state materials. Moreover, in contrast to the large family of 2D RPPs exhibiting either chirality or ferroelectricity, 2D RPPs having both the properties are very scarce. Therefore, a novel and versatile approach is desirable for developing electrically switchable chiral nonlinear optics and enriching the nonlinear optical functionalities of 2D vdW semiconductors.

In this study, we solved these problems by focusing on biaxial ferroelectricity of an achiral ferroelectric 2D RPP. We synthesized achiral 2D RPP $(BA)_2(EA)_2Pb_3I_{10}$ single crystals, which exhibit biaxal ferroelectricity at room temperature [12]. We demonstrated reversible and continuous electrical switching of chiral second-harmonic generation (SHG) in exfoliated flakes of ferroelectric $(BA)_2(EA)_2Pb_3I_{10}$. The chiral SHG is characterized by SHG circular dichroism (SHG-CD), a second-order nonlinear chiroptical effect, and we observed large SHG-CD. To further investigate the chiral nonlinear optical responses, we performed polarization-resolved SHG imaging. We revealed that there exist the electrically induced ferroelectric domains with perpendicular spontaneous polarizations, which reflects the biaxial ferroelectricity of the material. The ferroelectric multidomain structure breaks the in-plane glide mirror symmetry and the resulting planar chirality leads to the chiral SHG. Our findings can be used to develop a simple and versatile electrical control of nonlinear chiroptical responses without having to design and modulate a chiral crystal structure and open new avenues for novel chiral photonic applications based on ferroelectric 2D RPPs.

Part of this study was supported by JSPS KAKENHI (Grant No. JP19H05465 and JP23K13623) and NEDO-GI (JPNP21016).

Large Exchange-Driven Intrinsic Circular Dichroism of a Chiral 2D Hybrid Perovskite *Shunran Li, Xian Xu, Diana Qiu and Peijun Guo; Yale University, United States*

In two-dimensional (2D) chiral metal-halide perovskites (MHPs), chiral organic spacers endow structural and optical chirality to the metal-halide sublattice, enabling exquisite control of light, charge, and electron spin. The chiroptical properties of 2D-MHPs have been measured by transmissive circular dichroism (CD) spectroscopy, which necessitates thin-film samples, and the results depend on the film thickness and morphology. Here, by developing a reflection-based approach, we characterize the intrinsic, circular polarization-dependent complex refractive index (RI) for a prototypical 2D chiral lead-bromide perovskite. Remarkably, comparison with ab initio theory reveals the large CD arises from the inorganic sublattice rather than the chiral ligand and is an excitonic phenomenon driven by electron-hole exchange interactions, which breaks the degeneracy of transitions between Rashba-Dresselhaus-split bands. The obtained RIs between opposing circular polarizations suggest that previous CD data of spin-coated films largely underestimate the true optical chirality, which we attribute to their lower crystallinity in comparison to single crystals. Our study provides quantitative insights into the intrinsic optical properties of 2D chiral MHPs, paving the way for their prospective chiroptical and spintronic applications.

11:45 AM QT01.04.09
Effects of Banded Morphologies on Circular Dichroism in Chiral Halide Perovskites *Matthew Hautzinger, Cho Ge and Matthew C. Beard; National Renewable Energy Laboratory, United States*

Chiral halide perovskites have exhibited strong chiro-optical properties including large circular dichroism and circularly polarized photoluminescence. One specific chiral halide perovskite, $(R/S\text{-}NEA)_2PbBr_4$ (NEA = 1-(1-napthyl)ethylammonium), exhibits interesting conduction band spin splitting due to the chirality, as well as interesting materials properties such as a low melting temperature and forming a glass phase. Here, we investigate how this glass behavior leads to interesting banded morphologies in thin films. Specifically, we varied the thin film deposition to produce a wide range of banded morphologies, with varying ridge to ridge distance and fibril like motifs as shown in optical microscopy and SEM. While appearance of these morphologies appear similar to be banded spherulites with potentially twisted helical structures, through cross polarized microscopy and X-ray diffraction we show that this is closer to a rhythmic precipitation. There are no changes in orientation between the bands (as is the case with banded spherulites) and the entire film is well oriented film with the inorganic halide perovskite planes parallel to the substrate. The circular dichroism of these samples, across multiple processing conditions/morphologies appear to follow little to no trend in behavior. We explain this with a simple model showing the impact of incident light angle on the extrinsic circular dichroism and suggest the ridged morphology induces changes in the incident light angle across the film, causing the changes in circular dichroism.

SESSION QT01.07: Low-Dimensional Chiral Perovskites II

8:30 AM *QT01.07.01
Low-Dimensional Chiral Perovskites and Their Heterostructures for Optoelectronic Applications *Dehui Li; Huazhong University of Science & Technology, China*

Low-dimensional chiral perovskites combines the chirality of chiral molecules and the outstanding physical properties of perovskites, which render them promising candidates for high-performance optical, electronic, and spintronic device applications. In particular, carriers in low-dimensional chiral perovskites are highly spin-polarized and thus they can be used as a spin source materials for spontronics and valleytronics. In this talk, I would like to first talk about how we introduce chirality into 2D perovskites and by using chiral 2D perovskite crystals we have demonstrated circularly polarized light emission and detected all polarization states based on chiral 2D perovskite photodetectors. Then, I will also introduce by stacking chiral two-dimensional perovskites and monolayer transition metal chalcogenides to form heterostructures to achieve efficient spin injection without an external magnetic field, thereby achieving valley freedom control. This valley polarization manipulation by using chiral 2D perovskites can also achieve in the interlayer excitons formed between chiral 2D perovskite and different types of monolayer transition metal chalcogenides. In addition, this strategy has been extended to zero-dimensional chiral bismuth-based perovskites, which shows high a high degree of circularly polarized photoluminescence and high spin injection efficiency within perovskite/WSe_2 heterostructure. Finally, I will talk about on-chip filterless full-Stokes polarimeter by using the optical anisotropy between the out-of-plane and in-plane direction of chiral 2D perovskites together with their chirality.

9:00 AM QT01.07.02
Determining Electron and Hole Spin Lifetimes in $CsPbI_3$ Nanocrystal Using Donor-Acceptor Interface *Amrita Dey; Vellore Institute of Technology, India*

Spin-dependent properties of lead halide perovskites (LHPs) have recently garnered significant attention. Nevertheless, separate measurements of the electron and hole spin lifetimes have been missing until now. The knowledge of the electron and hole spin relaxation times is crucial for comprehending the spin-dependent properties of LHPs. We employ polarization dependent ultrafast transient absorption spectroscopy to study room temperature electron and hole spin lifetimes in $CsPbI_3$ nanocrystals (NCs). A spin polarization imbalance is created between the photoexcited free charge carriers by introducing the soluble fullerene derivative $PC_{60}BM$ as an electron acceptor and $CsPbI_3$ as the donor. Using a kinetic model of spin-dependent charge carrier distributions, we determine the electron and hole spin lifetimes. Our findings reveal that the room temperature hole spin lifetime (τ_h = 5 ps) is 13 times longer than the electron spin lifetime (τ_e = 0.4 ps). We attribute the rapid electron spin relaxation to strong spin-orbit coupling in the conduction band, which is ineffective for holes in the s-type valence band.

9:15 AM QT01.07.03
Wavelength Control of Spin Lifetimes in Layered Metal Halide Perovskites *Valentino Romano[1], Martin Hörmann[1], Anna Stadlbauer[2], Felix Deschler[2], Giulio Cerullo[1,3] and Franco V. Camargo[3]; [1]Politecnico di Milano, Italy; [2]Universität Heidelberg, Germany; [3]Consiglio Nazionale delle Ricerche, Italy*

Quantum well structures made up by layered metal halide perovskites (L-MHPs) represent an interesting playground for a plethora of fundamental and technological research topics. Photoexcitation of L-MHPs result in the formation of stable excitons [1,2] that, because of the Rashba splitting characteristic of the electronic energy bands, [3] can be spin-polarized if the incident light source is circularly polarised. This optical injection of spin-

polarized carriers makes L-MHPs promising candidates for future opto-spintronic applications.[4]
In a previous work,[5] we used femtosecond time-resolved Faraday Rotation (TRFR) spectroscopy to investigate the spin lifetime of $(BA)_2FAPb_2I_7$ *(BA: Butylammonium; FA: Formamidinium). Interestingly, we observed that the spin lifetime can be increased by more than two orders of magnitude, at 77 K, just by using light with excess energy above the optical band-gap. Since perovskites are soft materials and the formation of stable polarons has been repeatedly reported in both bulk and layered structures,[6] we explained our observations by considering the formation of a polaron state. Indeed, although at low temperatures the phonon population is small, the photogenerated hot carriers cool down within the first hundreds of femtoseconds generating optical phonons that can form polarons. Polarons are characterised by a different exchange interaction with respect to excitons and, thus, we expect that the spin depolarization follows a different mechanism. In particular, we observe that the spin lifetime increases with increasing excitation wavelength, suggesting that the depolarization mechanism is slowed down as the number of generated polarons is increased.*
With the aim to address the role of the chemical structure of L-MHPs onto this phenomenon, here we use TRFR spectroscopy to study three L-MHP compositions from 4 to 300 K: $(Hexa)_2CsPb_2I_7$, $(Hexa)_2FAPb_2I_7$ *and* $(Hexa)_2MAPb_2I_7$ *(Hexa: hexylammonium; MA: methylammonium). All investigated samples exhibit the same trend: spin relaxation becomes slower at low temperatures when the materials are photoexcited with excess energy, but faster when no excess energy is provided. Furthermore, when samples are photoexcited in resonance with their optical band-gap, we observed that a mono-exponential regime is reached (with an associated lifetime of around 200 fs) by all the investigated chemical compositions, but at different temperatures. This finding suggests that below a specific temperature, the process leading to longer spin lifetimes is much slower than the spin relaxation of excitons, which further supports our hypothesis about the thermal-induced formation of polaron states. In particular, the observed thresholds are ~64K for* MA^+*, ~77K for* FA^+ *and ~130K for* Cs^+*. These values follow the opposite trend of the dipole moment values of* MA^+*,* FA^+ *and* Cs^+*, thus larger dipole moments contribute to the stabilization of polarons.*
Our results provide a pathway towards the wavelength-control of spin depolarization in L-MHPs, offering a possible application for the realisation of opto-spintronic devices.

Novel Low-Temperature Phase of CsSnI3 Nanocrystals *Kyle Kluherz, Jacob Shelton and Matthew C. Beard; National Renewable Energy Laboratory, United States*

In the halide perovskites, the B-site metal lone-pair s electrons are strongly suspected to underpin many of the interesting properties of the inorganic halide perovskites. Recently, a stable low-temperature monoclinic polar phase was predicted for CsSnI3, opening the possibility of direct investigation of a both these lone pair electrons and a ferroelectric distorted structure. To date there are no reports of such a structure in CsSnI3, and a known low-temperature monoclinic structure in CsSnBr3 remains unexplored. We have found optical evidence of a transformation occurring around 240 K in CsSnI3 nanocrystals, with several changes in optical behavior below this transition point, including novel high-energy photoluminescene and new states in the transient absorption *spectrum. We have successfully characterized the optical properties of this low-temperature phase and are working to acquire structural characterization to confirm its polar nature. Discovery of a stable monoclinic polar structure in the halide perovskites opens many new potential directions for further research and electronics applications.*

9:45 AM QT01.07.05
Tuning Rashba-Splitting to Brighten Ground State Exciton Via Structural Distortion in 2D Cs_2PbBr_4 *Basant A. Ali[1] and Charles B. Musgrave[2,1]; [1]University of Colorado Boulder, United States; [2]The University of Utah, United States*

Tuning the exciton fine structure in lead halide perovskites has emerged as a pivotal objective for researchers aiming to push the boundaries of optoelectronic performance and unlock new frontiers of efficiency and functionality. Although Rashba splitting has been associated with brightening the ground exciton state, the precise nature of the Rashba splitting responsible for this phenomenon remains unclear. In this study, we employed density functional theory (DFT) and the Model-Bethe-Salpeter Equation (m-BSE) to systematically investigate eighteen 2D Cs_2PbBr_4 systems with varying degrees of structural distortion. Our findings reveal that spin-orbit coupling (SOC) combined with inversion symmetry breaking induces spin splitting in both the valence band (VB) and conduction band (CB), leading to a misalignment between the valence band maximum (VBM) and the conduction band minimum (CBM). This misalignment typically results in a dark ground state exciton, even in the presence of Rashba splitting. However, by controlling inversion symmetry breaking in states with lower SOC, such as the VB in perovskites, the nature of Rashba splitting in the VBM can be modulated. To summarize the study outcomes, a comparative analysis of two systems from the eighteen distorted 2D Cs_2PbBr_4 highlights two distinct excitonic behaviors. The first system, 2-S-180, has two 180^0 and two slightly distorted consecutive tetrahedral angles. While, the second system, 2-L-P, has four highly-distorted tetrahedral angles, where each two opposite angles are equal and consecutive angles are unequal. In 2-S-180, the excitonic state is localized around the Γ point, with the CBM displaying a four-fold spin texture influenced by a combination of linear and cubic Dresselhaus splitting. This arrangement shifts the CBM away from the linear Rashba splitting peak in the VBM, resulting in the first excitonic state being a forbidden dark state with low charge carriers' effective masses. Conversely, in 2-L-P, the pronounced elliptical spin texture caused by a combination of linear Dresselhaus and linear Rashba splitting, with a dominant Rashba coefficient, leads to a flattened VB. This flattened VB allows the delocalization of excitons characterized by low exciton binding energy and high charge carriers' effective masses, ultimately producing a bright ground exciton. Tuning Rashba splitting in the VB can be achieved by engineering orbital non-centrosymmetric wavefunction distributions through deviations from ideal tetrahedral geometry. The large deviations can trigger a tetragonal-to-orthorhombic phase transition and flatten the VB structure, potentially aligning the VBM with the CBM and resulting in bright ground excitons. In conclusion, this study establishes a structure-property-performance relationship, linking structural distortions to Rashba-splitting nature, elucidating their effect on the bright ground state exciton formation. This fundamental understanding paves the way for future research, including high-throughput and machine-learning approaches, to accelerate the discovery and development of materials with bright ground states, driving innovation in cutting-edge optoelectronic applications.

Optical Access to Electron and Hole Spins in Lead Halide Perovskite Crystals and Nanocrystals *Dennis Kudlacik; Technische Universität Dortmund, Germany*

The exceptional optical quality of lead halide perovskites inspires studies of their potential for optical control of carrier spins, a pursuit that has been undertaken in other materials. The Landé factors (g-factors) of charge carriers are of significant importance in solids, controlling spin-dependent phenomena and providing insights into the electronic band structure. We present a comprehensive set of experimental data on the values and anisotropies of the electron and hole g-factors for a representative set of perovskites, including hybrid organic-inorganic and all-inorganic lead halide perovskites with the band gap energy varying from 1.5 to 3.2 eV. The studies include bulk crystals [1,2], nanocrystals [3] and 2D structures [4,5]. The electron and hole g-factors were determined by measuring the Zeeman splitting of electrons and holes using the spin-flip Raman scattering technique at a cryogenic temperature of 1.6 K and in a magnetic field up to 10 T. Furthermore, the spin relaxation and spin coherence times were studied via time-resolved Kerr rotation. We employ principal density functional theory (DFT) calculations in conjunction with tight-binding and k●p approaches to calculate the Landé factors in bulk [2] and 2D perovskites. Our findings illustrate the universal dependence of the electron and hole g-factor on the band gap energy across the diverse perovskite material classes.

We further demonstrate that the degree of optical orientation of carrier spins by circularly polarized light is highly stable against detuning of the laser photon energy from the band gap by up to 0.25 eV. This evidence suggests that spin relaxation mechanisms for free carriers are inefficient during their energy relaxation and thus spin relaxation for localized electrons and holes is provided by the hyperfine interaction with the nuclear spins [6,7]. The dynamic nuclear polarization via spin-oriented holes has been successfully realized. The lead (^{207}Pb) isotope has been identified optically by spin-flip Raman scattering in corresponding changes of the hole Zeeman splitting. This evidence demonstrates that the hole–nuclei interaction is dominated by the lead ions whilst the hyperfine interaction between electrons and nuclei is considerably weaker. In 2D perovskites, a Overhauser field of up to 0.6 T can be observed, due to the high contrast of hyperfine splitting in respect to the Zeeman splitting [4]. A detailed theoretical analysis of the specific properties of lead halide perovskite materials allows the evaluation of the underlying hyperfine interaction constants, both for electrons and holes.

The tunability of the band gap, the long spin dynamics and the narrow g-factor distribution demonstrate that perovskites are promising competitors for conventional semiconductors in spintronics.

Intra-Layer Coupling in Mixed-Valence Mosaic Alloys of Layered Halide Perovskites *Julian A. Vigil[1,2] and Hemamala Karunadasa[2]; [1]University of California, Berkeley, United States; [2]Stanford University, United States*

Layered (two-dimensional) halide perovskites present a rich structure-property space for the design of advanced electronic materials. Indeed, exploiting the molecular diversity in organoammonium cations—and myriad stable metal-halide frameworks—led to a systematic understanding of the confinement effects that distinguish these crystals from their three-dimensional congeners. Recently, our group discovered a new class of layered halide perovskites termed "mosaic" perovskites, which form through alloying of single and double layered perovskites. These mosaic alloys host three distinct metal ions at the putative B-site (e.g., in A_2BX_4; X = halide), notably offering an uncommon path toward mixed valency within the metal-halide framework. The first example of these disordered alloys comprised Cu(I), Cu(II), and In(III), leading to emergent optoelectronic properties rationalized by intervalence charge transfer between neighboring Cu ions.

Here, we build on these design principles to expand the family of mosaic layered perovskite alloys. We demonstrate that features of the known Cu(I)-Cu(II)-In(III) mosaic alloy—including the proposed role of the Cu(II) Jahn-Teller distortion and the intrinsic topology of the disordered metal-halide framework—can be used to evaluate candidates and synthesize new examples of mosaic perovskite alloys. The consequences of mixed valency on charge transfer pathways and magnetic exchange interactions will be discussed. Overall, these mosaic halide-perovskite alloys represent a platform for rational design of intra-layer coupling interactions within layered halides beyond the conventional compositional limitations of single or double perovskites. We discuss approaches to exploit such interactions alongside our perspective on the interplay between stability and disorder in these complex mixtures.

11:15 AM QT01.08.03

Magnetism in Low-Dimensional Organic-Metal Halide Hybrids *Md Sazedul Islam[1], Andrew Comstock[2], Zhenqi Hua[1], Puja Thapa[2], Yufang He[1], Azza Ben-Akacha[1], He Liu[1], Tarannuma F. Manny[1], Jarek Viera[1], Xinsong Lin[1], Bin Ouyang[1], Dali Sun[2], Peng Xiong[1] and Biwu Ma[1]; [1]Florida State University, United States; [2]North Carolina State University, United States*

Low-dimensional (LD) organic-metal halide hybrids (OMHHs) have recently emerged as new generation functional materials with exceptional structural and property tunability. Despite the remarkable advances in the development of LD OMHHs, optical properties have been the major functionality extensively investigated for most of LD OMHHs developed to date, while other properties, such as magnetic and electronic properties, remain significantly under-explored. Here, we report the studies of the magnetic and electronic properties of a series LD OMHHs, which exhibit distinct characteristics depending on the structures. For instance, zero-dimensional (0D) $(C_{24}H_{20}P)_2MnCl_4$, $(C_{24}H_{20}P)_2FeCl_4$, $(C_{24}H_{20}P)_2CoCl_4$, and $(C_{24}H_{20}P)_2CuCl_4$ hybrids are found to exhibit paramagnetic behavior, while one-dimensional (1D) $(C_8H_{22}N_2)Cu_2Cl_6$ displaying antiferromagnetic ordering with a Néel temperature of 24K, owing to the antiferromagnetic coupling between Cu atoms through chloride bridges in 1D $[Cu_2Cl_6^{2-}]_\infty$ chains. The arrangements of spins in 1D $(C_8H_{22}N_2)Cu_2Cl_6$ are confirmed by DFT calculations which reveals that the lowest energy structure contains Cu atoms with spins oriented anti-parallel to each other within the chain. The two-terminal (2T) electrical measurement on a $(C_8H_{22}N_2)Cu_2Cl_6$ single crystal confirms its insulating nature. This work shows once again the exceptional tunability of LD OMHHs, which could serve as a highly promising tunable quantum material platform for spintronics.

11:30 AM *QT01.08.04

Synthesis and Spectroscopy of Ferromagnetic 2D Chromium-Halide Perovskites, A_2CrX_4 Daniel R. Gamelin; *University of Washington, United States*

This talk will describe our group's recent progress in the development of new forms of chromium-based two-dimensional magnetic perovskites, A_2CrX_4 (A = monovalent cation, X = halide). Most prior work on A_2CrX_4 compounds was performed before the relatively recent renaissance of hybrid lead-based 2D perovskites, motivating further investigation into their chemistry and properties. We have synthesized large crystals of the new hybrid compound, $(PEA)_2CrCl_4$, via an antisolvent vapor-diffusion method. The structure of $(PEA)_2CrCl_4$ shows sheets of distorted $[CrCl_6]^{4-}$ octahedra spaced by PEA bilayers with a van der Waals gap between them, and we demonstrate that these crystals can be mechanically exfoliated down to single monolayers with micron lateral dimensions. In stark contrast with other known A_2CrCl_4 compounds, which are extremely hygroscopic and unstable toward oxidation, $(PEA)_2CrCl_4$ is found to be stable in air for many days, even after exfoliation. Magnetic measurements show in-plane ferromagnetic ordering, and electronic absorption measurements allow 2D spin correlations at zero field to be monitored via the evolution of Cr^{2+} spin-flip excitations. These and related findings will be presented.

1:30 PM *QT01.09.01

Spin-Optotronic Properties of Solids from Ab-Initio Density-Matrix Dynamics Yuan Ping *and Andrew C. Grieder; University of Wisconsin-Madison, United States*

Ab initio spin dynamics and transport simulations are critical for predicting new materials and realizing the potential of spintronics, spin-based quantum information science, and spin-selective photo-chemistry. In particular, simulations would be invaluable to predict key physical parameters including spin lifetime, spin diffusion and coherence length, magneto-optical spectra, and (spin)-photocurrent.

In this talk we will introduce our recently developed real-time density-matrix dynamics approach with first-principles electron-electron, electron-phonon, electron-impurity scatterings and self-consistent spin-orbit coupling, which can accurately predict spin and carrier lifetime, spin diffusion length, and pump-probe Kerr-rotation signatures for general solids, with examples of Si, GaAs, 2D materials, and halide perovskites[1-5]. We will show recent study of how g factor fluctuations lead to spin dephasing in halide perovskites under external magnetic field and their distinct electron-phonon contribution to spin and carrier relaxations[6]. We next will introduce our recent progress of developing methodology for spin-optotronic signatures, such as circular dichroism and circular/spin photogalvanic effect to chiral and broken-inversion-symmetry solids[7]. Importantly, with our real-time density matrix dynamics, we can explicitly include excitation, scattering, simulated and spontaneous emission processes from ab-initio calculations, at presence of electron-electron, electron-phonon, electron-impurity interactions. Such formalism describes complete kinetic processes and can be potentially applied to computing various transient and steady-state photocurrents or nonlinear optics[4].

Light-Induced Kondo-Like Spin-Spin Interaction in 4f Doped Hybrid Perovskites Semiconductors *Tao Xu; Northern Illinois University, United States*

Tuning the spin entangled electron and hole in a light-generated exciton is a fundamentally intriguing query for quantum science. Taking the advantage of easy doping nature of semiconducting hybrid perovskite, we discover that Nd2+-doped CH3NH3PbI3 (MAPbI3) perovskite exhibits a Kondo-like exciton-spin interaction under cryogenic and photoexcitation conditions. The feedback to such interaction between excitons in perovskite and the localized spins in Nd2+ is read out as notably prolonged carrier lifetimes measured by time-resolved photoluminescence, ~10 times to that of pristine MAPbI3 without Nd2+ dopant. From a mechanistic standpoint, such extended charge separation states are the consequence of the antiparalell exchange interaction between the light-induced exciton and the localized 4f spins of the Nd2+ in the proximity, as evidenced by scanning tunneling microscopy. Importantly, this Kondo-like exciton-spin interaction can be modulated by either increasing Nd2+ doping concentration that enhances the coupling between the exciton and Nd2+ 4f spins as evidenced by elongated carrier lifetime, or by using an external magnetic field that can nullify the spin-dependent exchange interaction therein due to the unified orientations of Nd2+ spin angular momentum, thereby leading to exciton recombination at the dynamics comparable to pristine MAPbI3.

2:15 PM QT01.09.03
Enhancing Carrier Mobility in Chiral One-Dimensional Perovskites with Strong Chirality Through Molecular Design of Naphthalenediimide Cations *Xiaoyu Zhang, Yuanze Xu, Shripathi Ramakrishnan, Adewale J. Babatunde and Qiuming Yu; Cornell University, United States*

Chiral hybrid organic-inorganic perovskites have emerged as promising materials for spin-optoelectronic and spintronic devices owing to their excellent spin-polarization properties. By incorporating relatively large chiral organic cations, chiral perovskites can be extended to low-dimensional crystalline phases, bringing unique electronic structures that arise from quantum confinement effects and structural distortions. Compared to chiral two-dimensional (2D) perovskites, chiral one-dimensional (1D) perovskites exhibit stronger octahedral distortion, less orbital overlap, and greater quantum confinement, resulting in higher chirality, larger band gap, but lower charge transport ability. Therefore, designing chiral cations with excellent charge transport ability and strong chirality is highly desired for chiral 1D perovskites. Here, we present a molecular design strategy that utilizes the n-type semiconducting material naphthalenediimide (NDI) as the core of the chiral cations to enhance charge transport while maintaining the strong chirality of chiral 1D perovskites. We synthesized chiral NDI-based cations, *namely R-NDIEPAI, by introducing R-propane-1,2-diamine, ethylamine, and iodide ion to the NDI core. The R-NDIEPAI thin film shows a strong absorption peak between 350 - 400 nm (corresponding to the optical band gap of 3.54 - 3.10 eV) and a strong positive CD signal (~3200 mdeg) at 400 nm, indicating the R- chirality is carried to R-NDIEPAI. Moreover, the R-NDIEPAI thin films demonstrate a high degree of crystalline order, characterized by (h00) lamellar peaks in the out-of-plane direction ($d_{(100)}$= 19.6 Å) and the (010) π–π stacking peak in the in-plane direction ($d_{(010)}$= 4.65 Å). The corresponding 1D chiral perovskite (R-NDIEPA)PbI_3 thin films annealed at 200 °C show a strong exciton peak at 410 nm, which is comparable to conventional 1D perovskites. Importantly, the CD spectrum shows a CD signal of ~450 mdge corresponding to the exciton peak, demonstrating that the chirality is transferred from the R-NDIEPA$^+$ cations into the 1D inorganic chains. Based on the HOMO and LUMO levels of R-NDIEPA$^+$ determined by cyclic voltammetry, the (R-NDIEPA)PbI_3 exhibits a type II band energy alignment. This type II band energy alignment between the organic and inorganic motifs results in a significant quenching of the photoluminescence of (R-NDIEPA)PbI_3 compared to that of R-NDIEPAI thin films, indicating an efficient charge separation at the interface of the $[PbI_6]^{4-}$ inorganic chain and the R-NDIEPA$^+$ organic layer. The carrier mobility of 1D chiral (R-NDIEPA)PbI_3 perovskites will be studied through the space charge-limited current measurement of hole-only and electron-only devices to futher investigate their electronic properties.*

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

SESSION QT01.10: Spin Control III

Wednesday Afternoon, December 4, 2024
Sheraton, Fifth Floor, Jamaica Pond

3:30 PM *QT01.10.01
***Chiral Hybrid Perovskite Spintronics** Dali Sun; North Carolina State University, United States*

Researchers have shown that hybrid organic-inorganic perovskites (or organometal trihalide perovskites) are not only aimed to be used in solar cell applications but also pursue a vast variety of fundamental research directions. In this talk, we will discuss the spin-optoelectronic properties of solution-processed chiral hybrid perovskites and their fundamental spin-dependent physical behavior in hybrid antiferromagnets. (i) We will show that the Dzyaloshinskii–Moriya-Interaction (DMI), a chiral antisymmetric exchange interaction that occurs in emergent magnetic systems with low symmetry, can be presented in layered magnetic hybrid perovskites of which the metal site, Pb is replaced by Cu. We show that layered Cu-based hybrid perovskite antiferromagnets with an interlayer DMI will lead to a strong intrinsic magnon-magnon coupling strength up to 0.24 GHz, which is four times greater than the dissipation rates of the acoustic/optical magnonic modes. (ii) We will show the observation of spintronic-Terahertz (THz) radiation in layered chiral hybrid perovskites interfaced with a ferromagnetic metal, produced by ultrafast spin current under femtosecond laser excitation. The generated THz radiation reverses its polarity depending on the chirality due to the formation of transient electric dipoles along the chiral axis produced via the chirality-induced spin selectivity effect. Our work demonstrates the great potential of hybrid perovskite-based spintronic applications by harnessing broken mirror symmetry in a highly tunable, solution-processable material platform.

4:00 PM QT01.10.02
***Intrinsic Ion Migration Dynamics in a One-Dimensional Organic Metal Halide Hybrid** Zhenqi Hua[1], Azza Ben-*

Akacha[1], Qingquan He[1,2], Tianhan Liu[1,3], Gillian Boyce[1], Margaret v. Deventor[1], Xinsong Lin[1], Hanwei Gao[1], Biwu Ma[1] and Peng Xiong[1]; [1]Florida State University, United States; [2]Zhejiang University of Technology, China; [3]University of California, Los Angeles, United States

Metal halide perovskites possess many physical properties amenable to optoelectronic applications, but the realization of these potentials has been hampered by their environmental and electronic instabilities. The morphological and molecular low-dimensional perovskites and perovskite-related materials have shown much promise in enhancing the chemical stability due to their unique molecular structures. Here we report on robust and reproducible four-terminal (4T) electrical measurements in a one-dimensional (1D) organic metal halide hybrid, (R)-α-methylbenzylammonium lead triiodide ((R-α-MBA)PbI_3), made possible by its chemical stability. The results reveal a distinct single exponential intrinsic ion migration dynamic, which underlies the unique 4T I–V characteristics. The dynamic is directly verified by real-time measurements of the transient ionic current. Our observations are consistent with photoactivation and field-assisted ion migration. The elucidated intrinsic ion dynamics may provide the physical basis for understanding and modeling the ubiquitous hysteresis in metal halides-based electronic devices and new insights into the dynamics of ion migration in metal halide perovskites and hybrids in general.

4:15 PM QT01.10.03
Large Area Spin Polarization Measurements of Chiral Metal Halide Perovskites *Manchen Hu, Pournima Narayanan, Sebastian Fernandez, Arynn O. Gallegos and Daniel Congreve; Stanford University, United States*

Chiral metal halide perovskites (MHPs) have emerged as promising materials for spin-related applications due to their unique chiral-induced spin selectivity (CISS) effect. Numerous studies have employed electrical methods to measure spin transport through perovskites using atomic force microscopy (AFM). However, AFM provides local measurements that do not represent large-area films, which are crucial for devices like spin light-emitting diodes (spin-LEDs) and spin lasers. In this study, we develop a large-area method to quantify the spin polarization of perovskite films. By addressing this gap, our method offers an accurate assessment of spin polarization in practical device applications, paving the way for improved performance of perovskite-based spintronic devices.

4:30 PM QT01.10.04
Chirality Transfer and Chirality-Induced Spin Selectivity in Metal Halide Semiconductors *Md Azimul Haque[1], Joseph Luther[1], Dali Sun[2] and Matthew C. Beard[1]; [1]National Renewable Energy Laboratory, United States; [2]North Carolina State University, United States*

Hybrid organic-inorganic halide perovskites are intriguing chiral material systems owing to their excellent and tunable optoelectronic properties. Typically, chiroptical properties arise due to structural symmetry breaking from chiral A-site organic cation to the inorganic framework. Here, we demonstrate a proximity effect of remote chirality transfer to induce chirality in otherwise achiral 2D halide perovskites. Chirality-induced spin selectivity (CISS) effect is employed to electronically measure the effect of chirality on magnetoresistance (MR) of halide perovskites using spin valves. The spin polarization in chiral perovskites is as high as over 90%, but the efficiency of the spin valves using chiral perovskites is low, with MR values lower than 2%. Addressing the factors contributing to the low performance in spin valves using the CISS effect leads to a significant increase in MR.

4:45 PM QT01.10.05
Ultrafast Non-Equilibrium Electron and Spin Dynamics in Perovskite Nanocrystals *Linjie Dai[1,2] and Neil Greenham[2]; [1]Massachusetts Institute of Technology, United States; [2]University of Cambridge, United Kingdom*

Understanding and control of ultrafast non-equilibrium processes in semiconductors is crucial for making use of quantum states, opening opportunities to surpass traditional limits in optoelectronic devices for energy harvesting, light emission, and quantum technologies. In this paper, we first demonstrate our work in slowing down hot carrier relaxation through strategies involving electronic structure management, phonon structure management, and decoupling carriers from defects. These approaches effectively engineer carrier-phonon, phonon-phonon, and carrier-carrier (defect) interactions. Subsequently, we demonstrate the alignment of the transition dipole moment in self-assembled nanoplatelets, resulting in polarised electroluminescence with a high degree of polarization comparable to single nanocrystals.

First of all, we introduce new perovskite nanocrystals, formamidinium tin iodide nanocrystals (FASnI3 NCs), where quantum confinement significantly influences the electronic structure. The evolution in electronic structure from a continuous band structure to separate energy states is directly observed with decreasing nanocrystal size. The appearance of separate energy levels slows down the cooling of hot carriers by two orders of magnitude at low injected carrier densities. We attribute the slowed carrier cooling to a phonon bottleneck effect, where the discrete energy level structure effectively suppresses carrier cooling by optical phonon emission, leading to significant enhancement in cooling time. Importantly, this slow cooling is observed in the limit of low-intensity illumination, making it practically relevant. In addition to manipulating the electronic band structure, we demonstrate the management of the phonon band structure by introducing tin into lead halide perovskites. Increasing the tin content leads to screened Fröhlich interaction, suppressed Klemens decay, and reduced thermal conductivity (acoustic phonon transport), contributing to slowed relaxation mediated by the hot phonon bottleneck effect. To further control ultrafast non-equilibrium processes on a timescale of tens to hundreds of femtoseconds, we decouple hot carriers from sub-bandgap defects via sodium doping, resulting in a decreased energy loss rate during the thermalisation process. The control over non-equilibrium electron dynamics we achieved offers new insights into the intrinsic photophysics of perovskite nanocrystals, with direct implications for hot carrier solar cells.

In addition to adjusting the electronic and phonon structures, we also achieve the modulation of exciton fine structure, along with the precise alignment of the transition dipole moment in self-assembled nanoplatelets. This results in a substantial number of excitons recombining at a specific energy level within the triplet manifold with minimal relaxation to other triplet states, leading to polarised electroluminescence with a high degree of polarisation approaching that of single nanocrystals. Our approach addresses the critical challenge of translating the high degree of polarisation found in photo-excited individual nanocrystals to an electrically driven film level, opening up a new frontier for enabling spin-related technologies through precise control of dynamics at the fine-structure level.

Topological Spin Structures & Spin-Orbitronics in 2D—From van der Waals Systems to Multilayers *Mathias Klaeui; Johannes Gutenberg University of Mainz, Germany*

Novel spintronic devices can play a role in the quest for GreenIT if they are stable and can transport and manipulate spin with low power. Devices have been proposed, where switching by energy-efficient approaches is used to manipulate topological spin structures that are stable in multilayers [1] but also in 2D van der Waals systems [2].
We combine ultimate stability of topological states due to chiral interactions [3,4] with ultra-efficient manipulation using novel spin torques [3-5]. In particular orbital torques [6] increase the switching efficiency by more than a factor 10. Going towards 2D van der Waals systems, we explore bulk spin – orbit torques resulting from the particular symmetry [7]. In such 2D heterostructures of ferromagnets and antiferromagnets, also enhanced exchange bias is observed allowing one to control the switching [8].
Finally, we use skyrmion dynamics for non-conventional stochastic computing applications, where we developed skyrmion reshuffler devices [9] based on skyrmion diffusion, which also reveals the origin of skyrmion pinning [10]. Such diffusion can furthermore be used for Token-based Brownian Computing and Reservoir Computing [11].

Low Power and Scalable Digital Skyrmion Logic Circuits Based on Synthetic Antiferromagnetically Coupled Skyrmions *Rawana Yagan[1], Arash Mousavi Cheghabouri[2], Ahmet Bahadir Trabzon[2] and Mehmet C. Onbasli[1,1]; [1]Koç University, Turkey; [2]Boğaziçi University, Turkey*

Skyrmion-based logic gates and circuits provide an advantageous combination of non-volatility and high-density operations compared to standard CMOS-based logic device technologies. Skyrmions are magnetic nanoscale structures that are protected by topology in various ferromagnetic (FM) systems. Nevertheless, in these systems, skyrmions are negatively impacted by the transverse motion resulting from the skyrmion Hall effect (SkHE). This motion hinders their performance in longitudinal nano tracks and prevents their application in cascadable logic circuits. Building upon our previous research on scalable FM skyrmion logic gates [1], we present a study focused on low-energy logic gates that utilize skyrmions in ferromagnetic interfaces. These interfaces are synthetic antiferromagnetically (SAF) coupled, which helps to stabilize the skyrmions and remove the SkHE (Skyrmion Hall Effect). The work employs micromagnetic models to create and showcase SAF skyrmion logic gates and circuits that rely on interactions between current-driven skyrmions and skyrmion-domain walls. Skyrmions have undergone thorough investigation and have been successfully stabilized in SAF layers, exhibiting dynamics free from SkHE. We first present the SAF skyrmion logic inverter gate's operation and show that it performs better than its FM skyrmion gate counterpart [1]. We maintained a switching time of 7 ns that was comparable to that of the FM counterpart while operating the inverter block with lower current density magnitudes. Subsequently, this is evident in the Joule heating, which is substantially reduced from approximately 10^{-14} J in the FM case to approximately 10^{-18} J. Next, we employ the inverter gate block to construct logic circuits, which include NOR, OR, AND, and NAND. We compare and evaluate the energy consumption and performance of SAF skyrmion logic gates at various stages with those of FM logic gates. We have shown that the SAF gates can operate at lower current densities, which is expected to result in a significant decrease in Joule heating costs. Ultimately, these gates demonstrate scalability, cascadability, and stability in the absence of SkHE, even when utilizing a more intricate design, such as the multiplexer circuit. The SAF skyrmion circuits can achieve higher performance metrics, reduced energy consumption, and low drive current densities with high skyrmion velocity in comparison to the FM skyrmion circuits. Our results have the potential to facilitate the development of spintronic computing devices that are both energy-efficient and fast, and that employ nanoscale skyrmions as information carriers.

Enhanced Stabilization and Dynamic De-Pinning of Spin Textures by Exchange Bias Muhammad Usama

Hasan[1,2], Siying Huang[1] and Geoffrey Beach[1]; [1]Massachusetts Institute of Technology, United States; [2]Bangladesh University of Engineering and Technology, Bangladesh

Devices using electron spin are being explored for next-gen data storage and logic applications. A promising approach involves using spin textures like domain walls or skyrmions as bits in racetrack-based devices, which are moved using current, offering advantages such as high speed, low energy consumption and high density. Significant progress has been made in perpendicularly magnetized heterostructures, where nanoscale chiral spin textures are stabilized by interfacial spin–orbit coupling and driven by spin–orbit torques (SOTs) from a heavy metal layer.

In addition to achieving small bits that can be moved at high speeds, a long-standing challenge in racetrack device research has been minimizing pinning, which sets the currents required for displacement. However, when pinning is reduced, thermal energy alone is sufficient to drive spin textures from their nominal resting place, adversely affecting device operation. This is the basis of a general tradeoff between stability and writability and is akin to the similar phenomenon in hard drive storage and MRAM: the anisotropy barrier must be high to ensure thermal stability, but low to allow for low-power writing. Although a lot of work has been done to understand and develop material systems such as ferrimagnets or synthetic antiferromagnets that can host nanoscale spin textures and allow for ultra-fast movement of them, the basic tradeoff between stability and writability remains in all these systems.

In this work, we present a novel approach to address the stability/writability tradeoff by incorporating an exchange biasing antiferromagnet (AFM) layer into the racetrack. The AFM is tuned so that its blocking temperature is above the device's nominal standby temperature but below the temperature reached during current pulse injection for moving spin textures at device relevant speeds. In this design, an injected current pulse deactivates the exchange bias, allowing the spin textures to move freely while after the write current pulse, a field-cooling effect imprints the spin texture onto the AFM, creating a strong pinning component independent of the disorder-induced pinning potential of the FM. We show that current pulses as short as ~2 ns can induce this effect in Pt/Co heterostructures with CoNiO as the AFM. Our experiments confirm this strategy's effectiveness for both domain walls and bubble skyrmions, providing additional stability in the standby state while maintaining dynamic behavior and achieving domain wall motion up to ~90 m/s. Our findings establish exchange biasing as a promising method to overcome the stability/writability tradeoff in racetrack devices, applicable to any spin texture hosting heterostructure.

Strain-Tuned Skyrmions—Revolutionizing Next-Generation Spintronics and Memory *Tanvir Sohail and Swarnava Ghosh; Oak Ridge National Laboratory, United States*

Traditional electronic devices, plagued by high volatility, increased power consumption, and slow speeds, have driven the exploration of topological magnetic defects—such as monopoles, domain walls, vortices, and skyrmions—as potential candidates for future spintronic applications. Among these, skyrmions, induced by chiral interactions in non-centrosymmetric magnetic compounds or thin films, stand out for their exceptional promise. These nanoscale structures, capable of being manipulated, created, and annihilated, are ideal for advanced information storage and logic applications. Their soliton nature, stabilized by the Dzyaloshinskii-Moriya interaction (DMI), allows for size manipulation, leading to higher information density compared to other topological defects. Our study presents a comprehensive numerical micromagnetic analysis of skyrmions in B20 materials, such as FeGe, examining the effects of varying skyrmion core strengths under anisotropic DMI influenced by strain. As strain alters DMI, we can gain a thorough understanding of the interaction between skyrmions and defects in crystals. Furthermore, we investigate the influence of magnetic fields on the energy landscape, offering insights into the design of next-generation memory devices. The application of external magnetic fields, both along the direction of the core and against it, allows us to manipulate skyrmion stability and dynamics. This dual approach of *strain tuning and magnetic field application provides a robust framework for optimizing skyrmion properties for practical use.*

Photo-Thermal Tweezer for Magnetic Skyrmions *Jaeyu Kim[1], Dongha Kim[2], Seungmo Yang[3], Kyoung-Woong Moon[3], Changsoo Kim[3], Chanyong Hwang[3] and Min-Kyo Seo[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Stanford University, United States; [3]Korea Research Institute of Standards and Science, Korea (the Republic of)*

Magnetic skyrmions are localized magnetization swirls with non-zero topological charges. Magnetic skyrmions exhibit interesting topological characteristics such as high stability against external perturbations, or various topological phenomena including the skyrmion Hall effect. Furthermore, their small size, ranging from a few nanometers to microns, and electrical mobility with very low threshold current present strong advantages for their potential use as information carriers in future low-power spintronic devices. However, precise and individual control of skyrmions using electrical manipulations remains challenging. Skyrmions deflect due to the skyrmion Hall effect at high current densities and stochastic motion at low current densities. Achieving local and precise control of topological spin textures is crucial for enhancing the reliability of skyrmionic devices and studying interactions between spin textures based on their topologies.

In this research, we present the photo-thermal tweezer for individual control of magnetic skyrmions. Non-uniform spin configurations in ferromagnetic media possess higher energy compared to a uniform state. In the presence of interfacial Dzyaloshinskii-Moriya interaction (DMI) and perpendicular magnetic anisotropy (PMA), the domain wall energy density can be formulated as $\sigma=4\sqrt{(AK_{eff})}-\pi D+(\ln 2/\pi)\,\mu_0 M_s^2 d$*, where A is exchange stiffness,* K_{eff} *is PMA energy density per volume, D is DMI energy density per surface, and* M_s *is the saturation magnetization. These magnetic coefficients decrease monotonically with increasing temperature, reducing the total energy density. Consequently, a locally nonuniform temperature distribution creates a potential energy landscape drifting the adjacent spin textures toward the local energy minima. Using photo-thermal effect from focused laser, we can create a micron-scale hot spot which acts as a potential well. The sharp temperature gradient surrounding the beam spot creates a potential barrier that prevents spin textures from escaping. By moving the beam position, we can pinch and drag local spin textures quickly and efficiently.*

We used MgO (1 nm) / Ta (0.1 nm) / CoFeB (1.2 nm) / W (3 nm) / TaO_x *(3 nm) stack on a* Si/SiO_2 *wafer. The deposited sample was subjected to post-baking process for 1 hour at 350 under Torr vacuum. Real-time magnetization states were measured using a magneto-optical Kerr effect microscopy setup. Local photo-thermal heating was induced by a focused continuous-wave 638-nm laser. A piezo-electric motor moves the sample, allowing the focused beam to sweep across it. The laser beam is focused onto a magnetic skyrmions, and the sample is moved along in one direction. The skyrmion got trapped within beam spot and dragged along the sweep direction. With this photo-thermal tweezer, we could capture and arrange the skyrmions into arbitrary patterns. Furthermore, we also have demonstrated the photo-thermal trapping of a single skyrmion under external electrical current. Our findings suggest that this photo-thermal approach holds great potential for realizing novel skyrmionic devices and advancing our understanding of interaction between skyrmions.*

2D Van der Waals Layers for Spintronics *Stuart S. Parkin; Max Planck Institute of Microstructure Physics, Germany*

Van der Waals layers for spintronic phenomena are highly interesting. We discuss all-antiferromagnetic tunnel junctions that are formed from bilayers of the van der Waals antiferromagnetic CrSBr that are twisted at angles ranging between 0 and 90 degrees. Each CrSBr layer is ferromagnetic with a strong in-plane magnetic anisotropy that results from its low symmetry. In the bulk the interlayer coupling between the CrSBr ferromagnetic layers is antiferromagnetic (AF) but twisting diminishes this interaction considerably so that we show that a device formed from two AF bilayers exhibits two non-volatile states in zero magnetic field with a giant tunnelling magnetoresistance exceeding ~700%. Nevertheless, each bilayer thus has no net magnetization, a necessity for applications where stray magnetic fields otherwise result in interactions within and between nanoscopic magnets. We show from theoretical modelling that the origin of the tunnelling magnetoresistance is via the accumulated k-dependent transmission through the individual semiconducting CrSrBr layers which depends on the twist angle[1].

We also discuss superconducting proximity effects in non-superconducting van der Waals layers from adjacent superconducting van der Waals layers [2]. We show that vertical Josephson junctions formed from WTe$_2$ *show a Josephson Diode effect with a large non-reciprocity in the critical supercurrent when a small magnetic field is applied perpendicular to the supercurrent within the plane of the* WTe$_2$ *flake. The diode effect strongly depends on the orientation of the magnetic field within the plane of the* WTe$_2$ *with respect to the crystal structure of the* WTe$_2$*. These results clearly indicate that the Josephson diode effect has an intrinsic origin. Such an effect could have important applications as a novel magnetic field detector at cryogenic temperatures, for example, to “read” magnetic domain walls in a cryogenic racetrack memory*[*]*.*

Proximity-Induced Phenomena in Designer van der Waals Heterostructures *Josef Svetlik[1,2], Williams Savero Torres[1], Lorenzo Camosi[1], Franz Herling[1], Thomas Guillet[1], Kai Xu[2], Juan S. Reparaz[2], Vera Marinova[3], Dimitre Dimitrov[3,4], J.F. Sierra[1] and Sergio O. Valenzuela[1,5]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]Universitat Autònoma de Barcelona, Spain; [3]Institute of Optical Materials and Technologies, Bulgaria; [4]ISSP, Bulgaria; [5]ICREA, Spain*

The atomically thin nature of 2D materials opens exciting possibilities for designing van der Waals heterostructures through proximity effects arising from short-range interactions [1]. These heterostructures offer a versatile platform for customizing electrical, magnetic, optical, and spin transport properties, making them highly suitable for advanced spintronic applications [1,2]. The interplay between thin layers of magnetic and non-magnetic materials at their interfaces is particularly crucial for these functionalities. For example, hexagonal transition metal dichalcogenides such as WS$_2$ *can induce valley-Zeeman spin-orbit coupling (SOC) in graphene, leading to spin* *lifetime anisotropy between in-plane and out-of-plane spin orientations [3] and spin Hall and inverse spin galvanic effects [4]. However, the inherent threefold symmetry of these materials often results in isotropic in-plane spin dynamics [5].*

In our recent work, we demonstrate that low-symmetry heterostructures can induce unprecedented gate-tunable SOC in graphene, leading to remarkable modulation of the spin lifetime for in-plane spins at room temperature [6]. Such heterostructures also enable the generation of unconventional charge-to-spin conversion components [7].

In this presentation, I will discuss our approach to demonstrate proximity effects through spin transport dynamics, with a focus on spin relaxation anisotropy and charge-to-spin interconversion [8,9]. I will highlight the crucial role of crystal symmetry and how reduced-symmetry systems can lead to unconventional spin-orbit fields that influence these phenomena, providing new insights into the design and engineering of next-generation spintronic devices.

2D Quantum Materials for Spin-Based Logic and Memory Devices *Saroj P. Dash; Chalmers University of Technology, Sweden*

Two-dimensional (2D) materials represent a new platform for realizing novel quantum and spin-based phenomena and device applications. Engineering 2D heterostructures by combining the best of different materials in one ultimate unit can offer a plethora of opportunities in condensed matter physics. While materials such as graphene are suitable for spin-polarized electron transport, magnets and materials with topological spin textures are useful for spin-polarized electron sources. We utilized large-area CVD graphene for spin interconnect and realized multifunctional spin logic operations at room temperature [1,2]. To generate spin polarization and their electrical control, we engineered 2D material heterostructures by combining the 2D semiconductors [3], topological

insulators [4,5] and magnetic materials [6] with graphene to realize strong proximity-induced spin-orbit coupling and magnetism in graphene.
Furthermore, nontrivial topology in the electronic band structure of quantum materials also makes them potential candidates for emerging technologies. We showed that their unique band structure and lower crystal symmetries can provide an unconventional spin polarized current [7] and out-of-plane spin-orbit torque [8] needed for field free magnetization switching. The out-of-plane spin Hall conductivity in such 2D quantum materials are estimated to be an order of magnitude higher than the conventional materials.
Finally, 2D magnets are promising owing to their tunable magnetic properties with gating and doping, where the strength of magnetic interactions can be tuned according to the desired applications. However, most of the 2D magnet based spintronic devices are mostly limited to cryogenic temperatures. We reported above room temperature van der Waals magnet-based spin-valve [9,10] and spin-orbit torque memory [11] devices. In the latter case, we could demonstrate field-free magnetization switching utilizing the co-existence of ferromagnetic and anti-ferromagnetic orders with intrinsic exchange bias in the system giving rise to a canted magnetism. These findings open a new platform for realizing devices using all-2D heterostructure devices.

9:00 AM *QT02.03.02
***Spintronics with Ferrimagnetic and Antiferromagnetic Insulators** Andrew D. Kent; New York University, United States*

The discovery that electric currents can excite spin waves and reverse the magnetization of a magnetic material by transporting spin angular momentum has had a significant impact on magnetism research and technology [1,2]. While the initial focus of the field was on ferromagnetic materials and magnetic tunnel junctions, new research opportunities are with materials and nanostructures with different types of magnetic order, electronic structure and geometries. In this talk, I will provide an overview of my group's experiments investigating current-induced excitation and reorientation of the Néel vector in antiferromagnetic materials, including experiments in my group on hematite (a-Fe_2O_3) thin films [3-5]. I will also discuss a means of quantifying spin torques in antiferromagnetic thin films using the harmonic Hall effect, which makes it possible to determine the form and magnitude of the spin torques that act on the Néel vector [4,5]. Further, I will discuss a new type of spin Hall nanooscillator based on hybrid magnetic nanostructures, specifically ferromagnetic metal/ferrimagnetic insulator heterostructures and permalloy/epitaxial lithium aluminum ferrite [6]. These heterostructures are particularly interesting due to the very low damping of the ferrimagnetic insulators, which enables the excitation of spin waves at lower currents and oscillators with higher output power and quality factors. This new type of spin Hall nanooscillator has potential applications in neuromorphic computing by enabling electrically isolated oscillators to communicate through spin waves in an extended insulating ferrimagnetic film.

10:00 AM QT02.03.03
Evolution of Antiferromagnetic Spin Texture and Magnon Transport in MBE-Grown Epitaxial Multiferroic BiFeO3 *Maya Ramesh[1], Peter Meisenheimer[2], Isaac Harris[2], Sajid Husain[2], Xinyan Li[3], Sherry Zhou[4], Arundhati Ghosal[4], Zhi Yao[5], Paul Stevenson[6], Lucas Caretta[4], R Ramesh[3,2] and Darrell Schlom[1,7,8]; [1]Cornell University, United States; [2]University of California, Berkeley, United States; [3]Rice University, United States; [4]Brown University, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]Northeastern University, United States; [7]Kavli Institute for Nanoscale Science, United States; [8]Leibniz-Institut für Kristallzüchtung, Germany*

Bismuth ferrite (BiFeO3) is a lead-free magnetoelectric multiferroic with antiferromagnetic order and a large spontaneous polarization at room temperature. This antiferromagnetic order in BiFeO3 is complex, where, as a consequence of the Dzyaloshinskii-Moriya interaction (DMI), a small canting of the antiferromagnetic order forms a chiral spin cycloid. Understanding the interplay between the ferroelectric polarization and the spin cycloid, as well as its electric field manipulation, is of significant interest for antiferromagnetic spintronics and next generation computation. There is still much to learn about BiFeO3's intrinsic antiferromagnetic structure in thin films, where epitaxial strain imposed by an underlying substrate can influence the spin texture. As a model system, we have synthesized epitaxial thin films (2-100 nm) of BiFeO3 on (110) TbScO3 substrates via oxide molecular-beam epitaxy (MBE). This allows us to look at BiFeO3 thin films with an unparalleled structural quality where even small amounts of strain (0.1% in the case of TbScO3) can have a large impact on the spin texture. In this work, we explore how the interplay between epitaxial strain from the substrate and elastic energy from the 109 degree domains affects the formation and orientation of the spin cycloid in BiFeO3 using scanning nitrogen-vacancy magnetometry as well as spin transport measurements. NV magnetometry uses a nitrogen vacancy implanted at the tip of a diamond cantilever which acts as a single-spin magnetometer to sensitively map nanoscale surface stray fields. Using this method, we have the resolution necessary to image BiFeO3's spin cycloid. Electric-field-dependent spin transport shows that the spin cycloid is of critical importance to spin transport in BiFeO3 and can be manipulated by switching the ferroelectric polarization, which is of great interest in low dissipation magnonic devices. We find that reducing the film thickness from 100 nm to 30 nm changes the propagation direction of the spin cycloid from perpendicular to parallel to the 109 degree domains. As we further decrease the film thickness to 15 nm, we find that the spin cycloid is no longer coherent and any further decrease leads to an absence of the spin cycloid.

Combining Superconductivity, Wide Bandgaps and Magnetism in Epitaxial Cubic Nitride Heterostructures

Brelon J. May[1], Zach Cresswell[1,2], Sabin Regmi[1], Volodymyr Buturlim[1], Kevin D. Vallejo[1], David Hurley[1] and Krzysztof Gofryk[1]; [1]Idaho National Laboratory, United States; [2]University of Minnesota Twin Cities, United States

Group III-Nitride materials have found applications in optoelectronics and photonic devices. Recent research has pursued the integration of this well-established material system with transition-metal nitrides to create complex heterostructures with additional magnetic or superconducting functionality. The thermodynamically stable wurtzite phase of group III-Nitrides is ubiquitous in the optoelectronics industry due to the large variation in direct bandgap which can be tuned from the infrared to the deep ultraviolet. The wurtzite phase of GaN has a direct bandgap of 3.4 eV, can be made both n-type or p-type, and imbued with room temperature ferromagnetism when doped with transition metals. The III-N family also has a metastable zinc blende allotrope which is much less explored; the bandgap of cubic-GaN is reduced to 3.2eV but remains direct. Unlike the wurtzite phase, cubic-GaN is centrosymmetric and therefore does not have issues with polarization, and the higher symmetry simplifies interfacing with the other cubic materials. The rocksalt structured transition metal nitrides are of interest for applications requiring high chemical and thermal stability, high hardness, superconductivity, or plasmonics. ZrN and NbN are well-known refractory superconductors with critical temperatures of 10K and 16K, respectively. Additionally, the similar lattice constant of cubic GaN (4.50Å) with ZrN (4.58Å) and NbN (4.44Å) results in an estimated lattice mismatch of the metal nitrides of only -1.4%, and +1.4%, respectively, suggesting the possibility of epitaxial and strain-tunable growth.

This work will discuss the molecular beam epitaxy synthesis of cubic-GaN and the additiona of magnetic transition metal elements. The primary focus will be on the epitaxial integration of cubic-GaN with known superconducting nitrides. The hexagonal-free nature of the GaN and epitaxial relationship with the transition metal nitrides are confirmed via in-situ reflection high energy electron diffraction, ex-situ X-ray diffraction, photoluminescence, and transition electron microscopy. Electrical transport and optical properties of transition metal nitrides deposited directly on 3C-SiC(001), cubic-GaN(001), and wurtzite GaN (0001) substrates are compared. The growth windows for GaN and some metal nitrides are close, which allows for deposition of epitaxial metal-dielectric heterostructures with sharp interface control. Epitaxial synthesis of a cubic wide-bandgap material with tunable magnetic functionality and superconducting metallic nitrides opens a new world of possibilities in band engineering, metamaterials, spintronics, and quantum science. This will create an avenue for new device architectures for hierarchical matter by combining materials with dissimilar properties with atomic layer precision.

Magnetization Reversal by Coherent Spin Waves in Hybrid $Ni_{81}Fe_{19}/SiO_2/Y_3Fe_5O_{12}$ Nanostructures

Andrea Mucchietto[1], Korbinian Baumgaertl[2] and Dirk Grundler[2]; [1]Los Alamos National Laboratory, United States; [2]École Polytechnique Fédérale de Lausanne, Switzerland

Using short-wavelength spin waves (SWs) for an all-magnetic approach towards bit writing promise a major advance for in-memory wave-based computing platforms [1]. The first experimental report on the reversal of nanomagnets by travelling coherent SWs addressed mainly the power efficiency of one dipolar SW mode only [2]. Here we investigate the SW wavelength (λ) dependence of the magnetization reversal of individual 20-nm-thick $Ni_{81}Fe_{19}$ (Py) nanostripes integrated onto 113-nm-thick yttrium iron garnet (YIG). An intermediate SiO_2 spacer between the YIG and the Py allows only for dipolar coupling and suppresses both exchange interaction and spin pumping. We observe the nanostripes reversal with SWs having different λ = 7222 nm, 195 nm and 148 nm. The critical power to initiate reversal shows a non-monotonic trend as a function of SW λ. The minimum critical power occurs at the λ matching the nanostripes' periodicity. Our findings additionally prove that this reversal can be *triggered by dipolar coupling between Py/YIG alone. Our results are encouraging towards the fabrication of a future magnetic memory where propagating SWs are writing magnetic bits without conversion to the electrical domain. Our work [3] further foster both materials and device optimisation to achieve a SW-based in-memory computing device.*

The research was supported by the Swiss National Science Foundation via grant number 197360.

Emerging Quantum Spintronics with Semiconductors *Cyrus Zeledon[1], Jonghoon Ahn[2], Connor P. Horn[1], Christina Wicker[1], Nolan Bitner[1,2], Jiefei Zhang[2], Benjamin Pingault[1,2], Supratik Guha[1,2], F. J. Heremans[1,2] and David Awschalom[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States*

Spin-based defects within semiconductors are used to construct devices that enable information processing and sensing technologies based on the quantum nature of electrons and atomic nuclei [1]. These systems have attracted interest as they possess an electronic spin state that can be employed as a quantum bit over a range of temperatures and may be integrated into electronically-active devices. These spin qubit systems have a built-in optical interface that emit in the visible and telecom bands, retain their quantum properties over millisecond timescales or longer, and can be manipulated using a simple combination of light and microwaves. We discuss recent advances in this area including the integration of single spin qubits into silicon carbide (SiC) devices, and significant extension of spin coherence times [2] for scalable technologies.

SiC offers a mature technological platform, clear pathways to device integration, and broad compatibility with CMOS fabrication techniques to address challenges in integration. The neutral divacancy complex (VV0) has been isolated in SiC optoelectronic devices, which results in lifetime limited single-photon emission [3], and present generalized strategies for addressing charge noise sensitivity. We can further improve the fundamental quantum properties of these defects through isotopic engineering of the local nuclear spin environment [4]. Combining all these elements would make divacancy defects in SiC an ideal device integrated platform, with access to both excellent optical properties and long-lived nuclear spin memories.

In addition to exploring the physics of the neutral divacancy (VV0), we are engineering new defect-based spin qubits in SiC. Transition metal ions such as vanadium have host-agnostic orbital structures and operate in the (near) telecom regime [5], and therefore could be naturally integrated into pre-existing telecommunications networks without the need for complicated frequency conversion schemes. With decreasing temperature, we observe a remarkable four-orders-of-magnitude increase in spin relaxation and identify the underlying relaxation mechanisms which involve a two-phonon Orbach process[6]. These results position vanadium as a prime candidate for scalable quantum nodes in future quantum networks.

Finally, we will discuss techniques for the removal and transfer of SiC layers in the tens-of-microns thickness range for heterogenous integration of hybrid quantum systems [7]. By employing new approaches for stressor layer design and crack initiation, we demonstrate controlled spalling of 4H-SiC, the highest fracture toughness material spalled to date. We achieve coherent spin control of neutral divacancy (VV0) qubit ensembles and measure robust spin coherence in the spalled films.

A New Phase of Silicon and a Study of Its Magnetic and Optoelectronic Properties *Naveen Narasimhachar Joshi, Siba Sundar Sahoo, Roger Narayan and Jagdish Narayan; North Carolina State University, United States*

The pursuit of ferromagnetism in materials outside of transition metals and rare earths has excited scientists worldwide for a long time. This is because spin-polarized electrons can be used to process and store information with atomic resolution. However, materials with an even number of electrons such as carbon and silicon without unpaired spins were not considered seriously in terms of bulk ferromagnetism. The dangling bonds in bulk carbon and silicon materials usually reconstruct and eliminate sources of unpaired electrons. However, at the free surfaces of covalently bonded materials, steps and kinks can provide sources of dangling bonds and unpaired spins, which can lead to paramagnetism and ferromagnetism, provided these spins can achieve long-range ordering. Our recent discovery showed the occurrence of robust ferromagnetism in Q-carbon, which consisted of randomly packed diamond tetrahedra. The bonding within the tetrahedra in Q-carbon was determined to be sp^3 with no dangling bonds. However, the bonding between the tetrahedra was a mixture of sp^3 and sp^2 with an overall fraction of about 85% sp^3 and 15% sp^2. Thus, dangling bonds and unpaired spins between the tetrahedra played a critical role in producing robust ferromagnetism in Q-carbon. It should be mentioned that defect-induced intrinsic ferromagnetism has been observed in oxides and nitrides and other related materials with laser annealing, vacuum thermal annealing, and ion implantation. In oxides, such as ZnO, ferromagnetism is related to paramagnetic Zn vacancies, which are coupled through oxygen vacancies for room-temperature ferromagnetism. Herein, we report the outstanding magnetic, and optoelectronic properties in a new phase of silicon (Q-silicon) formed by nanosecond pulsed laser melting and quenching of amorphous silicon. Through detailed structure-property correlations in Q-silicon films, we show that the bonding characteristics in Q-silicon are the same as crystalline silicon, but with a 60% higher atomic density. Consequently, Q-silicon is shown to have a narrow bandgap of 0.6 eV (laser-annealed at 0.3 Jcm^{-2}) with the enhanced density of states near the Fermi level. The isothermal field-dependent magnetization plots confirm room-temperature ferromagnetism in Q-silicon with a finite coercivity of ~ 100 Oe at 300 K, which is characteristic of long-range ferromagnetic ordering. Furthermore, the blocking temperature estimated from the temperature-dependent magnetization plots is greater than 400 K, confirming the robust ferromagnetic interactions in Q-silicon. It should be noted that amorphous silicon before laser annealing shows a diamagnetic behavior, where silicon dangling bonds between tetrahedra are saturated. The tetrahedra in amorphous silicon are not as closely packed as in Q-silicon, resulting in the reconstruction of sp^3 dangling bonds. The Curie temperature of Q-silicon is estimated to be over 500 K, obtained by the extrapolation of fits to experimental data using modified Bloch's law. Thus, the discovery of Q-silicon with exceptional *functionalities opens a new frontier for spin-based computing and atomic-level storage.*

Spin Order and Fluctuations in van der Waals Magnets *Xiaoqin Elaine E. Li; The University of Texas at Austin, United States*

I discuss a few examples of how optical probes are applied to study spin order and fluctuations in van der Waals magnets. First, we discuss magnons measured in two septuple layer (SL) thick $MnBi_2Te_4$ (MBT) via Raman spectra. Although single SL MBT is topologically trivial, two or more SLs present distinct topological phases according to their magnetic order and number of layers. Magnon characteristics evolve as an external magnetic field tunes the ground state through three ordered phases: antiferromagnet, canted antiferromagnet, and ferromagnet. The Raman selection rules are determined by both the crystal symmetry and magnetic order while the magnon energy is determined by different interaction terms. Using non-interacting spin-wave theory, we extract the spin-wave gap at zero magnetic field, an anisotropy energy, and interlayer exchange in bilayers. We also find magnetic fluctuations increase with reduced thickness as expected. Secondly, we discuss sharp exciton resonances in antiferromagnet $NiPS_3$ that have been reported to correlate with magnetic order, i.e., the exciton photoluminescence intensity diminishes above the Neel temperature. Here, we find that the polarization of maximal exciton emission rotates locally, revealing three possible spin chain directions. This discovery establishes a new understanding of the antiferromagnetic order hidden in previous neutron scattering. Our study shows that anisotropic exciton photoluminescence can be used to read out local spin chain directions in antiferromagnets.

2:00 PM *QT02.05.02
Controlling Spins and Magnetization Dynamics of Two-Dimensional Materials Using Ultrashort Laser Pulses
Marcos Guimaraes; University of Groningen, Netherlands

Van der Waals (vdW) materials are ideal systems for the study of spins and magnetism in low dimensions since they maintain their excellent optical, magnetic and electronic properties down to the atomically-thin limit. Because of their low dimensionality, these materials possess another exciting property, they are extremely sensitive to external stimuli, such as light and electric fields.

In this talk, I will show how we can use ultrashort (fs) laser pulses to detect and control spins and magnetization in vdW systems. After a brief introduction to magneto-optics and ultrafast magnetization dynamics, I will present our recent results on the 2D semiconductor MoSe2[1] where we use ultrashort laser pulses to generate a spin accumulation and study its time dynamics which is controlled by an out-of-plane magnetic field.

I will also show examples on how the magnetization of vdW magnets can be similarly manipulated using ultrashort laser pulses, and how their magnetization dynamics can be efficiently controlled by both magnetic and electric fields. I will show how we can control the spin lifetime in the metallic vdW magnet Fe_3GeTe_2 by rotating its magnetization[2], controlling the ultrafast demagnetization dynamics in this material. I will also show how electric *fields can be used to tune the magnetization dynamics in the semiconducting vdW magnet $Cr_2Ge_2Te_6$ [3], and how coherent opto-magnetic phenomena can be used and controlled to manipulate the magnetization of this material in the ultrashort timescales.*

Our studies illustrate the potential of vdW materials for combining optics, spintronics and magnetism, making them appealing for new opto-spintronic and opto-magnetic device architectures for future integrated photonic systems.

Depth-Dependent Magnetic Properties in the Ferromagnetic van der Waals Semiconductor VI_3

Giancarlo Panaccione[1], Alessandro De Vita[2], Roberto Sant[3], Gian Marco Pierantozzi[1], Giovanni Maria Vinai[1], Tai Kong[4], Nicholas B. Brookes[5], Giorgio Rossi[6,1] and Robert J. Cava[7]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Max Planck Society, Germany; [3]Politecnico di Milano, Italy; [4]The University of Arizona, United States; [5]European Synchrotron Radiation Facility, France; [6]Università degli Studi di Milano, Italy; [7]Princeton University, United States

Two-dimensional van der Waals (vdW) magnetic semiconductors display emergent chemical and physical properties arising from both intra-layer and inter-layer interaction, both providing a versatile toolkit for studying quantum phenomena in heterostructures and few layers systems, as well as holding promise for novel quantum spintronic functionalities [1,2].

Among 3d transition-metal vdW, VI_3 has recently attracted significant attention, as due to a) the presence of both structural and magnetic transitions as a function of temperature, suggesting a relevant role of magnetoelastic interactions and b) the interplay of dimensionality with relevant interactions, such as spin–orbit coupling (SOC), where a crossover of 3D vs. 2D electronic properties is expected [1]. However, detailed experimental information on ground state electronic properties as well as on spin/orbital degrees of freedom are still lacking, mainly due to its extreme air sensitivity and challenging chemical environment.

Here we present chemical and layer sensitive X-ray electron spectroscopies results supported by model calculation, where we report via PhotoElectron Spectroscopy (RESPES and ARPES) a complete characterization of the electronic ground states of VI_3, showing that orbital filling drives the stabilization of a quasi-Mott insulating state at the surface, with strong influence of dimensionality effects [3]. Moreover, Temperature-dependent X-ray Absorption Spectroscopy (XAS) and X-ray Magnetic Circular Dichroism (XMCD) experiments clearly reveal a reduced dimensionality of magnetic order, due to electronic correlations, providing evidence of (a) an unquenched orbital magnetic moment (up to 0.66(7) μB/V atom) in the ferromagnetic state and (b) an instability of the orbital moment in the proximity of the spin reorientation transition [4,5].

Our results have direct implications in band engineering and layer-dependent properties of two-dimensional systems, suggesting VI_3 as a relevant candidate for the study of orbital quantum effects in spintronics interface and heterostructures.

2:45 PM QT02.05.04
Injecting, Transmitting and Detecting Magnons Through a 2D Antiferromagnet/Graphene Heterostructure Using Non-Local Transport and Edge States *Yangyang Chen[1], Hailong Fu[1], Seng Huat Lee[1], Kenji Watanabe[2], Takashi Taniguchi[2], Zhiqiang Mao[1] and Jun Zhu[1]; [1]The Pennsylvania State University, United States; [2]National Institute for Materials Science, Japan*

Antiferromagnetic insulators harbor spin waves, or magnons, the manipulation of which offers a potential pathway to transmit information in an energy-efficient manner. In this work we developed a new experimental method to generate and detect magnons in a van der Waals antiferromagnet/graphene heterostructure using pure electrical transport means and exploiting the spin polarized quantum Hall edge states of graphene. Magnons are injected at a $MnPS_3$/bilayer graphene interface, transmitted through a pristine $MnPS_3$ region, and detected by another $MnPS_3$/graphene interface. Both linear and second order non-local responses are observed and we report injection/detection efficiency several orders of magnitude higher than the conventional (inverse)spin Hall setup. The magnetic field induced phase transition of the $MnPS_3$ impacts the sign and amplitude of the magnon signal. By analyzing the temperature dependence of the observed signal, we extract the Gilbert damping coefficient of $MnPS_3$, which is ~ 0.01 in our sample. This method can potentially be generaled to probe the magnetic order and low energy excitations of other van der Waals magnets.

Antiferromagnetic Spintronics *Ramamoorthy Ramesh; Rice University, United States*

A few years ago, an intriguing new spin based logic-in-memory architecture, MESO, was described which used magnetoelectric multiferroics (ME) and spin-orbit (SO) metals as key building blocks. Over the past year, there have been some new developments in SOT based manipulation of magnets. Particularly, the role of epitaxy and *electronically perfect interfaces has been shown to significantly impact the spin-to-charge conversion (or vice versa). We are studying spin transport in La-BFO using a combination of NV imaging and spin Hall measurements. This talk will give you a summary of our progress so far.*

Terahertz Pulse Shaping and Chirality Control Using a Spintronic-Semiconductor Hybrid Emitter *Weipeng Wu, Wilder Acuna, Zhixiang Huang, Xi Wang, Lars Gundlach, Matthew Doty, Joshua Zide and Benjamin Jungfleisch; University of Delaware, United States*

Terahertz (THz) radiation, spanning from 0.3 - 30 THz, fills the crucial gap between the microwave and infrared spectral range. THz technology has found applications in various fields, from imaging and sensing to telecommunication and biosensing. However, the full potential of these applications is often hindered by the need for precise control and manipulation of the frequency and polarization state, which typically requires external THz modulators [1].

Here, we demonstrate a hybrid THz source that overcomes this limitation by integrating two THz emitters into a single device to enable pulse shaping and chirality control of the emitted radiation without any external components [2]. The two sources are a spintronic emitter (SE) [3] and a semiconductor photoconductive antenna (PCA) [4]. The two emitters respond independently to external parameters: the PCA is controlled by the applied bias voltage while the SE is controlled by the applied magnetic field. Moreover, a dual-wavelength excitation scheme allows for control of the relative time delay between the THz emission from each constituent. These properties of the hybrid emitter enable precise control of the mixing of the two signals to control the frequency, polarization, and chirality of the overall THz radiation. This on-chip hybrid emitter thus provides a powerful platform for engineered THz radiation with wide-ranging potential applications.

This research was supported by NSF through the University of Delaware Materials Research Science and Engineering Center, DMR-2011824.

Electric Field Control of Antiferromagnetic Magnons in Multiferroic BiFeO$_3$ *Sajid Husain[1], Isaac Harris[1,2], Maya Ramesh[3], Peter Meisenheimer[2], Shashank K. Ojha[4], Lucas M. Caretta[5], Paul Stevenson[6], Darrell Schlom[3], Lane W. Martin[1,2], Sayeef Salahuddin[2], Zhi Yao[1] and Ramamoorthy Ramesh[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Cornell University, United States; [4]Rice University, United States; [5]Brown University, United States; [6]Northeastern University, United States*

The interplay between the spin and charge degrees of freedom is an exciting area of research from the perspectives of both fundamental science and applications such as high-performance, energy efficient computing. Magnon-based memory could be substantially efficient due to its ability to avoid Joule heating during *information transfer. Additionally, magnetoelectric (ME) materials offer the ability to control magnetization control using an electric field. In this talk, I will discuss our recent work on a non-volatile, non-destructive memory device utilizing a magnon-driven sensing of the antiferromagnetic state in the multiferroic. This device leverages strong spin-orbit (SO) coupling of spin Hall metal to achieve large output voltages through spin-charge conversion. By employing a simple geometric configuration, we introduce a new ME-SO non-volatile magnetic memory element as a promising alternative to existing random access memory technology. I will also discuss the recent development of MESO and possible pathway to understand the existing issues with materials engineering with open challenges for future research.*

4:45 PM QT02.06.04

Imaging Orientation Dependent Spin Cycloids in BiFeO$_3$ *Shashank K. Ojha[1], Pratap Pal[2], Maya Ramesh[3], Sajid Husain[4], Xinyan Li[1], Darrell Schlom[3], Yimo Han[1], Chang-Beom Eom[2] and Ramamoorthy Ramesh[1,4,5]; [1]Rice University, United States; [2]University of Wisconsin-Madison, United States; [3]Cornell University, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]University of California, Berkeley, United States*

Materials with multiple order parameters have been one of the major themes in condensed matter research for several decades. Of particular interest is the study of magnetoelectric (ME) multiferroic BiFeO$_3$, where the coupling between antiferromagnetic and ferroelectric order parameters leads to a plethora of novel functionalities such as electric field controlled antiferromagnetic order, which is crucial for the development of spin-based ultra-low power electronics. The antiferromagnetic order in BiFeO$_3$ is notably complex, as the inherent ME coupling, along with Dzyaloshinskii–Moriya interaction, results in the formation of spin cycloid. With the recent advent of high-resolution nanoscale imaging techniques, such as scanning nitrogen vacancy magnetometry (SNVM), it is now possible to image these cycloids in real space. This advancement has not only enhanced our understanding of ME coupling but has also been extremely beneficial in analyzing its response to epitaxial constraints and electrostatic/geometrical boundary conditions, which are fundamental to the development of any electronic devices. In this work, we employ high-resolution SNVM to image how spin cycloids evolve with the orientation of thins films grown by sputtering and molecular beam epitaxy. We find that for (111)$_{pc}$ (pc: pseudo cubic) oriented films where the cycloid propagation vectors lie within the surface of the film, a complete morphogenesis occurs, leading to the formation of Turing patterns. We investigate its response to an external electric field and compare our results with the (100)$_{pc}$ and (110)$_{pc}$ films made on substrates of different orientations. These results will lay the foundation for understanding the formation of the spin cycloid vis-à-vis crystal orientation which would be monumental in understanding the spin transport in multiferroics.

SESSION QT02.07: Materials and Devices for Spintronics III

8:30 AM *QT02.07.01

Spin-Orbit Torque Phenomena in Complex Oxide Heterostructures *Eric Fullerton; University of California, San Diego, United States*

Energy-efficient magnetic spin orbit torque nano-oscillators and coupled oscillator arrays are being explored for low-power neuromorphic computing systems [1]. Commonly studied oscillator material systems are mostly based *on metallic ferromagnet(FM)/ heavy metal(HM) (FM=CoFeB, Py, NM=Pt, Ta, W) bilayers with a relatively high intrinsic Gilbert damping of the order of 10^{-2}. I will discuss recent efforts to replace the metallic layers with complex oxides with coupled spin, electron and lattice degrees of freedom [2]. Large spin-charge conversion, low damping, and small resonance linewidth are essential constituents for development of energy efficient oscillators. In this regard half-metallic perovskite ferromagnet, $La_{0.67}Sr_{0.33}MnO_3$ (LSMO) is studied as the magnetic free layer combined with transition metal oxides such IrO_2, $CaIrO_3$.and $NdNiO_3$ as the spin-orbit torque layer provide potentially new functionality. LSMO has a very low damping that is anisotropic in the plane and nearly 100% spin polarization giving large spin torque signals. IrO_2 and $CaIrO_3$ have unique electronic structures, where the density of states near the Fermi level is dominated by only 5d electrons with strong spin orbit coupling and large charge to spin conversion [3]. $NdNiO_3$ (NNO) exhibits a first-order metal-insulator transition centered at 200K in bulk. The onset of the metal-insulator phase transition is also accompanied by a complex E' type anti-ferromagnetic ordering in this material. Spin-orbit torque measurement of the constituent materials and progress towards an all oxide nano-oscillator will be discussed. The work is done in collaboration with Biswajit Sahoo, K. Akilan, Sarmistha Das, Sébastien Petit-Watelot, Carlos Rojas, and Alex Frano and supported by US Department of Energy under Grant No. DE-SC0019273.*

9:00 AM *QT02.07.02

Engineering Magnetic Tunnel Junctions Using He⁺ Ion Radiation *Dafiné Ravelosona[1,2]; [1]Spin-Ion Technologies, France; [2]CNRS & University Paris Saclay, France*

We have developed a unique manufacturing process based on He^+ ion irradiation to tailor the structural properties of ultra-thin magnetic materials at atomic level and enhance their performance. The utilization of light ions provides the precise control of inter-atomic displacements through low energy transfer. The key feature of the technology is the post-growth control at the atomic scale of structural properties and the related magnetic properties. When realized through a mask this technology enables lateral modulation of magnetic properties without any physical etching.

In this talk, I will demonstrate that He^+ ion irradiation can be used to enhance the performance of Magnetic Tunnel Junctions with perpendicular magnetic anisotropy for application to MRAM, magnetic sensors and neuromorphic computing.

9:30 AM BREAK

10:00 AM QT02.07.03

Direct Evidence of Non-Oxidative Mechanism in Oxygen Based Magnetoionics *Alessio Lamperti[1], Tanvi Bhatnagar-Schöffmann[2,3], Maria-Andromachi Syskaki[4], Juergen Langer[4], Dafiné Ravelosona[5] and Liza Herrera-Diez[2,3]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Centre National de la Recherche Scientifique, France; [3]Université Paris-Saclay, France; [4]Singulus AG, Germany; [5]Spin-Ion Technologies, France*

The convergence of microelectronics and neuroscience in research on artificial synapses as base element for the fabrication of artificial neural networks mimicking the brain activity, opens the potential for magnetoionics, where the magnetic anisotropy of the ferromagnet layer is modulated by the ion migration from an adjacent oxide layer by voltage application [1, 2, 3]. In this respect, the understanding of the chemistry at the oxide/ferromagnet interface

is the key for a direct evidence of the mechanism at the root of magnetic state change.
Here we report an advanced chemical characterization based on time-of-flight-secondary ion mass spectrometry (ToF-SIMS) and X-ray photoelectron spectroscopy (XPS) of the magnetic stack $Ta(5)/Co_{40}Fe_{40}B_{20}(1)/Pt(0.09)/MgO(2)/HfO_2(3)$ *(nominal thickness in nm) on top of* $Si/SiO_2(300)$ *substrate analyzed as-grown and after the exposure to different voltages for several seconds.*
A careful analysis of ToF-SIMS depth profiles evidences that, when a voltage of -3.5 V is applied for 360 s, a decrease of the OH^- *inside the MgO layer is revealed, implying a depletion of oxydrilic groups, or hydrogen, from pristine MgO. It is worth noting that, concomitantly,* $18O^-$ *and* Mg^- *intensity remains unchanged. High resolution XPS analysis corroborates this finding by showing a shift in the binding energy of the Mg(2s) edge compatible with an initial* $Mg(OH)_2$ *reverting to MgO upon voltage application [4]. Such change in the MgO layer is observed to have implication on the magnetic anisotropy, moving from in-plane anisotropy to out-of-plane anisotropy, as seen with anomalous Hall effect (AHE) and magneto-optic Kerr microscopy (MOKE), thus proving that is feasible to change the magnetic state in ultrathin ferromagnets by the application of a controlled external voltage assisted by ion migration.*

10:15 AM QT02.07.04
Characterisation of Complex Interfaces Using Hard X-Ray Photoelectron Spectroscopy *Anna Regoutz; University of Oxford, United Kingdom*

The use of hard X-rays in X-ray photoelectron spectroscopy (XPS) extends this traditionally surface-sensitive technique to probing depths that allow the measurement of bulk samples, buried layers, and, crucial for many device technologies, buried interfaces. By using synchrotron sources, the X-ray properties, including energy and polarisation, can be tuned to allow for varying depth resolution as well as discrimination of different atomic and orbital contributions to spectra, allowing the disentanglement of, for example, complex valence states in extended solids and at interfaces.
This talk will briefly overview the key capabilities of hard X-ray photoelectron spectroscopy (HAXPES) for the comprehensive characterisation and exploration of interfaces. A complex oxide interface designed to create a high room-temperature electron mobility two-dimensional electron gas (2DEG) serves as a prototypical application example of the information gained from buried, strongly localised interfaces. The termination at the interface of the perovskite oxides $BaSnO_3$ *and* $LaInO_3$ *can be designed to either suppress or strongly enhance the formation of the 2DEG. Energy-dependent HAXPES delivers a non-destructive depth profile of the chemical states across the multilayer structure as well as provides information on the band alignment, including interfacial band bending key for the existence of a 2DEG. Most importantly, HAXPES directly probes key electronic states, such as the free charge carriers at the Fermi energy resulting from a 2DEG formation. To conclude, the talk will provide an outlook on the most recent technique developments and future applications of the technique across a range of novel materials and device designs.*

10:30 AM QT02.07.05
Start-to-Finish Tuning of Magnetic Anisotropy in Iron Garnet Thin Films *Allison Kaczmarek, Tomas Grossmark, Maria Aguiar, Geoffrey Beach and Caroline A. Ross; Massachusetts Institute of Technology, United States*

Engineered anisotropy in garnet thin films has enabled progress in domain wall motion and switching experiments. Specific anisotropy landscapes and interface symmetries can expand the applications of iron garnet (IG) materials with low Gilbert damping for magnonics and field-free switching. While magnetic anisotropy arises from a host of contributions in garnet materials, many of these are determined by parameters that are intrinsic to the composition (e.g. magnetostriction constants, magnetocrystalline anisotropy constants, and saturation magnetization) and by the substrate orientation and lattice parameter, and are not easily varied once the thin film *is grown.*

In contrast, magnetotaxial[1], or growth-induced, anisotropy arises from cation ordering in nonequivalent dodecahedral sites present at the growth surface and can be tuned throughout the stages of film growth and post processing, since this phenomenon is determined by kinetic factors during growth of the film. Magnetotaxial anisotropy is expected for any garnet with multiple different cations on the dodecahedral site. For any mixed-cation garnet, the degree of order, and thereby the magnetotaxial anisotropy, can be tuned in three ways: (1) via the orientation and lattice parameter of the substrate, which changes the sets of nonequivalent sites available to the arriving cations; (2) via the kinetics during growth which controls the tendency of cations to order into the dodecahedral sites; and (3) by annealing the films to encourage cation diffusion and randomization, reducing the order and the magnetotaxial anisotropy.

In this work, we systematically explore this parameter space to control magnetotaxial anisotropy in mixed (Bi, Lu, Y)IG thin films (thickness ~30 nm) made by pulsed laser deposition on single crystal (111)-oriented garnet substrates with a range of lattice parameters. Structure and strain state of the thin films were measured by high-resolution X-ray diffraction and magnetic properties by vibrating sample magnetometry and ferromagnetic resonance, which showed damping in the range of ~ 0.001-0.0001 and saturation magnetizations of approximately 140 kA/m. Cation order leads to the appearance of a forbidden peak or superlattice X-ray diffraction peak that is not present in a garnet film without dodecahedral order, hence the degree of order was estimated from the intensity of the order-induced [1-10] superlattice peak. We show that the degree of growth-induced order is dependent on film-substrate lattice mismatch in BiYIG films, with greater cation ordering reported for more in-plane compressively strained films. We also highlight the importance of growth parameters, namely laser repetition rate of 1-30 Hz, on the kinetics of ordering of Lu and Y in LuYIG. Lastly, we demonstrate the reduction of cation order and anisotropy in LuYIG films by post-growth annealing. This work shows the role of growth-induced cation order for the production and tuning of magnetic anisotropy in garnet materials for applications in spintronic devices.

Use of Focused Ion Beam to Investigate Supercurrent Propagation in Topological-Insulator Single-Crystals

Jose M. De Teresa[1], Rubén Gracia-Abad[1], Amaia Sáenz-Hernández[1], Soraya Sangiao[1] and Geetha Balakrishnan[2];
[1]Universidad de Zaragoza, CSIC, Spain; [2]University of Warwick, United Kingdom

Focused Ion Beam (FIB) techniques enable subtractive and additive high-resolution nanopatterning processes with a wide range of applications [1, 2]. In particular, FIB milling as well as FIB-induced deposition (FIBID) processes have found application in the development of quantum technologies [3]. FIBID relies on a gas precursor that is injected into the area of interest and decomposed by FIB irradiation. Using the $W(CO)_6$ precursor and Ga^+ or

He$^+$ FIBID processes, we have grown and investigated the properties of a large number of in-plane and out-of-plane superconducting W-C nanostructures [4], in particular Josephson junctions and nanoSQUIDs [5]. We have recently developed a new approach to extract small crystals from a larger piece, place it on a prepatterned substrate and grow electrical contacts to study its magnetotransport properties [6]. In my talk, I will show the obtained results regarding the use of topological-insulator Bi_2Se_3 crystals and W-C superconducting contacts. We have observed that it is possible to create supercurrents between the W-C contacts that travel through the (sub)surface of the Bi_2Se_3 crystals, despite the fact that the crystal becomes amorphized a few nm below the surface after the Ga$^+$-FIB milling process. It is also found that the conduction channels travelling through the crystal can give rise to unconventional interference patterns in the dependence of the critical current with the applied magnetic field. The interfacial states between the amorphous and crystalline parts of the crystal could play a role, as recently claimed in the case of Bi_2Te_3[7].

***Pushing the Boundaries of Topological Materials** Robert Moore; Oak Ridge National Laboratory, United States*

A little over a decade ago, the field of condensed matter physics entered a new topological era with the discovery of Dirac materials. These materials are distinguished by electronic band structures that belong to a different topological class than those of traditional metals and insulators. As effects of the band structure, theoretical predictions have accurately described a variety of exotic states, such as Dirac fermions, Weyl fermions, chiral fermions, and axions, which emerge from the confluence of topology, quantum mechanics, and relativity. However, the inclusion of electronic correlations and the reduction to lower dimensions have rendered these predictions less certain and experimental verification increasingly complex. In this talk, I will outline our use of molecular beam epitaxy (MBE) in conjunction with spin and angle-resolved photoemission spectroscopy (SARPES) and scanning tunneling microscopy (STM) to create an idealized topological superconductor aimed at detecting Majorana modes—particles that are their own antiparticles. I will demonstrate how we manipulate the interfacial spin-electronic structure between $FeTe_{1-x}Se_x$, an s-wave superconductor, and Bi_2Te_3, a topological insulator, to foster the emergence of Majorana modes within a proximitized topological superconducting system. We will discuss the enhancement of the superconducting transition by reducing Bi_2Te_3 and the evolution of the spin structure through a topological Lifshitz transition. Additionally, I will show how experiments can still lead to discoveries in the topological era with the spin-electronic structure of monolayer bismuthene on SnS(Se), a 2D Weyl material system. I will elucidate the concept of a 2D Weyl system and explore the bulk-boundary correspondence to reveal the 1D analog of a Weyl Fermi arc.

***Nonlocal Detection of Vector Spin Accumulation in Graphene for Probabilistic Computing** Yuanqiu Tan, Rahul Tripathi, Joerg Appenzeller and Zhihong Chen; Purdue University, United States*

The deceleration of Moore's law has led to an increasing demand for unconventional computing approaches.

Probabilistic bits (p-bits) using the Heisenberg model as the energy-based model (EBM) represent a cornerstone in the field of probabilistic computing, enabling stochastic sampling, probabilistic inference, and combinatorial optimization [1]. The Heisenberg interaction, which describes the exchange interaction between localized spins, can indirectly influence angle-dependent spin transport measurements in a non-local spin valve. However, directly observing Heisenberg interactions through these measurements requires a detailed understanding of how these interactions affect spin dynamics and spin transport properties.
In this work, we consider two different orientations of spin injection into a graphene channel and analyze their interactions. We experimentally demonstrate the vector spin accumulation through 2D graphene channels using lateral spin valve by varying polarization direction of spin accumulation in ferromagnetic spin injectors. The results realize the angular control of spin and readout the interaction between two spin states [2]. This demonstration paves the way for mapping Heisenberg model with stochastic low barrier magnets as vector components for scalable probabilistic spin circuits.

Nonreciprocal Transport in Interfacial Rashba Ferromagnets *Agnès Barthelemy and Manuel Bibes; Laboratoire Albert Fert, France*

Interfacial systems displaying a Rashba spin-orbit coupling (SOC) may be used to realize spin-charge interconversion with great efficiency (through the direct and inverse Edelstein effects), and as such be used as sources and detectors of spin currents[1]. Because of their broken inversion symmetry, they also display nonreciprocal transport phenomena[2], such as unidirectional magnetoresistance. While the Rashba SOC is a universal feature of surfaces and heterointerfaces, transition metal oxides also often display unexpected magnetic properties at their surfaces and interfaces[3]. However, the interesting interplay that may arise between the Rashba-type SOI and surface or interfacial ferromagnetism, that would then qualify the system as a Rashba ferromagnet[4], has been little investigated. In this talk, we will explore the possibility to endow Rashba systems with a magnetic order and explore the consequence of the interplay between these two phenomena. In particular, we will discuss how magnetism can strongly enhance the spin-charge interconversion efficiency[5] and yield spontaneous non-reciprocal transport, in the absence of external magnetic field.

Bulk-Rashba Effect with Spin-Coherent Transport in a Novel Polar Phase of BiInO₃ *Deokyoung Kang[1], Xue-Zeng Lu[2], Megha Acharya[1], Sajid Husain[1], Menglin Zhu[3], Bridget Denzer[3], Isaac Harris[1], Piush Behera[1], Ching-Che Lin[1], Alex Smith[1], Francesco Ricci[1], Shu Wang[1], Tae Yeon Kim[1], Lucas M. Caretta[4], Jeff B. Neaton[1], James M. LeBeau[3], Ramamoorthy Ramesh[5], James M. Rondinelli[6] and Lane W. Martin[5]; [1]University of California, Berkeley, United States; [2]Southeast University, China; [3]Massachusetts Institute of Technology, United States; [4]Brown University, United States; [5]Rice University, United States; [6]Northwestern University, United States*

The Rashba effect, which arises from spin-orbit coupling induced by broken inversion symmetry, has been sought for use in low-power spintronics. While polar materials have been reported to exhibit bulk-Rashba effect arising from the polar crystal symmetry, the exploration of this effect has been hindered by the scarcity of polar materials exhibiting the bulk-Rashba effect and rapid spin-relaxation effects dictated by the D'yakonov–Perel' (DP) mechanism. Theoretical works suggest that persistent-spin texture (PST) can be realized via inducing unidirectional spin texture enforced by crystal symmetry, such that the spin-relaxation effect is suppressed. Experimental evidence for the bulk-Rashba effect with unidirectional-spin texture, however, remains elusive so far. $BiInO_3$, for example, has been theoretically predicted to exhibit PST in a polar $Pna2_1$ version but stabilizing that polar structure has proven to be challenging. Prior efforts had, in turn, produced a non-polar Pnma version of $BiInO_3$ (henceforth, O-$BiInO_3$) in thin-films.

Here, two key observations are made: a novel polar $LiNbO_3$-type R3c phase of $BiInO_3$ (henceforth, a R-$BiInO_3$) can be stabilized using epitaxial control and this phase exhibits a bulk-Rashba effect with suppressed spin relaxation as the result of unidirectional-spin texture. While non-polar O-$BiInO_3$ was stabilized when grown on MgO (001) substrates, R-$BiInO_3$ was grown with twinned domain structures on $DyScO_3$ $(110)_O$ substrates (henceforth, (001)-oriented R-$BiInO_3$ film), and a monodomain structure on $SrTiO_3$ (111) substrates (henceforth, (111)-oriented R $BiInO_3$ film). The domain structures and polar symmetry of $BiInO_3$ films were confirmed using extensive structural characterization studies including X-ray diffraction, scanning transmission electron microscopy, second-harmonic generation spectroscopy. Compared to the O-$BiInO_3$ films, the R-$BiInO_3$ films showed higher electrical conductivity due to a slightly reduced optical band gap and enhanced dielectric and piezoelectric responses corresponding to its polar nature. First-principles density functional theory (DFT) calculations explore both the structural stability of the R-$BiInO_3$ phase and reveal Rashba-type spin splitting with unidirectional spin texture around the Fermi level (E_F) exceeding no more than 3 meV above the conduction band minimum energy (E_{CBM}). The R-$BiInO_3$ films were systematically annealed in slightly oxygen-deficient environments to create oxygen vacancies such that the carrier concentration was tuned to access the potential unidirectional spin texture (i.e., E_F-E_{CBM} < 3 meV) and so that the films were adequately conductive for transport measurements. Crystallographic orientation-dependent anisotropic transport behavior was observed, where weak antilocalization (WAL) with spin relaxation was observed in annealed (001)-oriented R-$BiInO_3$ films, while weak localization (WL) showing spin-coherent transport with long spin-relaxation times exceeding 3.36 ns was observed in annealed (111)-oriented R-$BiInO_3$ films; the latter effects are likely due to the removal of the multidomain structure and anisotropic spin diffusion. Additional transport measurements revealing planar-Hall effect, anisotropic magnetoresistance, and non-reciprocal charge transport on the annealed (111)-oriented R-$BiInO_3$ films confirm the bulk-Rashba effect with a Rashba coefficient of 760 meV●Å. All told, a previously unreported polar phase, R-$BiInO_3$, simultaneously exhibits the bulk-Rashba effect and spin-coherent electron transport due to unidirectional spin texture. These findings offer insights into spin-orbit coupling physics within a polar materials system and suggest potential applications in emerging spin-based applications.

Spin Superfludity Enabled by a Geometrically Tunable Nonlocal Spin Hall Magnetoresistance *Michael D.*

Kitcher and Geoffrey Beach; Massachusetts Institute of Technology, United States

Spin superfluidity (SSF) inovles the near-dissipationless transport of spin angular momentum across a magnetic material via a cohrently precessing spin spiral [1], making it a promising route towards magnetic analogs of superconducting devices, as well as novel spintronics devices [2]. While conventional easy-plane magnets can exhibit SSF in theory [3], the required device geometries are incompatible with current fabrication methods and/or spin injection via the spin Hall effect (SHE) in an adjacent heavy metal. Considering the ideal case of an insulating magnet, we analyze the nonlocal spin and charge transfer efficiencies of SSF devices with a lateral geometry [4], which has been underexplored due to an absence of compatible materials. Using a hydrodynamic formulation of the Landau–Lifshitz–Gilbert equation in conjunction with magneto-circuit theory, we show that the spin transfer efficiency is maximized when the area of the injector is much larger than the combined area of the detector and transport channel. Moreover, we relate the charge transfer efficiency and the nonlocal resistance at the detector to the conventional spin magnetoresistance (SMR) at the heavy metal/insulator interface and consider its geometrical tunability. Our analysis extends the theory of conventional SMR by identifying these relationships as manifestations of its unrecognized Onsager reciprocal, which is negative: spin-pumping–induced SMR.

Field-Free Spin Orbit Torque Switching in a Single Crystalline Ferromagnetic Semiconductor Film with Perpendicular Anisotropy *Kyung Jae Lee[1], Sanghoon Lee[1], Xinyu Liu[2], Margaret Dobrowolska[2] and Jacek Furdyna[2]; [1]Korea University, Korea (the Republic of); [2]University of Notre Dame, United States*

We reports observation of field-free spin-orbit torque (SOT) magnetization switching within a single layer of (Ga,Mn)(As,P) ferromagnetic film exhibiting perpendicular magnetic anisotropy. The SOT switching phenomenon is characterized by distinct transitions between two Hall resistance (HR) states during current scans. When subjected to an in-plane bias field, the observed switching chirality in the HR hysteresis loop consistently aligns with SOT induced by spin polarization stemming from Rashba- and Dresselhaus-type spin-orbit fields (SOFs) within the tensile-strained crystalline structure of (Ga,Mn)(As,P) film. Remarkably, SOT switching is demonstrated to occur even in the absence of an external bias field, with its chirality reversing according to the direction of magnetization initialization. We attribute this field-free switching to symmetry breaking facilitated by an internal coupling field, the orientation of which is decided by the external field experienced during magnetization initialization. Further evidence supporting the presence of this coupling field includes a shift in the field-scan HR hysteresis depending on the direction of magnetization initialization. Structural analysis reveals a surface layer enriched in Mn and O, indicating the presence of oxide-based magnetic structures that are magnetically coupled with the (Ga,Mn)(As,P) film. The temperature dependence of field-free SOT switching corroborates this *explanation, as the internal coupling field disappears above 40 K, consistent with the expected magnetic transition in the Mn_3O_4 structure. Our discovery of field-free SOT magnetization switching in a single-layer film represents a significant advancement, offering a novel pathway for the development of simpler and more energy-efficient spintronic devices.*

QT02.10.02

The Robustness of the Interlayer Exchange Coupling of the Wedge-Type Perpendicularly Magnetized Pt/Co/Pt/Ru/Pt/Co Multilayers

Jaehun Cho[1], Sunghyun Min[2,1] and June-Seo Kim[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]DGIST, Korea (the Republic of)

Magnetic tunnel junctions (MTJs) with perpendicular magnetic anisotropy (PMA) attract much interest since they allow to scale down the dimension of spintronic devices to the latest technological node while keeping sufficient thermal stability [1]. Among the various types of magnetoresistive (MR) based spintronic devices, the MgO-based tunneling magnetoresistance (TMR) can provide a very high MR ratio and high field sensitivity to detect small changes in magnetic field. MTJs with PMA (p-MTJs) use a perpendicular synthetic antiferromagnet (SyAF) layer which consists of two ferromagnetic layers antiferromagnetically coupled through a nonmagnetic spacer such as Ru. The stray field generated from the SyAF on the storage layer can be greatly reduced, leading to two low and high resistance states with equivalent thermal stability and critical switching current [2]. Furthermore, SyAF structure is extensively studied for antiferromagnetic spintronics such as a spin-torque oscillator [3], spin-orbit torque device [4], and a magnetic domain wall motion device [5]. The SyAF is the consequence of the interlayer exchange coupling (IEC), which is essentially a Ruderman-Kittel-Kasuya-Yosida (RKKY) coupling. RKKY coupling originates from spin-dependent Friedel-like spatial oscillations in the spin density of the nonmagnetic spacer induced by the adjacent ferromagnet.

Here, we systematically investigate IEC in the perpendicular SyAF structure of Pt/Co/Pt layers. The structure of SyAF are Ta(4)/Pt(4)/Co(1.2)/Pt(0.2)/Ru(0 - 5.6)/Pt(0.2)/Co(1.3)/Pt(3.0) and Ta(4)/Pt(4) /Co(1.2)/ Pt(0.2)/ Ru(0.9) /Pt(0.2)/Co(0 – 2.0)/Pt(3.0) (thickness in nm). The polar magneto-optic Kerr effect (MOKE) measurements were employed to measure the Ru thickness-dependent magnetic hysteresis curve. The maximum exchange field is 360 mT at 0.9 nm Ru for the calculated maximum exchange energy is 0.49 mJ/m2 for the Ru wedged sample. We strongly anticipate that our observations can improve the SyAF-based spintronic devices.

QT02.10.03

Utilizing Vacancies to Generate Unconventional Spin Torque with the Ta-N System

Zach Cresswell[1,2], Tony Low[1], Brelon J. May[2] and Jian-Ping Wang[1]; [1]University of Minnesota Twin Cities, United States; [2]Idaho National Laboratory, United States

SOT-MRAM has long been plagued by difficulties with switching a magnet with perpendicular anisotropy without the assistance of an external magnetic field. Many solutions have been proposed and experimentally demonstrated, but they often suffer from an irregular geometry, a complicated synthesis path, or a lack of suitable substrates, that inhibits their ability to scale upward to wafer sizes.

Ta_4N_5 is a unique material in this way; its crystal structure is the same as that of cubic TaN, apart from an ordered array of Ta vacancies. This means its symmetry is reduced to that of space group 87, which enables

unconventional spin current generation necessary for field-free switching [1], while also lattice matching well to several conventional substrates. Tantalum has long been a useful material for spin-orbit torque applications [2], and cubic TaN has been shown to have a modest SOT efficiency as well [3]. Additionally several papers have reported theoretical calculations that show changes in transport properties between the two structures from the full rock-salt structure [4,5] that suggest a more favorable performance as an SOT device than TaN.

I will detail our group's efforts in synthesizing epitaxial Ta_4N_5 *for the first time, via molecular beam epitaxy (MBE). The Ta-N phase diagram is explored via MBE and, guided by theoretical works on its stability, a growth window is obtained for high-quality* Ta_4N_5*. Experimental transport properties of* Ta_4N_5 *compared to previous theoretical calculations as well as its rock-salt structure counterpart are discussed. Tests of SOT efficiency, as well as its capability for field-free switching, are ongoing.*

Spin Transport in Epitaxial $Lu_3Fe_5O_{12}$ ***Garnet Films*** *Casey P. Kerr[1], Pralay Paul[1], Sumit Goswami[1], Sreehari Puthan Purayil[1], Benjamin Summers[1], Hanjong Paik[1], Horst Hahn[1,2], R. Kruk[2] and T. Venky Venkatesan[1,3]; [1]The University of Oklahoma, United States; [2]Karlsruhe Institute of Technology, Germany; [3]National Institute of Standards and Technology, United States*

Ferrimagnetic insulator (FMI) and heavy metal (HM) heterostructures are attracting significant interest in the field of spintronics due to the unique combination of properties they offer. FMIs exhibit low magnetic damping and robust spin filtering, while HMs provide high spin-orbit coupling, facilitating efficient spin current generation and manipulation. Systems exhibiting spin-orbit torque (SOT) effects coupled with perpendicular magnetic anisotropy (PMA) are particularly desirable for technological applications, as they enable higher bit densities [1]. While extensive research has been conducted on SOT switching in PMA ferromagnetic metals (e.g., Co, CoFeB), similar studies employing oxide ferro/ferri-magnetic materials are scarce [2]. Oxide ferro/ferri-magnetic materials offer two main advantages: favorable scaling behavior and the prevention of current shunting from the SOT-producing HM layer, as PMA is a bulk property rather than an interfacial one [3].

In this study, we report on the growth, structural, and magnetic properties of rare-earth lutetium iron garnet (Lu3Fe5O12, LuIG) thin films deposited on Gd3Ga5O12 (GGG) substrates oriented along the (111) direction. The *films were grown using a pulsed laser deposition technique (248-nm KrF laser). High-resolution X-ray diffraction (HRXRD) revealed the epitaxial nature of the films, with a full width at half-maximum (FWHM) of approximately 0.08 degrees for the film (compared to 0.005 degrees for the substrate) and the presence of optical fringes on both sides of the LuIG (444) peak, indicating high film quality. Magnetization measurements revealed antiferromagnetic ordering in the films. A comprehensive study of the thickness-dependent magnetic properties of LuIG films and spin pumping phenomena in LuIG/Pt heterostructures will also be presented.*

QT02.10.05

Interfacial Charge-Transfer in 3D/5D Oxide Heterostructures *Dirk Fuchs[1], Arun Jaiswal[1], Fabrice Wilhelm[2], Andre Rogalev[2] and Matthieu Le Tacon[1]; [1]Karlsruhe Institute of Technology, Germany; [2]European Synchrotron Radiation Facility, France*

The synthesis of artificial oxide heterostructures and superlattices has gained increasing interest during the last decade due to the ability of epitaxial growth with atomic precision. The combination of different complex oxides not only results in the possibility of tuning the intriguing phenomena of the bulk constituents via lattice strain and symmetry change but also often generates new exotic phases at the interface of the correlated electron systems. Interfacial charge-transfer (ICT) between two different oxide layers, such as in the seminal experiments on $LaAlO_3/SrTiO_3$ heterostructures, seems to be most prominent for these observations. Besides the combination of 3d perovskites, which generally display strong electron correlation, heterostructures consisting of 5d perovskites additionally display distinct spin-orbit coupling, which might be useful for e. g., spin manipulation in spintronic devices. In the following, we have studied systematically the ICT in 5d $SrIrO_3$ (I) heterostructures in combination with the 3d perovskites $LaMnO_3$ (M), $LaFeO_3$ (F), $LaCoO_3$ (C) and $NdNiO_3$ (N). High quality heterostructures [IiXi]m (X = M, F, C, N) with a layer thickness of i monolayers each and a periodicity of m were prepared on (001) oriented $SrTiO_3$ substrates by pulsed laser deposition. The ICT was studied by measurements of the Hall resistance and x-ray absorption spectroscopy at the Ir $L_{3,2}$ edge. For all the samples an electron transfer from the $5d^5$ I to the neighbored $3d^n$ layer X was observed. The ICT was found to be confined to the first layer with respect to the interface and systematically increases with increasing n up to n = 6 amounting to $\triangle n \approx 0.35$ electrons. For n = 7 (X = N) ICT reduces again. The increase of $\triangle n$ with n can be well understood assuming the alignment of oxygen states at the interface due to the continuity of the common oxygen matrix by the corner sharing I and X octahedra [1], whereas the reduced ICT for X = N is likely explained by hybridization effects in the N layer, lowering $\triangle n$ significantly with respect to $LaNiO_3$[2].

Near Room-Temperature Ferrimagnetic Ordering in a Noncentrosymmetric Polar Metal *Zachary Messegee[1], Vasile O. Garlea[2], Igor Mazin[1], Yan D. Xin[3], Harish B. Bhandari[1], Nirmal Ghimire[4] and Xiaoyan Tan[1]; [1]George Mason University, United States; [2]Oak Ridge National Laboratory, United States; [3]National High Magnetic Field Laboratory, United States; [4]University of Notre Dame, United States*

Compounds that crystallize in noncentrosymmetric polar crystal structures and exhibit magnetic ordering can show interesting and exotic electronic and physical properties that have potential applications in spintronics and quantum technology. However, the reported polar magnetic materials with metallic behavior and ferromagnetic/ferromagnetic ordering near or above room temperature are rare. Here, we present an interesting noncentrosymmetric polar metal that shows a ferrimagnetic ordering temperature near room temperature. It *adopts the orthorhombic system with a complex structure featuring trigonal prisms, icosahedra, and pentagonal prims. The polar crystal structure is confirmed by the Rietveld refinement using neutron diffraction data and the convergent-beam electron diffraction. The determined magnetic structure, experimental data of resistivity, heat capacity, and giant magnetoresistivity will be presented. The results of density functional theory calculations used to confirm the metallic behavior and magnetic structure will be presented as well.*

QT02.10.07

Enhanced Spin-to-Charge Conversion Through Interface Modulation Between Co and $Bi_{1-x}Sb_x$ *Seungwon Rho[1], Hanbum Park[2], Jeehong Park[1], Kwangsik Jeong[1], Hyeongmun Kim[3], Seok-Bo Hong[1], Jonghoon Kim[1], Hyeon Wook Lim[1], Jaeseok Huh[1], Yeonjin Yi[1], Chul Kang[4] and Mann-Ho Cho[1,1]; [1]Yonsei University, Korea (the Republic of); [2]National University of Singapore, Singapore; [3]Chonnam National University, Korea (the Republic of); [4]Gwangju Institute of Science and Technology, Korea (the Republic of)*

Materials with strong spin-orbit coupling (SOC), such as heavy metals (HMs) and topological materials (TMs), are highly valued for their ability to convert charge currents into spin currents and vice versa. The efficiency of spin-charge interconversion, defined as the spin Hall angle, is crucial for spintronic applications. TMs, due to the Edelstein effect, exhibit significantly larger spin Hall angles compared to HMs. Among these materials, $Bi_{1-x}Sb_x$ alloys stand out for their colossal spin Hall angle and superior conductivity. For instance, $Bi_{0.9}Sb_{0.1}$ has a spin Hall angle of 52 and conductivity of approximately $10^5\ \Omega^{-1}m^{-1}$. Recent studies using THz emission spectroscopy on $Co/Bi_{1-x}Sb_x$ heterostructures have shown that the topological surface state (TSS) of $Bi_{1-x}Sb_x$ is key in spin-to-charge conversion (SCC).

Our study focuses on enhancing SCC efficiency by modulating the interface between Co and $Bi_{1-x}Sb_x$. We systematically investigated the SCC and band properties when inserting HMs at this interface using THz emission spectroscopy and density functional theory (DFT) calculations. We found that inserting a bismuth 3 bilayer (3 BL) between Co and $Bi_{0.8}Sb_{0.2}$ increases THz emission by 171%, compared to $Co/Bi_{0.8}Sb_{0.2}$ heterostructures. Conversely, the $Co/Bi/Bi_{0.2}Sb_{0.8}$ structure showed a negligible increase in THz emission amplitude compared to $Co/Bi_{0.2}Sb_{0.8}$. DFT calculations and ultraviolet photoelectron spectroscopy revealed that the insertion of Bi creates a non-trivial and efficient band structure, enhancing SCC efficiency depending on x in $Co/Bi/Bi_{1-x}Sb_x$.

We also investigated the insertion of various HMs (e.g., Sb, Pt) between Co and $Bi_{1-x}Sb_x$. Enhanced SCC efficiency was observed only in the Co/Bi(3 BL)/$Bi_{0.8}Sb_{0.2}$ structure, while other HMs decreased THz emission amplitude. However, varying the thickness of Sb in Co/Sb(t nm)/$Bi_{1-x}Sb_x$ showed that SCC efficiency could be optimized by leveraging spin Berry curvature at specific high symmetry points. This study highlights interface modulation as a promising strategy for designing efficient spintronic devices.

QT02.10.08

Tunable Magnetic Properties and Thermal Stability of Co/Pt Superlattice Films for High-Performance Spintronic Devices *Yongha Shin and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)*

*In this study, we explore the magnetic and structural properties of ultrathin Co/Pt superlattice films, emphasizing their potential for MgO-based perpendicular magnetic tunnel junctions (p-MTJs). These superlattice films, consisting of monatomic layers of Cobalt and Platinum in a [Co/Pt]*4 configuration, demonstrate significant perpendicular magnetic anisotropy and thermal stability, essential for spintronic applications. The multilayer structure is Ru / [Co/ Pt]*4 / MgO / Ru . These films will be deposited on three different substrates: SiO2, Al2O3 and MoS2 exfoliation. And then, the films will undergo rapid thermal annealing (RTA).*

The magnetic properties of these films will be characterized by using a vibrating sample magnetometer (VSM) to evaluate parameters such as coercivity, saturation magnetization, and hysteresis behavior. Additionally, magnetic force microscopy (MFM) will be employed to investigate the micromagnetic structures, providing detailed imaging

of domain configurations. By manipulating the Co and Pt bilayer thicknesses, we observe a controlled variation in micromagnetic structures, notably the formation and density modulations.
These findings indicate that Co/Pt superlattices, with their precise tunability and robust performance under thermal stress, are promising candidates for future high-performance memory devices. The annealing process is expected to enhance the perpendicular magnetic anisotropy, contributing to the stability and efficiency of the MTJs. This study aims to demonstrate that such superlattice films can maintain their superior properties across various substrates, thereby broadening the applicability of this technology in different device architectures. Furthermore, the integration of 2D and 3D magnet superlattice structures offers the potential to create novel magnetic materials with unique properties, paving the way for innovative spintronic applications.

QT02.10.09

Robust Anomalous Hall Effect in Polycrystalline FeRh Thin Film During Ferromagnetic-Antiferromagnetic Phase Transition *Yun Ho Kim, Jung-Min Cho, Jae Won Choi, Gangmin Park and Sang-Kwon Lee; Chung-Ang University, Korea (the Republic of)*

Research on antiferromagnets and ferromagnets is actively progressing, focusing on the antisymmetric properties of ferromagnets and the proximity effect between ferromagnet and heavy metal layers. Antiferromagnets are notable for their high-speed operating frequency (THz) and vanishing field characteristics, and both materials exhibit anomalous optical and transport phenomena. FeRh, which exhibits temperature-dependent ferromagnetic (FM), ferromagnetic-antiferromagnetic metastable, and antiferromagnetic (AFM) phases, holds significant promise for spintronics applications. This phase transition is thermally influenced and can be controlled by chemical substitution, magnetic fields, lattice strain, and pressure. Measuring the magnetic properties of FeRh, such as magnetoresistance, Hall effect, and Nernst effect, is critical. These time-reversal symmetry-breaking characteristics make FeRh essential for spintronics devices, with the anomalous Hall effect offering potential for field-dependent switching devices.
However, the complexity and precision required for growing FeRh challenge its application at the device level. FeRh is typically grown as a single crystal on MgO substrates, which exhibit minimal lattice strain (c-parameter ~0.5% to 0.62%). While high epitaxial quality is crucial at the experimental stage, it complicates industrial-scale application using methods such as sputtering. Therefore, analyzing the properties of large-area polycrystalline FeRh is essential. Despite its significance, there has been limited analysis of FeRh grown on Si substrates. Observations of polycrystalline FeRh reveal significant magnetic properties. Notably, key indicators of the anomalous Hall effect, such as conductivity and anomalous Hall angle, are robust in both single-crystalline and polycrystalline FeRh on Si substrates.
This study aims to analyze the temperature-dependent magnetic transition and anomalous Hall effect of polycrystalline FeRh grown on Si substrates, providing new insights for developing spintronics devices.

QT02.10.10

Next-Generation Ferroelectric Devices Optimizing HZO and Graphene Hetero Structures *Gyuri Choi and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)*

Ferroelectric devices have emerged due to lower power consumption, faster switching speeds, and improved data retention. Moreover, HZO(Hf0.5Zr0.5O2) films have shown high permittivity, which refers to the material's ability to store electrical energy when an electric field is applied, high dielectric constant, making it suitable for applications where high charge storage density is desired, such as in non-volatile memory devices and excellent endurance making them ideal for repeated switching cycles without significant degradation.
In this study, we fabricated 10-nm-thick ferroelectric HZO(Hf0.5Zr0.5O2) thin films as a Ferroelectric dielectric with Graphene film as a semiconductor. The ferroelectric properties of HZO were enhanced through control

stoichiometries and post-metal annealing, leading to the Orthorhombic phase—synthesis of Large-Scale 3D-HZO and 2D-Graphene Films for FE-FET via Wet Transfer Method with Preservation of Graphene Degradation. The ferroelectric properties of HZO were enhanced through control stoichiometries and Post Metal Annealing, leading to Orthorhombic phase and PFM Amplitude and Phase, P-E, and C-V curve provide evidence supporting the presence of spontaneous remanent polarization in the HZO. We aim to produce large-scale FE-FETs based on HZO and graphene for next-generation nonvolatile memory devices. The final goal is to achieve wide hysteresis windows of approximately 2V, a high current on/off ratio of about 10^6, and a subthreshold swing of 250mV in the transfer characteristics of this Fe-FET device. These HZO and graphene Fe-FET devices may be attractive for various applications in advanced electronics. These optimized HZO and graphene Fe-FET devices have great potential for applications in neuromorphic computing, artificial intelligence, and energy-efficient electronics.

SESSION QT02.11: Spin-Charge Interconversion II
Session Chairs: Manuel Bibes and Jaeyu Kim

8:30 AM *QT02.11.01
Switching of Perpendicular Magnetization by Spin-Orbit Torque *Qianbiao Liu[1], Daniel C Ralph[2] and Lijun Zhu[1,3]; [1]Chinese Academy of Sciences, China; [2]Cornell University, United States; [3]University of Chinese Academy of Sciences, China*

Electrical switching of magnetization is central to spintronic memory and computing. Despite the enormous investigations in the past two decades, the understanding of spin-orbit torque and the switching of perpendicular magnetization remains elusive as indicated by a number of remarkable long-standing puzzles (see [1,2] for reviews of this problem in thin-film and van der Waals systems). First, this talk will show that the spin-orbit torque is not simply an interfacial spin transfer effect but varies strongly with the relative spin relaxation rates within the magnetic layer, such that a given spin-current generator can exert the strongest spin-orbit torque on 3d ferromagnets but much weaker one on nearly compensated ferrimagnets [3]. This talk will also discuss that, in many spin-orbit torque (SOT) heterostructures, such as heavy metal/ferromagnet bilayers with perpendicular magnetic anisotropy (PMA), the scaling of the switching current density with the SOT and the applied magnetic field is in strong disagreement with the predictions of the existing macrospin and chiral-domain-wall depinning models [4]. These remarkable puzzles can, in most cases, be explained by the long-range intralayer Dzyaloshinskii-Moriya interaction effect in magnetic heterostructures [5].

9:00 AM *QT02.11.02
Spin Texture Control with Low Symmetry 2D Heterostructures *Luis Hueso; Nanogune, Spain*

Spintronics has made important contributions to electronic devices, fundamentally in the fields on magnetic recording and non-volatile random-access memories. More recently, post-CMOS applications, such as the MESO one from Intel, aim to integrate logic and memory in spin-based devices [1,2]. A key player in several recent spintronic proposals is the spin-to-charge conversion, which permits to electrically create and detect pure spin currents without using ferromagnetic materials.
In this talk I will show how low symmetry materials can add new possibilities to spin-to-charge conversion. Moving beyond single crystalline bulk materials such as chiral Tellurium [3], I will show how twisted, low symmetry, graphene/chalcogenide structures display a complex spin texture and charge-to-spin conversion effects that could allow us to move beyond spintronic devices with standard metallic layers [4].

Unraveling the Role of Au and Al Interlayers in Observing Spin-Charge Conversion in Sb_2Te_3 Topological Insulator *Emanuele M. Longo[1,2], Matteo Belli[2], Claudia Wiemer[2], Alessio Lamperti[2], Andrey Matetskiy[2], Polina M. Sheverdyaeva[2], Paolo Moras[2], Marco Fanciulli[3] and Roberto Mantovan[2]; [1]Universitat Autònoma de Barcelona, Spain; [2]Consiglio Nazionale delle Ricerche, Italy; [3]University of Milano-Bicocca, Italy*

Topological insulators (TIs) can be used to control the magnetization of ferromagnetic (FM) layers in TI/FM heterostructures through spin-charge conversion (SCC) mechanisms driven by the topological surface state (TSS).[1] Non-magnetic interlayers at the TI/FM interface are frequently employed to enhance SCC efficiency, as demonstrated in Sb_2Te_3/Au/Co(Fe) heterostructures.[2,3] However, the effect of Au on the TSS of Sb_2Te_3 was not fully characterized.
Here, we study the different impact of Al and Au interlayers at the interface of Sb_2Te_3/Co heterostructures. Spin pumping experiments show that SCC is not observed in the presence of Al, in net contrast to the use of Au.[2,3] To understand the origin of this behavior, in-situ X-ray Photoemission Spectroscopy and Angle-Resolved Photoemission Spectroscopy measurements with synchrotron radiation were conducted during the deposition of Al and Au thin films on the Sb_2Te_3 surface. The analysis reveals the highly reactive character of Al and the disappearance of TSS upon deposition of only 1 nm thick Al film, at variance with the case of Au, which preserves the TSS.
These findings highlight the critical choice of non-magnetic material interlayers in devices for SCC applications and underscore the importance of preserving the TSS for efficient device performance.

Interfacial Orbital Engineering—Collapse of the Standard Magnetic Domain Structure in Thin Cobalt Films Hybridised with Molecular Layers *Valentin Dediu[1], Mattia Benini[1], Rajib K. Rakshit[1], Andrei Shumilin[2], Viktor Kabanov[2], Andrea Droghetti[3], Stefano Sanvito[3], Patrizio Graziosi[1], Alberto Riminucci[1], Ilaria Bergenti[1] and Manju Singh[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Jozef Stefan Institute, Slovenia; [3]Trinity College Dublin, The University of Dublin, Ireland*

I will show that, upon the chemisorption of organic molecules, Co thin films display a novel magnetic phase that we temptatatively call ferromagnetic glass state. This is characterised by a giant magnetic hardening and by the violation of the Rayleigh law for magnetization reversal. Such new phase originates from the modification of the surface magnetic anisotropy induced by the molecule/film interaction, whose result is to produce a correlated random anisotropy field. The ferromagnetic glass state then emerges when the correlation length of the random anisotropy field is close to the characteristic exchange length that, in our case, is of the order of 10nm. At the microscopic level, the ferromagnetic glass state is defined by blurred pseudo-domains intertwined by diffuse and irregular domain walls. Intriguingly, the magnetization reversal process of such configuration terminates with vortex-like structures, predicted by theory and measured by magnetic-force microscopy. Our work shows how the strong electronic interaction of standard components, Co thin films and readily available molecules, can generate structures with remarkable new magnetic properties, and thus opens a new avenue for the design of tailored-on-demand magnetic composites.

10:45 AM *QT02.12.02

Polarization of Electron Spin and Orbitals from Structural Chirality—Spin-Selective Transport in Chiral Molecular Junctions on Semiconductors *Peng Xiong[1], Yuwaraj Adhikari[1], Tianhan Liu[2], Hailong Wang[3], Zhenqi Hua[1], Haoyang Liu[1], Hanwei Gao[1], Pedro Schlottmann[1], Paul S. Weiss[2], Binghai Yan[4] and Jianhua Zhao[3]; [1]Florida State University, United States; [2]University of California, Los Angeles, United States; [3]Chinese Academy of Sciences, China; [4]Weizmann Institute of Science, Israel*

Electrical generation and transduction of polarized electron spins in semiconductors via nonmagnetic means are *of broad interest in spintronics and quantum information science. One such pathway exploits chiral/helical spin textures in electronic structures; a contrasting approach utilizes the interplay of electron spin with chirality in real space. Breaking of spatial inversion symmetry has profound effects on the electronic properties of materials. One prominent manifestation of such effects of much recent interest is chirality-induced spin selectivity (CISS), where real-space structural chirality induces spin polarization of electrons from a nonmagnetic electrode[1]. CISS has been reported in a variety of chiral molecules and hybrid chiral crystals, however, definitive understanding of its physical origin remains elusive. We have studied the CISS effect through measurement of spin-selective transport in chiral molecular junctions comprising a nonmagnetic normal metal electrode and a self-assembled monolayer of chiral molecules (α-helix L-polyalanine) on magnetic (GaMnAs) or nonmagnetic (n-GaAs) semiconductors, where the spin polarization is detected via measurements of the spin-valve conductance and Hanle effect, respectively. The pronounced CISS effect in the robust semiconductor-based molecular device platform enabled systematic and rigorous examination of its dependences on the molecular structure, normal metal material, and bias current. The results reveal several key characteristics of the CISS effect: i) nontrivial linear-response magnetoconductance in two-terminal CISS spin valves, in apparent violation of the Onsager reciprocal relation[2]; ii) crucial role of the spin-orbit coupling in the normal metal electrode, suggesting the importance of orbital polarization in the chiral molecules[3]; iii) spin generation by CISS in semiconductors[4]. Our experiments have provided significant new insights on CISS and demonstrated its potential for enabling semiconductor spintronics free of any magnetic materials.*

Design of N-Doped $BaTiO_3$/$CoFe_2O_4$ Multiferroic Heterostructures and Their Physical Properties

Pamella Pinho[1], Céline Blaess[1], Jean-Baptiste Moussy[1], Sylvia Matzen[2], Alina Vlad[3], Christophe Gatel[4] and Antoine Barbier[1]; [1]French Alternative Energies and Atomic Energy Commission, France; [2]Université Paris-Saclay, France; [3]Synchrotron SOLEIL, France; [4]Université de Toulouse, France

N-doped oxides and/or oxynitrides have recently emerged as promising materials in the field of optospintronics, blending optical, electronic, and spin-related functionalities to enable innovative device applications. In particular, the controlled incorporation of nitrogen into the crystal lattice of oxide semiconductors offers the possibility of modulating the value of their optical band gap, resulting in novel functionalities. The design of such single crystalline thin films is highly challenging. In this work, we have grown and fully characterized single crystalline N-doped oxide heterostructures, i.e. $CoFe_2O_4$/N:$BaTiO_3$/$La_{2/3}Sr_{1/3}MnO_3$/$SrTiO_3$(001). The aim is to develop an artificial opto-multiferroic structure. Hence, barium titanate ($BaTiO_3$) was chosen for its ferroelectricity and its favorable absorption spectrum, while cobalt ferrite ($CoFe_2O_4$) provided the additional ferrimagnetism [1]. Growth was performed in a dedicated oxygen (or nitrogen) plasma-assisted molecular beam epitaxy [2]. Then, their structural, chemical and physical properties were thoroughly studied. Operando electron diffraction, ex situ X-ray diffraction and reflectivity were used to obtain structural information on the thin films, such as epitaxial relationship between growing layers, crystalline structure, lattice parameters, film thickness and roughness. The stoichiometry and electronic structure of the layers were verified in situ by photoemission spectroscopy. The film microstructure was investigated via high-resolution transmission electron microscopy on CEMES-CNRS laboratory. The ferroelectric properties of the layers were probed by piezoelectric force microscopy and capacitance measurements. Finally, the fine structure and magnetic behavior of the ferrite top layers were studied at the European Synchrotron

Radiation Facility on beamline ID32. The Fe and Co cation site distribution was determined by exploring the $L_{2,3}$-edges X-ray absorption (XAS) and circular dichroism (XMCD) spectra [3]. Element specific magnetic behavior was studied using field-dependent XMCD hysteresis loops at Fe and Co L_3-edges. We will show in detail the ferroelectric and ferromagnetic properties of the heterostructures as a function of nitrogen doping, correlated with a comprehensive description of the crystalline and electronic structures of the materials.

Voltage-Controlled Magnetism for Energy-Efficient Spintronics *Bhagwati Prasad[1], Akash Surampalli[1], Anup Kumar Bera[1], Yen-Lin Huang[2] and R Ramesh[3]; [1]Indian Institute of Science, India; [2]National Yang Ming Chiao Tung University, Taiwan; [3]University of California, Berkeley, United States*

Conventional spintronics-based memory devices use electrical currents to control electron spin direction and dynamics. While effective, this method has high energy costs and limited device endurance [1]. To address the demand for faster, smaller, and ultra-low-power electronic devices, research into voltage control of magnetism has recently intensified, promising ultra-low-power non-volatile memory solutions for next-generation computing systems [2]. We present our advancements in voltage-controlled magnetism through various approaches, including voltage-controlled magnetic anisotropy, voltage-controlled exchange coupling, and multiferroic-based magnetoelectric coupling for spintronics applications. Our studies have led to several significant discoveries. One key finding is the large tunability of perpendicular magnetic anisotropy (PMA) achieved by inserting ultrahin Ir, Mg-Al, and Pt layer at the MgO/Ferromagnet interface [3]. We also demonstrated the modulation of interlayer exchange coupling using an Ir spacer layer and non-ionic liquid gating like MgO [4]. This novel approach improves magnetic interaction control, reducing power consumption. Additionally, we showed that the magneto-electric coupling effect in a bismuth ferrite-based multiferroic system can modulate magnetism [5-7]. This discovery opens new possibilities for using multiferroic materials in spintronic applications, achieving low-power operation. These efforts offer multiple pathways to modulate resistance states in spintronic devices, paving the way for next-generation energy-efficient computing devices.

Nearly Perfect Spin Polarization of Noncollinear Antiferromagnets *Evgeny Y. Tsymbal; University of Nebraska-Lincoln, United States*

Ferromagnets with high spin polarization are known to be valuable for spintronics—a research field that exploits the spin degree of freedom in information technologies. Recently, antiferromagnets have emerged as promising alternative materials for spintronics due to their stability against magnetic perturbations, absence of stray fields, and ultrafast dynamics. For antiferromagnets, however, the concept of spin polarization and its relevance to the measured electrical response are elusive due to nominally zero net magnetization. Here, we define an effective transport spin polarization and reveal an unexpected property of many noncollinear antiferromagnets to exhibit nearly 100% spin polarization in a broad area of the Fermi surface. This property leads to the emergence of an extraordinary tunneling magnetoresistance (ETMR) effect in antiferromagnetic tunnel junctions (AFMTJs). As a representative example, we predict that a noncollinear antiferromagnet Mn_3GaN exhibits nearly 100% spin-polarized states that can efficiently tunnel through low-decay-rate evanescent states of perovskite oxide $SrTiO_3$ resulting in ETMR as large as 10^4%. Our results uncover hidden functionality of material systems with noncollinear spin textures and open new perspectives for spintronics.

2:00 PM *QT02.13.02
Origins of Electromagnetic Radiation from Spintronic THz Emitters Unraveled by Time-Dependent Quantum Calculations Combined with Jefimenko Equations *Branislav Nikolic; University of Delaware, United States*

Microscopic origins of charge currents and electromagnetic (EM) radiation generated by them in spintronic THz emitters [1]—such as, femtosecond laser pulse-driven single magnetic layer or its heterostructures with a nonmagnetic layer hosting strong spin-orbit coupling (SOC)—remain poorly understood despite nearly three decades since the discovery of ultrafast demagnetization. We introduced [2] a first-principles method to compute these quantities, where the dynamics of charge and current densities is obtained from real-time time-dependent density functional theory (TDDFT), which are then fed into the Jefimenko equations for properly retarded electric and magnetic field solutions of the Maxwell equations. By Fourier transforming different time-dependent terms in the Jefimenko equations, we unravel that in 0.1–30 THz range the electric field of far-field EM radiation by Ni layer, chosen as an example, is dominated by charge current pumped by demagnetization, while often invoked magnetic dipole radiation from time-dependent magnetization of a single magnetic layer is a negligible effect. Such an overlooked case of charge current pumping by time-dependent quantum system, whose magnetization is *shrinking while its vector does not rotate, does not require any spin-to-charge conversion via SOC effects. In Ni/Pt bilayer, EM radiation remains dominated by charge current within Ni layer, whose magnitude is larger than in the case of single Ni layer due to faster demagnetization, while often invoked spin-to-charge conversion within Pt layer provides additional but smaller contribution. By using the Poynting vector and its flux, we also quantify efficiency of conversion of light into emitted EM radiation, as well as the angular distribution of the latter. While TDDFT treats a closed quantum system, realistic experimental setups are always open systems, which ensures that currents eventually decay to zero. We can open them by coupling magnetic multilayer to bosonic dissipative environment (as provided by phonons) [3] or fermionic reservoirs [4], which will be illustrated by the Lindblad quantum master equation or time-dependent nonequilibrium Green's functions combined with Jefimenko equations.*

Exchange Bias in $La_{0.67}Sr_{0.33}MnO_3/YFeO_3$ Ferromagnet/Antiferromagnet Heterostructures *Paul Fourmont[1,2], Eunsoo Cho[2], Sylvain G. Cloutier[1] and Caroline A. Ross[2]; [1]École de Technologie Supérieure, Canada; [2]Massachusetts Institute of Technology, United States*

Thin film multilayers can exhibit emerging phenomena at their interfaces which are absent in their individual constituents. In particular, magnetic exchange interactions at the interfaces between ferromagnetic and antiferromagnetic-based materials provide a broad range of possibilities for fundamental studies and development of novel devices based on exchange bias. Various oxide-oxide, metal-metal or metal-oxide ferromagnet-antiferromagnet interfaces show exchange bias after field-cooling which produces a shift of the magnetic hysteresis loop. Perovskites with ABO_3 composition can exhibit ferromagnetism (e.g. $La_{0.67}Sr_{0.33}MnO_3$, LSMO), or antiferromagnetism (e.g. orthoferrites, $AFeO_3$) among other properties, and therefore provide a rich environment for exploring interfacial exchange in an all-oxide heterostructure.

Here, we investigate and optimize magnetic coupling of perovskite multilayers made of LSMO and $YFeO_3$ (YFO) as ferromagnetic and antiferromagnetic layers respectively. Films were made by pulsed laser deposition which produced heterostructures with interface widths of around one unit cell (1 u.c. = 0.4 nm), according to atomically resolved scanning transmission electron microscopy coupled with electron diffraction spectroscopy. We first fabricated single layers and bilayers of YFO and LSMO on $SrTiO_3$ (STO) substrates. Field cooling from 673 K in a 10 kOe field led to an exchange bias of up to 306 Oe at 50 K for 10 u.c. LSMO/49 u.c. YFO/STO with a Curie temperature around 280 K. Although exchange bias increases with decreasing ferromagnetic thickness, the LSMO layers must be thick enough, usually around 3-5 nm, to maintain their magnetic ordering and suppress magnetic dead layers. LSMO thickness also influences the Curie temperature of the LSMO layer, and the blocking temperature of the LSMO/YFO bilayer which was slightly below room temperature. On the contrary, exchange bias increases with thicker YFO layers until reaching a saturation value at 49 u.c. YFO for a fixed LSMO thickness of 10 u.c..

Most work on exchange bias in perovskite heterostructures has been done on bilayers, but we demonstrate here that perovskite-based multilayers exhibit enhanced exchange bias. A five-layer LSMO [10 u.c.]/YFO[49 u.c.]/LSMO[10 u.c.]/YFO[49 u.c.]/LSMO[10 u.c.]/ stack yields a 424 Oe exchange bias at 50 K after field cooling at 10 kOe. To demonstrate a heterostructure with both pinned and unpinned layers, an all-perovskite spin-valve stack was synthesized consisting of STO/LSMO(10 u.c.)/STO(8 u.c.)/LSMO(10 u.c.)/YFO(26 u.c.). After field cooling *at 10 kOe and 673 K the hysteresis loops shows two steps switching from the unpinned and pinned layers, and parallel and antiparallel remanent states can be achieved at 200K. These results show the capabilities of PLD for making oxide heterostructures with sharp interfaces, and show how oxide heterostructures can exhibit spin valve behavior analogous to that of exchange-biased metallic spin valves.*

***Probabilistic Computing Using Stochastic Magnetic Tunnel Junctions** Shunsuke Fukami; Tohoku University, Japan*

Conventional electronics relies on deterministic operation of electronic devices, where stochastic behavior is attempted to be minimized. In contrast to this perspective, in 1981, R. P. Feynmann gave a suggestion of unconventional computing paradigm, so-called the probabilistic computing. This approach leverages intentionally enhanced probabilistic behavior of physical system within computing hardware to simulate physical phenomena that are inherently probabilistic. The demand for such probabilistic computers has risen recently as a rapid increase in computing tasks that can be efficiently addressed by probabilistic algorithms. Probabilistic bit (p-bit) is a fundamental unit constituting the probabilistic computer and recent studies have revealed that probabilistic spintronics devices, in particular, the stochastic magnetic tunnel junction (s-MTJ), shows promise for constructing the p-bit.
In this talk, I show various proof-of-concepts for the spintronic probabilistic computers and also discuss the physics and engineering of s-MTJ. I first outline the basic properties and characteristics of the p-bit with s-MTJ and then showcase several demonstrations including combinatorial optimization [1], Boltzmann machine learning [2], quantum simulation [3], and Bayesian inference [4]. After that, I delve into the physics of the stochastic magnetic tunnel junction elucidating the time-domain [5,6] and time-averaged [7,8] properties. I also discuss advanced design of the s-MTJs [9-12] tailored for reliable, large-scale computers.
These studies are carried out in collaboration with H. Ohno, S. Kanai, W. A. Borders, K. Hayakawa, K. Kobayashi, R. Ota, H. Kaneko, G. Finocchio, S. Datta, and K. Y. Camsari, and were partly supported by JST-CREST JPMJCR19K3, JST-AdCORP JPMJKB2305, JST-ASPIRE JPMJAP2322, MEXT X-NICS JPJ011438 and RIEC Cooperative Research Projects.

Anatomy of the Anomalous Nernst and Spin Seebeck Effects in Fe-Based Metallic Multilayers *Jesus Alejandro De Sousa[1], Silvia Damerio[1], Sabri Koraltan[2] and Can Onur Avci[1]; [1]Universitat Autònoma de Barcelona, Spain; [2]University of Vienna, Austria*

The relationship between heat, spin, and charge transport in magnetic materials is a central topic in materials physics [1]. In the past decade, the spin Seebeck effect (SSE) has been in the spotlight of research efforts as it allowed the generation of spin currents in magnetic materials without an accompanying charge flow [2]. In the SSE, the spin current flows parallel to the temperature gradient with polarization along the magnetization axis. The SSE can be detected by injecting the generated spin current into a metal layer with large spin-orbit coupling (e.g., Pt) and measuring the inverse spin hall effect voltage [3]. The SSE has been predominantly studied in magnetic insulator/heavy metal systems because, in all-metallic systems such as Co/Pt and Fe/Pt, the inverse SHE signals in Pt become indistinguishable by symmetry from the anomalous Nernst effect (ANE) signal in the magnetic layer [4]. Despite its difficulty, the possibility of simultaneous and additive generation of SSE and ANE and rich fundamental physics different from insulating systems make ferromagnetic metal (FM) heterostructures appealing from both applied and fundamental perspectives [4].

Among 3d FMs, the case of Fe is especially intriguing. The ANE coefficient of Fe exhibits an atypical thickness dependence. It is positive in ultrathin films (typically < 5 nm) and becomes negative for thicker films and the bulk [5]. This starkly contrasts with all other 3d FMs where the ANE coefficient is positive independently of the thickness. As a result, while in, e.g., Co/Pt, the ANE and SSE voltages are expected to be always additive, in Fe/Pt, they can be additive or competing depending on the Fe thickness and other interface-related parameters. Consequently, Fe-based heterostructures provide a suitable platform for engineering thermoelectric devices once underlying physical mechanisms are properly understood.

In this work [6], we study the ANE and SSE in a wide variety of Fe-based multilayer films under the influence of ΔT applied perpendicular to the film plane. Single Fe layers show thermoelectric signals of purely ANE origin, controlled by the power (P_h) dissipated through the heater. In contrast, in Fe/Pt, we find a large SSE contribution comparable to the ANE characterized in Fe alone. We find that both ANE and SSE consist of two components, one temperature-independent (linear in P_h) and another temperature-dependent (quadratic in P_h), the latter typically overlooked in such measurements. We identify a combination of Fe and Pt thicknesses where the quadratic term dominates the thermoelectric signals due to the linear terms of ANE and SSE nearly canceling each other. At this regime, the thermoelectric signals in the same device undergo a sign reversal at a critical P_h, which was not reported or observed before. Collective data suggest that the quadratic ANE term is due to the reduction in the saturation magnetization of Fe at higher temperatures, whereas the quadratic SSE term pinpoints bulk magnon contributions. We furthermore show that both the linear and quadratic terms can be precisely controlled by changing the multilayer composition and stacking order, Fe and Pt thicknesses, and nonmagnetic metal doping of Fe. These results provide a solid ground for understanding the thermoelectric effects in similar structures and developing engineering strategies for micro-energy harvesting devices or heat flow sensors.

Unveiling High Spin Polarization in Mn-Rich Co-Mn-Ge Heusler Alloys via High-Throughput XMCD Analysis

Takahiro Yamazaki[1], Alexandre Lira Foggiatto[1], Ryo Toyama[2], Kentaro Fuku[1], Kohei Yamagami[3], Hitoshi Ohsawa[3], Takuo Ohkochi[4,3], Yuma Iwasaki[2], Yuya Sakuraba[2] and Masato Kotsugi[1]; [1]Tokyo University of Science, Japan; [2]National Institute for Materials Science, Japan; [3]Japan Synchrotron Radiation Research Institute, Japan; [4]University of Hyogo, Japan

The rapid growth of digital data has necessitated higher recording densities in HDDs. Current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) devices have attracted significant attention as next-generation HDD read heads, potentially replacing tunnel magnetoresistance (TMR) devices. However, conventional ferromagnetic materials have inadequate magnetoresistance (MR) ratios, highlighting the need for materials with higher spin polarization to achieve significant MR ratio enhancements[1]. This study focuses on the half-metallic Heusler alloy Co_2MnGe, based on predictions from machine learning-driven virtual material discoveries. Specifically, the goal is to identify with higher spin polarization in Mn-rich regions by fabricating compositional-spread thin films and performing high-throughput soft X-ray magnetic circular dichroism (XMCD) measurement.

Co-Mn-Ge compositional-spread thin films were deposited on MgO substrates using a magnetron sputtering system. X-ray structural analysis confirmed the $L2_1$ ordered structure across a wide compositional range. XMCD measurements at the Co and Mn $L_{2,3}$ absorption edges were performed at the BL25SU beamline of SPring-8, Japan to evaluate the magnetic moments of the respective elements. Anisotropic magnetoresistance (AMR) measurements were conducted post-device fabrication to assess the AMR ratios for various compositions. First-principles calculations were employed to analyze the electronic density of states and spin polarization.

The results from XMCD and AMR measurements suggest a correlation between the increased spin magnetic moment of Co in Co_2MnGe alloys and the enhancement of the AMR ratio. Notably, the high negative AMR ratios observed in Mn-rich regions are attributed to the high saturation magnetization of Co_2MnGe alloys with an $L2_1$ ordered structure. The significant negative AMR ratios indicate high spin polarization in Mn-rich regions. These experimental results are consistent with first-principles calculations, which also suggest high spin polarization in Mn-rich Co_2MnGe alloys. Therefore, it is evident that the manifestation of high spin polarization is both experimentally and theoretically predictable. This study highlights the potential of Mn-rich Co_2MnGe alloys as high-performance materials for CPP-GMR devices, contributing to the advancement of next-generation HDD read heads with significantly enhanced MR ratios. The combination of experimental and theoretical approaches provides a robust framework for predicting and validating high spin polarization in new materials.

Integrating Experiments and Machine Learning for Measuring Topological and Quantum Materials *Mingda Li; Massachusetts Institute of Technology, United States*

In recent years, there has been a surge in research on the application of machine learning in chemistry and materials sciences. Machine learning has led to the discovery of new pharmaceutical molecules and energy materials, marking a paradigm shift in both research and industry. However, quantum materials have faced significant challenges despite numerous reports on machine learning applications. These challenges arise due to the complex interplay between charge, spin, orbital, and lattice degrees of freedom, and the frequent occurrence of out-of-distribution (OOD) problems. In particular, for topological materials, identifying experimental signatures to reveal topology is critical since "topology" itself is not directly measurable.

In this MRS seminar, we present our recent efforts to connect machine learning with various topological and quantum materials, particularly through experimental techniques. For band topology materials with weak correlation, we introduce our classifier that determines the topological class based on x-ray absorption (XAS) signals [1]. For topological quantum computation, we discuss our approach to applying machine learning to distinguish Majorana zero modes from other spurious signals in tunneling spectroscopy [2]. For quantum materials where phonons play a role, we showcase a graph neural network method that predicts phonon dispersion relations much faster than traditional machine learning potentials [3]. Finally, recognizing that discovered materials represent only a small fraction of all possibilities, we describe our efforts to generate new materials with constrained lattice types. We conclude by highlighting additional examples that demonstrate the increasingly important role of machine learning in topological and quantum materials, despite data scarcity and computational challenges.

***Leveraging Breakthroughs in Topological Physics to Understand Chemical Reaction Dynamics** Lukas Muechler; The Pennsylvania State University, United States*

The integration of topology, a branch of mathematics, into the analysis of electronic states in crystalline materials has had a revolutionary impact on the field of condensed matter physics.
Topological band theory has delivered new approaches and tools to characterize the electronic structure of materials, resulting in the discovery of new phases of matter with exotic properties. In the framework of topological band theory, the crossings between energy levels of electrons are characterized by topological invariants, which predict the presence of topological boundary states.
Given the common occurrence of energy level crossings on molecular potential energy surfaces, extending these topological concepts to molecular systems holds potential for significantly enhancing our comprehension of reaction dynamics. However, the disparate quantum mechanical frameworks used to describe solids and molecules present substantial challenges.
This talk will present recent efforts of our group to reconcile these two approaches, focusing on the characterization of features of the potential energy surface such as conical intersections and second order saddle points using topological invariants, and exploring their implications on reaction dynamics. We demonstrate our results by studying 4π electrocyclization reactions relevant for photoswitch design. Here, second-order saddle points and changes in invariants are pivotal for understanding the competition between conrotatory and disrotatory pathways.

Topological Interpretation of Classical Granular Network Through Realization of Berry Phase and Elastic Bit
Kazi Tahsin Mahmood and M. Arif Hasan; Wayne State University, United States

The study of the Berry phase in classical and quantum systems has opened new possibilities in the field of quantum information science and technology. The Berry phase, which emerges from an adiabatic cyclic process, can create a relation with the dynamics of an elastic system. In this study, we show the formation of a Berry phase in a quantum analogue two-level system, an elastic bit. We investigate the formation of the elastic bit by harmonically driving the system in a classical nonlinear system that consists of two single-point contact granules, which creates a Hertz-type nonlinearity. The formation of different coherent superpositions of states are generated by tuning the frequency or amplitude separately or simultaneously. First, we show the effect of the driving parameters in forming elastic bits in a linearized system, where the superposition of states is time-independent. When mapped onto the Bloch sphere, the state vector's trajectory of this elastic bit in parameter space can be precisely manipulated using the external drivers' amplitude, phase, and frequency, resulting in a specific Berry phase. The quantized Berry phase observation indicates that the elastic bit exhibits trivial and nontrivial topologies. An equal superposition of states of the elastic bit yields the nontrivial Berry phase of . In contrast, the zero Berry phase corresponds to pure states, and any superpositions of states can take values different from or . We also show the nonlinearity effect in the Berry phase's experimental formation, where the coherent states are time-dependent. Using the orthonormal basis for nonlinear responses and mapping the displacement coefficients in Bloch states, we show how time affects the manipulation of the elastic bit and its states. Our analytical and experimental studies reveal the Berry phase's involvement in exposing numerous topological properties of the classical granular network. These properties are important in topological computing, especially in the non-abelian computation, which acquire a Berry phase when braided around each other. This phase encodes quantum information in a way that is inherently protected from local noise and perturbations, providing robustness against decoherence. In non-Abelian computing, holonomic quantum gates are implemented using the Berry phases *acquired by the system.*

11:45 AM QT03.01.04

Electronic Structure in a Rare-Earth-Based Antiferromagnet $TbNi_3Ga_9$ *Sabin Regmi[1], Volodymyr Buturlim[1], Binod K. Rai[2], Peter Oppeneer[3], Tomasz Durakiewicz[1] and Krzysztof Gofryk[1]; [1]Idaho National Laboratory, United States; [2]Savannah River National Laboratory, United States; [3]Uppsala University, Sweden*

Rare-earth-based intermetallics provide flexibility to study the electronic, magnetic, superconducting, and topological properties by tuning the crystal structure, composition, and spin-orbit coupling. Recently, $RNi_3(Ga/Al)_9$ intermetallic materials have been studied for their richness in broad range of exotic crystal, magnetic, heavy fermion, and quantum criticality behaviors. However, momentum-resolved electronic structure studies are lacking. Here, we present results of the angle-resolved photoemission spectroscopy measurements to reveal the underlying electronic structure and topology in $TbNi_3Ga_9$, both above and below the Néel temperature. This study will open up exciting avenues towards exploration of electronic properties in the chiral family of $RNi_3(Ga/Al)_9$ materials with wide range of intriguing properties.

GeTe Ferroelectric Rashba Semiconductor—From Growth to Electronic Properties *Boris Croes[1,2], Alexandre Llopez[1], Fabien Cheynis[1], Stefano Curiotto[1], Pierre Müller[1], Yannick Fagot-Revurat[3], Calvin Tagne Kaegom[3], Bertrand Kierren[3], Salia Cherifi-Hertel[2], Olivier Thomas[4], Thomas W. Cornelius[4], Michaël Texier[4], Sylvain Massabeau[5], Jean-Marie George[5] and Frédéric Leroy[1]; [1]Centre interdisplinaire de Nanoscience de Marseille, France; [2]Institut de physique et chimie des Matériaux de Strasbourg, France; [3]Institut Jean Lamour, France; [4]Institut Matériaux Microélectronique Nanosciences de Provence, France; [5]Laboratoire Albert Fert, France*

Among ferroelectrics, a new class of materials for spintronics has recently been introduced: The Ferroelectric Rashba semiconductors [1,2]. The main results, obtained on GeTe thin films, have demonstrated that reversal of the ferroelectric polarization leads to a change in the spin chirality of the band structure [3,4]. A spin-to-charge conversion has also been demonstrated at room temperature in ferromagnetic-GeTe structures [5-7].
In this presentation, I will discuss the organization of ferroelectric nanodomains present in GeTe thin films grown on Si(111) [8], the type of domain wall and the structure of the interface with the substrate. Quasi-monocrystalline GeTe thin films can be produced on Si(111) by molecular beam epitaxy, by first depositing an atomic monolayer of Sb [9,10,11]. This substrate enables ferroelectric domains to be studied and controlled, as they are not limited by grain boundaries. Ferroelectric nanodomain volume fraction and domain size were measured by X-ray diffraction and low energy electron microscopy (LEEM) over a wide range of film thicknesses (10-1800 nm). Second harmonic generation (SHG) microscopy combined with polarimetric analysis revealed the local symmetry of these domains.

Using high-resolution transmission electron microscopy (HR-TEM), we show that the domain walls are at 71° and that the GeTe/Si interface is stabilized by dislocations that relax the large parametric mismatch between the two crystal lattices. The reversible appearance/disappearance of ferroelectric nanodomains by thermal cycling, visualized by LEEM in situ, is attributed to thermal stresses induced by the thermal expansion differential between the two materials [12]. At last we demonstrate a giant Rashba effect in GeTe thin films by Angle Resolved Photo Emisson Spectroscopy for thin films down to a 1 nm thick layer. We also put in evidence significant THz emission through spin-to-charge conversion in a Fe/GeTe/Si(111) stack.

Novel Growth of Phase-Pure α-Sn Quantum Microstructures on Si Using a Ge Seed Layer *Shangda Li[1], Shang Liu[1], Jules A. Gardener[2], Austin Akey[2], Xiaoxue Gao[1], Xiaoxin Wang[1] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]Harvard University, United States*

The elemental topological quantum material α-Sn has recently gained significant attention for its unique transport properties and potential spintronics applications [1]. Overcoming the notorious "tin pest" instability, α-Sn with its diamond cubic structure offers promising integration possibilities for topological quantum devices on Si. However, direct growth on Si is challenged by a significant lattice mismatch. Growths of α-Sn on Si were reported, but the thickness was limited to below 10 nm [2].

In this study, we introduce a novel method to grow 200 nm-thick α-Sn microstructures with lateral dimensions reaching 0.4-1 μm on a Si substrate by employing a 2 nm-thick Ge seed layer via physical vapor deposition [3]. Up to 86% of as-deposited β-Sn converts to α-Sn under optimal thermal annealing conditions, which significantly enhances the phase purity compared to ~50% α-Sn in our previous work of Ge-doped α-Sn grown on native oxide on Si [4]. Cooling process is found to be critical to α-Sn formation. Using in situ Raman spectroscopy, we confirm that as-deposited β-Sn melts during rapid thermal annealing (RTA) at 350-450°C and solidifies into α-Sn upon cooling, facilitated by heterogeneous nucleation on the Ge layer. High-resolution transmission electron microscopy (HRTEM) and energy dispersive X-ray spectroscopy (EDS) reveal single-grain α-Sn microdots with identical crystallographic orientation within each microdot. Approximately 1 at.% Ge diffuses into the α-Sn, aiding thermodynamic stabilization and processing. Tuning cooling conditions and employing HCl etching, we further achieve phase-pure α-Sn microstructures suitable for quantum device applications. This α-Sn incorporates a compressive strain of ~-0.59%, induced by the Ge seed layer, confirming its nature as a 3D topological Dirac semimetal compatible with Si-based quantum devices [5]. Our discoveries provide a platform for several potential applications, including exploring point-contact induced superconductivity [6], investigating transport properties

[7], and studying optical modulation [8]. Our method's compatibility with CMOS technology presents a significant advancement toward quantum materials integration on Si and opens up opportunities for practical applications in quantum electronics and spintronics. Future work will explore a broader range of Ge seed layer thicknesses and epitaxial growth of Ge seed layer on Si substrate to further optimize the α-Sn growth process and device integration.

Epitaxial Stabilization of Molybdate Pyrochlore Thin Film Near Phase Boundary *Kyeong-Yoon Baek, Margaret A. Anderson, Charles Brooks and Julia Mundy; Harvard University, United States*

In quantum materials, colossal responses can emerge near phase boundaries. The molybdate pyrochlore oxides, $R_2Mo_2O_7$ (R = rare earth), form a series of compounds where there is a transition from a ferromagnetic metal to a spin glass insulator as a function of the R^{3+} radius [1]. To date, most of the work on this family of materials has been on bulk polycrystalline samples [2]. In this work, we synthesized pyrochlore $Gd_2Mo_2O_7$ and $Tb_2Mo_2O_7$ in thin film form using molecular beam epitaxy (MBE); in the bulk samples, $Gd_2Mo_2O_7$ and $Tb_2Mo_2O_7$ are a metallic ferromagnet and an insulating spin glass, respectively, both sitting adjacent to the phase boundary. $Gd_2Mo_2O_7$ thin films show insulating ferromagnetic behavior which is not present in the reported phase diagram of molybdate pyrochlore investigated in bulk form. Our work realizes novel phases of molybdate pyrochlore near phase boundary enabled by the thin film geometry.

3:00 PM QT03.03.01

Molecular Beam Epitaxy of Doped Topological Insulators for Spintronics and Quantum Anomalous Hall

Effect Applications *Mehmet C. Onbasli[1], Ebrahim Zahrabi[1], Ahmad El Zatari[1], Aykut Can Onel[1], Roya Kavkhani[1], Kerem Anar[1] and Ferhat Katmis[2]; [1]Koç University, Turkey; [2]Massachusetts Institute of Technology, United States*

Topological insulators stand out in many fundamental magnetotransport, spintronic and quantum anomalous Hall effect (QAHE) studies due to their unique electronic band structures. Their bulk band gap, topologically protected surface states with Dirac cone features, dopant-tuning of Fermi level and large spin-orbit coupling characteristics enable the exploration of a wide range of new condensed matter phenomena, materials physics and new quantum device applications. Among these applications, QAHE is an important basic scientific and applied area of condensed matter physics, which helps define the fundamental units of resistivity and help develop metrology-grade extremely sensitive and precise magnetic field and current sensors. An important issue in this field is the requirement of 30-50 mK range of magnetotransport measurements, which limits the field to fundamental scientific studies and prevents using this highly promising mechanism for sensing or other device applications. Several materials breakthroughs are needed to enable QAHE at higher temperatures such as few-Kelvin ranges.

In this study, we present molecular beam epitaxial growth and optimization of topological insulator Bi_2Te_3 and Sb-doped Bi_2Te_3 and a detailed structural and magnetotransport analysis of the films grown expitaxially on sapphire. Bi_2Te_3 is notable among TIs because of its substantial bulk band gap. The quality of these topologically protected surface states is heavily influenced by the quality of the deposited thin films. However, the epitaxial growth behaviors, thickness, and phase segregation of Bi_2Te_3 and its Sb-doped variant are not well understood. Our study clarifies the effects and significance of growth kinetics on the quality of thin films, focusing on deposition rates, annealing time, substrate temperature, and growth duration. We used X-ray diffraction (XRD), X-ray reflectivity (XRR), and atomic force microscopy (AFM) for structural characterization, X-ray photoelectron spectroscopy (XPS) and energy-dispersive X-ray spectroscopy (EDX) for electronic characterization, and Raman spectroscopy for optical characterization.

To elucidate the effect of stoichiometry, defects, and strain on the TI quality, we pursued two main research paths. First, we investigated the effect of elemental flux of deposited material in MBE on strain and Bi_2Te_3 thickness. Second, we investigated the influence of different doping levels in Sb in Bi_2Te_3, keeping all other growth parameters constant. In our analysis, we detected an unwanted secondary phase peak at 015 and Bi_2Te phase in both Bi_2Te_3 and Sb-doped Bi_2Te_3 and films. Reducing the growth rate for Bi_2Te_3 films almost eliminated this 015 secondary phase. Increasing the Sb flux also significantly reduced this secondary phase. In both cases, pronounced thickness fringes indicated coherence between the film surface and the substrate. Our growths identified that the flux ratios of bismuth to tellurium must be optimized for achieving full film growth. A higher bismuth flux rate than for tellurium causes hexagonal island growth and no films.

Finally, we present a broader analysis describing the intrinsic and extrinsic effects that hold the magnetic ordering temperature for QAHE low in the mK ranges. We identify that the intrinsic effects are material chemistry related and those effects are magnetic ordering temperature (Curie temperature), doping limitations (V, Sb and the associated dilution of magnetic moments), material defects and nonuniform dopant distributions, the weak interaction between magnetic dopants the host materials' electronic states, and a likely competition between spin-orbit coupling and robust magnetic interactions limits QAHE in the mK ranges. Extrinsic effects include finite size effects, interference from bulk states, and materials engineering challenges. We conclude that MBE growth optimization is necessary for precise control of the properties of high-quality Bi_2Te_3 and its Sb-doped films.

Solution-Based Iron Doping of Solvothermally Grown Hexagonal Bismuth Telluride Nanoplates *Kadaba Swathi, Gabriel Marcus, Timothy W. Carlson and David Carroll; Wake Forest University, United States*

Theoretical studies have shown that impurity addition in the form of magnetic or non-magnetic nanoparticles, to a topological material such as Bismuth Telluride (Bi_2Te_3), is an interesting route to study the correlation of symmetry-breaking and coherent spin transport. Moreover, a solution-based synthesis method to form the Bi_2Te_3 crystals and dope them can expand the parameter space for exploring dopant-host interactions. In this work, we study the distribution and chemical nature of iron nanoparticles that electronically dope single-crystal Bi_2Te_3 nanoplates. Using a solvothermal method, Bi_2Te_3 nanoplates are reacted with iron salts ($FeCl_2$) to promote the formation of metallic iron interfaces. The presence of a reducing agent (L(+)-ascorbic acid) along with $FeCl_2$ results in a homogeneous dispersion of iron across the Bi_2Te_3 nanoplate surface. In comparison, non-reduced iron doping results in the growth of iron/iron oxide nanoparticles on the nanoplate edges. Counterintuitive to elemental analysis which showed a lower iron atomic percent in the reduced iron-doped Bi_2Te_3 sample, transport measurements on thin films indicate a higher metallic iron concentration, which oxidizes gradually upon ambient exposure. In comparison, non-reduced iron-doped Bi_2Te_3 thin films exhibited a lower conductivity to begin with and faster air degradation, suggesting iron oxide growth during the doping process itself. The thermoelectric power factor also expresses the modifications from oxidation providing an indirect probe of the dopant's influence on the host Bi_2Te_3's electronic properties. Interestingly, in the oxidized state, magnetic force microscopy images showed a distinct difference in the formation of magnetic phases for non-reduced and reduced iron. We observed that oxidation post-doping does not form magnetic phases, whereas oxidation during the doping process is suitable for obtaining magnetically doped Bi_2Te_3 nanoplates. Our results reveal a unique synthesis approach to obtain magnetic/non-magnetic impurity doping of the topologically relevant Bi_2Te_3 using a solution-based route.

Probing Spin-injection in the Time Domain in Topological Insulators via THz-TDS Spectroscopy *Henri Jaffres; Université Paris-Saclay, France*

Spin-to-charge conversion (SCC) in femtosecond laser excited magnetic heterostructures may generate high efficiency and wide-bandwidth terahertz emission with a magnetically controllable polarization state[1]. The origin of this THz emission has been assigned to the generation of a spin-polarized current and subsequent conversion of the spin current to a transverse charge current[2]. Two main SCC mechanisms are generally involved: the Inverse Spin Hall Effect (ISHE) and the Inverse Rashba- Edelstein Effect (IREE). The discovery of metallic quantum states at the surface of 3D topological insulators (TIs) has opened exciting new functionalities owing to their time-reversal symmetry property and their spin-momentum locking (SML) properties. The resulting SCC combining strong spin-orbit coupling (SOC) and SML is expected to be enhanced compared to the spin Hall effect (SHE) of heavy metals. SCC has been demonstrated in a range of Bi-based TI compounds, including bismuth selenide Bi_2Se_3, bismuth telluride Bi_2Te_3, $Bi_2(Se,Te)_3$ or $Bi_{1-x}Sb_x$ (BiSb). To benefit fully from IREE, the charge currents should be confined in the surface states and any current flowing through the bulk states should be avoided.

In this talk, I will report particularly on our detailed investigation of the surface state SML properties of ultrathin (111)-oriented $Bi_{1-x}Sb_x$ epitaxial films. They exhibit a topological phase as recently confirmed by angular-resolved photo-emission spectroscopy (ARPES)[3] and mainly in-plane spin texture as shown by SARPES. SCC mediated by the BiSb surface states is probed at the sub-picosecond timescale. Unprecedentedly large SCC is measured with efficiencies beyond the level of carefully optimized Co/Pt systems. I will present our more recent results dealing with the fabrication of sputtered BiSb materials giving rise to very efficient spin-charge conversion in the time domain at the level of up-to-date best bilayers spintronics emitters.

Controlled Filling of Landau Levels on the 2D Topological Insulator Bi_2Te_3 Using Magnetic Force Microscopy
Timothy W. Carlson and David Carroll; Wake Forest University, United States

In this work well defined, stoichiometric two-dimensional (2D) nanoplates of the topological insulator, Bi_2Te_3, were imaged using magnetic force microscopy (MFM) and atomic force microscopy (AFM). Nanoplates with a diameter range of 0.5 to 1.5µm and ~6-15nm thick were supported on highly ordered pyrolytic graphite (HOPG) and examined in air. Magnetic force contrast localized to the perimeter of the nanoplates was observed at room temperature. The relative strength of the edge-fields was measured at variable heights detailing a unique relationship between the dynamics of the magnetic cantilever and the nanoplates under observation. We suggest time-reversal symmetry breaking in the Bi_2Te_3 nanocrystal from the field of the imaging magnetic cantilever which results in induced, topologically-protected currents. The addition of an applied DC bias to the tip enables the controlled filling of Landau levels by lowering or raising the fermi level. Previous studies suggest Bi_2Te_3 nanoplates of similar proportions to lie within the 3D topological insulator family and therefore harbor 2D surface states, however, based on the nature of the contrast seen in the MFM, electron energy loss spectroscopy (EELS), and our synthesis method we argue these nanoplates fall within the 2D topological insulator family. These studies reveal the existence of persistent currents in our 2D Bi_2Te_3 system at room temperature and point to MFM as a powerful tool for probing such topologically protected quantum spin hall states.

Investigating Edge States in Bi_2Se_3 Nanocrystals with Controllable Dimensions *Jara Vliem[1], Jesper Moes[1], Pedro de Melo[1], Thomas Wigmans[1], Andrés Botello-Méndez[1], Rafael Mendes[1], Ella van Brenk[1], Ingmar Swart[1], Lucas Maisel Licerán[2], Henk Stoof[2], Christophe Delerue[3], Zeila Zanolli[1] and Daniel Vanmaekelbergh[1]; [1]Debye Institute for Nanomaterials Science, Netherlands; [2]Institute for Theoretical Physics and Center for Extreme Matter and Emergent Phenomena, Netherlands; [3]University of Lille, France*

Nanoscale topological insulators, with bismuth selenide (Bi_2Se_3) being a prototypical example, exhibit intriguing physics due to the combination of topological properties and confinement effects. Three-dimensional Bi_2Se_3 is characterized by an insulating bulk with topologically protected quantum states at its surface. Interestingly, a reduction of the crystal thickness down to 1-6 quintuple layers (QLs) results in gapping of the surface states due to hybridization.[1,2] Such two-dimensional crystals are predicted to host one-dimensional helical edge states,[3,4] which can be characterized with cryogenic scanning tunneling spectroscopy (STS). To study the topological properties of 2D Bi_2Se_3, a synthesis method is required to produce nanoscale Bi_2Se_3 with controllable dimensions. By modifying the precursor reactivity in a hot injection synthesis, we were able to synthesize ultrathin, colloidally stable Bi_2Se_3 nanoplatelets (NPLs) with a well-defined lateral size and a thickness of 1-6 QLs. The improved size control and homogeneity of the Bi_2Se_3 nanocrystals enables us to measure the density of states of individual NPLs with STS. For crystals of 4-6 quintuple layers, we observe an 8 nm wide, one-dimensional state along the edge of the crystal[5]. We use a low-energy continuum model and ab initio GW-Tight Binding theory to investigate the nature of this state.

4:30 PM *QT03.03.06
New Electronic Properties with a Shake Maia Vergniory; Université de Sherbrooke, Canada

Charge density waves (CDWs) have been a major focus of research in condensed matter physics for several decades due to their potential for quantum-based technologies. In particular, CDWs can induce a metal-insulator transition by coupling two Dirac fermions, resulting in the emergence of a topological phase. Following this idea, on the first part of this talk we explore the behaviour of three different CDWs in a 2D layered material, SnP, using both density functional theory calculations and experimental synthesis to study its stability. In 3D, the charge-density wave (CDW) mechanism and resulting structure of the AV3Sb5 family of kagome metals has posed a puzzling challenge since their discovery
somer years ago. In fact, the lack of consensus on the origin and structure of the CDW hinders the understanding of the emerging phenomena. On the second part of this talk, by employing a non-perturbative treatment of anharmonicity from first-principles calculations, we reveal that the charge-density transition in CsV3Sb5 is driven by the large electronphonon coupling of the material and that the melting of the CDW state is attributed to ionic entropy and lattice anharmonicity. The calculated transition temperature is in very good agreement with experiments, implying that soft mode physics are at the core of the charge-density wave transition. Contrary to the standard assumption associated with a pure kagome lattice, the CDW is essentially three-dimensional as it is triggered by an unstable phonon at the L point. The absence of involvement of phonons at the M point enables us to constrain the resulting symmetries to six possible space groups. The unusually large electron-phonon linewidth of the soft mode explains why inelastic scattering experiments did not observe any softened phonon. We foresee that large anharmonic effects are ubiquitous and could be fundamental to understand the observed phenomena also in other kagome families.

SESSION QT03.04: Theory and New Modeling Approach for Topological Materials II
Session Chair: Paolo Bondavalli
Tuesday Morning, December 3, 2024
Sheraton, Fifth Floor, The Fens

8:30 AM *QT03.04.01

Phonon Chirality and Thermal Hall Transport *Benedetta Flebus; Boston College, United States*

In recent years, a rapidly increasing amount of studies has reported novel physical phenomena arising from lattice vibrations that carry angular momentum, i.e., chiral phonons. In this talk, I will discuss both intrinsic and extrinsic sources of chiral acoustic phonon transport and their connection to phonon topology. First, I will show that in ionic crystals a phonon Hall viscosity contribution can emerge as a result of the Lorentz forces on moving ions. I will then explain how phonon scattering from defects that break time-reversal symmetry, such as charged impurities, can yield giant thermal Hall effects that are consistent with recent experimental observations.

Theoretic Insights of Design and Synthesis of Intrinsic Two-Dimensional Organic Topological Insulators

Yuyang Zhang, Yiyang Yin, Yixuan Gao, Lizhi Zhang and Shixuan Du; Chinese Academy of Sciences, China

Two-dimensional organic topological insulators (OTIs) have attracted numerous attentions due to the incredible variety of organic compounds and their combinations. Up to now, designing OTIs with large gaps and realizing topological states in experiments remain as the biggest challenge in this realm. We investigate a total number of 232 honeycomb-Kagome metal-organic networks formed by two types of metal clusters and tetrahydroxybenzene (THB) molecules using high-throughput DFT calculations. Among the 232 MOFs, 16 intrinsic OTIs are discovered. Typically, the \alpha-Pb_3Zn_4-THB structure has a nontrivial gap of 97.5 meV, almost 4 times larger than its flat with bandwidth (22.5 meV), which can be an ideal platform for realizing fractional quantum Hall effect. This work provides a new avenue for designing 2D topological MOFs with large topological band gaps. To obtain topological materials with large nontrivial gaps, another strategy besides increasing SOC is to design materials with high-order topological states. Chiral symmetry breaking (CSB) is promising to realize a series of exotic topological phenomena due to the coupling of Dirac fermions at inequivalent valleys. We propose a strategy to introduce CSB by applying a novel Kekule distortion in a spinless honeycomb lattice, resulting in the emergence of second-order topological phase as the period of superlattice is 3m \times 3m (m =1, 2 ...). Following the strategy, Si_xC_y and circumcoronene-based two-dimensional (2D) honeycomb lattices are predicted to be second-order topological insulators (SOTIs) that are identified via the topological invariants and the presence of in-gap topological corner modes. Although a few materials like Cu-dicyanoanthracene (Cu-DCA) have been experimentally synthesized, observation of topological states remain hard due to the interference of substrates. To discover suitable substrates for synthesizing Cu-DCA while preserving its topological band structures, we search for candidates in a database of 2D materials exfoliable from experimentally known compounds with 1825 2D materials. We find 35 semiconductors in the database having suitable lattice and interaction strength and 11 of them preserve the intrinsic kagome band of Cu-DCA, with transition metal dichalcogenides(TMD) materials like $MoSe_2$ as representative. Further ab-initial molecular dynamics simulations show that Cu-DCA remains dynamically stable on $MoSe_2$ substrate under 300K room temperature, and growth and expansion of the organic framework is also dynamically possible on the surface. This work provides guidance for experimental synthesis of 2D OTIs.

Defect Dependent Electronic and Structural Properties of Monolayer Two-Dimensional Transition Metal

***Dichalcogenides** Berna Akgenc Hanedar[1,2] and Mehmet C. Onbasli[1]; [1]Koç University, Turkey; [2]Kirklareli University, Turkey*

Transition metal dichalcogenides (TMDs) exhibit a wide range of electronic properties due to their structural diversity. Understanding their defect-dependent properties might enable the design of efficient, bright, and long-lifetime quantum emitters. Here, we use density functional theory (DFT) calculations to investigate the 2H, 1T, and 1T' phases of MoS_2, WS_2, $MoSe_2$, and WSe_2 and the effect of defect densities on the electronic band structures, focusing on the influence of chalcogen vacancies.

The pristine 2H, 1T, and 1T' phases display distinct structural and electronic characteristics. The 2H phase, thermodynamically stable, is a direct band gap semiconductor, while the 1T phase, despite its higher formation energy, exhibits metallic behavior conducive to energy-related applications. The metastable 1T' phase demonstrates unique electronic configurations, with potential applications in quantum spin Hall effect and high conductivity electrocatalysts. 1T' phases with spin-orbit coupling show significant band inversion (0.61, 0.77, 0.24 and 0.78 eV for MoS_2, $MoSe_2$, WS_2 and WSe_2, respectively), which can be used for device applications.

Based on state-of-the art DFT calculations provide a detailed understanding of the structural, electronic, and phonon properties of these TMD phases. The cohesive and formation energies, lattice constants, bond lengths and Raman spectra are calculated for each phase. We discovered that for all four MX_2 systems, the energy difference between 2H, 1T and 1T' phases decrease with increasing concentration of vacancy (from %3.13 to %21.88). The study further explores the effect of varying chalcogen vacancy concentrations on the electronic band structure, revealing a strong dependence on defect density and configuration.

Chalcogen vacancies, whether isolated or in clusters, significantly alter the electronic properties of TMDs. Here, we found a significant decrease in the band gap when we introduced chalcogen vacancies. For instance, the band gap of 2H WS_2 reduced from 1.81 (1.54 eV) at GGA (GGA+SOC) to 0.78 eV. These defects can introduce direct to indirect band gap transition, semi-metallic or magnetic band structures, influencing phonon-magnon and phonon-exciton interactions. The study highlights the necessity of optimizing molecular beam epitaxy (MBE) processes to control defect densities for targeted applications.

Overall, this study advances the understanding of defect-dependent electronic properties in TMDs, providing valuable insights for engineering advanced materials for quantum information processing, sensing, and energy conversion technologies. Our findings offer guidelines for experimental screening of 2D TMD defects, paving the way for the development of next-generation spintronic, electronic, and optoelectronic devices.

9:30 AM QT03.04.04

***Diradicals as Topological Charge Carriers in Metal-Organic Toy Model $Pt_3(HAB)_2$** Maarten Goesten[1] and Leslie Schoop[2]; [1]Aarhus University, Denmark; [2]Princeton University, United States*

We explore the eclipsed stacking of a metal-organic Kagome lattice containing heavy-metal nodes. Our model is Pt3(HAB)2, a hypothetical but viable member of a well-known family of hexaaminobenzene (HAB) based metal-organic frameworks (MOFs). Applying space group theory, it is shown how molecular diradicals, brought into play by a non-innocent ligand, become topologically nontrivial bands when moving in a periodic potential. Three factors are required to enable this: 1) eclipsed stacking, which shifts the Fermi level near a symmetry-protected band crossing 2) the emergence of an electride-like 'pore band' that renders the topological Z_2 invariant equal to 1, thus nontrivial, and 3) Pt-induced spin-orbit coupling, to turn the crossing into a bulk band gap.
For this MOF, as should be the case for this entire family of MOFs, the Kagome band dispersion is controlled

through (weak) π antibonding interactions between ligand and metal. These interactions mediate superexchange, through the metal node, between diradicals localized on the organic struts. In the scenario of highly ordered, eclipsed stacking, the Fermi level shifts to a position where these levels belong to free framework charge carriers. We predict the Kagome band to shape Dirac cones, which become gapped in the presence of strong spin-orbit coupling, brought upon the system by Pt. An analysis of the topological Z_2 invariant suggests that robust topological surface states must appear within that gap. There is a special role for the pore band, itself an apparent case of nonlocality. This highly delocalized band describes charge density that is not centered around nuclei, but rather within the tubular pores of the system, and between layers. Strongly related to the well-known interlayer band, it plays a significant role in rendering the system topologically nontrivial, i.e., without pore band, the Z_2 invariant would be equal to zero. The pore band should be of interest to various applications, including catalysis and superconductivity. And a porous topological semimetal, like this framework, should offer new opportunities for quantum materials. For example, if topological surface states would emerge on the interior surface, i.e., the pore, filling the pores of the MOF with an appropriate substrate would constitute a novel way of creating an interface between domains.*

The direct connection between diradical chemistry and topological states gives chemical control over nonlocal physics; we know states to becomes more delocalized upon increasing the diradical character, which we know scales with S < NH < O for organic linker substituents. Given MOFs and their building blocks are highly tunable, this could pave the wave to tailored topological electronics. We hope this work motivates the pursuit of synthesizing highly perfect, electronically conductive MOF crystals. Eclipsed-stacked Pt3(HAB)2 is a toy model, but a realistic one. Its realization would be highly compelling for a variety of electronic applications.

9:45 AM QT03.04.05

Unraveling Magnetic Structure in Zero Field—Single Crystal Neutron Diffraction Insights into EuRhGe$_3$ *Kamini Gautam[1], Yukako Fujishiro[1], Oscar Fabelo[2], Yoshinori Tokura[1] and Arima Taka-hisa[1]; [1]RIKEN, Japan; [2]Institut Laue-Langevin, France*

The EuTX$_3$ series, characterized by d-electron transition metals (T) and Si or Ge (X) with the tetragonal non-centrosymmetric BaNiSn$_3$-type crystal structure (space group I4mm), has emerged as a pivotal subject of study for understanding novel topological magnetic phases. Notably, recent neutron diffraction studies on EuNiGe$_3$ have revealed important insights into the hybrid skyrmion phases, marking a significant advancement in the field of topological magnetic states [1]. Expanding on the research in these systems, our study delves into another interesting compound of this family, EuRhGe$_3$. Its magnetic and transport properties reveal a complex magnetic phase diagram [2]. Interestingly, EuRhGe$_3$ shows a significant anomaly in magnetoresistance at the magnetic phase transitions [2].

Using zero-field neutron diffraction on EuRhGe$_3$ single crystals, we aim to uncover its nuclear and magnetic structures. We have found no crystallographic structural changes down to 2 K. An antiferromagnetic transition is observed at T_N~11.5 K. The magnetic propagation vector is along the c-axis (0, 0, 0.8), forming a proper screw-type magnetic arrangement that propagates along the c-axis at 2K. The observed magnetic structure differs from other reported Eu-based ternary germanides [3, 4].

Quantum Geometry and Response in Topological Quantum Materials *Raquel Queiroz; Columbia University, United States*

In this talk, we will discuss how quantum geometry fully determines the response of topological quantum materials and how it provides a unifying structure to describe consistently instantaneous properties of various insulators, such as effective mass, dielectric constant, or orbital magnetic moment. We will relate geometry to chemical bonding in infinite lattices and discuss general implications.

11:00 AM QT03.04.07

A First Principles Study of the Stark Shift Effect on the Zero-Phonon Line of the NV Center in Diamond *Louis Alaerts[1], Yihuang Xiong[1], Sinead M. Griffin[2] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]Lawrence Berkeley National Laboratory, United States*

Quantum defects in semiconductors are pivotal for quantum information science applications due to their potential as spin-photon interfaces and single-photon emitters. However, the coupling between changes in the dipole moment upon electronic excitation and stray electric fields near the defect, known as the Stark shift, can cause significant spectral diffusion in the emitted photons, thus hindering their quantum applications. In this talk, I will use the nitrogen-vacancy (NV) center in diamond as a critical example to showcase our work employing first-principles calculations to revisit and refine the methodology for computing Stark shifts up to the second order. Utilizing a slab approach, we monitor the zero-phonon line (ZPL) shifts under applied electric fields using constrained density functional theory (DFT) and compare these results with those derived from the modern theory of polarization. I will discuss the methodological challenges associated with charged slabs and the issues arising from the modern theory of polarization approach. Our work not only highlights the complexity of simulating Stark shifts but also provides important insights into their effects on ZPL and spectral diffusion.

11:15 AM QT03.04.08

Weyl Points on Non-Orientable Manifolds *Sachin Vaidya[1], André Fonseca[1], Thomas Christensen[2], Mikael Rechtsman[3], Taylor Hughes[4] and Marin Soljačić[1]; [1]Massachusetts Institute of Technology, United States; [2]Technical University of Denmark, Denmark; [3]The Pennsylvania State University, United States; [4]University of Illinois at Urbana-Champaign, United States*

Weyl fermions are chiral, massless particles that play an important role in quantum field theory and the Standard Model of particle physics. Although elusive as fundamental particles, they have been observed as quasiparticle excitations in various domains, from solid-state materials to photonic and acoustic crystals. In these contexts, they are referred to as Weyl points, with their chirality determined by whether they act as sources or sinks of Berry curvature. According to the Nielsen-Ninomiya theorem, Weyl points in three-dimensional lattice systems always occur in pairs with opposite chirality, implying that there are exactly as many sources as sinks. This fundamental constraint ultimately arises from the properties of the space in which Weyl fermions exist, specifically a toroidal Brillouin zone.

Here, we demonstrate that by modifying the topology of the underlying space, it is possible to circumvent this fundamental theorem. Specifically, we achieve this by transforming the underlying momentum space fundamental domain into a non-orientable one. Furthermore, we show that this modification leads to the emergence of novel Z2 topological charges carried by Weyl points, and the conservation of these charges results in a different no-go theorem. We experimentally demonstrate all aspects of the theory using a photonic platform with synthetic degrees of freedom.

11:30 AM *QT03.04.09

Topological Excitonic States and Their Fingerprints on Electronic Structure *Alessandra Lanzara[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States*

Time and angle resolved photoemission spectroscopy has been recently shown to be a powerful tool to reveal exciton formation in the single particle spectral function, opening the exciting frontier to study momentum dependent exciton driven band structure renormalization, and ultimately search distinctive signature of exciton condensation in the band structure. Here I will discuss our recent work utilizing XUV and UV time resolved ARPES to study exciton formation in real time and across the exciton Mott transition. I will show how their formation can uniquely modify the band structure in a k dependent way and will reveal under which conditions these excitonic state can be driven in the presence of topological invariants, what properties of the topological state persists and what are their fingerprints in the material's band structure. I will also discuss the potential of these materials to drive excitonic condensation.

SESSION QT03.05: Growth and Synthesis of Topological Materials II

1:30 PM *QT03.05.01

Epitaxial Growth of Group 14 Post-Graphene by Deposition and Segregation *Junji Yuhara; Nagoya University, Japan*

The synthesis and characterization of post-graphene materials have been intensively studied to utilize novel two-dimensional (2D) properties. Most studies adopted molecular beam epitaxy to synthesize 2D materials grown on clean, crystalline surfaces. In my talk, I will talk about the epitaxial growth of (1) germanene, (2) stanene, and (3) plumbene by segregation and deposition methods [1–11].
(1) Germanene on Ag(111) thin film by segregation [1]: On annealing the specimen of Ag(111) thin film grown on Ge(111), the Ge atoms segregate on the surface, and germanene has been epitaxially formed on the surface. Low-energy electron diffraction clearly shows incommensurate "(1.35×1.35)" R30° spots, corresponding to a lattice constant of 0.39 nm, in perfect accord with close-up scanning tunneling microscopy (STM) images, which reveal an internal honeycomb arrangement with corresponding parameter and low buckling within 0.01 nm. From the STM images, two types of protrusions, named hexagon and line, form a $(7\sqrt{7}\times7\sqrt{7})$R19.1° supercell concerning Ag(111) with a significant periodicity of 5.35 nm.
(2) Stanene on Ag_2Sn surface alloy by deposition [2]: The lattice parameters of Ag_2Sn surface alloy and free-standing stanene are close. The Ag(111) readily reacts with Sn atoms on annealing, while the Ag_2Sn surface alloy is chemically inert against the Sn atoms. Thus, the Ag_2Sn surface alloy is a physically and chemically ideal surface for the epitaxial growth of stanene. We have successfully prepared large-area planar stanene on Ag_2Sn surface alloy by Sn deposition.
(3) Plumbene on $Pd_{1-x}Pb_x$(111) alloy surface by deposition and segregation [3]: The bulk Pb-Pd system exists in fcc solid solution with a Pb concentration up to 10 ~ 17 %. The Pb atoms deposited dissolve into the Pd crystal and segregate on the surface on annealing. Plumbene is epitaxially grown on the $Pd_{1-x}Pb_x$(111) surface through these processes. The surface also exhibits a unique morphology in the STM images resembling the famous Weaire-

Phelan bubble structure of Beijing's Olympic "WaterCube."

Thermomechanical Epitaxy—A Novel Approach to One-Dimensional Topological Nanomaterials *Yi-Xiang Yang[1], Naijia Liu[2], Cai Lu[3], Sebastian A. Kube[4], Arindam Raj[2], Sungwoo Sohn[1], Xiaoyu Zhang[1], Miguel B. Costa[5], Ze Liu[3] and Jan Schroers[1]; [1]Yale University, United States; [2]Northwestern University, United States; [3]Wuhan University, China; [4]University of Wisconsin-Madison, United States; [5]University of Cambridge, United Kingdom*

Nanostructures enhance the topological states of materials by increasing the surface-to-volume ratio, crucial for their applications and characterization. Despite numerous proposed topological materials, their realization in nanostructured forms remains limited due to current fabrication challenges. In this study, we introduce a novel fabrication technique for creating one-dimensional topological nanomaterials via thermomechanical processing. By applying pressure on bulk topological materials against rigid nanocavities, we facilitate atom transport through interface diffusion, leading to precise, wafer-scale epitaxial growth of high-quality single crystalline nanowires. This diffusional mechanism applies to general materials, enabling the creation of nanomaterials from a broad range of topological phases, including topological insulators and topological semimetals, and some nanomaterials that are previously unattainable with existing technologies. Our method broadens the scope of accessible topological nanomaterials, paving the way for significant advancements in physical sciences and the development of next-generation nanodevices.

2:15 PM QT03.05.03

Single-Chain Knot/Cyclized Polymers from Controlled Multivinyl Monomer Polymerisation and Their Biomedical Applications *Jing Lyu and Wenxin Wang; University College Dublin, Ireland*

Classical theory has long claimed that the polymerizations of multi-vinyl monomers (MVM) lead to insoluble cross-linked materials, as defined by P. Flory and W. Stockmayer 80 years ago (F-S theory). Therefore, the (homo)polymerization of MVMs is still considered as a formidable task in chain growth polymerization. We first proposed a deactivation enhanced ATRP (DE-ATRP) method to homopolymerize MVMs. This approach has broken through two barriers for the polymerization of MVMs: uncontrollable homopolymerization and highly diluted reaction conditions, and successfully achieved the controlled homopolymerization of MVMs in concentrated conditions. Via this approach, a new class of single-chain knot/cyclized polymers can be formed due to the enhanced promotion of intramolecular cyclization and the suppression of intermolecular crosslinking. Our breakthrough lies in the ability to alter the growth manner of polymerization by controlling the kinetic chain length together with manipulating chain growth conditions to achieve different polymer structures, which opened an

efficient and practical road for the design and synthesis of knot/cyclized polymers from economical available monomers. The produced knot/cyclized polymeric materials have demonstrated the great potentials in biomedical applications.

Fabrication of Hierarchically Converging Polymer Nanofibers via Liquid Crystal-Templated Chemical Vapor Polymerization and Their Mathematical Modeling via Graph Theoretical Analysis *John Kim[1], Soumyamouli Pal[2], Sangchul Roh[3], Xiong Y. Xiao[4], Shixuan Li[4], Arit Patra[1], Paul Bogdan[4], Nicholas L. Abbott[2] and Joerg Lahann[1]; [1]University of Michigan, United States; [2]Cornell University, United States; [3]Chonnam National University, Korea (the Republic of); [4]University of Southern California, United States*

The presence of fibrous arrays on the surfaces of the biological systems often provides essential functions such as adhesion properties of gecko setae, absorption of nutrients by intestinal villi, and propulsion of cilia on microorganisms. There have been attempts to mimic the structures of arrayed fibers via fabrication techniques (e.g., microcontact printing, 3D printing, and hydrothermal growth) enabling their applications as a sensor for fluid biopsy, superhydrophobic surface, and microneedles for monitoring biomedical signals. Recent trends in complex nanostructures engineering have started to demand diverse structural and chemical modulations. In this context, templated chemical vapor polymerization (CVP) into a liquid crystalline (LC) film has gained attention as a promising technique that can tailor the chemical and topological features of the nanofibers array on the surfaces. Tunable aspects of templated nanofibers enabled interesting features such as chirality, photoluminescence, and programmed response to external stimulus. Although the opportunities for LC-templated CVP are underway, it is still elusive how the nanofibers grow within the LC phase. By observing the intermediate structures of the nanostructures, we discover the growth sequences of the templated nanofibers and provide mathmatical modelling to describe their growth. We ran computational analysis (StructuralGT) that employs graph theory to mathmatically translate the hierarchical features and fitted our model into empirical results.

3:15 PM *QT03.06.01

Topological Josephson Effect in Hinge State of WTe_2 *Gil-Ho Lee; Pohang University of Science and Technology, Korea (the Republic of)*

Higher order topological insulators (HOTIs) are a new class of topological insulators that exhibit topological boundary modes at two or more dimensions lower than them. For example, three-dimensional HOTIs can host the topologically protected one-dimensional hinge states or zero-dimensional corner states. Although recent experimental reports suggest the existence of conducting channels at the hinges of non-centrosymmetric Td-WTe_2 crystals, the investigation of their topological nature remains an ongoing requirement. Here, we investigate Shapiro steps in Al-WTe_2-Al proximity Josephson junctions (JJs) under microwave irradiation and propose the topological nature of the hinge states in WTe_2. We have analyzed the doubling of Shapiro steps at different microwave *frequencies in edge-contacted JJs, which is explained by the 4π-periodic current-phase relationship of topological Josephson junctions. Our observation reveals the topological nature of the hinge states in T_d-WTe_2 and would stimulate the investigation of topological superconductivity with topological hinge states in superconducting hybrid devices based on higher-order topological insulators, leading to the realization of realizing Majorana zero modes and topological quantum physics.*

3:45 PM QT03.06.03

Controlling Skyrmions in Cu_2OSeO_3 Through Doping—An Insight to the Relationship Between Crystal Structure and Magnetic Ordering *Samuel Yick[1,2], Marco Vas[1,3,2], Alexander Ferguson[4], Joseph Vella[1,2], Elliot Gilbert[5], Clemens Ulrich[6] and Tilo Soehnel[1,2]; [1]The University of Auckland, New Zealand; [2]MacDiarmid Institute, New Zealand; [3]Australian Institute of Nuclear Science and Engineering, Australia; [4]University of Fribourg, Switzerland; [5]Australian Nuclear Science and Technology Organisation, Australia; [6]University of New South Wales, Australia*

Magnetic Skyrmion lattices (SkL) are topologically protected spin ordering due to their quantised winding number. This, along with other helimagnetic orderings offer a plethora of fascinating phenomena for fundamental research and applications.[1] Cu_2OSeO_3 is an insulating multiferroic material that has shown to host SkL under specific conditions.[2] It possesses a magnetic structure with both ferromagnetic (FM) and antiferromagnetic (AFM) super exchange interactions being present and has a 3-up 1-down ferrimagnetic arrangement of Cu^{2+} ions.[3] The lack of inversion symmetry in the corner shared O-Cu_4 tetrahedra lattice results in an appreciable DMI between Cu^{2+} sites; this competes with FM/AFM interactions leading to spin canting formation of helical/conical spin textures at different fields and temperature conditions.[2] Due to the absence of a crystallographic transformation throughout the temperature range alongside the formation of the magnetic phases, it has been commonly assumed that the structure plays a passive role in magnetic ordering.[3] Yet, published studies have challenged this assumption. The work by Wu et al. shows that internal expansion leads to a decrease in T_c for the helical to paramagnetic transition.[4] Furthermore, observation by Nishibori et al. shows that by applying a pressure, T_c increases as the unit cell volume contracts.[5]

In this work, we incorporated non-magnetic Te ions into the Cu_2OSeO_3 host. The inclusion of Te into the Se-sites changed the crystal structure by a noticeable lattice expansion. The skyrmion dynamics and spin interactions within these materials were then studied using synchrotron X-ray powder diffraction, neutron diffraction, neutron scattering, and magnetometry. Using X-ray powder diffraction at the Australian synchrotron, we identify a structural anomaly where the Cu network distorts around the paramagnetic-helical ordering temperature. This alludes to the possibility that structure is also a contributing factor to the magnetic ordering of the material despite the lack of a structural phase transition. Using small angle neutron scattering, we were able to confirm the presences of the various magnetic ordering despite the doping. Through neutron diffraction, we found that the magnetic response of the spin ordering is highly susceptible to chemical doping. This implies that the rigidity of the spin coupling might be affected by both magnetic and non-magnetic dopants. Lastly, we used magnetometry to study how the lattice expansion affected thed spin interaction of the system. These results gave us further insight to the relationship between the atomic and magnetic ordering. This highlights the importance of the crystal structure and an avenue to design novel spintronic materials for emerging technological applications.

4:00 PM QT03.06.04

Tuning the Band Structure and Electronic Properties of (Bi1-xSbx)2Te3 Films *Abby Liu, Zecheng You, Shriya Sinha, Armando Gil, Roy Clarke, Ctirad Uher, Cagliyan Kurdak and Rachel S. Goldman; University of Michigan, United States*

Topological insulators, such as BiSe-, BiTe- and SbTe-based materials, are an exciting class of quantum materials possessing a bulk band gap and gapless topological surface states. Bi2Te3 and Sb2Te3 are of particular interest for spintronics due to their native electronic properties. For example, Te anti-site defects lead to n-type conduction in Bi2Te3. Sb vacancies and Sb anti-site defects lead to p-type conduction in Sb2Te3. However, the Fermi level of Bi2Te3 (Sb2Te3) is pinned within the bulk conduction (valence) band, leading to native n-type (p-type) conduction. Furthermore, the Dirac point is pinned within the valence band for Bi2Te3. It is of current interest to bring the Dirac point to a position within the insulating gap, which effectively reduces bulk conduction while making surface electrons accessible for transport.
In this work, a series of Bi2Te3-Sb2Te3 alloy films were grown by MBE on Al2O3 (0001) substrates. The film thicknesses, Bi:Sb flux ratios, and post-growth annealing in a Te flux were utilized to tune the Fermi level across the band gap. Scanning tunneling microscopy (STM) was performed to probe the local band structure of the films at room temperature. For all samples, the effective band gaps range from 0.15 to 0.22 ± 0.10 eV. Interestingly, as the film thickness is increased from 6 nm to 30 nm, the Fermi level shifts from the valence band edge (VBE) towards the conduction band edge (CBE), indicating a p-type to n-type transition. Furthermore, as the Sb composition of film is increased from x = 0.58 to x = 0.64, the Fermi level shifts from CBE to VBE, indicating a n-type to p-type transition.

Cross-sectional high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) images reveal distinct differences at atomic scale between the 6-nm and 30-nm-thick Bi2Te3-Sb2Te3 alloy films. The 6-nm-thick films consist of a stack of five quintuple layers abruptly interfaced with the Al2O3 substrate. In some regions, the quintuple layer stacks appear misaligned in [10-10] and [11-20] cross-sectional HAADF-STEM images, indicating the presence of surface-terminating screw dislocations. On the other hand, the 30-nm-thick films consist of multi-stacks of quintuple layers with an SbxTe1-x layer at the film/substrate interface. Both of the 6 nm and 30 nm films contain 60° twin boundaries, either within or between quintuple layers. Interestingly, the density of the twin boundary in 30 nm film is higher than in 6 nm film. We hypothesize free carriers can be created at the twin boundary, resulting in different electronic properties. Magneto-transport measurements and multi-channel analysis will also be discussed to further understand conductivity contributions of different carrier species from different carrier channels.

4:15 PM *QT03.06.05

Enhanced Ferromagnetism in Cr_2Te_3 via Topological Insulator Coupling *Hang Chi; University of Ottawa, Canada*

Exchange-coupled interfaces are pivotal in exploiting two-dimensional (2D) ferromagnetism. Due to the extraordinary correlations among charge, spin, orbital and lattice degrees of freedom, layered magnetic transition metal chalcogenides (TMCs) bode well for exotic topological phenomena. In this talk, we present the realization of wafer-scale Cr_2Te_3 down to 1 unit cell (u.c.) on insulating $SrTiO_3(111)$ and/or $Al_2O_3(0001)$ substrates using molecular beam epitaxy. Robust ferromagnetism emerges in 1 u.c. Cr_2Te_3 with a Curie temperature T_C = 100 K. Moreover, when Cr2Te3 is proximitized with topological insulator (TI) $(Bi,Sb)_2Te_3$, the magnetism becomes stronger – with T_C boosted to 135 K. Our experiments and theory strongly indicate that the Bloembergen-Rowland interaction is likely a universal aspect of T_C enhancement in TI-coupled magnetic heterostructures. The topological-surface-enhanced magnetism in 2D TMC enables further exchange coupling physics and quantum *hybrid studies, including paving the way to realize interface-modulated topological electronics.*

SESSION QT03.07: Topological and Quantum Materials II

8:30 AM *QT03.07.01

Topological States and Phase Transitions in Germanene and Germanene Nanoribbons *Pantelis Bampoulis; University of Twente, Netherlands*

Investigating topological phases and their transitions is crucial for discovering new quantum states and advancing topological device technology. Here, we present experimental evidence of topological phase transitions in a monoelemental quantum spin Hall insulator, specifically low-buckled epitaxial germanene. We demonstrate that germanene is a quantum spin Hall insulator with a large bulk gap and robust metallic edges. Applying a critical perpendicular electric field closes the topological gap, transforming germanene into a Dirac semimetal. Further increasing the electric field opens a trivial gap and eliminates the metallic edge states.
Additionally, we explore width-induced transitions in germanene nanoribbons. Below a critical width of about 2 nm, we observe a transition to a 1D topological insulator phase, marked by the disappearance of 1D edge states and the emergence of zero-dimensional end states. The topological phase behavior is shown to depend non-monotonically on ribbon width, spin-orbit coupling, staggered mass, and termination.
This tunability of germanene with electric field and nanoribbon width makes it suitable for room-temperature devices, such as topological field-effect transistors, potentially revolutionizing low-energy electronics.

9:00 AM *QT03.07.02

Terahertz Spintronic Emission from 2D Transition Metal Dichalcogenides and Their van der Waals Heterostructures *Rahul Sharma[1], Khasan Abdukayumov[1], Martin Micica[2], Fatima Ibrahim[1], Libor Vojacek[1], Sylvain Massabeau[3], Celine Vergnaud[1], Alain Marty[1], Jean-Yves Veuillen[4], Pierre Mallet[4], Isabelle Gomes de Moraes[1], Djordje Dosenovic[5], Abdelkarim Ouerghi[6], Vincent Renard[7], Frederic Bonell[1], Hanako Okuno[5], Mairbek Chshiev[1], Jean-Marie George[3], Henri Jaffres[3], Sukhdeep Dhillon[2] and Matthieu Jamet[1]; [1]Spintec, France; [2]École Normale Supérieure, France; [3]Laboratoire Albert Fert, France; [4]Institut Néel, France; [5]CEA Grenoble, France; [6]Université Paris-Saclay, France; [7]Université Grenoble Alpes, France*

Terahertz (THz) Spintronic emitters based on ferromagnetic/metal junctions have become an important technology for the THz range, offering powerful and ultra-large spectral bandwidths [1,2]. These developments have driven recent investigations of two-dimensional (2D) materials for new THz spintronic concepts. 2D materials, such as transition metal dichalcogenides (TMDs) and their van der Waals heterostructures, are ideal platforms for spin-to-charge conversion (SCC) as they possess strong spin-orbit coupling (SOC) and reduced symmetries [3]. Moreover, SCC and the resulting THz emission can be tuned with the number of layers, electric field, strain or by stacking different TMDs.
In this work [4], we have grown large area single crystalline mono and multilayers of 1T-$PtSe_2$ on graphene by molecular beam epitaxy, followed by in situ deposition of amorphous CoFeB by sputtering, with atomically sharp interfaces. We used a full set of characterization tools to demonstrate the structural and chemical preservation of $PtSe_2$ after CoFeB deposition. SCC was then studied on these advanced 2D samples using THz emission

spectroscopy as a function of $PtSe_2$ thickness (from 1 to 15 ML), that showed the generation of efficient THz electric fields. In comparison, THz emission from CoFeB/WSe_2 and CoFeB/VSe_2 are negligible. The THz emission with $PtSe_2$ is shown to arise from the 1T crystal structure and large spin-orbit coupling. The measured THz peak electric field as a function of the number of $PtSe_2$ monolayers clearly shows a two-step dependence with $PtSe_2$ thickness, which we interpret as the transition from the inverse Rashba Edelstein effect (IREE) in the semiconducting regime to the inverse spin Hall effect (ISHE) in the semimetallic regime (around 3 to 4 MLs). As shown by ab initio, the IREE arises from the large Rashba spin splitting at the $PtSe_2$/graphene interface by the combination of large spin-orbit coupling and electron transfer from graphene to $PtSe_2$, generating an interface electric field. By fitting the thickness dependence, we can extract the out-of-plane spin diffusion length in $PtSe_2$ to be 2-3 nm and find that SCC by IREE at the $PtSe_2$/Gr interface is twice as efficient than that of ISHE in bulk $PtSe_2$.

To investigate further THz emission from vdW heterostructures, we compared the spintronic THz emission from epitaxial $PtSe_2$/Gr with the one from $PtSe_2$/$MoSe_2$/Gr. Remarkably, by adding one monolayer of $MoSe_2$ between $PtSe_2$ and graphene, we changed drastically the sign and magnitude of spin-charge conversion demonstrating the monolayer control of THz emission in vdW heterostructures [5]. Finally, we designed specific THz emitter devices made of $PtSe_2$/$MoSe_2$ bilayer transferred on SiO_2/Si to apply a back gate voltage. Our goal is to adjust the Fermi level position of the system to modulate the SCC and THz signal. We conclude that 2D materials and their vdW heterostructures are promising materials for intense and tunable spintronic THz emission.

Observation and Analysis of Low-Energy Magnons with Raman Spectroscopy in Atomically Thin $NiPS_3$

Siwon Oh[1], Woongki Na[1], Pyeongjae Park[2,3], Junghyun Kim[3], Allen Scheie[4], Alan Tennant[5], Hyun Cheol Lee[1], Je-Geun Park[3] and Hyeonsik Cheong[1]; [1]Sogang University, Korea (the Republic of); [2]Oak Ridge National Laboratory, United States; [3]Seoul National University, Korea (the Republic of); [4]Los Alamos National Laboratory, United States; [5]The University of Tennessee, Knoxville, United States

$NiPS_3$ is one of the layered van der Waals magnetic materials, showing XXZ-type antiferromagnetic ordering below the Néel temperature (TN) of 155 K [1]. The antiferromagnetic ordering is suppressed in the monolayer [2]. Recently, several groups reported low-energy excitations in bulk $NiPS_3$, measured using different experimental tools such as THz spectroscopy, the pump-probe method, and electron-spin resonance (ESR), [3-5] and the signals have been identified as low-energy magnons gapped from the ground state. Here, we employed Raman scattering techniques to observe directly the low-lying magnon (~1 meV) even in bilayer $NiPS_3$. The unique advantage is that it offers excellent energy resolutions far better on low-energy sides than most inelastic neutron spectrometers can offer. More importantly, with appropriate theoretical analysis, the polarization dependence of the Raman scattering by those low-lying magnons also provides otherwise hidden information on the dominant spin-exchange scattering paths for different magnons. By comparing with high-resolution inelastic neutron scattering data, these low-energy Raman modes are confirmed to be indeed of magnon origin. Because of the different scattering mechanisms involved in inelastic neutron and Ramahn scattering, this new information is fundamental in pinning down the final spin Hamiltonian. This work demonstrates the capability of Raman spectroscopy to probe the genuine two-dimensional spin dynamics in atomically-thin vdW magnets, which can

provide novel insights that are obscured in bulk spin dynamics.

Enhanced Spin Hall Conductivity in Low-Resistivity Metal/Semimetal Thin Film Heterostructure *Asir Intisar Khan, Cheng-Hsiang Hsu and Sayeef Salahuddin; University of California, Berkeley, United States*

The sustainability of numerous data-driven artificial intelligence applications will benefit from low-power nonvolatile memory [1]. Magnetic memory devices based on spin-orbit-torque (SOT)-driven switching offer fast switching, and high endurance [2]. However, high electrical resistivity of the traditional SOT-generating materials e.g., heavy metals and topological insulators often leads to large switching power in such devices [2,3]. To address this challenge, a SOT material system with simultaneously low electrical resistivity and large SOT efficiency together can result in an enhanced spin Hall conductivity required for low-power magnetic memory [4].
In this work, we uncover a large spin Hall conductivity at room temperature in Ta/TaP metal/topological semimetal thin film heterostructures. Using harmonic Hall measurement in a 4 nm/ 2 nm Ta/TaP bilayer film (with 4 nm Co as the ferromagnet), we measured a spin Hall conductivity of ~ 2.1×10^5 (h/2π/2e) $\Omega^{-1}m^{-1}$. This value is ~2× larger compared to that of control 6 nm metal Ta, and larger than most SOT materials (e.g., heavy metals, topological insulators) at similar thicknesses [4].
The enhanced spin Hall conductivity in Ta/TaP bilayer is primarily enabled by the low electrical resistivity of the 2 nm thin TaP semimetal, which we attribute to a proportionally higher conduction through a surface channel in the ultrathin topological semimetal films [5]. We note that, the SOT efficiency in our Ta/TaP bilayer heterostructure is comparable to our control heavy metal Ta (≈ - 0.1).
We sputter deposited these Ta/TaP heterostructures at relatively low temperatures of 400 °C on MgO or sapphire substrate yielding non-crystalline semimetal thin films. Remarkably these non-crystalline films lead to an enhanced spin Hall conductivity in our work that is otherwise expected from topological semimetals in their crystalline form because of their strong spin polarization and large momentum relaxation times of their surface states [6,7].
In summary, we find an enhanced spin Hall conductivity in non-crystalline ultrathin TaP semimetal on a metal Ta seed layer. The results and the fundamental insights obtained here could inspire the ultrathin topological semimetal family as the next-generation SOT materials for high-density, low-power magnetic memory technology.

Structural Chemistry and Magnetic Property Study of Potential Dirac Semimetals RE-Zn-Bi$_2$ (RE = La, Ce, Pr, Nd, Gd) *Jian Wang and Karishma Prasad; Wichita State University, United States*

In recent years, there has been a surge of interest in materials incorporating Bi square nets due to their intriguing *properties, including characteristics such as Dirac behavior and the emergence of semi-topological features. Among many ternary bismuthides, the RE-T-Bi_2 (RE=La-Lu, T=Mn, Fe, Co, Ni, Zn) family has caught our attention due to the comprehensive interplay between carrier electrons, bismuth square nets, and magnetic elements. Compared with the neighbor family, the AE-T-Bi_2 (AE=alkali earth metals, T=Mn, Fe, Co, Ni, Zn), the RE-T-Bi_2 family is less explored. Many structural chemistry questions remained. Vacancies exist at the transition metal site, which makes the RE-T-Bi_2 system always electron-rich. Through changing transition metal contents, the carrier concentration can be significantly tuned. How to let extra electrons interact with magnetic rare earth elements and Bi square nets would be the topic of this presentation. In this study, we focus on investigating the RE-Zn-Bi ternary system, with a particular emphasis on structural characterization. Overall, this research provides insights into the synthesis, and structural properties of RE-Zn-Bi ternary compounds, tuning the transition metal vacancy and how it will change the bonding and physical properties.*

10:45 AM QT03.07.06

Designing Giant Hall Response in Layered Topological Semimetals *Grigorii Skorupskii[1], Fabio Orlandi[2], Iñigo Robredo[3], Milena Jovanovic[1], Rinsuke Yamada[4], Fatmagül Katmer[1], Maia Vergniory[3], Pascal Manuel[2], Max Hirschberger[4] and Leslie Schoop[1]; [1]Princeton University, United States; [2]ISIS Pulsed Neutron and Muon Source, United Kingdom; [3]Max Planck Institute for Chemical Physics of Solids, Germany; [4]The University of Tokyo, Japan*

Noncollinear and noncoplanar magnets are promising candidates for future data storage technologies. Of particular interest are materials that show electrical transport signatures originating from the magnetic order, such as Hall effect anomalies. Few materials are known to host those, and we have no clear chemical understanding of their origin.

Here, we present a chemical design strategy that allowed us to discover a series of noncoplanar magnets Ln_3Sn_7 (Ln = Tb, Dy). Our strategy is based on targeting materials that combine several magnetic sublattices with dissimilar magnetic anisotropies, along with a square-net topological semimetal layer. Ln_3Sn_7 show high carrier mobilities upwards of 17,000 $cm^2/(V\ s)$, and, critically, display large anomalous Hall conductivities in excess of 40,000 S/cm, which is the highest value reported to date in a noncoplanar magnet.

11:00 AM QT03.07.07

V-Doping Induced Enhancement of Weak Antilocalization in SnTe *Subhadip Ghosh; Indian Institute of Technology Kharagpur, India*

SnTe is a well-known topological crystalline insulator with topological surface states (TSS) protected by crystal symmetries. This, along with an associated Berry phase p, results in a positive quantum correction in the electrical conductivity, known as weak antilocalization (WAL). The TSS protection breaks down with the application of a magnetic field, resulting in a cusp-like negative magnetoconductance (MC). SnTe intrinsically has a large amount (~ $10^{21}/cm^3$) of Sn vacancies and associated charge carriers and, hence, a considerable bulk conductivity. This results in a parabolic background over the WAL MC. In this work, we observe a WAL signal in circular nanodisc-shaped SnTe nanoparticles (NPs) of radii 20-50 nm by electron spin resonance (ESR) measurements. We further demonstrate that doping of SnTe NPs with V reduces the contribution of bulk MC via charge transfer-induced hole localization and, thus, increases the observability of the WAL effect. The process of charge transfer between V and Sn is also supported by density functional theory computations.

Enhancing Thermoelectric Efficiency of Bi_2Te_3 Nanoribbons Through In Situ F_4-TCNQ and Ex-Situ Cr Interfacial Alloying *Jun Beom Park, Rijan Karkee and Michael T. Pettes; Los Alamos National Laboratory, United States*

Nanostructured Bi_2Te_3 has shown promise in enhancing thermoelectric characteristics as predicted theoretically. However, its practical performance often falls short of that of bulk Bi_2Te_3 due to defects, impurities, and surface oxidation. To address these issues, various techniques such as oxygen plasma treatment, non-oxidizing superacid treatment, and atomic layer deposition (ALD) of Al_2O_3, have been explored to precisely control the surface chemical potential of nanostructures, aiming for long-lasting and high-performance thermoelectric applications. Among these techniques, extrinsic doping by coating carrier-rich or metallic layers has shown potential in modulating carrier concentration and chemical potential.

In this presentation, we introduce two distinct strategies to enhance the thermoelectric performance of Bi_2Te_3 nanoribbons through the incorporation of external dopant layers: an in-situ F_4-TCNQ layer and an ex-situ Cr layer. The in-situ coated F_4-TCNQ layer induces a transformation of the major carrier from n-type to p-type, resulting in sixfold enhancement of the Seebeck coefficient. At the same time, the core-shell structure effectively shields the Bi_2Te_3 core from oxidation, demonstrating no surface oxidation or loss of thermoelectric properties even after one month in ambient air.[1] On the other hand, the surface-coated Cr layer induces a 70% reduction in nanoribbon resistance along with a 24% increase in the Seebeck coefficient, resulting in twofold enhancement of thermoelectric figure of merit (zT). Moreover, we will share physical investigations of these enhanced thermoelectric characteristics through energy band simulation and Raman spectroscopy analysis. We expect our findings to provide an approach for nanostructured thermoelectric materials to achieve performance competitive with bulk materials while leveraging the inherent advantages of nanostructures.

Predicting Phase Transitions in Correlated Topological Quantum Materials *Panchapakesan Ganesh; Oak Ridge National Laboratory, United States*

One of the most promising route for manipulating the properties of correlated solids for technological applications is through controlled perturbations via atomic-defects, doping, stoichiometry, strain as well as heterostructuring. However, the mechanisms that drive the electronic, magnetic and/or topological transitions in these materials and the specific role of these perturbations is not fully understood. For example, the perovskite $SrCoO_3$ is a ferromagnetic metal, while the oxygen-deficient (n-doped) brownmillerite $SrCoO_{2.5}$ is an antiferromagnetic insulator. Similarly, 2D topological materials such as $MnBi_2Te_4$ and WTe_2 show different topological phases depending on how they are stacked or heterostructured. Inducing local strain via ion-implantation or dimensional confinement can modify magnetic and related properties in correlated metals such as $PdCoO_2$ and $TbMn_6Sn_6$. The challenge in predicting and understanding these behaviors from the intricate couplings of charge, spin, orbital, and lattice degrees of freedom. These at times challenge standard modeling approaches, requiring either significant empiricism or adoption of new methodologies to make progress. As such, in addition to using density functional theory, we outline our use of the highly accurate ab initio quantum Monte Carlo (QMC) approach to address these challenges. To control computational costs, we have developed a protocol of using QMC results to validate more scalable approaches via magnetic moments, charge densities, and thermodynamic properties. Building on our earlier work predicting metal-insulator transitions in bulk and heterostructures of correlated oxides such as VO_2[1,2] and correlated-perovskites[3], we will present the role of stacking-faults in inducing topological transitions in $MnBi_2Te_4$ [4], how ion-implantation can lead to novel magnetic transitions in $PdCoO_2$ [5] delafossite systems, and effects of dimensional confinement in realizing the Chern phase in $TbMn_6Sn_6$ [6], following this protocol.

Chiral Superconductivity on a Silicon Surface *Hanno Weitering; The University of Tennessee, Knoxville, United States*

Chiral superconductors represent an exotic and heavily pursued state of matter where the angular momentum state of the Cooper pairs is 'unconventional' and time-reversal symmetry is broken. While there are several candidates for the realization of chiral superconductors, conclusive evidence for the existence of chiral superconductivity has yet to be established. Here, I present experimental and theoretical evidence indicating the presence of a superconducting ground state in a dilute monatomic Sn layer on the Si(111) surface. This triangular lattice antiferromagnetic single-band Mott insulator becomes superconducting upon hole doping with a critical temperature reaching 9 K. With a coverage of only 1/3 monolayer of Sn, this represents the thinnest and most dilute superconductor known to date. Importantly, quasi-particle interference spectra below the superconducting T_c indicate that time-reversal symmetry is broken, while scanning tunneling spectroscopy data recorded along the edges of the superconductive domains are consistent with the calculated edge states for a chiral d-wave order parameter. Whereas most candidates for chiral superconductivity are complex materials, the simplicity and experimental control of this (and related) surface-science platforms provides a powerful testbed for theoretical models and discovery of elusive phases of quantum matter.

Red or Black Phosphorus Yield the Same Blue *Alberto Verdini[1], Alessandro Sala[1], Maria Caporali[1], Manuel Serrano-Ruiz[1], Francesco Armillotta[2], Erik Vesselli[3,1], Francesca Genuzio[1], Tevfik Onur Mentes[4], Andrea Locatelli[4], Giovanni Comelli[3,1,4], Simone Del Puppo[5], Pietro Biasin[3], Paola Mantegazza[6], Ivan Pasqua[7], Elena Ghidorsi[3], Andrea Resta[8], Alessandro Coati[8] and Maria Peressi[3]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]Università degli studi di Trieste, Italy; [4]Elettra Sincrotrone Trieste, Italy; [5]SDG Group, Italy; [6]University of Birmingham, United Kingdom; [7]Scuola Internazionale Superiore di Studi Avanzati, Italy; [8]Synchrotron SOLEIL, France*

After the discovery of graphene, many other 2D materials have been theoretically predicted and successfully synthesized. Among these, single-sheet black phosphorus—known as phosphorene—has emerged as a promising contender in the field of 2D semiconductors. Phosphorene offers a wide tunability of the band gap, ranging from 0.3 to 2 eV depending on the film thickness, along with other intriguing properties such as high carrier mobility and an anisotropic structure that modulates its physical and chemical characteristics. These features pave the way for novel and exciting applications, particularly in field-effect transistors and optoelectronic devices.In previous studies, a single layer of blue phosphorene interspersed with Au atoms was synthesized using purified black phosphorus as a precursor. Building on the observation that phosphorus vapor primarily consists of P clusters, our research aimed to produce blue phosphorus using the more cost-effective purified red phosphorus as an evaporant. Utilizing a combination of complementary experimental techniques and theoretical calculations, we demonstrate that depositing black or red phosphorus on Au(111) substrates results in the formation of the same blue phosphorus film. Furthermore, our comprehensive approach, which integrates experimental data with theoretical predictions, confirms the complex atomic model of this novel 2D material. While this is not a novel point, we emphasize that exploiting tools capable of diagnosing the possible presence of host heteroatoms in the 2D mesh is crucial for this quest. Overall, the development of reliable and sensitive comparison protocols between experimental results and theoretical forecasts can serve as the foundation for engineering next-generation materials.

Finite-Temperature Hole-Magnon Dynamics in an Antiferromagnet *Kaijun Shen[1], Kewei Sun[2], Maxim F. Gelin[2] and Yang Zhao[1]; [1]Nanyang Technological University, Singapore; [2]Hangzhou Dianzi University, China*

Employing the numerically accurate multiple Davydov Ansatz in combination with the thermo-field dynamics approach, we delve into the interplay of the finite-temperature dynamics of holes and magnons in an antiferromagnet, which allows for scrutinizing previous predictions from the self-consistent Born approximation while offering, for the first time, accurate finite-temperature computation of detailed magnon dynamics as a response and a facilitator to the hole motion. The study also uncovers a pronounced temperature dependence of the magnon and hole populations, pointing to the feasibility of potential thermal manipulation and control of hole dynamics. Our methodology can be applied not only to the calculation of steady-state angular-resolved photoemission spectra but also to the simulation of femtosecond terahertz pump–probe and other nonlinear signals for the characterization of antiferromagnetic materials.

3:45 PM QT03.08.04

Measuring the Quantum Geometry and Topology of Chiral Systems *Francesco Di Colandrea[1,2], Nazanin Dehghan[1], Alessio D'Errico[1] and Ebrahim Karimi[1]; [1]University of Ottawa, Canada; [2]University of Naples Federico II, Italy*

The quantum dynamics of two-band wavepackets is controlled by the quantum geometric tensor [1]. The Berry curvature (the imaginary part of the tensor) accounts for adiabatic trajectories, while the quantum metric (the real part of the tensor) describes non-adiabatic corrections. The quantum metric also features a fundamental geometrical interpretation, expressing the distance between the system eigenstates [2]. It has been linked to relevant phenomena, such as flat-band superfluidity, exciton Lamb shift, and orbital magnetic susceptibility. In chiral-symmetric systems, only the metric contributes to the quantum geometric tensor. The latter can be experimentally retrieved by measuring the mean chiral displacement of delocalized wavefunctions [3]. On the other hand, when the system is initialized in a localized state, the mean chiral displacement is observed to *converge to the bulk topological invariant [4]. These findings have been experimentally demonstrated in a topological quantum walk of structured light.*

Atomically Sharp Internal Interface in a Chiral Weyl Semimetal *Nitish Mathur[1], Fang Yuan[1], Guangming Cheng[1], Sahal Kaushik[2], Iñigo Robredo[3], Maia Vergniory[3,4], Jennifer Cano[5], Nan Yao[1], Song Jin[6] and Leslie Schoop[1]; [1]Princeton University, United States; [2]Stockholm University, KTH Royal Institute of Technology, Sweden; [3]Max Planck Institute for Chemical Physics of Solids, Germany; [4]Donostia International Physics Center, Spain; [5]Stony Brook University, The State University of New York, United States; [6]University of Wisconsin-Madison, United States*

Internal interfaces in Weyl semimetals (WSMs) are predicted to host distinct topological features that are different from the commonly studied external interfaces (crystal-to-vacuum boundaries). However, the lack of atomically sharp and crystallographically oriented internal interfaces in WSMs makes it difficult to experimentally investigate hidden topological states buried inside the material. Here, we study a unique internal interface known as merohedral twin boundary in chemically synthesized single-crystal nanowires (NWs) of CoSi, a chiral WSM of space group $P2_13$ (No. 198). High resolution scanning transmission electron microscopy (HRSTEM) reveals that this internal interface is a (001) twin plane which connects two enantiomeric counterparts at an atomically sharp interface with inversion twinning. Ab-initio calculations show localized internal Fermi arcs at the (001) merohedral twin boundary of CoSi that can be clearly distinguished from both external Fermi arcs and bulk states. These merohedrally twinned NWs provide an ideal material system to probe unexplored topological properties associated with internal interfaces in WSMs.

4:15 PM *QT03.08.07

Orbital Angular Momentum and Spin-Hedgehogs in Chiral Topological Semimetals *Niels Schröter; Max Planck Institute of Microstructure Physics, Germany*

The term chirality is derived from the Greek word for ‘hand’ χειρ (kheir) and generally describes objects that are distinct from their mirror image. It is long known that chirality plays a crucial role in nature, providing powerful functionality to chiral molecules in living organisms. Our goal is to extend this concept from the molecular to the solid state to discover new chirality-enabled functionalities in crystals that could form the basis for new technologies. One particular focus is on chiral topological semimetals, a new class of quantum materials at the intersection of structural and electronic chirality. We discovered the first example of this material class a few years ago (1) and have since demonstrated that they host new fermionic quasiparticles without analogue in high-energy physics, which carry large and controllable topological charges (2).
In this talk, I will present new results beyond these initial works and demonstrate that these materials realise an isotropic parallel spin-momentum locking that can be considered the natural counterpart of Rashba spin-orbit coupling, which leads to spin-hedgehogs in momentum space (3). Moreover, I will also present fingerprints of parallel locking of the linear momentum to the orbital angular momentum (4). If there is time, I will also discuss magnetic chiral topological semimetals and the effect of spin-dependent correlations on the quasiparticle lifetimes of bulk and chiral surface states.

Investigating Layered Topological Magnetic Materials as Efficient Electrocatalysts for Hydrogen Evolution Reaction Under High Current Densities *Sanju Gupta[1,2]; [1]The Pennsylvania State University, United States; [2]Gdansk University of Technology, Poland*

Despite significant progress in the catalyst development for hydrogen generation with highly efficient performances, there is still a lack of durable catalysts operating under large current densities (i.e., > 1000 mA/cm^2). Therefore, in search of efficient cost-effective PGM-free electrocatalysts for sustainable clean energy this work investigates the catalytic behavior of emergent layered quantum ferromagnetic semiconducting materials for hydrogen evolution reaction (HER). Specifically, the materials of interest include transition metal trihalide (i.e., $CrCl_3$, VCl_3, VI_3, and VI_2) multilayers and for a given structural unit, the layered structure is formed by tri-layers where Cr (or V) atoms is sandwiched between two halide layers. A few layers of these crystals were exfoliated on conducting substrates and electroanalytical tests were conducted for HER in both acidic and alkaline media. We find that the HER evolves systematically with changing halogen atom (Cl or I). Our results demonstrate reasonable activities for all the materials under 1000 mA/cm^2 requiring overpotentials ranging around 233-281 and 245-297 mV in 0.5M H_2SO_4 and 1M KOH electrolytes, respectively. The weak interlayer coupling, spontaneous surface oxidation (e.g., O-$CrCl_3$), intrinsic Cl or I vacancy defects or presence of bulk oxygen giving rise to in-gap states and sufficiently conductive support interaction lowering charge transfer resistance endow interesting electrocatalytic properties of which the novel structure-to-electrochemical property relations is established. Such behavior would be extrapolated to monolayers for further demonstration and these findings exemplify the critical role of substrate and significant potential for designing industrial-relevant HER electrocatalysts.

QT03.09.02

Investigation on Bi2Te3 Nanoplatelets Solvothermal Synthesis with Interest in Centered Single Nanopore

Motahhare Mirhosseini and David Carroll; Wake Forest University, United States

Two-dimensional hexagonal Bismuth Telluride (Bi2Te3) nanoplates can exhibit a chiral edge current due to the presence of a metallic edge state within the bulk band structure, reflecting their topological nature. The precise control over the morphology and composition of crystalline Bi2Te3 nanoplates using solution-based synthesis is well-established. Introducing a pore at the center of these nanoplates results in a Corbino geometry, providing a platform to observe edge currents at both the inner and outer edges and explore correlations between them. In this study, we present a solvothermal synthesis method to create and control pore sizes at the center of a few quintuple-layered Bi2Te3 nanoplates. We characterize the nanopore distribution, size, and morphology using transmission electron microscopy and atomic force microscopy. We show that the removal of tellurium (Te) nanorods, which act as nucleation sites for nanoplate growth, leaves behind nanopores. Furthermore, as the thickness of the Te rods increases, the nanopore size also increases. Finally, we employ magnetic force microscopy to map the magnetic forces at the inner and outer edges, providing insights into the topological properties in a Corbino geometry.

QT03.09.03

Flat Band Generation Through Interlayer Geometric Frustration in Dilutely Intercalated TMD

Yawen Peng and Guoxing Miao; University of Waterloo, Canada

Electronic flat bands can lead to rich many-body quantum phases by quenching the kinetic energy and enhancing electron correlation. The reduced bandwidth can be realized by either destructive quantum interference in frustrated lattices or generating heavy band folding with avoided band crossing in Moire superlattices. Here we propose a general approach to introduce flat bands into widely studied transition metal dichalcogenide (TMD) materials by dilute intercalation. A flat band with vanishing dispersion is observed over the entire momentum space in dilutely intercalated $Mn_{1/4}TaS_2$, arising from destructive hopping between Mn and Ta through S. Polarization dependent angle-resolved photoemission spectroscopy (ARPES) combined with symmetry analysis reveals the orbital characteristics of the flat band. The ubiquitous existence is furthermore extended to a wider collection of TMD family, as well as different intercalation situations. Such findings provide a new material platform to manipulate flat band structures and explore the emergent correlated properties.

QT03.09.04

Strain-Engineered Thermophysical Properties Ranging from Band-Insulating to Topological Insulating Phases in β-Antimonene

Sumit Kukreti; Indian Institute of Technology Jodhpur, India

Employing strain may lead to unusual modifications in the material's properties. Low-dimensional materials having large mechanical strength are well suited for strain engineering. In our work, we present the structural, electronic, thermal, and vibrational characteristics along with the phonon and carrier dynamics of β-Sb elemental monolayers for achieving the band-insulating phase at no strain and topological insulating phase at ~15% biaxial strain. The weakened π and σ bonds under strain, leading to anharmonicity in the system. It is further reflected by the drop in lattice thermal conductivity (κ_l) from 4.5 to 3.1 W m^{-1} K^{-1} at ~15% strain, i.e., in the topological phase. Helical edge states at 15% strain and meeting the Z_2 invariant criterion confirm the non-trivial topological state. Here we noticed the significant contribution of the out-of-plane A_{1g} vibrational mode in the topological phase compared with the band-insulating phase. Importantly, the dominance of the out-of-plane optical modes contributes significantly to the topological phase along the band edges, which is primarily due to the reduced *buckling height under strain. This work emphasizes the microscopic origin of the onset of the topological phase in strained β-Sb monolayers and provides strain-engineered structure–property correlations for better insights.*

QT03.09.05

The Role of Surfaces on the NO_2 Gas Sensing Performance of WO_3 Nanorods— Experimental and Theoretical Insights *Luís F. da Silva[1], Renan Ribeiro[2], Ariadne C. Catto[1], Frank Guell[3], Eduard Llobet[4] and Waldir J. Avansi[1]; [1]Universidade Federal de São Carlos, Brazil; [2]Minas Gerais State University, Brazil; [3]Universitat de Barcelona, Spain; [4]Universitat Rovira i Virgili, Spain*

Metal semiconducting oxides (MOXs) have stood out due to their functional properties. Among the various applications, the MOXs have been widely used as resistive gas sensors due to their sensitivity and fair stability. Tungsten trioxide (WO_3) is an n-type wide band-gap semiconductor applied as an active layer. Multiple factors behind gas-sensing properties have been considered responsible for improving sensing performance, however, an important aspect to consider is the relationship between sensing performance and MOX exposed facets/surfaces. The nature of surfaces exposed to the target gas becomes a key factor in enhancing the material sensing activity, as some facets exhibit higher reactivity to certain analytes than other surfaces. In this sense, we conducted an experimental and theoretical investigation regarding the nitrogen dioxide (NO_2) gas-sensing properties of WO_3 rod-like shape structures obtained via aerosol-assisted chemical vapor deposition. Electrical measurements showed the sensitivity of the nanorods towards NO_2 gas ranging from 0.1 to 1 ppm (parts-per-million), operating at room temperature under blue-light stimulation. Density Functional Theory calculations revealed that the surfaces play an important role in the NO_2 adsorption/desorption processes. Moreover, it was observed that the NO_2 adsorption energies followed the order (110) > (010) > (001) > (101), as well as indicating a physical adsorption mechanism with long-range W-O interactions. These results revealed the relationship between the NO_2 adsorption and the distinct WO3 facets, providing a better understanding of the morphological changes and the sensing performance of the rod-like structures.

QT03.09.06

Optoelectronic Response of Nodal Line Semimetal PbTaSe2 *Vivian J. Santamaria Garcia, Morgan Blevins and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States*

The discovery and synthesis of topological semimetals is an active field of research as new materials are realized and their applications are unlocked. Weyl semimetals, first discovered in 2015 [1], are topological materials characterized by linearly dispersing cones of Weyl fermions in their electron band structure with a single valence-conduction band touching point. Another class of topological semimetals are the nodal line semimetals (NLSM), which are characterized by topologically protected nodal lines within electron band structure, where the valence-conduction band touching points are sustained along a one-dimensional curve in the three-dimensional Brillouin zone [2,3] The nodal line states are manifested as protected surface states [4]. Early experiments have measured the anomalous and unique optical responses of nodal semimetals [5]. Possible applications for these materials include use in spintronics, nonreciprocal energy transport [6], as well as infrared and THz applications [7,8]. Given various exciting applications of nodal semimetals, it is imperative to fully characterize their opto-electronic response as well as assess the tunability of this response via external stimuli.
In our work, we analyze the optical response of PbTaSe2, a NLSM, under static and alternating electric fields. Using density functional theory (DFT), we predict the electronic structure and elucidate its optoelectronic properties. Ellipsometry is employed to gather information on polarizability, supported by the dielectric function derived from first-principles calculations.
To evaluate the electrical and optical conductivity, we use conductive atomic force microscopy (C-AFM) and Scanning Photocurrent Microscopy (SPCM), respectively. C-AFM measures the electrical conductivity under a DC

electric field, while SPCM assesses photocurrent generation under illumination. These techniques provide a comprehensive understanding of the performance of $PbTaSe_2$ under different conditions.
Further, we explore the material's optoelectronic response under strain to assess its tunability. This study allows us to correlate theoretical predictions of polarizability and electronic structure with experimental measurements of optical and DC conductivity. Our findings demonstrate how strain impacts the optoelectronic properties of PbTaSe2, showcasing the range of tunability achievable through nanoengineering techniques.

QT03.09.07
Unraveling the Nature of Coherently Strained Interfaces in Quasi van der Waals Epitaxy of Cr:(BixSb1-x)2Te3 on GaAs (111) Substrates for Quantum Anomalous Hall Effect *Yuxing Ren and Kang Wang; University of California, Los Angeles, United States*

Quasi van der Waals Epitaxy (qvdWE) has been realized for decades at the interfaces between 3D and 2D materials or van der Waals materials, and has recently been utilized for the epitaxial growth of various van der Waals materials. The growth of magnetic topological insulators (MTI) Cr: (BixSb1-x)2Te3 (CBST) on GaAs (111) substrates for Quantum Anomalous Hall Effect (QAH) is actually one of the examples of qvdWE, which is not well noticed despite the fact that its advantages have been used in growth of various MTI materials. This is distinguished from the growth of MTIs on other substrates. Although the qvdWE mode has been used in many 2D growth on some III-V substrates, the specific features and mechanisms are not well demonstrated and summarized yet. Here in this work, we have for the first time shown the features of both coherent interfaces and the existence of strain originating from qvdWE at the same time. Hetero-epitaxy of Cr:(BixSb1-x)2Te3 and other magnetic topological insulators on III-V substrates by MBE (Molecular Beam Epitaxy). Simulations are used to compare both in-situ and ex-situ characterization methods. Growth window of quantization regime is also studied. By controlling source flux and substrate temperatures, we have identified the growth of samples with quantum anomalous Hall effect at the boundary of mass-transport flow and adsorption-control mode on GaAs (111) substrates. With our work, now it becomes clear that the magnetic topological insulators Cr: (BixSb1-x)2Te3 (CBST) grown on GaAs (111) substrate for quantum anomalous Hall effect (QAHE) has the coherently strained interfaces.

Anomalous Quasiparticles in a Topological Metallic Ferromagnet *Gabriel Aeppli[1,2,3] and Yona Soh[3]; [1]ETH Zürich, Switzerland; [2]EPFL, Switzerland; [3]PSI, Switzerland*

There are long-standing ideas and experiments concerning the emergence of unconventional quasiparticles in strongly interacting Fermi systerms. The most dramatic are the fractional states originally observed for the two-dimensional electron gases in semiconductor heterostructures subjected to perpendicular magnetic fields, and explained shortly thereafter by Laughlin. Others found in zero field are more subtle in the sense that their peculiarity is reflected in scattering rates which rise linearly with the quasiparticle energies; these are the "marginal" fermions first conjectured for the layered cuprates also displaying high temperature superconductivity. Here we describe experiments revealing signatures of both types of anomalous quasiparticles in zero applied field. The material is Fe3Sn2, a ferromagnet kagome metal, with – according to calculations - numerous Weyl nodes near the Fermi level, and a high Curie temperature of ca. 640K. We investigated the anomalous quasiparticles appearing in the compound at low temperatures using microfocused, laser-based angle-resolved photoemission, together with density functional theory.

Spintronic Vertical Devices Using Two-dimensional Materials *Hiroshi Naganuma[1,1,2]; [1]Tohoku University, Japan; [2]Nagoya University, Japan*

L10-FePd has high bulk magnetocrystalline anisotropy (~2 MJ/m3) and low magnetic damping constant (aeff=0.007). [1] Therefore, the L10-FePd ordered alloy film is expected to be used as the recording layer of a nonvolatile magnetic random-access memory (MRAM). [2] However, the L10-FePd recording layer and MgO barrier have a high lattice misfit of about 10%. Graphene (Gr) is expected to have a relatively high MR ratio and low RA. [3] Furthermore, Gr has the advantage of being free from the restriction of lattice misfit because Gr is bonded by van der Waals (vdW) forces.

Here, hexagonal Gr was grown on a tetragonal L10-FePd epitaxial film by chemical vapor deposition and r.f. magnetron sputtering. Depth-resolved X-ray magnetic circular dichroism (XMCD) analysis revealed that interfacial perpendicular magnetic anisotropy (IPMA) was induced at the L10-FePd side of the Gr/L10-FePd interface. The scanning tunnel electron microscopy (STEM) showed that the interatomic distance between Gr and the FePd was 0.23 nm. Theoretical calculation indicated that a chemisorption type of van der Waals (vdW) force exists at the Gr/L10-FePd interface, shortening the interatomic distance between the Gr and L10-FePd interface. [4] This *chemisorption type of vdW force induces the hybridization of orbitals resulting in the appearance of IPMA at the Gr/L10-FePd interface.*

***Possible Filamentary Superconductivity in Janus Transition Metal Dichalcogenide TiSeS** <u>Mainpal Singh</u>, Pallavi Saha and Satyabrata Patnaik; Jawaharlal Nehru University, New Delhi, India*

A subclass of Transition Metal Dichalcogenides (TMDs) called Janus TMDs, which is nothing but having X_1-M-X_2 instead of X-M-X has grasped tremendous attention in the recent past. In addition to carrying over the benefits of traditional TMDs, Janus TMDs can also generate unique characteristics that set them apart from their counterparts, because the breaking of vertical mirror symmetry can lead to unique properties such as Rashba spin splitting. One such TMD is TiSeS, which is derived from the sulphur substitution in $TiSe_2$. On one side where $TiSe_2$ shows semimetallic character with a CDW transition around 200K, TiS_2 manifests semiconducting properties. TiSeS which is at the crossover of $TiSe_2$ and TiS_2 is a semimetal with suppression of CDW. Transport studies show localization character at low temperature due to Ti local moments. It is well established that the two phases, CDW and superconductivity stems due to electron phonon coupling and in general both compete with each other so a natural query comes up that the suppression of CDW in TiSeS can aid in the formation of superconducting state in the same. Here we report possible filamentary superconductivity in off-stoichiometric TiSeS. Magnetization data clearly shows a diamagnetic transition at 7K with clear hysteresis in ZFC and FC data. A second superconducting transition is also observed at 4K. Resistivity data shows a CDW transition near 80K which may be due to formation of minor $TiSe_2$ phase. Drop in resistivity is not clearly visible due to the fact that superconducting volume fraction is small so the inter-grain connectivity may not be present significantly and at low temperatures the localization dominates which causes the upturn into resistivity. Still a slight deviation near 4K could be observed towards the lower resistance. MR measurements at constant temperature below T_c shows clear signatures of shifting of onset resistance towards the lower field side that strengthens the existence of superconductivity in the material. This implies the interplay of CDW and superconductivity in novel chalcogenides can be studied in this system. Effect of metal intercalation in between van der Waals bonded layers will be useful to probe the novel characteristics arising due to various competing phases.

***Nonsymmorphic Symmetry Induced Correlated Topological States in 4D Perovskite Oxide Thin Films** <u>Yunkyu Park</u>[1], Seounghun Kang[1], Jeongkeun Song[1], Lin Shan[1], Hua Zhou[2], Jong Mok Ok[3], Mina Yoon[1], Satoshi Okamoto[1] and*

Ho Nyung Lee[1]; [1]Oak Ridge National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]Pusan National University, Korea (the Republic of)

Quantum materials (QMs) with strong correlation and nontrivial topology are indispensable to next-generation information and computing technologies and microelectronics. Exploiting topological band structure is an ideal starting point to realize correlated topological QMs. Despite its potential, observation of such topological band structure to enable quantum transport in oxide materials remains challenging. Our recent findings indicate that manipulating oxygen octahedral symmetry (OOS) is one of the key approaches in creating topological band structures near the Fermi level. In this work, we synthesize 4d niobate thin films (e.g., $SrNbO_3$ *and* $CaNbO_3$*) and manipulate crystal symmetry by epitaxial strain to induce the nonsymmorphic crystal symmetry, yielding the topological band structure and related physical properties. The 4d niobate thin films exhibited extremely high electron mobility and non-saturated extreme magnetoresistance due to the linear band dispersion near the Fermi level. Moreover, quantum oscillation from the magnetotransport measurements and the corresponding Landau-Fan diagram confirm a non-zero Berry phase. Therefore, the deliberate control of the octahedral symmetry provides a novel mechanism to host topological band structures in the strongly correlated oxide systems, which is an important step toward developing correlated topological quantum materials.*

11:00 AM *QT03.10.05
Magnetic Carbon Thomas Heine*; Technische Universität Dresden, Germany*

It is generally accepted that carbon is the most versatile element of the periodic table, and it offers a plethora of compounds ranging from biology to materials science. While the list of fascinating properties carbon materials offer is long, they are not yet famous for magnetism.
Indeed, most carbon materials are diamagnetic. Defects, dopants and dangling bonds can introduce paramagnetic centers without the potential to generate magnetic ordering. Recently reported magic-angle twisted bilayer graphene may become ferromagnetic due to a half-filled flat band at the fermi level and spin-orbit coupling [1]. A spectacular early report on magnetic carbon in pressurized fullerenes [2] was found to be caused by defects and the paper has been retracted five years later.
We propose an alternative concept to generate carbon materials with strongly coupled magnetic centers. Our materials are based on molecular triangulene and its derivatives, aromatic molecules intrinsically carrying one or two unpaired electrons. Using covalent linkages that preserve electron conjugation, we construct two-dimensional polymers with honeycomb-kagome lattice. The magnetic coupling between the monomers is facilitated by the linker groups. This has been examined in detail for the dimers [3]. When extending this concept to 2D polymers, we predict magnetic carbon materials with intriguing electronic structure that includes Stoner ferromagnetism with Weyl points at the Fermi level, and Mott-Hubbard insulator antiferromagnetism, which would be the first metal-free ferro- and antiferromagnetic materials with strong magnetic coupling with a Curie/Néel temperature above 250 K [4]. If we use two different building blocks in a heterostructure, we are even able to construct materials where a Curie temperature exceeding 500K.

Band Structure Engineering of van der Waals Heterostructures for Spintronics *Bruno Dlubak[1], Hao Wei[1], Frederic Brunnett[1], Simon Dubois[1,2], Victor Zatko[1], Marta Galbiati[1,3], Julian Peiro[1], Florian Godel[1], Etienne Carré[1], Jean-Christophe Charlier[2], Mauro Och[4], Cecilia Mattevi[4], Aymeric Vecchiola[1], Cécile Carrétéro[1], Karim Bouzehouane[1], Sophie Collin[1], Frédéric Petroff[1], Marie-Blandine Martin[1] and Pierre Seneor[1]; [1]Université Paris-Saclay, France; [2]Université Catholique de Louvain, Belgium; [3]Universidad de Valencia, Spain; [4]Imperial College London, United Kingdom*

The discovery of graphene has opened novel exciting opportunities in terms of functionalities and performances for spintronics devices.[1] This started a wide exploration of a large variety of 2D crystals for spintronics with the hope to exploit some of their unique topological properties. We will present here experimental results concerning integration of 2D materials in vertical Magnetic Tunnel Junctions (MTJ).[2] The direct growth of the 2D layers preserves the spin polarization properties of ferromagnetic spin sources, enabling the use of these van der Waals materials for spintronics devices. We will discuss the measured experimental spin signals in light of bulk band structure spin filtering effect as usually observed with MgO, but also highlight the role of interfacial hybridization (a.k.a. spinterface) for spin selection with ab-initio calculations in support. We will further introduce a novel pulsed laser deposition (PLD) approach for the definition of complex van der Waals heterostructures of 2D materials in magnetic tunnel junctions.[3] Overall, the presented experiments unveil promising approaches for the quantum engineering of multifunctional 2D materials heterostructures for spintronics.

Topological Insulators and Wigner Solids in Thin Films of Cadmium Arsenide *Susanne Stemmer; University of California, Santa Barbara, United States*

Bulk cadmium arsenide (Cd_3As_2) hosts topologically non-trivial bands in its electronic structure. In thin films, it can be engineered to a variety of new topological phases. In this talk, we will discuss topological and correlated insulator states in high-quality quantum wells of Cd_3As_2, which we grow by molecular beam epitaxy. Using Landau level spectroscopy, we show that the films transition to a two-dimensional topological insulator phase at quantum *well thicknesses around 20 nm. At lower thicknesses, the topological gap closes and reopens as a trivial gap. We show that new types of insulators appear near this critical thickness. Using transport measurements, we identify these new insulators as hole and electron Wigner solids, respectively, that form spontaneously at zero magnetic field. Hysteresis and voltage fluctuations point to domain motion across the pinning potential and disappear at finite temperature as thermal fluctuations overcome the potential. We discuss the interplay of topology, electron correlations, and spin-orbit coupling that gives rise to these novel insulating states.*

Searching for Ideal Topological Crystalline Insulators in Pb-Sn-In-Te System *Genda Gu; Brookhaven National Laboratory, United States*

The discovery of 3D topological insulator materials and topological superconductor open up a new research field in the condensed matter physics. In order to search for the topological superconductor, we have grown a large number of the single crystals of Pb-system (Pb-Sn-In-Te) topological crystalline insulator materials. We have measured the physical properties on these single crystals by various techniques. We have studied the effect of crystal growth condition, impurity and composition on the bulk electrical conductivity of these single crystals. We try to find out which composition and crystal growth condition is the best for the ideal topological crystalline insulator materials.

2:15 PM QT03.11.03

Probing the Interplay Between Exciton and Axion Order in Bilayer MBT *Olivia Liebman[1], Jonathan B. Curtis[2], Ioannis Petrides[1] and Prineha Narang[1]; [1]University of California, Los Angeles, United States; [2]ETH Zürich, Switzerland*

The unusual magnetoelectric transport present in certain topological materials can be compactly understood as manifestations of an emergent axion field, which itself is intrinsically related to the material's underlying topology and is determined by the microscopic band structure. However, unambiguous identification of the axion collective mode is challenging due to its inherent nonlinear dynamics, as well as competing order with other quasiparticle dynamics. Past work has shown that the dynamical axion collective mode may be detected through its nonlinear coupling to externally applied fields through a time-resolved Kerr measurement. Meanwhile, it has been previously shown that examining the bulk exciton spectrum can be a means to read out a material's underlying topology. As such, we propose a new route to study axionic phases of matter by examining the competing order between excitons and dynamical axion collective modes in the popular magnetic axionic insulator MnBi2Te4 (MBT). For a simplified model we consider the two-dimensional limit of a single MBT bilayer and carry out beyond mean field theory calculations to consider scattering events between fluctuations in exciton and axion order, which themselves are understood as collective fluctuations in the Néel order. We calculate the spectral function at finite temperature to probe the coupled dynamics and complex interplay of competing order in this topological bilayer system.

SESSION QT04.01: Molecular Qubits and Quantum Materials
Session Chairs: Anke Krueger and Fernando Luis
Monday Morning, December 2, 2024
Sheraton, Fifth Floor, Arnold Arboretum

10:30 AM *QT04.01.01
Quantum Computing with Molecules *Mario Ruben[1,1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]Université Strasbourg, France*

Metal complexes will be proposed to acting as active quantum units for Quantum Computing (QC). We report on the implementation of metal complexes into nanometre-sized (single-)molecular spintronic devices by a combination of bottom-up self-assembly and top-down lithography techniques. The controlled generation of magnetic molecular nanostructures on conducting surfaces/electrodes will be shown and persistence of their magnetic properties under confinement in Supramolecular Quantum Devices (SMQD) will be proven. The quantum behaviour (e.g.. superposition, entanglement) of the metal complexes will be addressed at the single molecule level[1-13] to finally implement a quantum algorithm on a $TbPc_2$ Qudit performing quantum computing operations.[10]

Molecular Spins on Layered Magnets for Their Integration in Quantum Cavities *Eugenio Coronado; Universitat de València, Spain*

Scalability is a current challenge in quantum technologies [1]. Molecular nanomagnets comprising multiple states, thus hosting more than one spin qubit, and their integration in quantum devices may provide a suitable approach to overcome this challenge [2]. Here we will report in a first step the design of spin qubits and qudits using as molecules polyoxometalate clusters. In a second step, we will explore the deposition and positioning of these molecular spin qubits on layered magnets of the type CrSBr. In a third step and in collaboration with the M. J. Martínez-Pérez team (INMA, Zaragoza), magnonic cavities based on these 2D magnets will be used to study the coupling of the molecular spin qubits with these magnons.

11:30 AM QT04.01.03
Strategies for Accessing Spin Molecular Quantum Processors *Guillem Aromí[1], David Aguila[1], Leoni A. Barrios[1], Olivier Roubeau[2] and Fernando Luis[2]; [1]Universitat de Barcelona, Spain; [2]Universidad de Zaragoza, Spain*

The controlled integration of single or multi-qubit magnetic molecules into superconducting circuits is key for the development of hybrid quantum computing architectures, as a suitable strategy for exploiting spin-based molecular quantum processors. This avenue might show competitive advantages over other solid-state schemes in view of the possibilities afforded by chemical design, allowing among other things to embed non-trivial quantum functionalities within each molecule (Nature Chem. ***2019****, 11, 301-309). We have shown that multinuclear complexes of lanthanide ions with inequivalent metal sites ([LnLn'] or [LnLn'Ln]) gather the conditions to behave as two- or three-qubit quantum gates (J. Am. Chem. Soc.* ***2014****, 136, 14215-14222; Chem. Sci.* ***2022****, 13, 5574-5581), 64-spin qudits (Commun. Chem.* ***2020****, 3, 176) or to realize quantum error corrections (Chem. Sci.* ***2020****, 11, 10337-10343). We show here that a [Dy_2] analogue of this family fulfills the main requisites to act as a two-qubit quantum processor and show that the dynamic magnetic properties characteristic of this behaviour are preserved when transferred in form of a few molecules thick layers inside the 20 mm wide loops of a gradiometric micro-SQUID sensor (Figure, middle and right). These results indicate that it may be possible to address multi-qubit molecular spin processors with on-chip superconducting circuits without altering their relevant properties. The* *use of soft nanolithography techniques may open the way to achieve this goal in practice.*

Vanadium Molecular Color Centers *Danna E. Freedman; Massachusetts Institute of Technology, United States*

Molecules comprise a unique platform for quantum applications. Molecules are tunable systems that can be designed for sensing applications. For example, molecular color centers feature tunable emission which can be harnessed for multi-modal sensing. Progress towards tuning emission frequency will be presented.

SESSION QT04.03: Lanthanide Base Molecular Qubits and Clock Transitions
Session Chairs: Alexander Kuehne and Mario Ruben
Monday Afternoon, December 2, 2024
Sheraton, Fifth Floor, Arnold Arboretum

3:30 PM *QT04.03.01
Hamiltonian Engineering in Molecular Lanthanide Spin Qubits *Stephen Hill; Florida State University & NHMFL, United States*

This presentation will highlight several recent examples involving optimization of coherence in molecular lanthanide (Ln) spin qubits through systematic engineering of so-called clock-transitions (CTs) [1-4] – avoided Zeeman level crossings at which the spin dynamics become desensitized to fluctuations (noise) in the local magnetic field. In this way, CTs provide optimal operating points at which the electron spin dynamics decouples from the magnetic environment leading to enhanced coherence [5]. The CT frequency can be controlled via crystal-field engineering in the case of integer spin-orbital moments, and the on-site hyperfine interaction in the half-integer case. In the first example, we describe a family of Ho^{III} *complexes based on an octadentate cage-like ligand that wraps around the metal center, resulting in a pseudo-fourfold molecular geometry, while leaving open an axial coordination site that permits tuning of the CT frequency,* Δ *[1]. This approach leads to dramatic increases in* Δ *relative to prior examples [5], thus reducing 2nd-order sensitivity to magnetic noise (which scales as* $1/\Delta$*). Meanwhile, in the half-integer spin case, we describe several molecular complexes in which the Ln ion adopts the rare 2+ oxidation state such that a lone electron occupies a mixed 5d/6s orbital. Again, ligand design principles enable realization of a doublet ground state with tunable 6s character, resulting in the possibility of engineering the hyperfine CT gap [2,3]. This latter approach has the advantage that the unpaired spin resides in an orbital with significantly reduced spin-orbit coupling relative to the 4f shell, giving rise to relatively long spin-lattice relaxation times.*

4:00 PM *QT04.03.02
Organometallic Lanthanide Complexes as Molecular Qubits with Robust Quantum Coherence Properties
Floriana Tuna; The University of Manchester, United Kingdom

There is significant current interest in the development of molecular quantum bits (MQBs) whose properties are suitable for the implementation of logic operations and algorithms. Metal complexes are promising MQB candidates due to their tunable properties and ability to form qubit arrays [1]. One impediment in using metal complexes as MQBs is the occurrence of quantum decoherence [2], a phenomenon that accelerates electron spin relaxation, reducing the longevity of the qubit and diminishing its ability to safely store and process the information carried in spins.

This talk will focus on how to engineer MQBs with improved coherence times. We will show that sufficiently long phase memory times allowing quantum spin manipulations even at ambient temperature are achievable in organometallic molecular systems with either C_3 or C_4 symmetry, even when the coordinated ligands are rich in nuclear spins. Examples include low-valent lanthanide and transition metal complexes bearing cyclopentadienyl derivatives, aryloxides and imides as ligands. The exceptionally long coherence times of these systems enabled mapping the spin densities that elucidate the decoherence path, with the aid of state of the art pulsed EPR methods, including HYSCORE, ESEEM, ENDOR. As an example, for $[LnCp'_3][K(2.2.2\text{-cryptand})]$ (Ln = Y, La or Lu; Cp' = C_5H_4SiMe), coherent Rabi oscillations were measured, including at 300 K in a single crystal [3]. We found that the pseudo-C_3 symmetry of these systems enables direct mixing of the metal valence s- and dz^2 atomic orbitals, resulting in a large and near isotropic metal hyperfine interaction, with a knock-on effect of retarding electron spin T_1 relaxation driven by spin−orbit coupling since the orbital angular momentum is largely quenched. The longer T_1 then does not limit Tm, the phase memory time, and thus allows coherent manipulation of the spin to higher temperatures (up to room temperature for the Y(II) example).

To further deepen our understanding of quantum decoherence, we have examined using HYSCORE the effect of different substituents (R) anchored to the cyclopentadienyl rings of La(II)Cp^R systems (R = $SiMe_3$ or CMe_3) [4], and found that the spin−lattice relaxation time T_1 and the electronic coherence T_{CPMG} times varies in line with the 6s-orbital character of SOMO. We measured significant spin density at the ^1H protons of Cp rings, as well as ^{29}Si of $SiMe_3$ groups, indicating that these nuclei participate to decoherence. Coherent spin manipulations were probed for up to eight hyperfine transitions, and the coherence times could be extended by CPMG methods up to 161 μs.

Enabling Clock Transitions in Divalent Lanthanide Complexes with $4f^n5d^1$ Configurations *Patrick Smith[1], Jakub Hruby[2], Stephen Hill[2] and Stefan G. Minasian[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Florida State University, United States*

The ability to create and control coherence in a quantum object, or "qubit", is key to the development of new concepts in quantum information science (QIS), including sensing, communication, and computing. Fundamentally, interrogating and manipulating quantum phenomena are at direct odds with sustaining coherence, as interactions between a qubit and its environment lead to decoherence and thus a loss of information. As such, long coherence times can often come at the expense of control over initialization and read-out, scalability, and entanglement. Our research uses synthetic chemistry to map the established physics of trapped ions onto molecular architectures, thereby effectively replacing ion traps with highly tunable, atomically precise ligand shells. Coherence times in electron-spin molecular qubits are improved at avoided energy-level crossings where the dependence of the transition frequency on the magnetic field vanishes. As such, the transverse relaxation time (T_2) is less sensitive to magnetic noise, engendering resistance to decoherence from near-neighbor magnetic sites and other nuclear spins in the molecule. Organometallic systems are particularly desirable because ligand field interactions in metallocenes can be adjusted by changing ring size and ring substituents to control both metal–C_{ring} distances and the electron withdrawing or donating character of the ligand itself. This presentation describes a general strategy for identifying molecules with high-frequency clock transitions based on systems wherein a d-electron is coupled to a crystal-field singlet state of an f-configuration, resulting in a minimally anisotropic ground state with strong hyperfine coupling. Using this approach, a 9.834 GHz clock transition was identified in a molecular Pr complex, $[K(crypt)][Cp'_3Pr^{II}]$, leading to T_2 enhancements up to threefold relative to other transitions in the spectrum. This result indicates the promise of the design principles outlined here for further development of f-element systems for quantum information applications.

SESSION QT04.04: Synthesis and Characterization of Molecular Qubits I
Session Chairs: Nuria Crivillers and Fernando Luis
Tuesday Morning, December 3, 2024

8:30 AM *QT04.04.01
Porphyrin-Based Molecular Qubits—From Quantum Gates to Photoinduced Spin Polarization Roberta Sessoli; *Università di Firenze, Italy*

Porphyrins are a unique molecular platform of interest for quantum technologies. Porphyrins can accommodate paramagnetic metal ions in a rigid scaffold with very good coherence time at high temperatures.[1] They can be used to generate multiqubit systems with control of the individual qubits orientation of the magnetic anisotropic tensors allowing single spin adressability. they have recently been employed for quantum sensing of the magnetic field.[3] Their chemical stability allows thermal deposition on surfaces.[2] Porphyrins are also widely used for their photophysical properties.[4]
In this presentation, I will review some recent results we have obtained in building homo- and heterometallic two qubits systems with single spin addressability.[5,6] Interestingly, vanadyl porphyrins promote exchange interactions having the right order of magnitude to allow controlled quantum gate operation, despite the metal magnetic orbital being non-bonding in character. The nuclear spin of ^{51}V is also a resource in quantum information science since the nuclear spin transitions can be selectively excited and coherently controlled through an effective quadrupolar interaction.[7]
Recently we have also explored the possibility of using light to control the spin polarization of the metal ion. Chromophores have often been used in combination with organic radicals to induce non-Boltzmann spin

population after light irradiation. Much less effort has been devoted to spins carried by metal ions. We have exploited meso-meso linked porphyrin dimers with selective metallation of one ring to uniquely excite the free porphyrin in its triplet state and, through moderate coupling to the permanent spin, obtain a long-lived spin-polarized quartet state even at room temperature. Interestingly, also the ^{51}V *hyperfine levels, well detected in the time-resolved EPR spectra, have a non-equilibrium population. These results open the perspective of using porphyrin-based qubits in combination with electron donor/acceptor dyads linked by chiral bridges to explore the phenomenon of chirality-induced spin selectivity as a resource for qubit control and readout.[8]*

[*] Some results that will be presented have been obtained in the frame of the ERC Synergy project CASTLe funded by the European Commission thanks to a collaboration between the Northwestern University (PI Prof. M.R. Wasielewski), the University of Parma (PI Prof. S. Carretta), and the University of Florence (PI Prof. R. Sessoli)

Organometallic Single-Molecule Magnets Containing Radicals and Bismuth *Selvan Demir; Michigan State University, United States*

Single-molecule magnets (SMMs) are molecules that possess an energy barrier to spin inversion, giving rise to slow magnetic relaxation and magnetic hysteresis. To realize their intriguing potential applications, ranging from molecular spintronics, quantum computing, to high-density information storage, spin-reversal barriers (U_{eff}) *and magnetic blocking temperatures* (T_B) *must be increased. Lanthanide ions are especially well-suited for the design of SMMs due to their large magnetic moments and magnetic anisotropy that originate from strong spin-orbit coupling of the 4f orbitals. One effective methodology to boost blocking temperatures of multinuclear compounds is to generate strong magnetic exchange between lanthanide centers using radical bridging ligands. In the event of large magnetic exchange coupling, undesirable relaxation pathways such as quantum tunneling of the magnetization can be suppressed. Here, the first isolation of the bisbenzimidazole radical anion* ($Bbim^{3-}$) *and its use in radical-bridged SMMs will be discussed.[1,2] A second approach to strong coupling employs heavy p-block elements since their diffuse valence orbitals facilitate better penetration of the core electron density of the lanthanide ions relative to diamagnetic ligands comprising lighter p-block elements. Here, we will present the first lanthanide bismuth cluster SMMs containing a* $[Ln_2Bi_6]$ *heterometallocubane core. We will also show that the* Bi_2^{3-} *radical anion can be tamed with rare earth ions to give the first SMMs featuring bismuth radicals.[3,4] We also synthesized complexes with diamagnetic* ^{89}Y ($I = ½$) *to gain insight into the electronic structure and spin density distribution.[5-9] The organometallic chemistry of the rare earth elements has been further advanced by first, employing dibenzocyclooctatetraene to give trismetallocene and sandwich complexes, respectively,[10,11] and second, the isolation of the first guanidinate complexes featuring a weakly coordinated tetraphenylborate anion,[12] which have ramifications for both magnet design and reactivity studies.[13]*

Donor Functionalized Trityl Radicals—Towards Organic Molecular Color Centers *Alexander J. Kuehne; Ulm University, Germany*

Trityl radicals are one class of stable organic radicals that can easily be functionalized to tune their properties. I will present a set of more than 40 donor functionalized trityl radicals and I will discuss the effect of donor strength on the emission properties, such as emission maximum and photoluminescence quantum yield. I will then discuss the effect of introduction of donors in a diradical setup and what strategies lead to light emitting diradicals with a triplet ground state.

Creating and Controlling Spin Qubits Through Molecular Engineering *Leah Weiss[1], Pratiti Deb[1], Noah Mendelson[1], Mykyta Onizhuk[1], Daniel Laorenza[2], Grant T. Smith[1], Ryan A. Murphy[3], Bahman Golesorkhi[3], Giulia Galli[1], Jeffrey A. Long[3], Danna E. Freedman[2] and David Awschalom[1]; [1]The University of Chicago, United States; [2]Massachusetts Institute of Technology, United States; [3]University of California, Berkeley, United States*

Spin-based defects within semiconductors are used to construct devices that enable information processing and sensing technologies based on the quantum nature of electrons and atomic nuclei [1]. These systems have attracted interest as they possess an electronic spin state that can be employed as a quantum bit over a range of temperatures. They have a built-in optical interface in the visible and telecom bands, retain their quantum properties over millisecond timescales or longer, and can be manipulated using a simple combination of light and microwaves. In a complementary approach, molecular spin systems are attractive building blocks for quantum information science. Bottom-up chemical design of qubits can enable atomistic tunability of spin and optical properties, scalability to multi-qubit architectures, and modularity between various host materials and devices. Designer qubits could be synthesized for a diverse range of applications from quantum sensing in biosystems to the creation of nodes in a quantum network. To this end, we discuss organometallic molecular ground-state spins with optical addressability [2]. These molecules comprise a central spin-bearing metal ion coordinated to surrounding ligands, enabling optical initialization and read out, as well as coherent microwave manipulation of the ground-state spin. We also show atomistic tunability of qubit properties by comparing molecules which differ *by the placement of a single methyl group on the coordinating ligands [3], the role of lattice symmetry in controlling coherence [4] and highlighting how molecular qubits can be tailored to enhance the coupling of spins to photons.*

2:00 PM QT04.06.02

NV(-) Centers in Diamond as Qubits for Local Sensing of Rotational and Translational Mobilities of Active Proteins *Anke Krueger[1], Anja Sadzak[1], Ivan Perez[2], Fedor Jelezko[3], Joerg Wrachtrup[1] and Michael Boersch[2]; [1]Universität Stuttgart, Germany; [2]Friedrich-Schiller-Universität Jena, Germany; [3]Universität Ulm, Germany*

Nitrogen- vacancy (NV) centers in nanodiamonds (10 to 100 nm diameter, FND) can be applied in biotechnology as single fluorescent quantum sensors. They react sensitively to changes in their environment, such as magnetic fields, temperature, or the presence of radical species. The extraordinary photo-physical properties such as very high photo-stability and non-blinking behavior allow for optical detection of magnetic resonance due to the NV triplet spin states. For a targeted interaction, the surface of nanodiamonds can be tailored e.g for specific binding to biological entities and can be modified to prevent non-specific interactions.[1,2] Here we want to exploit the single-spin properties of the luminescent NV-center in diamonds to reveal the dynamics of an active biological protein complex (FoF1-ATP synthase) at physiological conditions with highest spatio-temporal resolution. Enzyme dynamics include (A) ATP-driven subunit rotation and (B) reversible elastic deformation.
In order to specifically bind the respective protein, the surface of the FNDs needs to be modified. We have explored different linker strategies including the grafting of aryl moieties with clickable terminal groups, the use of oligo ethylenglycol spacers with different terminal groups and the binding via biotin/streptavidin. Here we will report on the effect of different linker architectures on the colloidal properties under physiological conditions, the influence on the ratio of NV(0) vs. NV(-) centers and the brightness of the particles for detection in the ABEL trap.
We will also present the characterization of individual nanodiamonds in solution. Using our confocal anti-Brownian electro-kinetic trap (ABEL trap) microscope we determine molecular brightness, spectral ratio and multi-exponential fluorescence lifetimes, but also diffusion coefficient and surface charge for each nanodiamond.
This research has received funding from the Carl Zeiss Foundation as a QPhoton project.

Simulating Open Quantum Systems with Molecular Spin Qudits *Sebastian Roca-Jerat[1], Emilio Macaluso[2], Alessandro Chiesa[2], Paolo Santini[2], Fernando Luis[1], David Zueco[1] and Stefano Carretta[2]; [1]Instituto de Nanociencia y Materiales de Aragón, Spain; [2]Università degli Studi di Parma, Italy*

The ever-growing development of quantum computers recently allowed for public accessibility to noisy intermediate-scale quantum (NISQ) computers [1]. Now, a great effort of conceptualization and implementation of efficient quantum simulations is realizing the future envisioned by Feynman [2] in which we are finally able to tackle quantum phenomena which go beyond classical computation [3]. However, interaction with the environment typical of open quantum systems (OQS) represents a double-edged sword in such applications. On the one hand it is the primary cause of the "noisy" nature of nowadays quantum simulators, limiting the computational power of algorithms developed on such platforms. On the other hand, since most quantum systems of relevant interest are effectively OQS, quantum simulators are faced with the problem of simulating *non-unitary time evolution together with the coherent Hamiltonian dynamics. This presents a significant challenge, since the dynamics of quantum computers is limited to unitary quantum gates.*

In this work [4], we have demonstrated how molecular nanomagnets coupled to superconducting resonators form a flexible playground that allows the implementation of different algorithms to simulate OQS. The ability of molecules to host systems with many addressable levels (qudits) makes it possible to reduce the complexity of such algorithms both in the number of operations (gates) to be implemented and in the number of units required. Through detailed numerical simulations, we have studied two conceptually different algorithms to show the advantages and disadvantages of each, and simulated proof-of-concept models that we believe can be taken to the laboratory in the near future, showing that in all cases molecular nanomagnets are an optimal ingredient in the study of OQS by means of digital algorithms.

Using Molecular Techniques to Control Environmental Spin Sensitivity *Joseph Zadrozny; The Ohio State University, United States*

Understanding how spins interact with the world is needed for the development of next generation quantum sensors. Molecular materials, with their atomistic-level tunability, offer a fantastic platform to obtain that understanding. My group studies environmental spin interactions for molecules and we focus primarily on using low-frequency magnetic resonance to do so. For example, we look at how the resonant frequency of a given system changes in response to temperature, pH, viscosity, etc, and focus where that frequency is sub 2 GHz. Our long term goals include translating aspects of quantum control learned from the study of molecular qubits to noninvasive chemical detection in biomedicinal applications. Hence, our preference on the low-frequency window is important because low-frequency radiation can penetrate water-rich tissue. In this talk, I will discuss our work with metal-based magnetic nuclei, as these respond to low-frequency radio waves and can readily penetrate living tissue. Our specific foci are the Cobalt-59 and Vanadium-51 nuclear spins, and I will show our demonstrations that molecular control is possible of these spins' environmental tunability.

Molecules for Quantum Technologies *Joris van Slageren; Universität Stuttgart, Germany*

Quantum technologies are set to change the world we live in in many more ways than one. Immense advances have been made, but potential show-stoppers, especially concerning scalability, loom on the horizon. Therefore, the search for an alternative quantum technological platform is on. Molecular quantum bits are the basis for such an alternative platform, because they are highly scalable, tunable and positionable. Coherence times have been shown by ourselves and others to be competitive with other quantum technological platforms.[1-3] *Current challenges in the field are individual readout and device integration.*

Here we present our past and recent advances in this area. First, we have immobilized molecular qubits in self-assembled monolayers on surfaces. We have conclusively proven monolayer formation. We have demonstrated quantum coherence in the immobilized qubits, which is an essential step towards device integration.[4] *Secondly, we have developed hybrid materials of molecular qubits with semiconducting polymers. We have shown by organic field-effect transistor measurements that the electrical properties of the polymers are unimpeded by the incorporation of the quantum bits. Furthermore, the embedded molecular qubits were shown to still possess long coherence times, even in the presence of mobile charge carriers.*[5] *These are important steps on the way to electrical readout of (individual) molecular quantum bis in spintronic devices.*

4:00 PM QT04.07.02

A General and Modular Approach for Solid-State Integration and Readout of Zero-Dimensional Quantum Systems and Molecular Qubits *Zoe Phillips[1], Marzieh Kavand[1], William Koll[1], Morgan Hamilton[1], Ethel Perez-Hoyos[1], Rianna Greer[2], Ferdous Ara[1], Dan Pharis[1], Mingyu Xu[3,4], Mehdi Maleki Sanukesh[5], Takashi Taniguchi[6], Paul C. Canfield[3,4], Michael E. Flatte[5], Danna E. Freedman[2], Jay Gupta[1] and Ezekiel Johnston-Halperin[1]; [1]The Ohio State University, United States; [2]Massachusetts Institute of Technology, United States; [3]Ames Laboratory, United States; [4]Iowa State University, United States; [5]The University of Iowa, United States; [6]International Center for Materials Nanoarchitectronics, Japan*

Electronic spectroscopy of zero-dimensional (0D) quantum systems, including point defects in solids, atomic states, and small molecules, is a critical tool for developing a fundamental understanding of these systems, with applications ranging from solid-state and molecular materials development to emerging technologies rooted in quantum information science. However, scanning-tunneling microscopy (STM) and scanning tunneling spectroscopy (STS) techniques for accessing this regime are powerful but not scalable, while device-based approaches that rely on embedding these systems within a solid-state tunnel junction are not generally applicable, requiring bespoke solutions for integrating each 0D system with a given host and excluding large classes of candidate quantum systems. Here, we present the demonstration of an all-electrical readout mechanism for these quasi-0D states that is modular and general, dramatically expanding the phase space of accessible quantum systems and providing an approach that is amenable to scaling and integration with other solid-state *quantum technologies. Our approach relies on the creation of high-quality tunnel junctions via the mechanical exfoliation and stacking of multi-layer graphene (MLG) and hexagonal boron nitride (hBN) to encapsulate the target quantum system (QS) in a MLG/hBN/QS/hBN/MLG heterostructure. This structure allows for electronic spectroscopy and readout of candidate quantum systems through a combination of Coulomb and spin-blockade, providing access to entire classes of quantum system that have previously only been accessible via optical spectroscopy or magnetic resonance measurements of large ensembles, if at all. As a demonstration of this approach, we report tunneling spectroscopy of vanadyl phthalocyanine (VOPc), a spin ½ molecular qubit that has demonstrated long coherence times and is compatible with standard evaporation techniques. Electronic spectroscopy of the MLG/hBN/VOPc/hBN/MLG heterostructure reveals resonances that quantitatively agree with tunneling spectroscopy obtained via STS of HOPG/hBN/VOPc half-devices.*

4:15 PM QT04.07.03

Quantum Control of Molecular Carbon *Lapo Bogani[1,2], Fanmiao Kong[1], Alessandro Lodi[1], Alex Gee[1], Hewen Chen[1], Ramon Torres[1], Ji Ma[3], Xinliang Feng[3], Jishan Wu[4], Wenhui Niu[3], Michael Slota[1], Tian Pei[1] and Simen Sopp[1]; [1]University of Oxford, United Kingdom; [2]University of Florence, Italy; [3]Technische Universität Dresden, Germany; [4]National University of Singapore, Singapore*

Magnetic states in graphene nanostructures have undergone intense theoretical scrutiny, because their coherent manipulation would be a milestone for spintronic and quantum computing devices. In nanoribbons, experimental investigations now show that quantum coherence of edge and localized graphene states is observable.[1] Several questions remain thus unsolved: how can molecular spins be integrated into electronic structures? Can topological states be used to improve the quantum coherence? Can metals be introduced so as to affect the carbon spin states? Can the quantum spin states be observed in devices? What is the role of electron-electron correlations? Here we try to provide an answer to these questions, exploring spin states in carbon by using molecular synthetic techniques.

Here we show how topological engineering of the carbon lattice can lead to improved coherence, higher than theoretical predictions.[2,3] We then show how such molecular structures can be included into molecular devices, producing magnetoresistive effects that are opposite to non-molecular devices.[4,5,6] The inclusion of metals then allows altering the spintronic properties. [7] We show how such electronic devices show quantum blockade up to room temperature, with different Luttinger liquid regimes available in different ranges.[8] The bright emissive modes offer the possibility of observing the quantum states optically.[9]

Electrical Detection of Magnetization Switching in Mn_{12} Single-Molecule Magnets *Amjad Alqahtani[1], Davonne Henry[1], Luke St. Marie[1], Lubomir Havlicek[2], Jakub Hruby[2], Antonin Sojka[2], Abdel El Fatimy[3], David Kurt Gaskill[4], Morgan Hale[5], Ivan Nemec[2], Petr Neugebauer[2], Amy Liu[1] and Paola Barbara[1]; [1]Georgetown University, United States; [2]Brno University of Technology, Czechia; [3]Université Mohammed VI Polytechnique, Morocco; [4]University of Maryland, United States; [5]Roanoke College, United States*

The unique magnetic properties of single-molecule magnets (SMMs) make them desirable candidates for quantum computing, high-density magnetic memory, and spintronics applications.[1-3] In all cases, we need to incorporate isolated or a few SMMs with suitable nanodevices that allow the detection and manipulation of their magnetic states. However, studies of SMMs have mostly focused on bulk crystals, and the development of hybrid SMM devices for an electric read-out of the magnetic state remains a sought-after milestone that has been achieved mainly for $TbPc_2$ at temperatures below 1 K.[4-7] Here we demonstrate electrical detection of magnetization switching for a modification of the archetypal SMM Mn_{12}, up to 70 K. The detection is based on the supramolecular spin valve effect using graphene quantum dot (GQD) devices.[8] Moreover, we show that the exchange interaction between the molecules and the graphene, as well as the GQD-mediated intermolecular interaction, can be directly extracted from the electrical response. This work opens the way to an effective characterization of the quantum properties of different types of SMMs in a wide temperature range.

QT04.08.03

On-Chip Magnetic Spectroscopy of a Molecular Spin Clock Transition in Competition with Spin-Spin Interactions *Marcos Rubín Osanz[1], Marina Calero de Ory[2], Juan Román-Roche[1], François Lambert[3], Feng Shao[4], Eric Rivière[3], Régis Guillot[3], Daniel Granados[5], David Zueco[1], Talal Mallah[3], Alicia Gomez[2] and Fernando Luis[1]; [1]Instituto de Nanociencia y Materiales de Aragón, Spain; [2]Centro de Astrobiología, Spain; [3]Institut de Chimie Moléculaire et des Matériaux d'Orsay, France; [4]Ocean University of China, China; [5]IMDEA Materials Institute, Spain*

We report a "spin clock transition" between the ground and first excited spin superposition states of a mononuclear Ni(II) molecular complex, [Ni(2-Imdipa)(NCS)](NCS), showing a characteristic non-linear magnetic field dependence that can be directly monitored by on-chip broadband transmission experiments. The sizeable quantum tunnelling splitting in this molecular system, with an S = 1 ground multiplet and strong anisotropy, provides a realization of the simplest non-Kramers system (integer spin). Lowering the temperature of the system down to the millikelvin regime in a dilution refrigerator allows exploring the competition between the onset of antiferromagnetic interactions and the energy gap of the spin clock transition in a fully concentrated sample. In addition, we show the coupling of the spin clock transition to lumped-element superconducting resonators, reaching very high cooperativity values. These results open the possibility of studying the interplay between long-range correlations and photon mediated interactions in a hybrid quantum platform.

QT04.08.04

Photoluminescent Stable Non-Kekulé Diradicals *Daniel Straub and Alexander J. Kuehne; Ulm University, Germany*

The utilization of the trityl motif to produce di- and multiradicals, is a synthetic challenge that is almost as old as the realization of the trityl monoradical itself. Kekulé diradicals (Thiele, Chichibabin, Müller hydrocarbons) have been widely explored and characterized. Here, the radicals are connected through the para-positions of the bridging phenylene rings, leading to substantial loss of diradical character through the formation of an equilibrium with the quinoidal structure. By contrast, meta-connected diradicals – so called non-Kekulé radicals – cannot form the closed-shell quinodal structure. Despite this obvious advantage and the possibility for triplet ground state formation, such meta-connected diradicals are hardly explored except for the Schlenk hydrocarbon. To investigate the spin coupling for meta-connected diradicals based on the tris(2,4,6-trichlorophenyl)methyl (TTM) motif, we synthesize a variety of novel diradicals. We vary the spacer-units to obtain a better understanding of this interesting class of diradicals.

QT04.08.05

Triphenylmethyl Radicals Functionalized with Azahelicenes for Circularly Polarized Doublet Emission

Markus Gross[1], Fangyuan Zhang[2], Mona E. Arnold[1], Princekumar Ravat[2] and Alexander J. Kuehne[1]; [1]Ulm University, Germany; [2]Julius-Maximilians-Universität Würzburg, Germany

I will present the synthesis and optical as well as the structural characterization of a series of azahelicene functionalized triphenylmethyl radicals. By employing Pd-catalyzed C-N cross coupling the radical character is retained during the azahelicene functionalization of the trityl radical, contrary to the conventional approach of using an aromatic nucleophilic substitution. The resulting dinaphtocarbazole and diphenanthrocarbazole substituted TTM radicals are chiral and can be separated into their respective configurationally stable enantiomers by using HPLC with a chiral stationary phase column. Both radicals exhibit circular dichroism, circularly polarized luminescence and photoluminescence quantum yields of up to 43%. The experimental results are supported by TD-DFT calculations. The newly reported azahelicene-based radicals demonstrate significant potential for advanced optoelectronics as well as quantum technological applications.

Modular Multi Coupling of Radical Residues to Bisterpyridine as Molecular Quantum Systems *Bernhard Putz, Felix Goll, Konstantin Grune, Nicolas Dießner and Ulrich Ziener; Ulm University, Germany*

2,X'-BTPs (bisterpyridines) and BBPs (bisbipyridines) have been the subject of research in our group for several years. They are ideally suited as a platform for targeted coupling of functional residues. Previously used for the *coupling of donor molecules (carbazole, acridine, phenoxazine), they can be substituted in two different ways: Either centrally single substituted as donor-acceptor type or peripherally double substituted as donor-acceptor-donor type.[1] It was shown that substitution via Buchwald-Hartwig coupling enables a very modular synthesis in which several donors can be attached as desired.*

If radical residues are used instead of the donor molecules, mono-, bi- and ter-radical systems can be synthesized in which two of the radicals are symmetrical to each other (bi-radicals) and asymmetrical to the third (ter-radicals). We succeeded in coupling HTTM and TTM residues to a BBP via Suzuki coupling according to this principle and obtained biradical with a significant contribution of triplet states (EPR). An alternative or additional coupling at the central site of the BBP can presumably be carried out analogously to the successful experiments with the donor molecules.

Furthermore, BBPs in a 4x4 zinc complex allow access to units with 8 HTTM residues, 4 adjacent to each other, which we were also able to show. This would allow structures with even higher spin density when repeated with TTM residues. 2,X'-BTPs and BBPs have potential as modular platforms for multi-radical systems for quantum applications.

Analysis of Crystalline Quality and Ion Beam-Induced Damage Recovery in Epitaxially Grown Rare Earth Oxide Thin Films via Rutherford Backscattering Spectrometry and Ion Channeling

Mritunjaya Parashar[1], Mohin Sharma[1], Darshpreet Kaur Saini[1], Todd Byers[1], Gary A. Glass[1], Sumit Goswami[2,3], Pralay Paul[2,3], Hanjong Paik[2,3], T. Venky Venkatesan[2,3,3] and Bibhudutta Rout[1]; [1]University of North Texas, United States; [2]The University of Oklahoma, United States; [3]University of Oklahoma, United States

Rare earth functional oxide (REFO) materials, such as CeO_2, are employed in a diverse range of applications today, including catalysis, gas sensing, photovoltaics, capacitors, and silicon-on-insulator (SOI) structures. Recently, their importance as quantum host has been highlighted due to the anticipated long coherence times in this system due to the lack of any nuclear interference. There are various methods for epitaxial growth of high quality REFO thin films such as molecular beam epitaxy (MBE) and pulsed laser deposition (PLD). However, to use these films effectively, precise knowledge of their composition and stoichiometry is essential. Rutherford Backscattering Spectrometry (RBS) provides a valuable non-destructive method for examining the elemental depth profile, diffusion of species in heterostructures, and estimating the stoichiometry of the films. For applications in quantum computing platforms, it is crucial that the deposited films are highly crystalline and epitaxial with the substrate. Thus, identifying the nature and inherent defects, whether interstitial or substitutional, is vital. This can be achieved through ion channeling via RBS (RBS/C), which involves directing a beam of incident probing ions (typically 1-3 MeV He^+) at a crystalline sample along specific crystallographic directions to quantitatively analyze substitutional and interstitial add-atoms.

In this study, we have investigated the elemental composition and lattice match of CeO_2, $Tm_xCe_{1-x}O_2$, and $Tb_xCe_{1-x}O_2$ films deposited via pulsed laser deposition (PLD) at various growth conditions on Si (111), and YSZ (100) substrates. Based on the observed RBS/C results, the films were more lattice-matched when deposited on YSZ (100) substrates as compared to Si (111). The best results were for $Tm_{0.1}Ce_{0.9}O_2$/YSZ (100) which showed the minimum backscattering yield (X_{min}) as 16.67%, 22.59%, and 16.21% for Ce, Tm, and YSZ, respectively, indicating a good match between Ce and YSZ lattice. The slightly higher X_{min} value for Tm may be due to the overlap between the surface peak of Ce and Tm. In the latter part of this study, we will assess the feasibility of ion irradiation and its role in ionization energy loss (IEL) induced damage recovery in annealing the pre-existing defects in the PLD

deposited film to improve its lattice match with the substrate. The results from this study aim to provide insights into the structural characterization of thin films with higher accuracy. Additionally, the novel use of ion irradiation to induce damage recovery in epitaxial films will open a new path for researchers to utilize IEL damage recovery across a wide range of materials and applications. We will also explore ion channeling to measure damage regrowth subsequent to anneals to measure solid phase regrowth in these crystalline oxide systems.

Keywords: Rutherford backscattering spectrometry (RBS), ion channeling, rare earth oxides, ionization energy loss (IEL), epitaxial growth

QT04.08.08

Growth of Ceria Films on Silicon with Rare Earth Doping

Pralay Paul[1], Sumit Goswami[1], Dhiman Biswas[1], Sreehari Puthan Purayil[1], Casey P. Kerr[1], Benjamin Summers[1], Hanjong Paik[1], Horst Hahn[1], Alisa Javadi[1], Bibhudutta Rout[2], Mritunjaya Parashar[2], Mohin Sharma[2], Darshpreet Kaur Saini[2], J. Tischler[1], H. J. Lezec[3], Dhruv Fomra[3], R. Kruk[4] and T. Venky Venkatesan[1]; [1]The University of Oklahoma, United States; [2]University of North Texas, United States; [3]National Institute of Standards and Technology, United States; [4]Karlsruhe Institute of Technology, Germany

For quantum memories, a critical parameter is the coherence time, which quantifies the duration for which a quantum state can be preserved. Rare Earth Ions (REIs) are known for their extended coherence times, especially when embedded within bulk solid-state crystalline hosts [1]. However, the coherence time of qubits is often compromised by magnetic noise arising from the nuclear and electron spin moments of the host atoms. This noise can be mitigated using isotopically purified samples, wherein nuclei with non-zero magnetic moments are eliminated [2]. On the other hand, naturally occurring Cerium (Ce) stands out among the lanthanoids as its stable isotopes all possess zero nuclear spin moments. Since oxygen exhibits a minimal presence of magnetic nuclei (0.3 per thousand), the intrinsic coherence time of a two-level system is expected to be preserved in a CeO_2 host crystal [2, 3]. CeO_2 is particularly advantageous due to its large bandgap, accommodating color centers from the visible spectrum—ideal for sensing applications—to the mid-infrared range, which is crucial for quantum communication. Additionally, CeO_2's compatibility with silicon enables the utilization of advanced nanofabrication techniques developed for silicon-based systems [4]. As a lanthanide-based host, CeO_2 effectively supports lanthanide color centers, which emit within the telecom spectrum, a key requirement for quantum communication and networking. Moreover, CeO_2's large optical refractive index (~2.45) makes it suitable for integration into silicon-based photonic devices.

High-quality CeO_2 films were grown on yttria-stabilized zirconia (YSZ)-buffered Si (100) substrates using RHEED and low angle x-ray spectroscopy (LAXS)-assisted PLD systems, resulting in single-crystalline films as confirmed by RHEED and HRXRD. Rocking curve measurements yielded FWHM values of 0.8, and 0.9 for the CeO2 (200), and YSZ (200) peaks, respectively, indicating excellent film quality.

Future work includes doping the CeO_2 matrix with less than 1% rare earth ions (Tm, Tb, Er, Yb, Ho) and conducting optical characterization, such as photoluminescence (PL) and photoluminescence excitation (PLE), to study the optical emission and lifetimes of these films. In addition, the coherence control of spin and nuclear moments will be explored by Hahn echo experiments and Ramsey coherence measurements.

Quantum Transport and Fractional Hall Effect in Moiré Correlated/Anticorrelated Channels

Farzaneh Shayeganfar[1,2] and Ali Ramazani[3]; [1]University of Michigan, United States; [2]Amirkabir University of Technology, Iran (the Islamic Republic of); [3]Massachusetts Institute of Technology, United States

Twisted bilayer graphene (tBLG) including interlayer interaction and rotational disorder shows anomalous electronic transport as a function of twist-angles (tAs). Quantum criticality of metal-insulator transitions of twisted nanostructures has been recently discovered and characterized by their transport measurement [1]. In this work, we address a new perspective of hybridization of fermions in twisted graphene nanoribbons (tGN) by representing a physical map of electronic properties and electronic transport of circular (with anticorrelated surfaces) and rectangular (with correlated surfaces) twisted tGN channels for two regimes of small and large tAs. Analysis of band structure reveals a phase transition of metal to semiconductor occurs in rectangular (correlated) case, sweeping small tAs to large ones. Local flat bands at the AA stacking of small and magic angles of circular (anticorrelated) twisted nanoribbons are formed by effective hybridization of local fermion momenta as f-orbitals and itinerant conduction electrons as c-orbitals, while electrons of extended topological conduction bands are responsible for transport and delocalization. This implies a different transport mechanism; where he energy resolved transmission of circular (anticorrelated) channels reveals pseudo-band and pseudo-gap depending on tAs. Moreover, rectangular channels with correlated surfaces indicate more electronic transmission than anticorrelated counterparts with wider pseudo-bands. Furthermore, the hybridization of f- and c- orbitals create the fractional Hall conductivity of circular (anticorrelated) tGNs. This study probes exotic quantum states in twisted van der Waals (vdW) homostructure with correlated/anticorrelated interfaces, engineering the quantum transport of twisted nanoribbons as building blocks for future quantum circuits and Hall sensors.

QT04.08.10

Sub-3nm Quantum Tunneling Nanogap Electrodes for Reliable Molecular Devices

Chengmin Zhang and Byung Yang Lee; Korea University, Korea (the Republic of)

We report on advanced sub-3nm nanogap electrodes with quantum tunneling characteristics, designed for use in molecular devices. Compared to current technologies, our quantum tunneling nanogap electrodes exhibit high controllability, satisfactory yield, stability, and reliability in single-molecule detection. Starting with a suspended SiN film on a wet-etched Si substrate, focused ion beam (FIB) milling triggers the release of internal tensile stress stored within the SiN film, inducing self-breaking behavior. We discuss various milling parameters that enable precise control over SiN nanogap sizes, ranging from 5 nm to 35 nm. The local metallization of the SiN gap using Pt ultimately defines the sub-3nm quantum tunneling nanogap electrodes.Electrical characterizations were recorded using the two-probe method, and quantum tunneling behavior was confirmed through Simmons model fitting, with the nanogap electrodes measured to have an average size of 1.51 ± 0.25 nm. The scalability of our methods was demonstrated by fabricating arrays of quantum tunneling nanogap electrodes.The reliability of the quantum tunneling nanogap electrodes as molecular devices was validated in multiple environments. Firstly, we confirmed the formation of single-molecule junctions using conjugated p-terphenyl-4,4''-dithiol (TPDT) molecules in both air

and vacuum, even at cryogenic temperatures (100K-250K), revealing a conductance of the Pt-TPDT-Pt molecular junction at 2.8×10^{-3} G_0. Additionally, we demonstrated the statistical identification of single DNA nucleotides in solution based on their electrical conductivity, which followed the trend dGMP > dAMP > dCMP > dTMP. The readout of short 5-mer DNA oligomers was also confirmed, with the conductance signals of the bases corresponding well to the measured conductance of individual nucleotides.We believe that our technology overcomes the challenges associated with fabricating sub-3nm quantum tunneling devices, opening new prospects for molecular electronics applications.

SESSION QT04.09: Molecular Photonics
Session Chairs: Paola Cappellaro and Stephen Hill
Wednesday Morning, December 4, 2024
Sheraton, Fifth Floor, Arnold Arboretum

8:45 AM *QT04.09.01
Exciton and Spin Dynamics of Luminescent Molecular Materials *Emrys W. Evans; Swansea University, United Kingdom*

The spin of ground and excited levels in molecular materials dictates the exciton mechanisms for any photonic, optoelectronic and quantum technology applications. This talk explores the photo- and spin physics of excitons as revealed by optical and magnetic resonance studies. Where organic semiconductors operate via singlet (spin, S = 0) and triplet (S = 1) excitons, achieving higher luminescence efficiency from these states will generally lead to higher performance, for example in OLEDs. Studies of spin conversion and the orbital-nature of the triplet excitons that dictates luminescence are presented for novel series of fluorescent and phosphorescent emitters. Recent interest in organic radicals containing unpaired electrons has emerged from the design of new materials that undergo efficient light absorption and emission from transitions between doublet spin (S = 1/2) ground and excited levels. As well as being potential candidates for functional emitters in light-emitting devices, opportunities emerge to couple their optical, spin and magnetic properties in molecular excitons that could enable future technology platforms.

9:15 AM QT04.09.02
Optimising Photoexcited Spin Interactions in Charge Transfer and Chromophore Radical Systems in the Pursuit of Quantum Sensors *Max J. Attwood[1], Wern Ng[1], Felix Xu[1], Michael Newns[1], Sam Bayliss[2], Mark Oxborrow[1], Sandrine Heutz[1] and Alberto Collauto[1]; [1]Imperial College London, United Kingdom; [2]University of Glasgow, United Kingdom*

Organic molecules are emerging as promising candidates for photoactivated quantum sensing devices such as masers and spin-ensemble detectors. In such systems, sensing relies on monitoring the spin coherence of paramagnetic states or the stimulated collapse of a spin-polarised state. However, due to inefficient spin dynamics, the molecular materials underpinning these technologies exhibit limited sensitivity and require strong light sources and supporting cavities with unrealistically high-quality factors. For these families of molecular quantum sensors to be widely applied we must develop new materials with enhanced spin dynamics that simplify their operation and improve sensitivity.
To tackle these issues, we have designed novel approaches to tune the quantum properties of candidate molecular systems and[2,3] synthesized several new triplet and radical-based materials capable of producing

strong and long-lived electron spin polarisation. Using transient optical spectroscopy and pulsed electron spin resonance spectroscopy it has been possible to link the electronic behaviour with their spin dynamics and, ultimately, determine their merit as quantum sensors. These results pave the way for the development of more widely applicable molecular quantum technologies.

9:30 AM QT04.09.03

Plasmonically-Enhanced Vibrational Excitations of the Stable Blatter Radical *Jonathan Bar-David[1], Abdoulghani Daaoub[2], Sarah Sibug-Torres[1], Sara Rocchetti[1], Gyeongwon Kang[1], Ross J. Davidson[3], Rebecca J. Salthouse[3], Chenyang Guo[1], Niclas S. Muller[1], Martin R. Bryce[3], Sara Sangtarash[2], Hatef Sadeghi[3] and Jeremy J. Baumberg[1]; [1]University of Cambridge, United Kingdom; [2]University of Warwick, United Kingdom; [3]University of Durham, United Kingdom*

Stable radicals are intriguing species with a plethora of proposed applications in fields such as energy storage, molecular electronics and quantum communication(1). However, surprisingly little is known of their optical properties and vibrational energy levels(2, 3). Furthermore, it is not clear how these are affected by the radical oxidation state, which is key for understanding electrical transport through these species in molecular electronics devices. Here, we explore the properties of 1,2,4-benzotriazin-4-yl, a doubly-thiolated variant of the stable Blatter radical(1), revealed through surface-enhanced Raman scattering (SERS). We investigate the vibrational modes of this molecule, its photoluminescence, and its optical response to reduction\oxidation and interactions with adjacent metallic surfaces.
To investigate these molecules, we bind them to gold (Au) films as a self-assembled monolayer (SAM) and combine this in Nanoparticle-on-Mirror(4, 5) (NPoM) plasmonic nano-cavities. NPoM nano-cavities are an efficient platform for light-matter interactions owing to extreme light confinement(4), enhancing processes such as Raman scatter by ~10^9. This allows us to probe molecular processes at the few-molecule level by measuring their time-varying SERS and extract new understanding of their behaviour.
We find the Blatter radical to have a photoluminescent (PL) excited state with LUMO\SOMO bandgap of ~1.9eV and vibronic side-band at ~1.7eV (shifted 1365cm^{-1}) which is the main vibration of the conjugated core as calculated by DFT. SERS signals from this vibration exhibit time-jitter on timescales <1sec and we show evidence that this is likely from coupling between the molecular vibration and the LUMO\SOMO orbital of the unpaired electron.
Our findings establish a previously- unknown coupling between the molecule SOMO\LUMO orbital, the radical spin, and molecular vibration and pave the way towards realizing efficient information-storage materials and molecular quantum devices.

9:45 AM QT04.09.04

Overcoming Molecular Decoherence at Room Temperature in DNA-Templated Plasmonic Resonators *Jeanne Heintz[1], Claudia Corti[1], Marco Capuzzo[1], Gabriel Vazquez[2], Nicolas Triomphe[2], Sylvie Marguet[3], Gaetean Bellot[2]*

and Sebastien Bidault[1]; [1]Institut Langevin, France; [2]Centre de Biochimie Structurale, France; [3]Commissariat à l'énergie atomique et aux énergies alternatives, France

Interactions between light and single molecules at room-temperature are fundamentally limited by electron-phonon coupling. For instance, while the excitation cross-section of a single molecule at cryogenic temperatures is close to one half of the wavelength of light squared (the so-called unitary limit), this value is reduced by 6 orders of magnitude at room temperature because of ultrafast decoherence. In order to render the exceptional optical properties of single molecules (such as indistinguishable single-photon emission and nonlinearities) accessible at room temperature, it is essential to overcome dephasing by accelerating emission rates using the Purcell effect. Over the last decade, gold nanostructures have shown amazing promise towards this goal thanks to their ability to enhance optical fields by several orders of magnitude in deeply sub-wavelength volumes. However, the nanoscale dimensions of these field enhancements mean that it is extremely difficult to address them in a controlled and reproducible way. To this end, we exploit DNA molecules to self-assemble plasmonic resonators with a control over both their nanoscale dimensions and their chemical environment. Using this strategy, we were able to enhance single-photon emission from fluorescent molecules by more than two orders of magnitude in a weak-coupling regime, while maintaining single photon emission statistics (ACS Nano 10, 4806 (2016)) and to reach a strong-coupling regime between a plasmonic resonator and 5 organic molecules, albeit with low reproducibility (ACS Nano 15, 14732 (2021)). We propose the use of dimers of plasmonic nanocubes in order to provide reproducible single-molecule strong coupling (J. Phys. Chem. Lett. 13, 11996 (2022)) and will present first results of the assembly of such architectures on DNA origamis with the aim of providing coherent interaction between light and single molecules at room temperature.

10:00 AM BREAK

SESSION QT04.11: Synthesis and Characterization of Molecular Qubits II
Session Chairs: Floriana Tuna and Joris van Slageren
Wednesday Afternoon, December 4, 2024
Sheraton, Fifth Floor, Arnold Arboretum

3:30 PM *QT04.11.01
Development of Stable and Efficient Luminescent Radicals via π-Extension of Carbazole Donor Ken Albrecht; *Kyushu University, Japan*

The development of emitting materials for OLEDs (Organic light emitting diodes) started with fluorescence, moved to phosphorescence, TADF (thermally activated delayed fluorescence), and reached doublet emitters.[1] Ground state singlet molecules have singlet and triplet excited states. Upon electrical excitation in an OLED device, 25% of the exciton will be singlet and 75% of the excitons will be triplet. OLED material has a history of harvesting the triplet excitons through the spin-flip process. In the case of doublet (radical) molecules, the ground and excited states are doublets. The electrical excitation process in an OLED device is expected to form 100% doublet excitons and all of the excitons can be harvested without the spin-flip process.
TTM (tris(2,4,6-trichlorophenyl)-methyl) radicals are known to have poor photostability, but the attachment of donor molecules such as carbazole can enhance the photostability.[2] At the excited CT (charge transfer) state, carbazole is a cation radical state. We have assumed that the photostability of carbazole-TTM system is dominated by the stability of the carbazole cation radical, i.e., attaching π-extended carbazoles that form a more

stable cation radical state can enhance the photostability. Here we report a series of carbazole-TTM dyads with π-extended carbazole donors.

Carbazole dendrimers and oligomers that consist of head-to-tail molecular structures show a unique electronic structure, i.e., an intramolecular potential gradient that is favorable as photonic and electronic materials.[3,4] Attaching carbazole dendrimers (dendrons) is expected as another approach to stabilize the TTM radical through electronic and steric effects. Here, we also report a carbazole dendron attached TTM radicals that are potentially expected as solution-processable OLED material.

The UV-vis and photoluminescence (PL) properties of all new radicals were measured in cyclohexane solution. The π-extension shifts the absorption and emission to a longer wavelength. This can be explained by the increase in the HOMO level of the carbazole donor. The PLQY was maintained even when the carbazole was π-extended. On the other hand, increasing carbazole dendrimer generation from G2 to G4 has shifted the absorption and emission to a shorter wavelength. Taking into account the results of DFT calculations, this can be explained by the larger electronic repulsion energy on the entire carbazole dendron. From G2 to G4 dendrimer, the PLQY has increased. This behavior could be explained mainly by the decrease of the knr (nonradiative decay constant). The photostability of the carbazole attached TTM radicals was also improved compared to the original carbazole-TTM radicals.

In summary, a series of π-extended carbazole attached TTM radicals and carbazole dendronized TTM radicals were synthesized, and their photophysical property was revealed. These results present new methods to improve the properties of luminescent TTM radicals. The OLED device fabrication is currently under investigation.[5,6]

4:00 PM QT04.11.02

Organic Radicals as Potential Molecular Qubits *Dennis Schäfter[1], Jonathan Wischnat[1], Lorenzo Tesi[1], Jesus Alejandro De Sousa[2], Marta Mas-Torrent[2], Jaume Veciana[2], Floriana Tuna[3], Joris van Slageren[1] and Nuria Crivillers[2]; [1]Universität Stuttgart, Germany; [2]Universitat Autònoma de Barcelona, Spain; [3]The University of Manchester, United Kingdom*

The progress in the molecular electronics field can be attributed to several factors that have enabled precise manipulation of molecular structures. The development of new synthetic protocols has expanded the range of functional molecules available, while improved characterization tools have enhanced our understanding of electronic properties at the nanoscale. The robust functionalization of surfaces with functional molecules is a key factor to progress towards device integration. In this context, our group has wide expertise in the synthesis of persistent organic radicals (open-shell) based materials and on the preparation of self-assembled monolayers (SAMs) based on these radicals. We particularly work with trityl radicals, specially the perchlorotriphenyl methyl (PTM). PTM radicals show inherent magnetic moment, they possess a rich electrochemistry, they are luminescent and chiral. Very recently we have demonstrated that PTM radicals possess extraordinarily long coherence times.1

Their synthetic tailorability enables preparing diradical systems that can be used for implementing two-qubit gates. But, long coherence times themselves are not sufficient for the fabrication of viable quantum devices, it requires the integration of MQBs into electronic device structures. In the presentation we will discuss different strategies for immobilization of these molecules on surfaces.

Molecular One- and Two-Qubit Systems with Very Long Coherence Times. Adv Mater 2023, 35 (38), 2302114. DOI: 10.1002/adma.202302114.

4:15 PM QT04.11.03

The Impact of Donor Orientation on the Emission Properties of Chlorinated Trityl Radicals *Mona E. Arnold[1], Markus Gross[1], Jonas Schmid[1], Nina Hagmeyer[2], Chunyu Li[2], Benjamin Dietzek-Ivansic[2] and Alexander J. Kuehne[1]; [1]Ulm University, Germany; [2]Friedrich-Schiller-Universität Jena, Germany*

The utilization of stable tris(2,4,6-trichlorophenyl)methyl radical (TTM) doublet emitters in OLEDs is promising, as it overcomes spin-statistical limitations to the efficiency.[1] Donor-functionalized TTM derivatives show long fluorescence lifetimes, which are in part originating from structural reorganization of the excited state, where the donor moiety becomes more perpendicular with regards to the TTM unit.[2,3] Suppressing such twisted intramolecular charge transfer is expected to shorten the fluorescence lifetime, potentially opening up other new applications of light-emitting radicals, for example in the field of organic lasers.

First, to suppress rotation and fix the donor in plane with the TTM acceptor, nitrogen atoms are incorporated into the triarylmethyl radical skeleton. This functionalization enforces a planar conformation of carbazole and radical moiety through hydrogen bonding. In fact, rotational confinement leads to shorter fluorescence lifetimes; however, at the cost of diminished photoluminescence quantum yield. While the rate constant for radiative relaxation remains unchanged, non-radiative processes appear accelerated.

Secondly, forcing the donor into a perpendicular orientation towards the radical moiety is achieved by additional chlorine atoms in the meta position. Thus, the electronic communication between donor and acceptor units is drastically diminished. This structural alteration leads to accelerated emission compared to the TTM analogue.[4] Simultaneously, non-radiative competitive processes are suppressed, increasing the photoluminescence quantum yield.

In general, such knowledge about the impact of the orientation of substituents towards the TTM moiety allows the rational design of radicals with desired optical and electronic properties. This is of particular importance when bridging two TTM units towards a diradical. The geometry of the resulting open-shell symstems is crucial for the communication between the unpaired spins, determining molecular properties such as spin mulitiplicity, diradical character, and emission properties.

Synthesis of Oligopyridine Based Biradicals as Promising Molecular Quantum Materials *Bernhard Putz, Felix Goll, Konstantin Grune and Ulrich Ziener; Ulm University, Germany*

In recent years, we have prepared a wide range of oligopyridines and related heteroaromatic oligomers. A modular *synthesis allows the combination of different cores (pyridine, pyrimidine, pyridazine or pyrazine units) and peripheral substituents (pyrazine, thiophene, phenol, etc.).[1] The 2,X'-BTPs (bisterpyridines) or -BBPs (bisbipyridines) can complex metal ions octahedrally. The resulting tetranuclear complexes form a grid-like structure with the four metal ions in one plane surrounded by four oligopyridine ligands. We have recently synthesised a BBP substituted with two tris-(2,4,6-trichlorophenyl)methyl (HTTM) units and the open-shell variant with TTM. It is known that meta-bonds between neighbouring rings of carbon biradicals are beneficial for radical stability and support a triplet ground state.[2] The BBPs contain a considerable number of meta-bonds in addition to para-bonds and could therefore favour ferromagnetic interactions. A radical content of 170 % per molecule has been determined from EPR measurements, indicating a significant contribution from triplet states. In addition, the closed-shell compound has been successfully converted to the Zn grid-type complex demonstrated by mass spectrometry and ^{1}H NMR spectroscopy. The formation of the grid-like metal complexes not only leads to a high density of functional substituents (a total of 8 HTTM units per complex), but can also be used to control the distance between the HTTM units between approx. 2.8 nm in the ligand and less than 1 nm in the complex. The structural variability shall allow fine-tuning of the intramolecular radical-radical interactions. Such flexible multi-spin systems are promising materials, e.g. for quantum sensing.*

SESSION QT05.01: Sensing Techniques to Probe Material Quantum Properties
Session Chairs: Paola Cappellaro and Daniel Jirovec
Monday Morning, December 2, 2024
Sheraton, Fifth Floor, Riverway

10:30 AM *QT05.01.01
Single-Spin Qubit Magnetic Spectroscopy of Correlated States of Electrons *Eugene Demler; ETH Zürich, Switzerland*

A single-spin qubit placed near the surface of a material acquires an additional contribution to its relaxation rate due to magnetic noise created by the low energy excitations of the electron system. I will discuss how this noise can be used to investigate different types of electronic states, including low dimensional superconductors and magnetic insulators.

11:00 AM QT05.01.02
Sensing Electron Spins of Copper Phthalocyanine via Relaxometry of Shallow Nitrogen-Vacancies in Diamond *Boning Li[1], Xufan Li[2], Guoqing Wang[1], Yifan Quan[1], Changhao Li[1], Shuang Wu[2], Avetik Harutyunyan[2], Ju Li[1] and Paola Cappellaro[1]; [1]Massachusetts Institute of Technology, United States; [2]Honda Research Institute USA, United States*

Molecular spin systems, particularly electron spin-bearing organic molecules with low spin-orbit coupling, such as copper phthalocyanine (CuPc), have recently emerged as a promising quantum platform. CuPc's electronic spin has demonstrated relatively long coherence times and can be highly customized through chemical modifications, enabling the creation of uniform, stable spin clusters for quantum applications, including quantum sensors and quantum random access memories. Compared to other solid-state spin defect qubits, the current techniques for depositing and fabricating molecular thin films offer greater flexibility and reliability in the manufacturing and usage of these qubits for sensing or interacting with external qubits.
To achieve initialization, detection, and manipulation of single electronic spins in CuPc, single nitrogen-vacancy (NV) centers in diamond serve as excellent tools to characterize quasi-2D samples of CuPc. In this work, α-phase CuPc thin layers (<25 nm) were deposited onto the surface of diamond. We demonstrate the interaction between shallow NV centers (depth <10 nm) and CuPc's electron spin through the relaxometry of NV centers. By demonstrating the interaction between CuPc and NV centers, this work paves the way to exploit this molecule-NV hybrid quantum system for quantum applications.

11:15 AM QT05.01.03
Near-Unity Charge State Initialization of NV Centers in Diamond via Multi-Color Excitation *Marjana Mahdia[1], Artur Lozovoi[1], Jared Rovny[1], Carlos Meriles[2] and Nathalie P. de Leon[1]; [1]Princeton University, United States; [2]The City College of New York, United States*

Nitrogen-vacancy (NV) centers in diamond have long spin coherence times and optical readout in ambient conditions, making them excellent quantum sensors. However, NV centers have significant state preparation error owing to charge dynamics under off-resonant excitation. Specifically, charge cycling under green illumination results in state preparation and measurement errors reaching up to 30%. One method for reducing this error is to use multicolor excitation to change the relative ionization and recombination rates [1]. However, previous demonstrations of this technique for bulk NV centers required relatively high excitation powers over a long period of time. In this work, through carefully calibrated excitation, we show that this multi-color initialization approach is also efficient for surface NV centers (5-15 nm deep) and that the relevant photophysics is preserved when the state-of-art diamond surface preparation is used [2]. From a meticulous examination of the experimental parameters, we identify a region within the parameter space where simultaneous near-infrared (905 nm) and green (520 nm) illumination of moderate powers can be used to achieve near-unity NV charge initialization within 10 μs while retaining its spin polarization. This work opens the door to high-fidelity initialization in multiplexed measurements and may enable quantifying many-point correlation functions.

11:30 AM *QT05.01.04
Color Centers in Diamond for Nanoscale Sensing—Material Aspects and Novel Approaches Elke Neu-Ruffing; *RPTU Kaiserslautern Landau, Germany*

Individual, luminescent point defects are stable, atomically small quantum systems. Such individual quantum systems especially the nitrogen vacancy (NV) center in diamond are extremely sensitive sensors, e.g., for magnetic fields. Their strength is to harness quantum mechanics for ultimate sensitivity and versatility while simultaneously boosting spatial resolution in imaging.
The talk summarizes our recent research in nanoscale quantum sensing using individual point defects. It will address material aspects especially targeting novel approaches to large area single crystal diamond materials and diamond nanofabrication. We will also summarize recent results on investigating magnetic materials and our work towards using sensing based on near-fields to extend the sensing capabilities of NV centers.

SESSION QT05.02: Quantum Phenomena in Novel Materials I

Spin Waves in a Bilayer Kagome Ferromagnet Fe_3Sn_2 Yona Soh; Paul Scherrer Institute, Switzerland

Magnetic metals with kagome structure can host various topologically non-trivial spin or electronic states, providing an extraordinary platform for studying the fundamental physics of quantum materials. The metallic kagome ferromagnet Fe_3Sn_2, which has large spin-orbital coupling, shows considerable interplay between magnetism and non-trivial electronic states. The material is a host of anomalous bulk properties, including a first order spin reorientation transition(1), an anomalous planar Hall effect(2), and field tunable electronic states(3, 4).

Recently, anomalous quasiparticles showing marginal Fermi liquid behavior and fractionalization have been observed in this system(5). Using Magnetic Circular Dichroism (MCD) Resonant Inelastic X-ray Scattering (RIXS) and X-ray absorption spectroscopy (XAS), we discover a flat spin wave band with large (compared to elemental iron) orbital moments in Fe_3Sn_2*(6). The flat mode energy is consistent with the high Curie temperature (~ 640 K) as well as the strong acoustic mode dispersion. Our results unveil that the defining units of this very popular topological metal are a triangular lattice of octahedral iron clusters rather than weakly coupled kagome planes. The spin waves are strongly damped when compared to elemental iron, opening the topic of interactions of topological bosons (spin waves) and fermions (electrons) with the very specific target of explaining boson lifetimes.*

Disorder- and Interaction-Dominated Quantum Criticalities in $\boldsymbol{WSe_2}$ *Nasir Ali[1], Fida Ali[2], Hyungyu Choi[1], Inhee Jeong[1], Hyokwang Park[1], Hoseong Shin[1], Kwangro Lee[1], Zhipei Sun[2] and Won Jong Yoo[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Aalto University, Finland*

Quantum fluctuations owing to strong Coulomb interactions or strong disorder lead to quantum phase transition (QPT) in 2D systems. However, understanding of disorder- and interaction-driven QPTs remains a fundamental challenge in condensed matter physics. Here, we use thickness-dependent WSe_2 *to elucidate the quantum phase metal-insulator transition driven by strong disorder, and strong Coulomb interactions in thin- and thick-*WSe_2*, respectively. An observation of crossover conductance ~*e^2/h *signifies the role of quantum fluctuations due to strong disorder in bi- and five-layer* WSe_2*. In contrary, the crossover conductance ~0.1* e^2/h *demonstrates bad-metal behavior associated with Mott quantum criticality owing to strong Coulomb interactions in ten-layer* WSe_2*. In the metallic phase, resistivity (ρ) follows Fermi-liquid (*$\rho \propto T^2$*) and non-Fermi-liquid (*$\rho \propto T^{1.5}$*) behaviors in bi- and five-layer* WSe_2 *from low to high temperatures, respectively. In ten-layer* WSe_2*, ρ displays a* T^2*-dependence at low temperatures while it shows a T-linear behavior at moderate temperatures in the deep metallic phase, suggestive of strange-metal behavior. Further, the strange-metal transforms into the bad-metal around the crossover point in ten-layer* WSe_2*. Moreover, conductivity (σ) exhibits a T-dependence as* $\delta\sigma \propto T^{3/2}$ *in the vicinity of critical point, suggesting the metallic glass phase which highlights the significant role of strong disorder and Coulomb interactions in bi- and five-layer* WSe_2 *devices. The absence of such a phase in ten-layer* WSe_2 *attributes that the Coulomb interactions dominate over disorder in ten-layer* WSe_2*. Critical scaling of conductivity as a function of temperature and carrier density reveals the disorder-dominated quantum criticality in bi- and five-layer* WSe_2*, and interaction-dominated quantum criticality in ten-layer* WSe_2*. This study provides compelling evidence that thickness-dependent* WSe_2 *serves as a new platform to study the disorder- and interaction-dominated QPTs in 2D systems.*

2:15 PM QT05.02.04

Superconducting Phase Diagram of Multi-Layer Square-Planar Nickelates *Grace A. Pan[1,2], Dan Ferenc Segedin[1], Sophia TenHuisen[1], Lopa Bhatt[3], Harrison LaBollita[4], Abigail Y. Jiang[1], Qi Song[3,1], Ari Turkiewicz[1], Mark P. Dean[5], Lena F. Kourkoutis[3], Charles Brooks[1], Matteo Mitrano[1], Antia S. Botana[4], Berit H. Goodge[6] and Julia Mundy[1]; [1]Harvard University, United States; [2]University of California, Berkeley, United States; [3]Cornell University, United States; [4]Arizona State University, United States; [5]Brookhaven National Laboratory, United States; [6]Max Planck Institute for Chemical Physics of Solids, Germany*

The discovery of superconductivity in square-planar nickelates has offered a rich materials platform to explore the origins of cuprate-like superconductivity. Experimental investigations however have largely been limited to within the infinite-layer $RNiO_2$ *nickelates. Here, we construct a phase diagram of the multi-layer square-planar* $Nd_{n+1}Ni_nO_{2n+2}$ *compounds and discover signatures of a superconducting dome for n = 4 – 8. Upon decreasing the dimensionality n, the superconducting anisotropy evolves due to 4f electron effects, and electronic structure characteristics approach cuprate-like behavior. Magnetic fluctuations persist from within the superconducting dome and into the over-doped, non-superconducting compound. Our work establishes this layered structural template, complementary to chemical doping, for creating new nickel-based superconductors. We indicate underlying commonalities and distinct differences across varying structural realizations of square-planar nickelates.*

2:30 PM QT05.02.05

Transport and Magnetism in Thin Films of the Superconducting Candidate La_2NiO_3F *Ari Turkiewicz, Abigail Y. Jiang, Grace A. Pan, Dan Ferenc Segedin, Suk Hyun Sung, Nicole K. Taylor, Charles Brooks, Ismail El Baggari, Jarad A. Mason and Julia Mundy; Harvard University, United States*

Since the discovery of superconductivity in infinite-layer nickelates, there have been continuous efforts to identify related materials with improved properties. Theoretical and experimental studies suggest that increasing the dimensional confinement across nickel oxide layers will lead to more 'cuprate-like' physics and higher superconducting critical temperatures. Here, we target thin films of the n = 1 Ruddlesden-Popper phase, La_2NiO_4*, which boasts single layers of electronically isolated nickel oxide. In the parent structure, nickel adopts a 2+ oxidation state with ground state antiferromagnetic ordering. Notably, the ground state magnetic structure of the high-*T_C *cuprates is proximate to an antiferromagnetically ordered phase. We therefore use two complementary methods to tune the nickel valence and ground-state magnetic properties. First, we use molecular-beam epitaxy (MBE) to synthesize thin films of the general formula* $La_{2-x}A_xNiO_4$ *(A = Sr, Ba) where nickel adopts an oxidation state of 2+x. After MBE synthesis, we leverage topochemical transformations including fluorine substitution and reductive de-intercalation [1,2] to synthesize thin films of the general formula* $La_{2-x}A_xNiO_3F_{2-y}$ *where nickel adopts an oxidation state of 2+x−y. Through these two methods, we can both electron- and hole-dope the nickel oxide layer, systemically probing the effect of valence on magnetic and electronic properties.*

3:15 PM *QT05.02.06
Magnetic Kagome Lattice—Topology and Frustration *Claudia Felser; Max Planck Institute, Germany*

Recently, there has been a surge of interest in topological quantum materials exhibiting nontrivial topological states, marking a dynamic frontier in condensed matter physics. [1]. Within the realm of topological quantum materials, those featuring a kagome lattice have recently garnered significant attention. This lattice not only gives rise to geometrically frustrated magnetism but also hosts a nontrivial topological electronic structure, showcasing Dirac points, van Hove singularities, and flat bands. The unique structure of the kagome lattice, coupled with multiple spin, charge, and orbit degrees of freedom, creates a fertile ground for exploring the interplay between frustrated magnetism, nontrivial topology, and correlation effects. This interplay results in a multitude of quantum states, offering a platform for investigating emergent electronic orders and their correlations. These materials can be broadly categorized into magnetic [2] and non-magnetic kagome materials such as CsV_3Sb_5*. Magnetic kagome materials, such as* Mn_3Sn *[3],* $Co_3Sn_2S_2$ *[4],* RET_6X_6 *[5] FeGe etc. primarily involve 3d transition metal-based (T=Ti, V, Cr, Mn, Fe, Co, Ni, Cu) kagome systems. The interplay between magnetism and the topological band structure significantly influences the electronic response, leading, for example, to the enhancement of the Berry curvature and the emergence of a large intrinsic anomalous Hall and Nernst effect due to the presence of massive Dirac or Weyl fermions. Additionally, the frustrated structure of kagome materials allows them to host topologically protected skyrmion lattices or noncoplanar spin textures, resulting in a topological Hall effect arising from real-space Berry phases.*

3:45 PM QT05.02.07
Determination of a Quantum Spin Liquid Ground State from Model Independent Evidence of Fractionalization *Vivek Bhartiya[1], Umesh Kumar[2], Taehun Kim[1], Shiyu Fan[1], Jonathan Pelliciari[1], Andrey Zheludev[3], Genda Gu[1], Igor Zaliznyak[1], Steven Johnston[4] and Valentina Bisogni[1]; [1]Brookhaven National Laboratory, United States; [2]Rutgers, The State University of New Jersey, United States; [3]ETH Zürich, Switzerland; [4]The University of Tennessee, Knoxville, United States*

Fractional magnetic excitations, spinons, are the most prominent emergent excitations in a quantum spin liquid (QSL) [1], and they are well understood within the Tomonaga-Luttinger liquid phase realized in one-dimensional (1D) Heisenberg antiferromagnetic (HAFM) spin chain [2]. Fractionalization reveals itself as a continuum of dynamical structure factor $S(q, \omega)$ *captured via inelastic neutron scattering (INS) [2]. However, its interpretation requires a material-specific dynamical structure factor* $S'(q, \omega)$ *that also explicitly depends on the unwanted interactions originating from anisotropy, disorders, and inhomogeneities in the bulk samples [3,4]. This challenge has triggered a desperate search for more robust emergent excitations, better materials, and model-independent experimental observables to diagnose a QSL. Here by employing high-resolution soft X-ray RIXS at Cu* L_3*-edge on a prototypical 1D-HAF chain* Sr_2CuO_3*, we demonstrate a model-independent determination of the RIXS spectra into two and multi-spinons excitations, hence the fractionalization. Firstly, we identify distinct resonances for the two-spinon and the multi-spinon excitations, e.g. four-spinon, with an energy separation dictated only by J. Secondly, we find that the multi-spinon resonance is narrower than two-spinon, giving the opportunity to enhance the pure two-spinon response (suppress the multi-magnon response) by properly detuning the incident photon energy. Our 1D t-J Hamiltonian-based exact calculations fully capture the low energy spin dynamics probed by RIXS and show that relative spectral weight enhancement/suppression is intrinsic to the symmetry of fractional excitations, i.e. it does not depend on the material-specific details. We further show that detuning-dependent spectral weight control can be employed to disentangle two-spinon excitations from multi-spinon, crucial for identifying fractionalization and thus, a quantum spin liquid ground state.*

4:00 PM QT05.02.08
Superconducting KTaO$_3$ Rashba Two-Dimensional Electron Gases as a Possible Monolithic Platform for Topological Quantum Computing *Hugo Witt[1,2], Srijani Mallik[1], Isabella Boventer[1], Nicolas Bergeal[2] and Manuel Bibes[1]; [1]Laboratoire Albert Fert, France; [2]École Supérieure de Physique et de Chimie Industrielles, France*

The two-dimensional electron gas (2DEG) at the interface between SrTiO$_3$ (STO) and LaAlO$_3$[1], displays a wide array of functionalities such as high electronic mobility, low temperature superconductivity[2] and tunable Rashba spin-orbit coupling (SOC)[3]. Understanding the physics of STO 2DEGs has challenged our community since that original discovery but also led to exciting properties for device applications into fields as diverse as power electronics, photocatalysis, spin-orbitronics[4] or topological quantum computing[5]. These latter two directions aim to specifically exploit the most unique properties of STO 2DEGs, namely Rashba SOC and 2D superconductivity. Yet, the Rashba coefficient in STO 2DEGs remains relatively small (a_R<50 meV.Å) and their superconducting T_C is low (~250 mK), hampering development towards these exciting goals.
Just like STO, KTaO$_3$ (KTO) is a quantum paraelectric material that in the bulk can be turned into a metal by minute electron doping, leading to high-mobility transport[6]. Because Ta is a 5d element, much heavier than Ti, KTO is also expected to possess stronger SOC and a high interest for spin-orbitronics.
In this talk, we will show how 2DEGs can be defined in KTO by deposition a few angstroms of Al by sputtering or molecular beam epitaxy. We will first focus on KTO(001) and discuss its electronic measured by angle-resolved photoemission spectroscopy (ARPES) and fitted by a tight-binding Hamiltonian. Our data provide the first direct visualization of Rashba-split bands in an oxide 2DEG[7] with a Rashba coefficient a_R»300 meV.Å, much higher than in STO 2DEGs. We will report charge-spin and spin-charge conversion from the direct and inverse Edelstein effects using bilinear magnetoresistance and spin-pumping experiments[8]. The deduced Rashba coefficient agrees well with values deduced from ARPES.
In a second part we will present the generation of 2DEGs on KTO(111) and KTO(110). Consistent with recent results on LAO/KTO[9–11] and EuO/KTO interfaces[10], the 2DEGs are superconducting with critical temperatures in the 1-2 K range, one order of magnitude higher than STO 2DEGs. This is unexpected since, unlike in STO, superconductivity is absent in bulk KTO. We will discuss the electronic structure of these KTO 2DEGs based on ARPES data and the nature of superconductivity from superfluid stiffness measurements[12]. We will also show how electrostatic gating can be used to tune it and out of the superconducting state, and present tunneling spectroscopy measurements suggesting that KTO 2DEGs are unconventional superconductors.

Synthesis and Characterization of Thin Films of the Quantum Spin Liquid Candidate $Tb_2Ti_2O_7$ *Margaret A. Anderson, Ismail El Baggari, Kyeong-Yoon Baek, Charles Brooks, Johanna Nordlander and Julia Mundy; Harvard University, United States*

Quantum spin liquids, exotic magnetic materials where spins fluctuate down to the lowest temperatures, are predicted to host fractionalized excitations and emergent gauge fields and are a potential platform for next-generation quantum computing. The thin film geometry offers potential advantages in quantum spin liquid synthesis and future device fabrication. Using reactive-oxide molecular beam epitaxy, we synthesize thin films of the rare-earth titanate pyrochlore $Tb_2Ti_2O_7$. We probe the impact of defects on the magnetic behavior of this enigmatic quantum spin liquid candidate with STEM imaging and SQUID magnetometry. We find that changing the film composition allows us to control the formation of extended defects which reduce the magnetic frustration in off-stoichiometry films.

This work was supported by the Air Force Office of Scientific Research (MURI Grant No. FA9550-21-1-0429).

4:30 PM QT05.02.10

Growth of Superconducting Sr_2RuO_4 Thin Films via Thermal Laser Epitaxy *Brendan D. Faeth[1,2,3], Varun Harbola[2], Felix Hensling[2], Lena Majer[2], Eren Suyolcu[2], Yu-Mi Wu[2], Hans Boschker[3], Peter A. Van Aken[2], Wolfgang Braun[3] and Jochen Mannhart[2]; [1]Cornell University, United States; [2]Max Planck Institute for Solid State Research, Germany; [3]epiray GmbH, Germany*

Thermal laser epitaxy (TLE) is a novel technique for thin film deposition which employs continuous wave lasers to simultaneously heat both the substrate and elemental sources. This laser heating approach allows for evaporation or sublimation of nearly all elements from the periodic table, ultrahigh substrate temperatures exceeding 2000 C, and broad compatibility with process gases at a wide range of pressures from UHV up to 1 Torr, among other benefits. As a result, TLE dramatically expands the parameter space available for thin film synthesis compared to existing epitaxy techniques. However, to date it has proven experimentally challenging to achieve simultaneous control of multiple laser based elemental sources with the flux stability and systematic fidelity necessary for the growth of ternary or multernary systems of interest such as complex oxides.

In order to establish the capabilities of TLE for the growth of such complex materials, we demonstrate here the successful epitaxial synthesis of several Ruddlesden-Popper phases of the Sr-Ru-O ternary oxide system via TLE. Near instant thermalization of both source elements and substrates from laser heating allows the process of thermodynamic phase control to be achieved rapidly during film deposition without the need for physical shuttering of sources. Additionally, we find that the “n=1” phase Sr_2RuO_4 can be reliably synthesized at substrate temperatures in excess of 1200 C and in a background environment of pure molecular oxygen, within an adsorption-controlled growth window that is inaccessible to conventional MBE approaches. We show that Sr_2RuO_4 films grown under these conditions demonstrate extremely high structural, electronic, and chemical quality, as *evidenced by the appearance of superconductivity at relatively high critical temperatures. In particular, the higher growth temperatures and elemental source fluxes afforded by laser heating allow us to achieve phase pure 214 without higher-N intergrowths typically observed in MBE-grown films, and growth rates more than 10 times faster than MBE. A detailed accounting of the experimental approach, growth thermodynamics and film characterization will be discussed. This work not only demonstrates the feasibility of TLE for the synthesis of high-quality complex oxide thin films, but also suggests new routes to achieving thin film growth in other materials systems that remain as-yet inaccessible to conventional epitaxy techniques.*

Transforming from Kitaev to Disguised Ising Chain *Hae-Young Kee; University of Toronto, Canada*

For many years, $CoNb_2O_6$ has served as an exemplar of the one-dimensional Ising model. However, recent experimental and theoretical analyses challenge its applicability to this material. Prior to that, a tailored spin model for $3d^7$ systems such as Co^{2+}, known as the J-K-Gamma model, has emerged, featuring Heisenberg (J), Kitaev (K) and Gamma interactions. While these interactions are permitted by the symmetry of the system, their role in $CoNb_2O_6$ remains enigmatic. I will present a microscopic theory based on spin-orbit entangled $J_{eff} = 1/2$ states, aimed at elucidating the roles of Kitaev and Gamma interactions in shaping Ising anisotropy. Leveraging strong coupling theory, a dominant ferromagnetic Kitaev interaction is identified. Furthermore, by comparing dynamical structure factors obtained via exact diagonalization with those from inelastic neutron scattering experiments on $CoNb_2O_6$, an antiferromagnetic Gamma interaction is found, which dictates the Ising axis and explains the mechanism behind moment pinning. Other spin-orbit coupled one-dimensional chains will be also discussed.

9:00 AM QT05.03.02
Anomalous Hall Effect in Antiferromagnetic MnTe *Marta Borysiewicz[1], Kacper P. Kluczyk[1], Dawid Bugajewski[1], Michal J. Grzybowski[1], Pawel Skupinski[2], Maciej Sawicki[2,3], Katarzyna Gas[2,4], Michal A. Borysiewicz[5], Tomasz Fas[1], Jan Suffczynski[1], Jaroslaw Z. Domagala[2], Krzysztof Grasza[2], Andrzej Mycielski[2], Michal Baj[1], Kyohoon Ahn[6] and Karel Vyborny[6]; [1]University of Warsaw, Poland; [2]Polish Academy of Sciences, Poland; [3]Tohoku University, Japan; [4]3Center for Science and Innovation in Spintronics, Japan; [5]Lukasiewicz Research Network, Poland; [6]The Czech Academy of Sciences, Czechia*

The presence of magnetic field-induced voltage is a prerequisite for many applications. Often, as e.g. in the case of giant magnetoresistance systems, it is related to magnetic reorientation of ferromagnetic layers. There is an ongoing effort to reach ferromagnetic functionalities in the antiferromagnetic (AF) materials, knowing that they are far more robust to magnetic environment and enable faster magnetization switching. One of promising effects may be the Anomalous Hall Effect (AHE), with presence of non-zero Hall voltage in the absence of magnetic field. Anomalous Hall effect has been confirmed in various antiferromagnetic oxides, where because of their insulating character Pt layer was used to reveal the AHE. There are just a few conducting AFs, where current may be passed directly though the antiferromagnetic material. Here we focus on a semiconductor: hexagonal MnTe. It has a high

*Neel temperature of 307 K and a bandgap of 1.3 eV. Haing been studied in the 60-ies, it has recently been rediscovered [1] with the prediction of large spin splitting [2], related to spin-group symmetry (within the so-called altermagnets). First observation of the AHE in this material were shown in thin films [3]. We are based on bulk samples, having no undesired parasitic background effects related to the substrate. Modifying the growth technique and using doping we were able to tune room temperature resistivity of our bulk crystals from 0.05 Ohm*cm to about 20 Ohm*cm. We clearly demonstrate the presence of the AHE at the room temperature, with a hysteresis loop with relatively large cohersive field of ~1T. The sign of the AHE hysteresis is opposite than in the case of thin films. The presence of the AHE is understood in terms of nonvanishing Berry curvature and also is predicted by the Dzyaloshinskii–Moriya type interaction, which explains also weak ferromagnetic-like signal revealed in the magnetization studies [4]. The studies of how the doping level (i.e. Fermi level position) affects the AHE will be presented and compared with the theoretical predictions, verifying this promising path for spintronic applications.*

The Synthesis, Tunable Properties and Emergent Superconductivity in the New Misfit Layered Compounds $(EuS)_{1+\delta}(NbSe_2)_n$ (n = 2,3)

Davor Tolj[1,1], Nicholas Ng[1], Xin Zhang[1,2], Daniel L. Foley[1], Berit H. Goodge[3], Mitra L. Taheri[1] and Tyrel McQueen[1,1,1]; [1]Johns Hopkins University, United States; [2]Princeton University, United States; [3]Max Planck Society, Germany

Heterostructured materials typically consist of two component materials layered on each other and bonded via "intermolecular" van der Waals (VdW) forces. Initially proposed as semiconductor materials due to their potential for advancing manufacture as well as enabling new technologies, substantial recent interest has focused on the use of 2D transition metal dichalcogenides (TMDs), as building blocks to provide novel electronic and magnetic properties.

An emerging class of materials that offers significant potential for the discovery of useful physical properties and phenomena are class of chemically bonded heterostructured materials, misfit layered compounds. The "misfit" portion of the misfit compound arises from the incompatibility in crystal structures of the component materials, most commonly a pairing of [001]-oriented cubic (NaCl type) and either hexagonal or trigonal structures. Normally, the layering of these structures would not be expected to form spontaneously as the degree of lattice mismatch is very high. However, due to the incommensurate structure (the ratio of the two structures is not an integer), it is possible with the misfit compounds. Misfit layered compounds can possess entirely different properties compared to their component materials which offers potential for the discovery of useful physical properties and phenomena. It is also possible to combine materials that typically contain mutually exclusive phenomena in a single material, such as ferromagnetism and superconductivity.

Here we report implementation of this strategy through combining ferromagnetic EuS and superconductive TMD $NbSe_2$*. The new misfit layered compounds* $(EuS)_{1+\delta}(NbSe_2)_n$ *($\delta \approx 0.13$; n = 2,3) have been successfully synthesized by solid state reaction (SSR) and chemical vapor transport (CVT). High resolution transmission electron microscopy (HRTEM), powder and single crystal X-ray diffraction confirm the misfit structure with c = 18.2 Å and 24.6 Å for n = 2 and 3, respectively. Magnetization, electrical resistivity, heat capacity, and thermal transport measurements show that the n = 2 material is a doped semiconductor with a low thermal conductivity of ~1 W/m-K and an antiferromagnetic ordering transition at* $T_N = 4.7$ *K. In contrast to the parent materials, the misfit is neither* *ferromagnetic nor superconducting down to $T = 0.4$ K. We find evidence of a field-driven transition to a ferromagnetic state due to reorientation of ferromagnetic layers. On the other hand, $n = 3$ is a superconductor with a transition temperature at $T_c \approx 2.8$ K. In both compounds the magnetic moment observed in the paramagnetic regime show that the magnetism is almost entirely caused by Eu^{2+} ions in the EuS layer. Transport properties, on the other hand, are expected to come primarily from TMD layer. The appearance of superconductivity in $n = 3$ compound can be attributed to the addition of a third $NbSe_2$ layer. As it is positioned between two other $NbSe_2$ layers, there is no direct contact with EuS layer. Lattice strain and charge transfer are therefore minimized allowing for the emergence of superconductivity.*

10:00 AM *QT05.03.04
Electronic Pseudogap from Fluctuations in Low Dimensional Excitonic and Superconducting Materials *Yu He; Yale University, United States*

Many metal-to-insulator and metal-to-superconductor transitions happen concurrently with an electronic energy gap opening and a broken symmetry. But there are electronic systems that develop energy gaps without any broken symmetry, most notably the "pseudogap" in cuprate superconductors. In this talk, I will show two examples of electronic pseudogap in unexpected places: the heavily hole-doped cuprates [1], and an excitonic insulator candidate Ta2NiSe5 [2]. The former is supposedly a good metal where mean-field BCS is thought to apply, and the latter is a structural symmetry-breaking system with strong electron-phonon coupling. Via angle-resolved photoemission spectroscopy and x-ray scattering, we show the electronic gap to persist well above the transition temperature in both systems. With insights from controlled numerical calculations, we discuss fluctuation as an important factor when describing the properties of low dimensional material systems. Finally, I will discuss potential new directions in sensing and metrology enabled by low dimensional fluctuations.

10:30 AM QT05.03.05
Modulating Ballistic Transport Across Organic Radical Molecular Wires *Zelin Miao[1], Shin-ichiro Kato[2], Juan Casado[3] and Masha Kamenetska[1]; [1]Boston University, United States; [2]The University of Shiga Prefecture, Japan; [3]Universidad de Málaga, Spain*

Integrating open-shell organic molecules with radical character into nanoscale junctions has been shown to promote more efficient quantum transport, particularly in longer molecule wires, with potential for next-generation electronic and spintronic devices. While much effort has been devoted to identifying potential molecular candidates, a fundamental and comprehensive understanding of how bridging conformations and external environmental factors, such as electric field and solvents, can modulate ballistic transport in such quantum systems is lacking. Here, we use the scanning tunneling microscope-based break junction (STMBJ) method to probe binding and electron transport through a class of oligophenylene group-bridged double triarylamine sulfide molecules (dTMeS) with two intrinsic radical centers within molecular backbone at room temperature. Measurements of neutral and diradical molecules synthesized ex-situ suggest that open-shell systems possess higher conductance than their original neutral analogs and can be generated in situ under an electric field in a non-polar solvent, such as 1-bromonaphthalene (BNP), without the addition of chemical oxidizing reagent. Unique binding behaviors are also observed, where radical character is quenched at early stages of junction evolution when the molecule is bound through the nitrogen embedded in the polycyclic end group but then regenerated *under electric field with further junction elongation when binding switches to the thioether linker further from the radical. The polarity of solvents also plays a critical role in modulating ballistic transport by shifting the energetic alignments between molecular resonances and the gold Fermi level. Our study demonstrates the feasibility of rational tuning of transport properties in the single open-shell molecular quantum system through geometry modulation and environment control.*

Transport Signatures from Novel Quantum Magnets *Jhinkyu Choi, Luis Leao, Bishnu Belbase, Arjun Unnikrishnan, Kiranmayi Dixit and Arnab Banerjee; Purdue University, United States*

Quantum magnetism is an emerging field where the energy is transported by means of spinons and magnons, in addition to phonons. However, these systems are often Mott insulators precluding conventional electric transport measurements on low-dimensional films. We describe our latest efforts to perform transport measurements, including thermal transport measurements, on these quantum magnets. We describe our calibration and new geometries we attempt for such a measurement and present results on a quantum spin liquid candidate material. We discuss the effects of interfaces, geometry, and the choice of substrates and materials for such a measurement.

11:00 AM *QT05.03.07

Exciton-Polaritons in Two-Dimensional Materials *Stephanie Reich; Freie Universität Berlin, Germany*

Polaritons are hybrid states of matter and light that form under strong and ultrastrong light-matter coupling. While the original research on polaritons focused on matter in external optical cavities, the concept of self-hybridization was introduced for polariton formation in thin flakes of layered materials. Here we discuss polaritons in two-dimensional (2D) monolayers as the ultimate limit of light-matter hybridization. Free standing monolayers of transition metal dichalcogenides show propagating exciton-polaritons that form between a photonic mode waveguided by the monolayer and the excitonic states of the material. We measured the dispersion of this exciton-polariton and found that it shows the characteristic back-bending observed for strong-light matter coupling. We discuss the consequences of these excitations, e.g., the prospect of combining polaritons in van-der-Waals type materials and the question of what limits the signature of matter contribution to polaritons in ultrathin 2D crystals.

11:30 AM QT05.03.08

Engineering Macroscopic Uniform 2D Moiré-Matter *Gregory Zaborski Jr.[1], Paulina Majchrzak[1], Samuel Lai[1], Amalya C. Johnson[1], Ashley P. Saunders[1], Ziyan Zhu[1], Yujun Deng[1,2], Donghui Lu[1,2], Makoto Hashimoto[1,2], Z-X Shen[1,1,2] and Fang Liu[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States*

Designing moiré matter interfaces provides an unprecedented and diverse platform for engineering exotic properties for quantum information science and technology. To date, however, current preeminent manufacturing methods of moiré matter have been laborious, yielding micrometer sample size, and fraught with crucial challenges such as low production efficiency and reproducibility, twist angle disorder, and interfacial contaminations. In this work, I introduce a rapid in situ exfoliation and stacking manufacturing technique for engineering moiré interfaces of twisted monolayer on bulk vdW systems with unprecedented scale and exceptional uniformity. Benefiting from the inherent lattice alignment of exfoliated monolayers within their original vdW layered crystal, the desired twist angle in homo twisted moiré structures can be meticulously controlled, either manually or through automated robotic processes. As a result, this technique offers distinct control over the twist angle compared to traditional methods. We directly characterize real space moiré and reciprocal space back-folded lattice, as well as moiré mini band structures, using piezoresponse force microscopy and torsional *force microscopy (PFM/TFM), low energy electron diffraction (LEED) and angle-resolved photoemission spectroscopy (ARPES), respectively. This technique enables effective batch assembly of highly customizable moiré interfaces, providing a platform for exploring hitherto inaccessible quantum phenomena with macroscopic advanced characterization techniques.*

11:45 AM QT05.03.09
A High-Efficiency, Single Port h-BN Sensor Chip with Easy Integration and High Optical Readout *Naveed Hussain[1], Alejandro Ruiz[1], Biswajit Sahoo[2], Debasish Banerjee[1], Shougo Higashi[1] and Songtao Wu[1]; [1]Toyota Research Institute of North America, United States; [2]University of California, San Diego, United States*

The past decade has witnessed several demonstrations on quantum sensing using solid-state spin-active boron vacancies in hexagonal boron nitride (h-BN). [1] *Some of the primary figures of merit for a functional sensor device include the easy chip integration of h-BN, energy efficiency and a high signal to noise ratio (SNR), which remains challenging. Due to the inherently low brightness of defects, a conventional optically detected magnetic resonance (ODMR) experimental setup requires a high laser flux and/or microwave power to achieve sufficiently high contrast. Hence, this introduces a significant risk of diminished resolution owing to heating effects, increased noise levels, and potential damage to the sample. Additionally, for ODMR experiments, the commonly employed cavity resonators,* [2] *and two-port coplanar waveguides or striplines* [1] [2] [3] [4] *are not feasible for incorporation into compact sensor designs.*
This work presents a novel quantum sensor chip utilizing h-BN on a compact gold shorted co-planar waveguide on a transparent sapphire substrate. The chip integrated with h-BN enables on-chip optical and microwave excitation, enhancing quantum magnetometry's practicality and sensitivity. Compared to conventional chips, our device offers improved impedance stability and radio frequency (RF) magnetic field concentration.[1] *As a result, our quantum sensor chip demonstrates an exceptionally high ODMR contrast of ~28% in response to the microwave (MW) power of 200 mW, and a high optical readout (several thousand PL counts/msec). This miniaturized chip reduces device size, enhances performance efficiency, and facilitates sensor performance with reduced power loss and signal reflection. Overall, our integrated quantum sensor chip design presents a significant advancement in scalable, efficient quantum sensors applicable to various fields, including external magnetic field sensing and ion detection. The work on improving the quantum sensitivity of hBN quantum sensor is ongoing.*

Super-Resolved Investigations of Luminescent Quantum Defects in SWIR Emitting Single Wall Carbon Nanotubes *Laurent Cognet; Université de Bordeaux, France*

Semiconducting single-walled carbon nanotubes (SWCNTs) exhibit a photostable excitonic fluorescence in the short wave near-infrared (SWIR). Recently, the covalent functionalization of nanotubes opened new avenues to manipulate and enhance their excitonic fluorescence to generate single photon sources or innovative nanoprobes in the SWIR. These luminescent quantum defects act as localized potential wells on the nanotube surface, trapping locally otherwise diffusing excitons. This new radiative pathway results in a shifting of the SWCNT emission towards longer wavelengths and allows SWCNT excitation on their first-order excitonic transition (ca. SWIR). Exciton trapping is also thought to results in an increase in the SWCNT emission, the trapped excitons avoiding possible quenching sites along the nanotube surface (structural defects, nanotube ends). This effect is however still debated and requires further nanoscopic investigations. Yet, altogether, these properties make quantum defect functionalized SWCNTs particularly attractive for various applications ranging from biological imaging to quantum information.
Because the spectroscopic properties of these nanohybrids is still poorly understood so that optimization of their synthesis is not yet controlled, novel nanoimaging approaches are needed. The task is not made easy since SWIR wavelengths are not an asset when an understanding of excitonic luminescence is desired such as for the study of exciton localization at the quantum defect sites or for imaging applications as standard imaging approaches are limited by the diffraction limit, e.g. ~500 nm in the SWIR.
Interestingly, single-molecule super-resolution localization microscopy has set a new paradigm in the field of optical imaging by delivering super-resolution images i.e. with resolution much better than the diffraction limit. To gain knowledge and control over these quantum defect, and in particular their SWIR emissive properties we will present the development a set of single-molecule based super-resolution imaging strategies at these particular wavelengths. This allowed the direct visualization of excitonic localization at quantum defect sites, the precise quantification of their luminescent properties in direct comparison with unfunctionalized SWCNTs and the further generation of ultrashort fluorescent nanotubes with enhanced emissive properties from individualized quantum defect sites.

2:00 PM QT05.04.02
Witnessing Entanglement in a 1D Hubbard Chain via RIXS *Sophia TenHuisen[1], Hari Padma[1], Ziqiang Guan[1], Zecheng Shen[2], Wei He[3], Filippo Glerean[1], Vivek Bhartiya[3], Jonathan Pelliciari[3], Valentina Bisogni[3], Yao Wang[2], Mark P. Dean[3] and Matteo Mitrano[3]; [1]Harvard University, United States; [2]Emory University, United States; [3]Brookhaven National Laboratory, United States*

Entanglement is an essential property of quantum materials and a crucial resource for quantum information *science, yet few experimental methods exist to measure it in macroscopic solids. Here we demonstrate that resonant inelastic x-ray scattering (RIXS) measurements on Sr_2CuO_3, a prototypical cuprate spin system, witness at least 6-partite entanglement. This entanglement is robust, with 4-partite entanglement persisting up to 220 K.*

To witness multipartite entanglement, we make use of the Quantum Fisher Information (QFI), which can be directly related to the dynamical spin structure factor[1]*, an approach which has recently been demonstrated in inelastic neutron scattering experiments*[2,3]*. We extend this formalism to RIXS, determining the dynamical spin structure factor of Sr_2CuO_3 in absolute units from RIXS measurements of the 2-spinon continuum in combination with calculations and comparison to theory.*

Witnessing entanglement with RIXS opens possibilities to study entanglement in a broad variety of contexts, including in thin films or in light-induced phases in- and out-of-equilibrium. Furthermore, moving beyond spin entanglement, RIXS is sensitive to a broad range of spin, charge, and orbital excitations. These degrees of freedom are also expected to be entangled, hence RIXS may provide a route to discover more general entangled states in real materials. This will provide a new framework for understanding collective properties and phases of quantum materials through understanding the structure of entanglement.

The Fate of Entanglement in Magnetism and Its Witnessing via Spintronic-Based Schemes *Branislav Nikolic; University of Delaware, United States*

The entanglement of many localized spins within solid magnetic materials is a topic of great basic and applied interest, particularly after becoming amenable to experimental scrutiny where recent neutron scattering experiments have witnessed macroscopic entanglement in the ground state of antiferromagnets persisting even at elevated temperatures. Furthermore, exotic magnetic materials, such as quantum spin liquid, are governed by long-range entanglement where the lack of experimental probes for its direct detection has also hampered confirming that candidate quantum materials really host such phase. On the other hand, it is common in spintronics and magnonics to assume that finite temperature and dissipative environment automatically ensure transition from quantum many-body entangled states of spins to their classical dynamics governed by the celebrated Landau-Lifshitz-Gilbert equation. We have very recently delineated [1] rigorous criteria for such transition to occur by analyzing dynamics of open quantum systems of many spins coupled to a dissipative environment. They also furnish examples of how specific classes of nonequilibrium magnets can generate stronger entanglement than in equilibrium. By integrating quantum spin liquids into spintronic devices, the presence of entanglement could be detected by its effect on spin-dependent transport measurements.

New Fun with the Quantum Nuclei *Ju Li; Massachusetts Institute of Technology, United States*

We have developed the first ab initio computational method to calculate the temperature shift of spin-transition energies (zero-field splitting, hyperfine interaction, nuclear quadrupole interaction) and zero phonon line (ZPL) in lattice defects such as the nitrogen-vacancy center in diamond. [J. Phys. Chem. Lett. 14 (2023) 3266] Supported by these computational predictions, Cappellaro group has shown that the temperature and strain variations in point-defect qubit ensembles can be largely filtered out in an "unbalanced spin echo" protocol, demonstrating a 20-fold increase in the dephasing time in an ensemble of 10^10 nuclear spins in diamond and robust quantum coherence protection. [PRL 131 (2023) 043602; PNAS 120 (2023) e2305621120] We have also developed a theory called optonuclear quadrupolar (ONQ) effect [Physical Review X 13 (2023) 011017], where two photons (100 THz and above) are used to manipulate nuclear spins that typically evolve at much slower (~MHz) timescales. The ONQ effect has been scoped for potential applications in laser cooling of nuclear magnons [PRL 130 (2023) 063602], quantum memory, microwave-to-optical quantum transduction, isotope spectroscopy, and for inducing population inversion between the isomeric and ground state of 229Th (8.3 eV) that could lead to gamma-ray laser, using a Watt-scale UV-B pumping laser and ultrawide bandgap thorium compound gain medium [PRA 108 (2023) L021502].

3:45 PM QT05.05.02
Non-Hermitian Spin-Spin Interactions Mediated by Chiral Phonons *Haowei Xu, Hao Tang, Paola Cappellaro and Ju Li; Massachusetts Institute of Technology, United States*

Chiral phonons, which are phonons possessing non-zero angular momentum, have garnered significant attention in recent years. These chiral phonons are found in chiral materials and represent the intrinsic asymmetry present in nature. They exhibit a variety of exotic properties, notably their ability to carry magnetic moments, enabling efficient coupling with both electronic and nuclear spins in solid-state systems. In this presentation, we will demonstrate that chiral phonons can mediate non-local, non-Hermitian spin-spin interactions. Specifically, we will show that one spin on the left can influence another spin on the right, but not vice versa. We will argue that under modest experimental conditions, the strength of such non-Hermitian spin-spin interactions can surpass the linewidth of the spins. Moreover, due to their non-local nature, chiral phonons can facilitate interactions among a large ensemble of spins, paving the way for the study of non-Hermitian many-body physics.

4:00 PM *QT05.05.03
Quantum Dot Arrays for Analog Quantum Simulation *Daniel Jirovec[1], Pablo Cova-Fariña[1], Stefan Oosterhout[2], Tzu-Kan Hsiao[1], Xin Zhang[1], Elizaveta Morozova[1], Amir Sammak[2], Giorgano Scapucci[1], Menno Veldhorst[1] and Lieven Vandersypen[1]; [1]Delft University of Technology, Netherlands; [2]TNO, Netherlands*

Semiconductor-based quantum dot arrays are versatile platforms for analog quantum simulations, potentially

offering insights into classically intractable many-body quantum phenomena with fewer resources compared to digital processors. The ability to engineer a variety of interesting regimes has led to the demonstration of exotic phases of matter, from Mott insulators and Nagaoka ferromagnetism to implementations of Heisenberg spin-chains and signatures of resonating valence bonds. However, for quantum advantage, large scale systems and new tuning strategies are required. Here, we present advancements in this direction in a 2x4 Ge-based quantum dot array. We apply digital state preparation and read-out schemes in combination with precise analog time evolution to the observation of magnon dynamics in a disordered system. Here magnons represent spin excitations traveling through the array via nearest-neighbor exchange interactions, amidst disorder provided by random effective g-factors in each dot, typical for holes in Ge.
We achieve exchange tunability up to 500 MHz, surpassing disorder by a factor of 50 at our operating magnetic field, while mitigating exchange crosstalk through a novel compensation method. For state preparation and read-out we leverage the intrinsic features of our Hamiltonian to initialize target spin-states and extract single-site spin-up probabilities across the array. This enables us to track magnon evolution in tailored configurations, from chains to rings.
Our experiment bridges digital single qubit operation with many-body physics concepts, indicating progress towards large-scale analog simulators and realistic near-term applications of semiconductor quantum dot systems.

4:30 PM *QT05.05.04
Data-Centric Learning of Quantum Many-Body States *Eun-Ah Kim[1,2]; [1]Cornell University, United States; [2]Ewha Womans University, Korea (the Republic of)*

I will discuss how to learn the nature of quantum many-body states encoded in the data through data-centric approaches using machine learning. Of particular interest are cases when the fingerprint of a given unusually complex state is not obvious from the outset. Using thoughtfully designed strategies that leverage key mechanism of given machine learning algorithm in conjunction one can gain new insight into unusual states such as gapless spin liquid or topological order in a mixed state. I will present cases s that led to fruitful insights and started to shape an approach to data sets of the new era.

Light-Induced Metastability in a Cuprate Ladder *Matteo Mitrano; Harvard University, United States*

Intense ultrashort lasers are an extremely effective tool for controlling the properties of quantum materials and inducing emergent states with novel functionalities. Some of the most spectacular light-induced phenomena, such as superconducting-like phases, transient charge density wave ordering, and excitonic condensation, are found to occur in materials dominated by strong electronic correlations with a large susceptibility to external stimuli. A key priority is to stabilize these effects to timescales far beyond the duration of the external excitation with the goal to better understand their microscopic physics and provide a path towards their functionalization. In this talk, I will focus on the problem of electronic metastability in Mott insulators, where prethermal and *metastable electronic distributions are necessary for the emergence of novel phenomena such as eta-pairing condensation and light-driven superconductivity. By studying a paradigmatic system, the cuprate ladder compound $Sr_{14}Cu_{24}O_{41}$, I will demonstrate the presence of a metastable electronic charge separation enabled by a transient symmetry breaking phenomenon. Further, I will illustrate how ultrafast x-ray spectroscopy enables interrogating the microscopic charge and spin dynamics of the metastable phase with unprecedented detail.*

Width-Dependent, Layer Controlled Growth of TMD Quantum Nanoribbons *Xufan Li, Shuang Wu and Avetik Harutyunyan; Honda Research Institute USA, United States*

Introducing additional degrees of freedom provided by the number of the layers, the width, and the strain of two-dimensional transition metal dichalcogenide (TMD) materials opens a new perspective for tuning their properties aiming at applications in quantum electronics and photonics. However, there is no facile, controllable growth method of TMD nanoribbons, especially for the appealing width range below 30 nm. Here we report a new method for growing single and double atomic layer of MeX_2 nanoribbons (Me=Mo, W; X=S, Se) with width down to sub-10 nm. The nanoribbon growth occurs via precipitation from pre-deposited seed nanoparticles with properly selected constituents in a chalcogen vapor atmosphere. We found linear dependence of growth rate on supersaturation, known as a criterion for continues growth mechanism, which decreases with decreasing of NR width driven by the Gibbs-Thomson effect. The grown bilayers nanoribbons demonstrate remarkable elastic robustness with strain up to ~14%. By applying external strains, TMD single layer nanoribbons generate high performance quantum emission of up to ~90% single photon purity, which is indicative of strain-induced localized electronic states. Moreover, width-dependent Coulomb blockade oscillations are observed in the transfer characteristics of MoS_2 nanoribbons with width <20 nm at temperatures up to 80 K due to the single electron transfer. Our new synthesis method provides a general route for width-controllable growth of families of atomic layer quantum nanoribbons, paving a pathway to the synthesis of novel quantum materials.

Magnetic-Flux Trapping and Self-Heating Phenomenon in Phase-Separated Superconducting Composite—Sn-Pb Solders and New Materials *Yoshikazu Mizuguchi[1], Takumi Murakami[1], Poonam Rani[1] and Hiroto Arima[2]; [1]Tokyo Metropolitan University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan*

In this presentation, we show electronic and thermal properties of phase-separated superconducting composites. The most targets are Sn-Pb solders with different Sn/Pb compositions, where Sn and Pb are basically phase-separated perfectly. Pure Sn and Pb are superconductors with transition temperatures (Tc) of 3.7 K and 7.2 K, respectively. Critical fields (Hc) of them are about 300 and 800 Oe for Sn and Pb. In Sn-Pb solders, for example, in Sn10-Pb90, magnetic field of 700 Oe is trapped after field cooling (FC). The high field greater than Hc of Sn is trapped in the Sn regions, and the stable flux trapping is achieved by supercurrent of Pb regions. The Sn regions loose bulk nature of superconductivity. Noticeably, the trapped field is depending on Sn concentration and decreases with increasing Sn concentration.
Using the flux-trapped states of Sn-Pb solders, we achieved nonvolatility of magneto-thermal switching (MTS), which is quite rare functionality useful for thermal control [1]. At the zero-field-cooling state, thermal conductivity is low due to the formation of Cooper pairs. After applying H > Hc (Pb), superconducting states of the solder is suppressed, and thermal conductivity becomes large. When external H is reduced to zero, fluxes are trapped in

the Sn regions, and thermal conductivity is still high, which is the nonvolatile-MTS states. In addition, we observed anomalous self-heating phenomenon when trapped-flux amount decreases [2]. The trapped field continuously decreases with increasing temperature, and the self-heating is observed from the lowest temperature to about 4 K. We discuss the possible explanation of the causes of the heating and correlation with the trapped fluxes. Our discussion will include possibilities of the presence of proximity superconducting states, intermediate states, vortices or vortex lattice in the flux-trapped Sn regions. In addition, we show exploration of new phase-separated superconducting composites and flux-related physical properties. Our prospect of phase-separated superconducting composites is the application as quantum sensors where the physical properties are controlled by the trapped fluxes in the superconducting composites.

Using X-Ray Spectroscopies to Quantify Quantum Fisher Information *Zecheng Shen[1], Jordyn Hales[1], Sophia TenHuisen[2], Matteo Mitrano[2] and Yao Wang[1]; [1]Emory University, United States; [2]Harvard University, United States*

Understanding and controlling entanglement in quantum materials is crucial for advancing quantum technologies. To quantify entanglement in many-body materials, we calculated Quantum Fisher Information (QFI) in order to witness entanglement. Using Density Matrix Renormalization Group (DMRG), we systematically investigate the dynamical spin structure factor in the extended Hubbard model, motivated by the significant near-neighbor attractive Coulomb interaction V observed in recent cuprate photoemission experiments. To validate our theoretical model, we compute QFI from the obtained via DMRG and compare it with QFI results derived from Resonant Inelastic X-ray Scattering (RIXS) experiments. Considering the Cu L-edge RIXS is a mixture of spin-flip and spin-conserved channels, we apply a q dependent normalization factor to the RIXS results. The QFI from normalized RIXS matches the DMRG-simulated QFI thus confirming the reliability of our approach.

Light-Driven Switch for Metastable Charge Trapping in a Cuprate Ladder *Hari Padma[1], Sophia TenHuisen[1], Zecheng Shen[2], Joshua Elliott[3], Filippo Glerean[1], Elizabeth Skoropota[4], Hiroki Ueda[4], Biaolong Liu[4], Byungjune Lee[5], Wei He[6], Seng Huat Lee[7], Yu Wang[7], Zhiqiang Mao[7], Matteo Calandra[8], Hoyoung Jang[5], Elia Razzoli[4], Mark P. Dean[6], Yao Wang[2] and Matteo Mitrano[1]; [1]Harvard University, United States; [2]Emory University, United States; [3]Diamond Light Source, United Kingdom; [4]Paul Scherrer Institute, Switzerland; [5]Pohang University of Science and Technology, Korea (the Republic of); [6]Brookhaven National Laboratory, United States; [7]The Pennsylvania State University, United States; [8]Università di Trento, Italy*

Precision control of charge carrier density is a key capability that underpins modern technology. It also plays a central role in strongly correlated materials, where the carrier density provides a powerful handle on emergent phenomena, for example enhancing superconducting critical temperatures by orders of magnitude and tipping the balance between competing ordered phases. However, conventional approaches to realizing this, such as chemical substitution, are slow, introduce deleterious structural disorder, and are furthermore a static and irreversible process. Here, we demonstrate a modality to dynamically control the carrier density, by transiently manipulating atomistic pathways for charge tunnelling in the $Sr_{14-x}Ca_xCu_{24}O_{41}$ *family of superconducting ladders. We achieve this using intense, ultrashort pulses of light that break the approximate fourfold symmetry of the* CuO_4 *plaquettes, activating a transient tunnelling pathway between the ladder sublattice and the charge reservoir layer.*

This results in a transfer of holes into the ladder, where they are subsequently trapped for several nanoseconds, manifesting as a characteristic reshaping of the time-resolved X-ray absorption spectra. Furthermore, employing time-resolved resonant X-ray scattering, we find that the trapped holes suppress the charge order and short-range spin correlations, even as the ladder approaches the carrier density at which superconductivity onsets. Our work demonstrates a new strategy towards achieving long-lived light-induced phenomena and paves the way towards functionalizing them.

11:00 AM *QT05.06.07
Quantum Control of Hubbard Excitons *Denitsa R. Baykusheva; Institute of Science and Technology Austria, Austria*

Intense ultrashort off-resonant fields can hybridize with material excitations, giving rise to interesting light-driven phenomena such as transient superconducting-like phases, charge ordering, and excitonic condensation [1]. A particularly intriguing platform for such studies are low-dimensional Mott insulators, where light-matter interaction is predicted to modify effective many-body interactions and lead to exotic nonequilibrium ordering phenomena such as eta-pairing superconductivity [2]. Here, we investigate a paradigmatic strongly correlated quantum chain, the quasi-one-dimensional cuprate compound Sr_2CuO_3. We find that intense mid-infrared excitation coherently dresses the many-body states underlying its large optical nonlinearity, resulting in a dramatic transient reshaping of the third emission spectrum. Combining exact numerical calculations with Floquet theory analysis, we attribute the dynamical modification of the harmonic emission to the interference of new light-induced quantum pathways reflecting the dynamical symmetry of the dressed many-body excitonic states. Our work marks the realization of a Floquet many-body phase in a condensed matter setting and provides a practical avenue towards the coherent manipulation of optical nonlinearities, as well as engineering macroscopically coherent electronic phases in complex materials.

SESSION QT05.07: Quantum Algorithms and Computing
Session Chairs: Daniel Jirovec, Yao Wang and Shuolong Yang
Wednesday Afternoon, December 4, 2024
Sheraton, Fifth Floor, Riverway

1:30 PM *QT05.07.01
2D Materials for Quantum Computing *James Hone; Columbia University, United States*

2D materials offer a unique opportunity to achieve new device functionality relevant to quantum computing. This talk will review our efforts in two areas: (1) Using layered heterostructures of ultra-pure 2D materials to create compact qubits; and (2) Measuring kinetic inductance in 2D superconductors and new device opportunities.

2:00 PM QT05.07.02
Characterization of Fabrication-Induced Noise Sources in Superconducting Niobium for Quantum

Information Science Applications *Dominic P. Goronzy[1], Carlos G. Torres-Castanedo[1], Thang Pham[1], Anthony McFadden[2], Nicholas Materise[3], David Garcia-Wetten[1], Nikolay Zhelev[4], James Sauls[5], Corey Rae H. McRae[2,6], Vinayak Dravid[1], Michael Bedzyk[1] and Mark C. Hersam[1]; [1]Northwestern University, United States; [2]National Institute of Standards and Technology, United States; [3]Colorado School of Mines, United States; [4]University of Oregon, United States; [5]Louisiana State University, United States; [6]University of Colorado Boulder, United States*

Superconducting niobium (Nb) has garnered significant attention for its application in quantum information technologies. In the production of two-dimensional superconducting qubits, current fabrication practices commonly employ fluoride-based chemical etchants, such as buffered oxide etch (BOE), to minimize surface contaminants and native oxides from Nb thin films, which can otherwise negatively impact quantum circuitry. However, these etchants also have the potential to introduce hydrogen into Nb thin films, leading to the formation of Nb hydrides, which may adversely affect microwave loss performance. In this study, we have conducted a comprehensive materials characterization of Nb hydrides formed in Nb thin films under various etchant treatments including hydrofluoric acid, BOE, and ammonium fluoride. Leveraging an array of techniques, including secondary-ion mass spectrometry, X-ray scattering, and transmission electron microscopy, we examined the spatial distribution and phase transformation of the resulting Nb hydrides. Our data reveal that the rate of hydride formation is dependent on both the hydrogen concentration in the solution and the etch rate of the native surface oxide, Nb_2O_5, which acts as a diffusion barrier for hydrogen incorporation into Nb. Through correlative device measurements, we demonstrate that Nb hydrides introduced by wet chemical etching are detrimental to the superconducting properties of Nb and result in increased power-independent microwave loss in coplanar waveguide resonators. In addition, our resonator results did not show a correlation between Nb hydrides and two-level system loss nor device aging mechanisms. Overall, this work provides valuable insights into the formation of Nb hydrides and their impact on microwave loss in superconducting quantum circuitry. It also suggests fabrication strategies to mitigate these effects, thus supporting ongoing efforts to enhance coherence time in superconducting quantum devices.

Superconducting Liquid Metals Interconnecting Quantum Computing Chips *Zhancheng Yao[1], Martin Sandberg[2], David W. Abraham[2] and David J. Bishop[1,1,1]; [1]Boston University, United States; [2]IBM T.J. Watson Research Center, United States*

Unlike reliable classical bits using transistors, superconducting qubits are vulnerable to fabrication defects and aging, necessitating their occasional replacement. A modular system allowing chip plug-and-play could tackle this challenge. Here, we propose liquid gallium alloys as interconnects between quantum computing chips, potentially enabling non-destructive replacement of these chips at room temperature after low-temperature benchmarking of the entire system. The comparable quality factors of conventional and liquid-metal-bridged coplanar waveguide resonators at millikelvin and single-photon regimes lay the foundation for leveraging such liquid metal interconnects in a modular quantum computer.

3:30 PM *QT05.07.04

Quantum Algorithms for Dynamics and Dynamical Observables *Alexander Kemper; North Carolina State University, United States*

Response functions are a fundamental aspect of physics; they represent the link between experimental observations and the underlying quantum many-body state. In particular, dynamicalresponse functions are part of *the toolbox that physicists use to unravel the nature of correlated matter. In this talk, I will discuss some aspects of obtaining response functions on quantum computers.*

First, I will introduce a new method for measuring response functions by using a linear response framework and making the experiment an inextricable part of the quantum simulation. This method can be frequency- and momentum-selective, avoids limitations on operators that can be directly measured, and is ancilla-free. As prototypical examples of response functions, we demonstrate that both bosonic and fermionic Green's functions can be obtained, and apply these ideas to the study of a charge- density-wave material. The linear response method provides a robust framework for using quantum computers to study systems in physics and chemistry. It also provides new paradigms for computing response functions on classical computers. I will illustrate the use of this idea for equilibrium and non-equilibrium Green's functions.

Second, I will discuss some of our recent work that uses a little-known property of Green's functions – and in particular Green's functions – to eliminate a large portion of the noise resulting from NISQ quantum computers. Green's functions are positive definite functions, a fact that high constrains the relationship between the values of the Green's function at each point in time. We make use of this by insisting that the measured (discretized) Green's function forms a positive semi-definite matrix, and project the noisy data onto the nearest positive function.

4:00 PM QT05.07.05

Magnon-Mediated Qubit Coupling Determined via Dissipation Measurements *Jonathan Marcks[1,2], Masaya Fukami[2], Denis R. Candido[3], Leah Weiss[2], Benjamin S. Soloway[2], Sean E. Sullivan[4], Nazar Delegan[1,2], F. J. Heremans[1,2], Michael E. Flatte[3] and David Awschalom[2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States; [3]The University of Iowa, United States; [4]memq, United States*

Optically addressable spin defects in solids such as nitrogen-vacancy (NV) centers in diamond are promising qubit platforms. A major obstacle to their integration in quantum technologies is the limited on-chip deterministic entanglement pathway. Magnon-mediated interaction mechanisms have attracted significant attention as a solution to this challenge, thanks to the intrinsic NV-magnon magnetic coupling. However, experimental demonstration of the signature of magnon-mediated NV–NV interaction is absent, urging a development of an experimental feedback mechanism to characterize the magnon-mediated coupling strength. Here, we quantify the magnon-mediated coupling of a prototypical weakly interacting system, the NV center with magnons in yttrium iron garnet, by combining qubit dissipation measurements and quantitative theoretical analysis. Our approach is applicable at room temperature, and our general treatment of interactions between two level systems and bosons can be generalized to other relevant quantum transduction platforms. Robustness of Optimization Methods in Hybrid Quantum Computing of the Electronic Structure of Diamond and Zincblende Crystals *Michal Duriska[1,2], Ivana Mihalikova[1,2] and Martin Friak[1]; [1]The Czech Academy of Sciences, Czechia; [2]Masaryk University, Faculty of Science, Czechia*

Variational Quantum Eigensolver (VQE) and its extension, Variational Quantum Deflation (VQD), have emerged as promising algorithms for computing ground and excited state energy eigenvalues of Hamiltonians, particularly in quantum physics, chemistry, and materials science. Despite their success, scalability remains a challenge due to limitations in classical optimization routines. In this study, we investigate the robustness of classical optimization methods, in particular, the Constrained Optimization BY Linear Approximation (COBYLA) and Differential Evolution

(DE), in optimizing the VQE and VQD algorithms for tight-binding models of diamond and zincblende crystal structures (Sn, C, Si, Ge, AlP, AlAs, AlSb, and GaP). We analyze the performance of these methods by comparing their results with classical solutions, assessing their convergence to the exact eigenvalues obtained through classical diagonalization method. Importantly, the DE optimization outperforms the COBYLA method by two orders of magnitude regarding the maximum number of function evaluations.

4:30 PM *QT05.07.07

A Topological Superconductor with Nearly Localized Electrons *Shuolong Yang; The University of Chicago, United States*

A topological superconductor, characterized by either a chiral order parameter or a chiral topological surface state in proximity to bulk superconductivity, is foundational to topological quantum computing. Similar to other topological phases of matter, it can be profoundly tuned by electronic correlations through the modification of low-energy Fermiology. Yet so far, correlation-driven tuning of topological superconductivity has not been realized. Here we uncover a unique topological superconducting phase in competition with electronic correlations in 10-unit-cell thick $FeTe_xSe_{1-x}$ grown on $SrTiO_3$ substrates. When the Te content x exceeds 0.7, we observe a rapid increase of the effective mass for the Fe d_{xy} band and the emergence of nontrivial topology using angle-resolved photoemission spectroscopy, while detecting the onset of superconductivity in electrical resistivity. Near the FeTe limit, the topological surface state appears unidentifiable, in concomitant with a suppressed superconducting transition. Theory suggests that the strongly correlated electronic structure is due to the rapid increase of electron-electron interactions in the odd-party xy^- band with a strong d_{xy} character, giving rise to an orbital selective correlated phase. Our work establishes $FeTe_xSe_{1-x}$ thin films as a unique material platform where topological superconductivity is bounded by a correlated electronic phase with localized electrons. It also highlights the exciting possibility to extend the phase boundary of topological superconductivity by engineering electron-electron interactions using a high-dielectric-constant environment or epitaxial strains.

Superconducting Properties and Electronic Structure of $CuAl_2$-Type Transition-Metal Zirconide $Fe_{1-x}Ni_xZr_2$

Ryunosuke Shimada[1,2], Yuto Watanabe[1], Lorenzo Tortora[2], Giovanni Tomassucci[2], Muammer Y. Hacisalihoglu[2,3], Hiroto Arima[1,4], Aichi Yamashita[1], Akira Miura[5], Chikako Moriyoshi[6], Naurang L. Saini[2] and Yoshikazu Mizuguchi[1]; [1]Tokyo Metropolitan University, Japan; [2]Sapienza Università di Roma, Italy; [3]Recep Tayyip Erdogan University, Turkey; [4]National Institute of Advanced Industrial Science and Technology, Japan; [5]Hokkaido University, Japan; [6]Hiroshima University, Japan

Transition-metal zirconides with a tetragonal $CuAl_2$-type crystal structure (I4/mcm, No. 140) are known as a superconductor family with a variable superconducting transition temperature (T_c) depending on the transition-metal (Tr) element. In this presentation, we report a new superconductor $Fe_{1-x}Ni_xZr_2$ exhibiting a T_c dome. Polycrystalline samples of $Fe_{1-x}Ni_xZr_2$ were synthesized by arc melting. From the synchrotron X-ray diffraction (SXRD), we confirmed that these compounds have a tetragonal $CuAl_2$-type crystal structure (I4/mcm, No. 140). Energy-dispersive X-ray spectrometry measurements confirmed that the actual Ni concentration was close to the nominal value, and X-ray photoelectron spectroscopy measurements showed that the trend of the estimated Ni concentration was also consistent with the nominal value. From magnetic susceptibility measurements, we observed bulk superconductivity for $0.4 \le x \le 0.8$, and the highest T_c of 2.8 K was observed for $x = 0.6$. In contrast, the diamagnetic signals for $x > 0.8$ are clearly small as a bulk superconductor, which indicates that the observed diamagnetic signals are caused by filamentary (trace) superconductivity states in those samples. No superconductivity was observed above 1.8 K for $0 \le x \le 0.3$. Therefore, the x dependence of T_c shows a dome-shaped trend, which is similar to the case of unconventional superconductors where magnetic fluctuations are essential for superconductivity pairing. For $x \le 0.3$ or $x \ge 0.9$, the bulk nature of superconductivity is suppressed. To explore a possible cause of the suppression of superconductivity, we estimated the c/a ratio of $Fe_{1-x}Ni_xZr_2$ using the SXRD data. In a sister compound $Co_{1-x}Ni_xZr_2$, a collapsed tetragonal transition was observed in a Ni-rich region, and the bulk nature of superconductivity is suppressed in the collapsed-tetragonal region. In the case of current system, although c/a linearly decreases with increasing x, the slope clearly changes at around $x = 0.1–0.3$ and $x = 0.7–0.9$. We consider that the change in the c/a ratio in the Ni-rich region is a kind of transition to collapsed tetragonal phases as revealed in $Co_{1-x}Ni_xZr_2$. On the absence of bulk superconductivity in the Fe-rich region, we have no explanation at present, but we assume that the disappearance of bulk superconductivity would be related to strong spin fluctuations and/or the transition to collapsed tetragonal phase. To clarify that, further investigation on the physical and structural properties is needed.

QT05.08.02

Revealing Hinge Modes in 2D Magnetic Topological Superconductor via Macroscopic Non-Local Transport

Wenyao Liu; Boston College, United States

A key signature of topological boundary modes, namely a non-local response [1,2], has remained elusive in topological superconductors(TSC). Here we focus on 1D higher-order TSC (HOTSC) chiral modes in $FeTe_{0.55}Se_{0.45}$, demonstrating they mediate non-local transport over macroscopic distances, owing to the topological-protection long-term coherence. We found the hinge-mediated transport in an anomalous large range, and produces a robust conductance plateau. Meanwhile, such plateau is robust against increasing temperature and magnetic field, and disappear without hinge contact or topological nontrivial phase of materials. Thus, our experiments reveal the first proof of robust, long-range, and non-local response from the 1D chiral hinge modes in $FeTe_{0.55}Se_{0.45}$, providing a new methodology to explore TSC [3,4].

Electrical Transport Measurements of Metallic $PdFe_xCo_{1–x}O_2$ and $PdCr_xCo1_{–x}O_2$ Delafossite Solid Solutions with Varying Concentration of Unpaired Spins

Yufan Feng[1,1], Qi Song[1], Ludi Miao[1], Xiaoxi Huang[1], Evan Krysko[1], Christopher T. Parzyck[1], Daniel C Ralph[1,2], Kyle Shen[1,2] and Darrell Schlom[1]; [1]Cornell University, United States; [2]Kavli Institute at Cornell for Nanoscale Science, United States

$PdCoO_2$ with a delafossite structure has emerged as a prominent material in condensed matter physics and

materials science, prized for its high conductivity. Another delafossite material, $PdCrO_2$, presents a metallic nature but shows antiferromagnetic (AFM) order at low temperature. Compared to $PdCoO_2$, $PdCrO_2$ has unpaired electrons in the CrO_2 layer. We are investigating the effect of unpaired electrons on the magnetic properties of these metallic delafossite materials by creating epitaxial films with solid solutions of a transition metal with no unpaired electrons (Co^{3+}) with transition metals with unpaired electrons (Fe^{3+} and Cr^{3+}), i.e., $PdFe_xCo_{1-x}O_2$, $PdCr_xCo_{1-x}O_2$, enabling the concentration of unpaired electrons to be continuously varied. Molecular beam epitaxy (MBE) is employed to precisely control the thin film growth of these solid solutions.
Our $PdCrO_2$ film shows an AFM peak in dρ/dT at low temperature, similar to that of $PdCrO_2$ single crystals. On the other hand, the $PdFe_xCo_{1-x}O_2$ films ($0 \le x \le 0.2$) present a dip at around 20 K. Moreover, our $PdCr_xCo_{1-x}O_2$ films show similar transport behaviors to the $PdFe_xCo_{1-x}O_2$ films, distinct from either pure $PdCrO_2$ or $PdCoO_2$ films. This raises questions about the disruption caused by the Cr-Co interaction to the AFM order in the pure CrO_2 layer. In this presentation, we present our quantitative analysis of the Cr-Co interaction in $PdCr_xCo_{1-x}O_2$ films with various chromium concentrations ($0 \le x \le 1$). Our findings provide new insights into tuning magnetic properties through targeted solid solutions that introduce unpaired electrons into delafossite materials.

QT05.08.04
Spectroscopic Analysis of Radical Molecules Using Charge Induced Spectroscopy *Tae-Ho Yang, Hye-Ri Joe, Jin-Sun Heo, Seongmin Kwon, Baeksang Sung, Jonghee Lee and Jae Hyun Lee; Hanbat National University, Korea (the Republic of)*

Enhancing the lifetime of organic devices is one of the essential considerations for achieving stable and high-performance devices. Small molecules in organic electronics are chemically or electrically stressed in the radical state, when they are oxidized or reduced for charge transfer through layers or for electrical doping to form charge transfer complexes. The lifetime research of organic light emitting diodes (OLEDs) primarily focuses on the understanding of the degradation characteristics that are prevalent in OLED devices during electrical operation. These characteristics; thermal or chemical instability of small molecules in OLEDs have been pointed out to be the reason behind the degradation of OLEDs which causes their short operational lifetime. Analyzing these degradation characteristics in organic materials prior to the fabrication of OLED devices is an unsophisticated method to achieve a better understanding of the stability of OLEDs.
In this research, we investigated the stability of various emitting molecules includeing bis(2-phenylpyridine)(acetylacetonate)iridium(III) ($Ir(ppy)_2(acac)$), which is widely used as a green phosphorescent dopant in OLED devices, through matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) and charge-induced spectroscopy (CIS). In the MALDI-TOF investigation, the thermally degraded (aged) $Ir(ppy)_2(acac)$ in a vacuum chamber was analyzed to have an m/z peak of 622.9 compared to its intrinsic m/z peak of 599.8. In the case of the CIS investigation, different absorption spectra were observed between the radical states of intrinsic and the degraded $Ir(ppy)_2(acac)$. The Gaussian fitting technique was subsequently employed to fit the absorbance spectra which distinguished the additional radical absorption peaks after degradation and elucidated the thermal degradation mechanism. We therefore propose that the solution state analysis of thermal or electrical stability of organic materials using CIS can be a considerable approach to investigate degradation mechanism of OLEDs.

QT05.08.05
Synthesis of $BaTiO_3$ Thin Films for Electro-Optic Applications *Anne Ruperto, Lucy Nathwani, Larissa Little, Temazulu S. Zulu, Benazir Fazlioglu Yalcin, Charles Brooks and Julia Mundy; Harvard University, United States*

Electro-optic modulators form the backbone of efficient data transfer necessary for modern optical communications. These modulators directly connect a driving electric field with optical properties of a material, efficiently converting an electrical signal to an optical signal. Modern data centers and high speed internet, as well *as sensing systems, heavily rely on these devices. The electro-optic modulators are often bulk crystals of lithium niobate with indiffused waveguides, limiting their size, speed, and efficiency. Although thin film lithium niobate offers improved scalability and higher bandwidth over its bulk counterpart, lithium oxides are not CMOS compatible and there is a growing need for higher bandwidth modulators with lower voltage requirements. Barium titanate ($BaTiO_3$) is an alternative material platform which exhibits an extremely high electro-optic coefficient (r_{42} ~ 900 pm/V), a reasonably high band gap (> 3eV), a relatively high refractive index (n = 2.4), and is compatible with traditional CMOS processing. Scalable methods for creating high quality, single ferroelectric domain films of barium titanate are therefore extremely attractive for highly efficient modulators and integrated optical devices. Here we present our work using reactive sputtering to make thin films of $BaTiO_3$ and characterize this materials for electro-optic applications.*

QT05.08.06

Exploring the Mechanisms of Transverse Relaxation of Copper-Phthalocyanine Spin Qubits *Boning Li[1], Yifan Quan[1], Xufan Li[2], Guoqing Wang[1], Changhao Li[1], Shuang Wu[2], Avetik Harutyunyan[2], Robert G. Griffin[1], Ju Li[1] and Paola Cappellaro[1]; [1]Massachusetts Institute of Technology, United States; [2]Honda Research Institute USA, United States*

Quantum information science has catalyzed a search for suitable qubit platforms that would enable powerful, at-scale quantum devices. Paramagnetic spins in molecular crystals have emerged as promising spin-qubits, owing to their coherence time and potential scalability via synthetic chemistry. A key factor governing qubit performance is the phase relaxation time, which limits the number of quantum operations. Here, we combined numerical methods and dynamical decoupling experiments to investigate dephasing of electron spins in copper-phthalocyanine (CuPc) embedded in a eta-XPc matrix, where X represents an non-paramagnetic atom. We find that at cryogenic temperatures the CuPc electron dephasing is dominated by interactions with off-resonance electrons in the material — a factor overwhelmingly dominant over interactions with nuclear spin species. We confirm this insight by comparing experimental results (including echoes and spin-locking experiments) with simulations. Our research further unveils that the XPc matrix has a marginal impact, even when X contains hydrogen nuclear spins, in principle enhancing the nuclear spin bath. Other effects, such as the stability of the molecular crystal as a function of X, influencing the T1 longitudinal relaxation times, might be more pronounced.

These insights are crucial for tailoring the molecular matrix to achieve specific thermal or optoelectronic properties, hinging significantly on the choice of the X atom, with potential impacts on advancing molecular spin qubit research.

QT05.08.07

Deep Level Transient Spectroscopy Investigation of Transition Metal Related Defects in Silicon for Viable Semiconductor Qubits *Shruti De; University at Albany, State University of New York, United States*

Quantum defects in semiconductor lattices are essential for advancements in quantum sensing, computing, and communication. In contrast to a few well-studied systems like diamond and SiC, quantum defects have not been extensively studied for silicon, a dominant semiconductor material in the current microelectronics industry demonstrating the ability for manufacturing a tremendous number of device components in a small footprint, which is indispensable for achieving scalable quantum computing in practice. Historically, a variety of structural defects and their electronic properties have been studied for electronics and optoelectronics purposes. However, their usefulness in quantum computing is elusive. A desired quantum defect in quantum computing should have electronic levels deep within the band gap and far from the band edges to resemble an isolated atom within the host, and in the meantime, it should be addressable with near-infrared light to change its spin state for initialization *and readout. Very recently there have been a few theoretical studies based on first-principles calculations to search for quantum defects as possible qubits in silicon (see Xiong et al., Sci. Adv. 9, eadh8617 (2023); Lee et al., npj Computational Materials 8, 172 (2022)).*

Here in our work, we conducted experiments to evaluate the electronic properties of various transition metal associate defects and their relevance to quantum information processing in silicon. Metal-oxide-semiconductor (MOS) and Schottky diode devices were fabricated using standard Si microelectronics technology, with multiple steps including oxidation of Si wafer, intentional doping of transition metals like Ag, Fe, Ti, etc. in Si via thermal diffusion process, Schottky and ohmic contact formation via metal thin film deposition and thermal annealing. Deep level transient spectroscopy (DLTS) was performed to study the properties of these transition metal related deep levels, such as their energy positions within the bandgap, level trapping and emission characteristics, as well as their spin-related and optical modulation through DLTS response in the presence of magnetic fields and optical excitations. This information will be important to identify and engineer viable quantum defects in Si for the creation of scalable quantum devices using the developed powerful microelectronics manufacturing technologies.

Alloying Effect of Rare-Earth Tritellurides on the Charge Density Wave and Magnetic Properties

Kentaro Yumigeta; The University of Arizona, United States

Among many van der Waals materials rare-earth tritellurides (RTe_3) allow studying several phenomena like magnetic, superconducting, and charge density wave (CDW). These studies show the effect of cationic alloying of antiferromagnetic RTe_3 for fully tunable near room-temperature CDW properties. $Dy_xGd_{1-x}Te_3$ and $Dy_xTb_{1-x}Te_3$ alloys were synthesized through a chemical vapor transport technique, and the rare-earth element composition was controlled by changing the ratio of rare-earth metal reagents. The results show that the lattice parameters can be continuously tuned with the composition of the rare-earth cations leading to the variation of the internal chemical pressure. Temperature-dependent Raman spectroscopy and electric transport measurement show that the CDW transition temperature (T_{CDW}) of RTe_3 alloys varies with lattice parameters/chemical pressure spannning across 300 - 380 K. Additional magnetism studies offer the first insights into the magnetic ordering in RTe_3 alloys. The emergence of multiple magnetic transitions implies complex magnetic interactions that arise from interactions between different rare-earth elements. Overall findings introduce ways to control the CDW behavior and provide valuable insights into the magnetic ordering in RTe_3 alloys, contributing to further investigation and a better understanding of their properties.

Fabrication and Microwave Characterization of Epitaxial Vanadium-Based Superconducting Resonators on Silicon Wafers

Yuichi Fujita, Yoshiro Urade, Yuki Hibino, Manabu Tsujimoto, Kunihiro Inomata and Wataru Mizubayashi; National Institute of Advanced Industrial Science and Technology, Japan

With the aim of realizing large-scale quantum processors, the coherence of superconducting qubits has been improved by developing low-loss material systems [1]. Loss mitigation has been demonstrated by tailoring the high-quality surfaces of superconducting metals and interfaces between substrate and superconducting metal interfaces [1]. To further mitigate these losses, it is imperative to focus on the crystallinity of the superconducting films. Although the effect of the structural ordering of superconducting films on losses has not yet been fully elucidated, epitaxial films can offer lower losses compared to disordered ones [1,2]. Here, we focus on vanadium (V) for use as highly ordered superconducting films. We fabricate and measure the epitaxial V-based superconducting resonators on Si wafers. We find that the loss factors other than two-level systems (TLSs) are dominant not only on the V surface but also in other parts of the V-based resonators.

A Nb buffer (5 nm)/V (200 nm)/Ta cap (5 nm) structure was sputtered on a buffered HF (BHF)-treated 4-inch Si(100) wafer (approximately 15 kΩcm). The sputtering pressure was less than 0.05 Pa. Using X-ray diffraction, we confirmed the epitaxial growth of the multilayer with an orientation relationship of (110)V || (110)Nb || (001)Si. We also prepared a sample without a Ta capping layer to examine the loss of the V surface. V-based coplanar waveguide λ/4 resonators were fabricated through microfabrication processes. They were designed to possess a resonant frequency of 10–11 GHz [3]. The resonators were immersed in a BHF solution to remove the oxidation layer on the exposed Si surface and then mounted in a dilution refrigerator within several hours. The complex transmission coefficient (S_{21}) spectra of the resonators were measured at 10 mK using a vector network analyzer at various averaged photon numbers ($\langle n_{ph} \rangle$) ranging from 10^{-1} to 10^{6}. By analyzing the observed S_{21} spectra, we derived the internal quality factor (Q_{int}) of the resonators [1,4]. From the Q_{int} as a function of $\langle n_{ph} \rangle$, we extracted the intrinsic TLS quality factor ($Q_{TLS,0}$) and derived the constant loss originating from residual resistance, radiation, and other sources (δ_{other}) [1,3].

We successfully observed S_{21} spectra and obtained Q_{int} values for the resonators with and without the Ta capping layer. Q_{int} at a single photon level ($\langle n_{ph} \rangle = 1$), $Q_{TLS,0}$, and δ_{other} for the resonator with (without) the Ta capping layer were derived to be 4.8×10^5 (3.6×10^5), 3.9×10^6 (4.6×10^6), and 1.8×10^{-6} (2.7×10^{-6}), respectively. The resonator with the Ta capping layer exhibits a larger Q_{int} at $\langle n_{ph} \rangle = 1$ and a smaller $Q_{TLS,0}$ and δ_{other} compared to the resonator without Ta capping. This suggests that the presence of the Ta capping layer enhances Q_{int} by mitigating losses from the V surface that originate from non-TLS sources, whereas surface oxidation of the Ta capping layer increases TLS loss. Furthermore, even for the resonator with the Ta capping layer, $Q_{TLS,0}$ and δ_{other} were considerably larger than those of the α-Ta resonators with the same circuit design [3]. Thus, it was concluded that TLSs were not the dominant loss factors, not only on the V surface but also in other parts of the V-based resonators. Further research on the chemical and electrical properties is required to fully understand the loss mechanism of V-based resonators.

This paper was based on results obtained from a project, JPNP16007, commissioned by the New Energy and Industrial Technology Development Organization (NEDO), Japan.

Ultralow Energy Measurement of Surface Phonons in MoS2

Aleksandar Radic, Boyao Liu, Andrew Jardine and Sam Lambrick; University of Cambridge, United Kingdom

We present sub-10 meV measurements of surface phonons in MoS2 with μeV resolution. Dispersion curves near the centre of the Brillouin zone were measured using the HeSE (Helium-3 Spin-Echo) technique and reveal the presence of vibrational modes previously thought to be limited to monolayer MoS2 on the surface of the bulk. The low beam energy (~8 meV) of the HeSE provides ultimate surface sensitivity, only allowing the probe particles to interact directly with the valence electron density of a sample.

Additionally, we present the current lowest energy measurements of surface phonons in MoS2 as a benchmark for theoretical calculations of its electronic and vibronic properties.

Ab Initio Calculation of Matter Wave Interactions with Strained Surfaces *Rafee Abedin[1,2], Aleksandar Radic[1], Sam Lambrick[1], Min Lin[1] and Andrew Jardine[1]; [1]University of Cambridge, United Kingdom; [2]University of Oxford, United Kingdom*

Helium atom scattering (HAS) is a powerful tool for investigating a wide range of systems with a previously inaccessible surface sensitivity. In the context of scanning helium microscopy (SHeM), the use of a low energy, neutral probe particle results in a variety of new image contrasts like chemical or Debye-Waller contrast. The work presented explores the possibility of using contrast imaging to study mechanical properties like strain. In particular, a first-principles calculation of
scattering from the (001) α quartz surface is done using a combination of density functional theory (DFT) and close-coupled scattering simulations. The approach outlined utilises the structure and potential determined using DFT to simulate the final diffraction pattern. The induced strain in α quartz due to an external electric field is then studied in the framework of perturbative DFT.
The resultant estimates of the lattice and response parameters were found to be in good agreement with experimentally measured values. In a static electric field of 1.1 kV mm^{-1}, the surface lattice parameter varied by about 0.004 Å. The consequent changes in diffraction peak positions and intensities indicate the feasibility of such a contrast mechanism.

QT05.08.12

Ab Initio Surface Electron-Phonon Coupling Theory of Elastic Helium Atom Scattering *Cristobal A. Mendez[1], Caleb Thompson[2], Michael Van Duinen[2] and Tomás Arias[1]; [1]Cornell University, United States; [2]The University of Chicago, United States*

Helium Atom Scattering (HAS) has emerged as a powerful and versatile technique used to investigate the structural and dynamical characteristics of material surfaces. Utilizing the interaction between low-energy helium atoms and surfaces, it offers non-destructive, atomic-scale resolution measurements of surface properties. In HAS, the incoming helium atoms primarily interact with the surface through the electron density, thereby revealing essential details about electron-phonon coupling and thus superconductivity at material surfaces.
This presentation will describe a novel ab initio approach which can help extract electron-phonon coupling information directly from HAS data. Specifically, recent studies have suggested using elastic HAS to study surface electron-phonon coupling through a Debye-Waller type effect. Current theories of this process, however, only consider fluctuations in the atomic positions and do not explicitly include the electrons, thereby radically limiting the information that can be extracted regarding the electron-phonon coupling. These models also require ad hoc assumptions regarding the range of interaction of the incoming helium atoms.
To address these defects, our approach employs the hard corrugated surface model (HCS) [1,2], in which helium atoms scatter at a specific surface electron-density contour, in an entirely new, ab initio context. After explicitly confirming the accuracy of this approach through ab initio calculations, we demonstrate how the resulting theory probes the electron-phonon coupling directly. We then apply the new approach to the metallic Nb(100) surface and the oxidized (3x1)-O/Nb(100) surface, finding excellent agreement with our experimental results and confirming recent conjectures regarding observed non-linear effects in the associated Debye-Waller exponents.
The ability to accurately model elastic HAS directly from first principles opens new possibilities for studying a wide range of surface phenomena, potentially leading to novel insights into surface dynamics and interactions.

Magnetic-Flux Trapping and Related Phenomena in Sn-Pb Solders *Takumi Murakami[1], Poonam Rani[1], Hiroto Arima[1,2] and Yoshikazu Mizuguchi[1]; [1]Tokyo Metropolitan University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan*

Superconductors have the properties of zero electrical resistance and exclusion of magnetic fields below superconducting transition temperature(T_c). In addition, the suppression of thermal conductivity (k)is seen below T_c, which is cause by the fact that the Cooper pairs do not transport heat, and the electrons conduct heat in the normal-conducting state. Recently, our group reported that a Sn45-Pb55 solder, a phase-separated superconducting composite composed of Sn and Pb, exhibits nonvolatile magneto-thermal switching. This is caused by the nonvolatility of magnetic flux trapping induced by the experience of magnetic field greater than critical field (H_c) of the solder[1]. Furthermore, the magneto-thermal switching properties strongly depend on the Sn/Pb concentration. Therefore, this study aims to elucidate the Sn-amount dependence of flux trapping states, magneto-thermal switching properties, and related physical properties.
We measured the magnetization of SnxPb100-x solders with various Sn ratios (x = 10-90). We investigated the dependence of the flux trapping on x. In Sn10-Pb90, we found that the magnetic flux trapping is 600 G, when measured at zero field after experiencing H = 1500 Oe at 1.8 K. Furthermore, the magnetization decreases when a positive field is applied after experiencing H = 1500 Oe. For negative-field data, data measured under opposite fields against the initial H = 1500 Oe, we observed flux jumps[2]. With increasing x, the amount of trapped magnetic flux is reduced, which means that the concentration and the size of Sn regions are correlating with trapped field. In the presentation ,we will show the correlation between x, trapped field, and magneto-thermal switching properties for various x.

Symmetry, Orbital Order and Long Range Order in Quantum Materials from Their Crystal Structure Building Blocks *Alexandru Georgescu, Emily Ward and Varsha Kumari; Indiana University, United States*

Correlated electron quantum materials' wide array of controllable properties (magnetism, superconductivity, metal-insulator transitions), arise from an interplay of local degrees of freedom (charge, orbital and spin) and emerging long-range order. In materials where the open d-shell of transition metal ions forms the building blocks of the emergent states, the local ionic environment of the transition metal site plays a key role in determining the local orbital states, possible exchange interactions and resulting quantum states. In this work, I will focus on symmetry-informed computational tools and the insights they provide to understand magnetic and multiferroic quantum materials, including the role of trigonal symmetry breaking in van der Waals 2D magnets with composition MX_2 and MX_3 (M a transition metal, X={Cl,Br,I}) halides, the role of trimer orbitals and correlations in ferroelectric and spin-liquid candidates Kagome Halides (M_3X_8) - which were recently used in field-free Josephson diodes [2] - , and in multiferroic materials containing stereochemically active lone pairs on Bi^{2+} and Pb^{3+} ions used to break inversion symmetry. We find that this interplay is key to understanding the materials' magnetic properties, metallic or insulating behavior, and even to the materials' stability.

The Effect of Pressure on the Electronic and Crystal Structure in the $La_{n+1}Ni_nO_{3n+1}$ Family and Superconductivity in $La_3Ni_2O_7$

Bipasa Samanta and Alexandru B. Georgescu; Indiana University Bloomington, United States

The recent discovery of superconductivity in the infinite layer nickelates (1) has reanimated the search for superconductivity in nickelates, with a new upsurge after the discovery of superconductivity in $La_3Ni_2O_7$ at relatively high temperature at applied pressure(2-3). Motivated by this, we study multiple related Ruddlesden–Popper (RP) oxide phases to understand the coupled electronic and crystal structure transition leading to superconductivity in multiple layered materials. We will present a detailed study on the effect of pressure on the structural, electronic, and magnetic properties of this materials class. We focus here on two key members of the $La_{n+1}Ni_nO_{3n+1}$ series namely $La_3Ni_2O_7$ (both the bilayer and monolayer-trilayer polymorphs) and $La_4Ni_3O_{10}$ (a trilayer system, for which we analyse multiple polymorphs). In agreement with the experiment, our first principles calculation showed that around ~15 GPa pressure the orthorhombic (monoclinic)-to-tetragonal transition takes place for most of these polymorphs, coupled to an electronic transition.

In addition to the electronic structure, we explore the effect of electronic correlations Hubbard parameter (U_{eff}) and pressure on this materials family. We observe a competition between the U_{eff} and the pressure on the magnetic moment, finding that a low U is key to allowing for the dimerization and structural transition allowing for superconductivity. Thus, in this work, we will provide further insight into the coupled electronic and crystal structure coupling relating these materials under pressure, which may underlie the already observed superconducting transition in $La_3Ni_2O_7$.

Strain-Induced Single Photon Emitters in Transition-Metal Dichalcogenide Nanoribbons

Samuel G. Wyss[1], Xufan Li[2], Joseph Stage[1], Matthew C. Strasbourg[3,1], Emanuil Yanev[3], Shuang Wu[2], Avetik Harutyunyan[2], Nicholas J. Borys[1] and P. J. Schuck[3]; [1]Montana State University, United States; [2]Honda Research Institute USA, United States; [3]Columbia University, United States

Semiconducting transition metal dichalcogenide (TMD) nanoribbons grown via chemical vapor deposition are a novel platform for investigating the effects of microscopic strain on single photon emitters (SPEs) in TMDs. Here, the effects of local strain and the emergence of single photon emitters in single-layer (1L) WSe2 and 1L-MoS2 nanoribbons are studied. The nanoribbons are transferred onto arrays of gold nanocones that impose localized strain on sub-100 nm length scales. Due to the nanoribbon geometry, which is more constrained than 2D crystallites, the nanocones generate a more systematically strained system that is more reproducible and void of complex arrays of wrinkles and folds. Correlated AFM topography and cryogenic photoluminescence confirm that SPEs emerge in these systems and are localized to regions where the ribbon is draped over a cone. The strained regions of the nanoribbons host several SPE states that are spectrally isolated from each other by several

nanometers and spatially isolated from other SPEs by the distance between adjacent nanocones. The nanoribbon-based SPEs in WSe_2 have linewidths as small as 10 µeV and photon purities of up to 90%, and their excited state lifetimes are longer than similar emitters from nanobubbles. The longer lifetimes signify that the nonradiative decay rates may be smaller in the nanoribbon materials. In contrast, the localized emitters in MoS_2 nanoribbons are considerably dimmer and have linewidths 100 times larger than emitters in WSe_2, more closely resembling states observed in prior studies generated by focused-ion-beam irradiation. These studies reveal how nanoribbons could serve as high-quality nanoscale quantum light sources that benefit from the reduced dimensionality of the quasi-1D structure.

QT05.08.17

Exciting Chiral Phonons to Induce Magnetism in Non-Magnetic Materials *Sin Hang Ho, Megan Biggs, Aldair Alejendro, Matthew Lutz, Clayton Moss and Jeremy A. Johnson; Brigham Young University, United States*

Materials that display magnetic properties are crucial to many electronic devices, with old and new applications in data storage. To increase the operating speed in new data storage paradigms, it is of great interest to study ways to control magnetic properties in ultrafast scales. Most current ultrafast studies of magnetic order reply on destroying the magnetic order with a visible or infrared (IR) laser pulse. On the other hand, to induce magnetic ordering, it has recently been proposed that exciting circular motion of ions using terahertz (THz) light can induce magnetic moment in materials. Light with resonant frequency can excite the IR-active phonon modes in materials; when pairs of perpendicular modes are excited, ions moving in circular ("chiral") loops can be induced.

One way to create ion loops is to use a pair of perpendicularly polarized THz pump pulses with relative phase delay. The pair of perpendicular THz pulses can excite pairs of perpendicular modes; mean while the relative phase delay serves as the means to control the path of the ionic motions (being linear, elliptical or circular). We will present our work on how we induced ion loops in two non-magnetic crystals – $LiNbO_3$ and beta $Ba(BO_2)_2$ (BBO) and measured the induced magnetic moment with the ultrafast Faraday effect.

We pick $LiNbO_3$ and BBO as the samples because they both have doubly-degenerate perpendicularly E modes that are excited with our chiral THz pulses. The lowest frequency modes in $LiNbO_3$ form phonon-polaritons, whereas BBO has three sets of E modes that can contribute to a magnetic signal.

With a 2D THz spectroscopy set up, we generate circularly polarized THz pulses by directing two perpendicular THz pulses to the same spot on the sample with adjustable relative delay. When combining the two THz pulses with different delay, different polarization states of combined THz pulses are achieved (linear when the phase delay is zero or 90 degree, circular when the phase delay is 45 degree or elliptical for other delays).

To detect the magnetic moment induced by the combined THz pulses, we use an ultrafast Faraday effect detection scheme – we direct an 800-nm probe to the sample and detect the polarization change of the probe. Based on the strength of the induced magnetic field, the polarization of the probe is rotated. To ensure our detected signal is from polarization change due to the chiral motions, we use a differential chopping scheme to measure the sample response in consecutive four laser shots – a single vertical THz pulse, a horizontal THz pulse, the combined (circular) THz pulse and no THz pulse. This allows us to isolate the signal arised only from the combined THz pulse, and not from the linear components of that circular THz pulse.

We also consider rather the induced magnetic field is induced from the chiral phonon motions or the inverse Faraday effect from electronic motions. Typically, the non-resonant electronic response decays very fast and only last within the duration of the driven force. Phonon-magnetism, on the other hand, has a longer lifetime because *atoms or molecules take longer time than electrons to lose energy. By modeling the electronic and ionic responses, we can account for our observed magnetic signal*

In conclusion, we induce an apparent magnetic moment in $LiNbO_3$ and BBO with intense circularly polarized THz pulses. The ability to manipulate chiral phonon motion using circularly polarized light open the door to potentially control materials in ways that could not been achieved before.

Rattling Chains Lead to a Charge Density Wave in Kagome Metal ScV_6Sn_6 *William R. Meier[1], Richa P. Madhogaria[1], Shirin Mozaffari[1], Madalynn Marshall[2], David E. Graf[3], Michael A. McGuire[2], Hasitha W. Arachchige[1], Takahiro Matsuoka[1], Raphael P. Hermann[2], Caleb L. Allen[1], Jeremy Driver[1], Huibo Cao[2] and David Mandrus[1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]National High Magnetic Field Laboratory, United States*

The connectivity of atoms on a kagome lattice can produce exciting electronic and magnetic behavior. Metallic kagome compounds show intricate magnetism, unusual superconductivity, and structural orders called charge density waves (CDWs). We discovered that the intermetallic compound ScV_6Sn_6 develops a CDW below 92 K [1]. Curiously, none of the other RV_6Sn_6 variants (R = rare earth) develop this phase transition despite their electronic and structural similarities.

We undertook a doping and crystallographic study to examine how substituting Y and Lu for Sc suppresses the CDW in ScV_6Sn_6 [2]. The structural details and doping trends we observed revealed that the small Sc atom in ScV_6Sn_6 leaves extra space needed for the modulated Sn-Sn bonding critical to the CDW. Replacing Sc with larger rare earths removes the extra space for these displacements, stifling CDW formation. Our model addresses why ScV_6Sn_6 is the only member of its family to form a structural modulation.

Synthesis of Long Scale Coherence Time Vacancy Defects in Silicon Carbide via Pulsed UV Laser and Photonic Curing for Industrial Scale Qubit Manufacturing *Douglas B. Chrisey, Sepideh Khalili and Najma Khatoon; Tulane University, United States*

Qubits have unique capability to exhibit superposition and entanglement which makes them stand out to exist in multiples states simultaneously with ability to perform parallel computations. Serving as a fundamental building block of Quantum computers (QC) which leverages the superposition and entanglement of Qubits to perform quantum parallel operations at exponential speed. The applications of QC include cryptography, solving optimization problems, materials science, drug discovery and materials science. IBM Quantum System One is the first QC powered by 127-Qubits reported by RPI of Troy, NY. The unmatching wonders of Qubits comes with certain challenges to make and build QC such as their susceptibility to environmental noise and decohering, and difficulty in their fabrication and scalability. In this work we utilized pulsed UV laser and a broad spectrum (220-1500 nm) intense and short (0.03–100 ms) pulsed light (called photonic curing) to create and anneal the vacancy defects in silicon carbide (SiC) respectively. The study of vacancy formation will help to explore the mechanism of defect formation after laser irradiation as well as the mechanism of the subsequent photonic annealing of residual damage. The combination of these processes will give us an extensive combinatorial library of data to be used to train a deep learning neural network algorithm to predict the best possible Qubit defect architectures, processing conditions, and their expected performance. Excimer lasers like ArF (10 nsec, 193 nm) are efficient in creating *color centers with 6.42 eV photons and can even etch SiC at a high enough laser fluence, < 2 J/cm^2. We propose to use an ArF excimer laser or a quintupled YAG (266 nm) and to optimize the conditions for different defect constructs and test their efficacy as defect-based Qubits.The as created defects will then be selectively annealed using photonic curing, which initiates rapid transformations, and reactions due to non-equilibrium processes. The acquired dataset will serve as the foundation for crafting a machine learning algorithm. This algorithm will be trained using innovative open-ended material selections to ensure statistically reliable predictions for future Qubit outcomes, with accuracy that can be empirically verified. Combination of Pulsed UV laser and photonic curing offers an instantaneous and roll-to-roll compatible approach for large-scale synthesis of Qubits.*

QT05.08.22

Observation of Rydberg Excitons in Epitaxially Grown Cu_2O Film on MgO Substrates *Sumit Goswami[1], Kinjal Barua[2], Arya D. Keni[2], Pralay Paul[1], Sreehari Puthan Purayil[1], Dhiman Biswas[1], Casey P. Kerr[1], Benjamin Summers[1], Horst Hahn[1,3], Hanjong Paik[1], Alisa Javadi[1], Hadiseh Alaeian[2,2] and T. Venky Venkatesan[1,4]; [1]The University of Oklahoma, United States; [2]Purdue University, United States; [3]Karlsruhe Institute of Technology, Germany; [4]National Institute of Standards and Technology, United States*

Recently, there has been a massive surge in interest amongst the scientific community regarding Cu_2O as a solid-state host for Rydberg excitons after it was observed that a naturally grown Cu_2O single crystal can host Rydberg excitons up to quantum numbers as high as n=25 [1]. Though the existence of Rydberg states in Cu_2O has been long known [2], it is this discovery of higher-level Rydberg excitons that made the field of solid-state Rydberg physics increasingly more interesting with the prospect of realizing similar kind of exciting quantum phenomenon as observed in their atomic counterparts [3], but now in a more technologically accessible solid-state environment. However, most of the available reports on Rydberg excitons of Cu_2O have focused on single crystals, either grown naturally or synthetically [1,4]. But for device fabrication, thin films and possible heterostructures are needed. Thin-film Cu_2O samples with thicknesses less than the blockade radius are especially appealing because they make the Rydberg blockade utilizable for nonlinear behavior in semiconductors [5].

In this work, we have grown epitaxial Cu_2O films on MgO (110) and (100) substrates using metallic copper (purity: 99.99%) as a target using a pulsed laser deposition (PLD) technique and observed full width half maxima (FWHM) of the XRD rocking curve as low as 0.3° for the films. Here we will present the low temperature (4 K) high-resolution absorption spectroscopy data for Cu_2O films elucidating the nature of higher Rydberg excitons. We will also demonstrate the effect of thickness, the degree of crystallinity (ranging from single crystalline to polycrystalline) of Cu_2O on the optical properties of the Rydberg excitons. In this manner, we demonstrate an oxide semiconductor as a CMOS-compatible and integrable platform, which can lead to quantum optical computing in the Rydberg regime [6].

QT05.08.23

Spectroscopic Signatures of Strong Electron-Phonon Coupling in Superconducting $LiTi_2O_4$ Thin Films *Zubia Hasan[1], Grace A. Pan[1], Suk Hyun Sung[1], Harrison LaBollita[2], Shekhar Sharma[2], Edward Mercer[3], Ismail El Baggari[1], Matthew Barone[4], Antia S. Botana[2], Brendan Faeth[4], Alberto Duran[3] and Julia Mundy[1]; [1]Harvard University, United States; [2]Arizona State University, United States; [3]Northeastern University, United States; [4]Cornell University, United States*

The mechanisms behind unconventional superconductivity have been intensely studied over the past few decades. Leading this thrust has been the high T_c cuprates, whose pairing 'glue' has been widely debated. $LiTi_2O_4$, a spinel oxide material, is an unconventional superconductor that preceded the cuprates [1]. However, despite having one of the highest T_c (~13.7 K) for a non-cuprate oxide, little is known about its' superconducting mechanism, with reports of both unconventional pairing [2] and traditional phonon-mediated BCS-like behavior [3]. There have also been signs of orbital and spin fluctuations persisting up to ~100 K, based on angle-dependent transport data [4]. Nevertheless, despite speculation about the nature of the superconducting mechanism in $LiTi_2O_4$, it remains clear that there is a strong presence of electron – phonon coupling in this material with phonon modes reported via different spectroscopic and scattering techniques [5,6]. Therefore, it becomes essential to investigate the nature and strength of these phonon modes and their relation to superconductivity. Our work combines the first ever MBE grown thin films of superconducting $LiTi_2O_4$ with spectroscopy to reveal the presence of strong phonon modes in $LiTi_2O_4$. Here, we present a comprehensive investigation of the strength and nature of electron – phonon coupling, visualized directly via Angle Resolved Photoemission spectroscopy (ARPES) experiments. We see clear spectroscopic signatures of coherent phonon oscillations for the first time in $LiTi_2O_4$ revealing the strength of electron – phonon coupling in this material. Finally, we discuss how the strength of the electron – phonon coupling in $LiTi_2O_4$ could potentially give rise to non- BCS behavior placing $LiTi_2O_4$ in an unconventional regime of superconductivity.

Electronically Driven Insulating to Conductive State in Correlated Oxides *Vivek Bhartiya[1], Roman Hartmann[2], Filomena Forte[3], Taehun Kim[1], Shiyu Fan[1], Jonathan Pelliciari[1], Angelo D. Bernanrdo[2,4], Antonio Vecchione[4], Mario Cuoco[3] and Valentina Bisogni[1]; [1]Brookhaven National Laboratory, United States; [2]Universität Konstanz, Germany; [3]CNR-SPIN, Italy; [4]Università degli Studi di Salerno, Italy*

On demand insulator-to-metal transition (IMT) offers a transformative pathway for next-generation brain-inspired computing [1,2]. Several correlated oxides exhibit electrically controlled IMT at remarkably low voltages [2]. Recent investigations suggest that electronic correlations, spin-orbit coupling, and structural distortions concurrently contribute to this electrically controlled non-standard Mott physics [3,4,5]. To decipher the leading mechanisms, it *is essential to probe these degrees of freedom simultaneously. However, a suitable in situ bulk-sensitive probe with access to these degrees of freedom has been missing so far. Here, we developed a novel transport-RIXS setup and employed it to investigate the electrically controlled IMT in a prototypical correlated oxide candidate:* Ca_2RuO_4 *(CRO) [6]. Our findings reveal an energy-selective suppression of RIXS spectral weight across the electrically driven IMT, distinct from the trend observed for the thermally driven case, thus supporting the involvement of a new mechanism. Through dedicated RIXS cross-section calculations, we propose that electronic correlations are the leading players behind the electrically driven IMT, creating new states - charge defects - at the Fermi level. These newly created states enable the flow of current, leading to conduction without melting the underlying Mott insulating state. This work sheds light on the fundamental mechanism of current-driven IMT endemic to correlated oxides. The newly developed transport-RIXS setup opens the way to electrically driven quantum materials and artificial structures, promising advancements in microelectronics and quantum technology.*

Novel Multi-Frequency Scanning Probe Microscopy Technique for Quantum Metrology *Cristian Staii; Tufts University, United States*

Quantum sensing technologies are at the forefront of achieving unparalleled sensitivities in measuring various physical quantities, which are crucial for advancements in various scientific fields, ranging from fundamental physics to biomedical research. In particular, new scanning probe modalities based on the Atomic Force Microscope (AFM) continue to emerge, allowing for highly controlled and precise operation, excitation, and manipulation of both the microcantilever probe and a specific sample region. Here, we present a novel multi-frequency AFM technique that leverages the nanomechanical interaction between the AFM tip and the sample surface in the quantum regime of the sample deformation states. We use this technique to image the vibrational modes of suspended carbon nanotube resonators. Specifically, we realize nanomechanical resonators consisting of arrays of single walled carbon nanotubes (SWCNTs) clamped between metallic contact electrodes and suspended above trenches etched in SiO2 substrates. TheSWCNTs are excited in various vibration states by *applying controllable voltages to an underlying back-gate electrode patterned on the substrate. The bending mode vibrations of these mesoscopic quantum oscillators are detected by means of a novel multi-frequency AFM approach that enables the measurement of vibrational states across a wide range of frequencies, from 0.1 – 1 GHz. We quantify the dynamics of these systems and measure the fundamental parameters that describe the system-environment interactions, including the sample quality factor, damping rates, and relaxation timescales. We demonstrate that this measurement technique is minimally invasive, involving sub-pN interaction forces, and thus it is optimal for a variety of quantum sensing and quantum metrology applications.*

Zero-Field Wigner Solids in Ultra-Thin Films of Cadmium Arsenide *Simon Munyan, Sina Ahadi, Binghao Guo, Arman Rashidi and Susanne Stemmer; University of California, Santa Barbara, United States*

The Wigner crystal is the ground state of a two-dimensional electron system in the low-density limit, where Coulombic repulsion between electrons overwhelms the kinetic energy and freezes them into a lattice. In this talk, we report transport signatures of electron- and hole-type Wigner solids in ultra-thin films of Cd_3As_2 *near the topological transition at zero magnetic field. Highly non-linear current-voltage behavior and voltage fluctuations arise from the pinned solid sliding over the disorder potential under finite bias. Hysteresis in the I-V appears due to domain motion, which disappears simultaneously with the aforementioned signatures above a critical temperature. Furthermore, a small magnetic field destroys the Wigner solids, in contrast to most other reports. We discuss their emergence in the context of spatial inversion asymmetry and spin-orbit coupling.*

9:00 AM *QT05.09.03

Chiral Induced Spin Selectivity as a Spontaneous Intertwined Order *Xiaopeng Li; Fudan University, China*

Chiral induced spin selectivity (CISS) describes efficient spin filtering by chiral molecules. This phenomenon has led to nanoscale manipulation of quantum spins with promising applications to spintronics and quantum computing, since its discovery nearly two decades ago. To support the observed CISS at room temperature, the required spin-orbit interaction (SOI) strength is unexpectedly large. In this talk, I will describe a multi-orbital theory for CISS, where an effective SOI emerges from spontaneous formation of electron-hole pairing caused by many-body correlation. This mechanism produces a strong SOI to the order of tens of milielectronvolts which could support the large spin polarization observed in CISS at room temperature. One central ingredient of our theory is the Wannier functions of the valence and conduction bands correspond respectively to one- and two-dimensional representation of the spatial rotation symmetry around the molecule elongation direction. The induced SOI strength is found to decrease when the band gap increases. Our theory may provide important guidance for searching other molecules with CISS effects.

Single Crystal Growth and Structure Solution of the Vacancy Ordered Oxide Perovskite $Sr(Sr_{1/8}Er_{1/4}W_{1/2})O_3$

Evan Crites, Maxime Siegler, Satya Kushwaha and Tyrel McQueen; Johns Hopkins University, United States

Abstract*: There is great potential for improvement of quantum information science technology when new and more complex materials are integrated. For quantum transduction specifically, rare earth ions –principally* Er^{3+}*– with weak interactions with each other and the environment are needed for high performance. Here we report a novel* Er^{3+}*-containing perovskite that has an ordered, highly spaced out, arrangement of Er ions. Magnetization measurements indicate weak interaction* $\Theta_{cw} < 1$ *K, with no signs of magnetic order down to* $T = 0.4$ *K. Single crystal XRD reveals a complex arrangement of Sr, Er, and W on the B-site of the perovskite structure, with signs of additional short range order. Incorporation of* Er^{3+} *is further indicated by the pink color of the crystals. Thus, this* *material has the potential to solve the challenges associated with the Er-ion implantation methods that are commonly used by reducing the structural disorder around the active Er^{3+} ions. Future work will look at the transduction response of this material.*

***Dynamic Control of Excitons in Single-Layer WSe₂ with Surface Acoustic Waves** Sheikh Parvez[1,1], John Fix[1,1], Joseph Stage[1], Samuel Berweger[2] and Nicholas J. Borys[1,1]; [1]Montana State University, United States; [2]National Institute of Standards and Technology, United States*

Two-dimensional (2D) single-layer transition metal dichalcogenide (1L-TMD) semiconductors have great potential to enable next-generation optoelectronic technologies because they are atomically thin two-dimensional systems with excellent optical and electrical properties. For example, 1L-TMDs exhibit bright optical emission due to their direct bandgap and large exciton binding energies. Among the family of 1L-TMD semiconductors, 1L-WSe_2 exhibits narrow optical emission at low temperatures from a large suite of different types of excitons, which are the dominant electronic excited states in the 2D semiconductor. These excitons govern light-matter interactions, from simple light absorption to the emission of non-classical states of light, such as single-photon generation. It is therefore essential to control and manipulate the excitons and their dynamics to employ these states in photonic, electronic, and quantum technologies. In this work, we study how surface acoustic waves (SAWs) dynamically manipulate excitonic states in mechanically exfoliated 1L-WSe_2 that is dry-transferred onto GaAs-based SAW devices. The fabrication procedure utilizes several steps to ensure efficient coupling between the SAWs and the 1L-WSe_2. The SAWs have frequencies of ~3.2 GHz and stimulate the 1L-WSe_2 with both electric fields and strain. Corroborating previous studies, we demonstrate photoluminescence quenching of the excitonic states in 1L-WSe_2 by the SAW stimulation at room temperature. In addition, the strength of the SAW modulation of the excitons is found to depend on excitation energy, as well as the speed of the modulation, and how the SAWs alter the spatial distribution of excitonic emission. Ongoing anti-stokes Raman spectroscopy is being used to understand how the SAW stimulation changes the lattice temperature of the 1L-WSe_2 along with time-resolved spectroscopy to characterize how the SAWs affect the relaxation dynamics to develop a comprehensive model of SAW-exciton interactions in 2D TMD semiconductors. The studies aim to open new opportunities for controllable optoelectronic and photonic quantum devices based on 2D semiconductors integrated with SAW devices.

***Engineering Chiral Helimagnetism in a Centrosymmetric Compound** Jennifer Fowlie[1,2,3]; [1]Northwestern University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Stanford University, United States*

Chiral helimagnetism is not uncommon. In most cases, it is borne by an underlying inversion-symmetry-breaking *of the lattice, which gives rise to a Dzyaloshinskii-Moriya interaction. In a minority of cases, it comes from a geometric spin frustration. Strontium ferrite ($SrFeO_3$), however, hosts chiral helimagnetism despite the centrosymmetric lattice and lack of frustration. Through a variety of techniques, we show how such magnetic order, which seems to be decoupled from the chemical order, can be engineered by a thin film environment.*

11:00 AM QT05.09.07

Floquet Effects and Relaxation of Hot Electrons in Graphene Under Continuous-Wave Mid-infrared Irradiation *Yijing Liu[1], Christopher Yang[2], Gabriel Gaertner[3], John Huckabee[3], Alexey Suslov[4], Luis E.F. Foa Torres[5], Gil Refael[2], Frederik Nathan[6], Cyprian Lewandowski[4,7], Iliya Esin[2], Paola Barbara[1] and Nikolai Kalugin[3]; [1]Georgetown University, United States; [2]California Institute of Technology, United States; [3]New Mexico Institute of Mining and Technology, United States; [4]National High Magnetic Field Laboratory, United States; [5]Universidad de Chile, Chile; [6]University of Copenhagen, Denmark; [7]Florida State University, United States*

High intensity Mid-Infrared radiation can induce Floquet-Bloch states with non- trivial topology [1,2,3]. We report on the experimental observation of photoinduced Floquet-related modifications in longitudinal conductivity and transverse photoresponse in graphene Hall bars irradiated with high-power linearly and circularly-polarized continuous-wave mid- Infrared radiation at cryogenic temperatures. We connect the experimentally-observed phenomena with processes of electron heating and relaxation in Floquet-modified graphene. The observation of Floquet signatures at lower power densities and in the continuous-wave regime lifts substantial experimental restrictions, helping to unlock potential applications for light-induced manipulation of material properties [4].

11:15 AM QT05.09.08

Probing the Role of Plasmonic Enhancement in Quantum Emission in Single-Layer WSe_2 Nanoribbons on Au Nanocones *Joseph Stage[1], Xufan Li[2], Samuel G. Wyss[1], Emanuil Yanev[3], Shuang Wu[2], P. J. Schuck[3], Avetik Harutyunyan[2] and Nicholas J. Borys[1]; [1]Montana State University, United States; [2]Honda Research Institute USA, United States; [3]Columbia University, United States*

Transition metal dichalcogenides (TMD) are a class of 2D semiconductors that host intense light-matter interactions. Using chemical vapor deposition with a nickel catalyst, single-layer (1L) TMD nanoribbons are grown that have distinct structural and electronic properties to their 2D crystallites because of their quasi-1D geometry. When 1L-WSe_2 nanoribbons are draped over arrays of Au nanocones, strain-induced exciton localization occurs. At these strained sites, the photoluminescence intensity is dramatically increased at room temperature and single-photon emitters emerge at cryogenic temperatures. In addition to the effect of strain, due to the subwavelength size of the Au nanocones, a localized surface plasmon resonance (LSPR) is present that can provide Purcell enhancement of the emitters as well as local field enhancement of the excitation field at the apex of the nanocone. COMSOL finite element modeling of the nanocones shows the resonance of the LSPR occurs at approximately 625 nm, which is ideal for excitation enhancement of strain-localized states near the cone apex. Here, we conduct excitation energy dependent spectroscopy and photoluminescence lifetime analysis to probe for signatures of both excitation enhancement and Purcell enhancement in the system. By sweeping the energy at *which the strained regions of the 1L-WSe$_2$ nanocones are excited and collecting the integrated intensity of the photoluminescence, we obtain an excitation spectra of many strain-localized emitters. This excitation spectrum and the statistical distribution of excited state lifetimes are then compared to both unstrained 1L-WSe$_2$ as well as locally strained 1L-WSe$_2$ emitters that do not have plasmonic stressors. By comparing these systems, we can identify signatures of nearfield excitation enhancement as well as Purcell enhancement. These studies provide insight into how the combined effects of strain and nanoplasmonics can increase the brightness of 1L-WSe$_2$ nanoribbon-based quantum light sources for application in a BB84 quantum key distribution protocol testbed.*

11:30 AM QT05.09.09

Engineering the Interface of Nickelate Thin Films via MBE and Soft-Chemical Synthesis *Abigail Y. Jiang, Ari Turkiewicz, Grace A. Pan, Suk Hyun Sung, Jarad A. Mason, Charles Brooks and Julia Mundy; Harvard University, United States*

Recent observations of rare-earth nickelate superconductivity have established the Ruddlesden-Popper (RP) $R_{n+1}Ni_nO_{(3n+1)}$ *and reduced square-planar* $R_{n+1}Ni_nO_{(2n+2)}$ *series as important comparisons to the high-*T_c *cuprates. To date, ambient pressure superconductivity has only been realized in epitaxial nickelate thin films, prompting ongoing inquiry into the role of epitaxy-imparted strain, dimensionality, and interfacial physics in nickelate electronic properties. Here, we synthesize a variety of RP nickelates via reactive oxide molecular beam epitaxy (MBE) with chemical doping and tunable strain states. We also demonstrate new soft-chemical reduction methods to modify the anion sublattice. Through transport measurements and electron microscopy, we investigate emergent electronic phases and corresponding local microstructures particularly at the nickelate and* $SrTiO_3$ *substrate interface, and discuss potential implications towards engineering superconductivity in higher-dimensional RP and square-planar systems.*

11:45 AM QT05.09.10

Strong-Field Control of a van der Waals Antiferromagnet MnPS$_3$ *Sheikh Rubaiat Ul Haque[1,2], Jiaojian Shi[1,2], Martin J. Cross[2], Sharon S. Philip[2], Christian Heide[2,1], Huaiyu Wang[2], Monique Tie[1], Leah Narun[1], Matthias Hoffman[2], Tony F. Heinz[1,2] and Aaron Lindenberg[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States*

Groundbreaking advances in laser technology has allowed for optical manipulation of quantum materials on ultrafast timescales. Exciting a material using intense laser pulses and pushing it out of equilibrium may enable discovery of myriad novel collective excitations which cannot be revealed by static parameters, i.e., pressure, temperature etc. Recently, significant efforts have been made in strong-field periodic driving with light having energy below a material band gap. Such a photoexcitation protocol holds exciting possibilities to modulate nonlinear optical properties as well as uncover phenomena that are otherwise inaccessible via driving above the band gap. This is accomplished using mid-infrared (MIR) or terahertz (THz) pulses. We target 2D van der Waals antiferromagnet (AFM) MnPS$_3$ that exhibits a Néel-type AFM ordering below K and a charge-transfer band gap of 3 eV. Previously, optical absorption and resonant inelastic X-ray scattering have revealed multiple onsite transition peaks below the band gap, and photoexciting below and above these transitions have produced strikingly different results. Here, we use strong-field below-gap pumping schemes ranging from nonlinear THz to MIR, and combine them with a suite of probing techniques. Thus, we delineate the dynamical attributes of MnPS$_3$ such as coherent phonons and light-induced shift of spectral weight that scales with the AFM order. Our study unravels intriguing signatures of nonlinear coupling between electron, lattice and magnetism, and can shed light towards efficient controlling of quantum magnets in strong-field regime.

SESSION QT05.10: Novel Spin Qubit Platforms
Session Chairs: Paola Cappellaro and Ju Li
Thursday Afternoon, December 5, 2024
Sheraton, Fifth Floor, Riverway

1:30 PM *QT05.10.01

Molecular Color Centers *Daniel Laorenza[1], Leah Weiss[2], Pratiti Deb[2], Sam Bayliss[3], David Awschalom[2], James M. Rondinelli[4] and Danna E. Freedman[1]; [1]Massachusetts Institute of Technology, United States; [2]The University of Chicago, United States; [3]University of Glasgow, United Kingdom; [4]Northwestern University, United States*

Molecules are tunable platforms for quantum technologies. Previously we harnessed synthetic chemistry to create molecular analogues of color centers which feature ground state optical read-out of spin information. Proceeding beyond this initial result to optimized systems requires careful design of new molecules in which coherence properties, environmental compatibility, and emission frequency can be controlled. Recent results on developing molecules featuring a spin/optical handle will be presented.

2:00 PM QT05.10.02

Combining Experiment and Computation to Investigate the Formation of Divacancies in 4H-SiC for Quantum Technology Applications *Taishi Kimura[1,2], Jonghoon Ahn[2], Nazar Delegan[2], Katherine Harmon[2], Alan Dibos[2], Jiefei Zhang[2], Benjamin Pingault[2,3], Cunzhi Zhang[3], Giulia Galli[2,3], Akira Uedono[4], David Awschalom[2,3] and F. J. Heremans[2,3]; [1]Toyota Motor North America, United States; [2]Argonne National Laboratory, United States; [3]The University of Chicago, United States; [4]University of Tsukuba, Japan*

Much research in recent years has focused on optically addressable defect spins, such as the negatively charged nitrogen-vacancy center in diamond and the divacancy (VV) in 4H-SiC, for quantum technology applications, including scalable quantum sensing, and quantum networking applications. In particular, VV in 4H-SiC is attracting widespread interest because of its optical addressability, near-infrared emission, and long coherence times. Previous work in understanding the formation dynamics of these color centers has primarily focused on the experimental determination of optimal process conditions such as annealing temperature and duration. Further optimization of the formation process has been recently explored through first-principle calculations [1,2], but to date, only limited experimental results are available. Hence, a systematic approach combining experiments, theory and computation, leading to a thorough understanding of defect formation and control is still lacking.
In this study, we carry out a systematic experimental study of the formation of VV in 4H-SiC and successfully validate the results on the formation mechanism obtained by first principle simulations. These calculations predict appropriate temperature ranges for the preferential formation of the VV near the surface of HPSI 4H-SiC, approximately between 1150–1300 K. At temperatures below 1150 K, the silicon vacancy (Vsi) is less likely to migrate and combine with a carbon vacancy (Vc) to form VV, and at annealing temperatures over 1300 K, VV can migrate easily to the deeper region in the substrate. We validate these simulations, and suggest that the VV formation may be limited by the Vsi migration. Importantly, our results provide a protocol to combine and integrate experimental and theoretical calculations to investigate the formation of defect spin qubits.

2:15 PM QT05.10.03
Electronic Structure of Chromium Ion Color Centers in hBN Thin Layers *Idan Haritan and Tamar Goldzak; Bar-Ilan University, Israel*

The emergent second quantum revolution is changing the technological and scientific world. The search for novel single photon emitters (SPE) that can operate at room temperature and have a high quantum yield is ongoing research in many fields. Point defect in 2D materials is a promising platform for designing room-temperature color centers. Thin layered hBN is a wide band gap semiconductor and is a perfect candidate for hosting point defects that will serve as a color center. SPEs in hBN were realized mostly based on nitrogen and boron vacancies, or by implantation of carbon atoms. However, their atomic structure as point defects in hBN is still under debate. Here we propose to design a novel SPE, achieved by chromium implantation in hBN, to create Cr color centers.
In this work, we will present state of the art electronic structure calculations beyond mean field theories to incorporate correlation effects which are extremely important in such complicated systems.
This work is a theoretical and experimental collaboration that aims to understand the atomic structure and chemical composition of Cr color centers in hBN for various experimental conditions such as annealing and applying strain on the structure.
Combining these simulations with experimental measurements will allow us to correlate the defect's atomic structure with its optical measurements. This can lead to designing Cr color centers in hBN by ion implementation, and engineering efficient SPEs by manipulating their optical and magnetic properties using external perturbations for quantum information, sensing, and communication applications.

3:00 PM *QT05.10.04
Nanoscale Covariance Magnetometry with Diamond Quantum Sensors *Nathalie P. de Leon; Princeton University, United States*

Correlated phenomena play a central role in condensed matter physics, but in many cases there are no tools available that allow for measurements of correlations at the relevant length scales (nanometers - microns). We have recently demonstrated that nitrogen vacancy (NV) centers in diamond can be used as point sensors for measuring two-point magnetic field correlators [1]. NV centers are atom-scale defects that can be used to sense magnetic fields with high sensitivity and spatial resolution. Typically, the magnetic field is measured by averaging *sequential measurements of single NV centers, or by spatial averaging over ensembles of many NV centers, which provides mean values that contain no nonlocal information about the relationship between two points separated in space or time. We recently proposed and implemented a sensing modality whereby two or more NV centers are measured simultaneously, from which we extract temporal and spatial correlations in their signals that would otherwise be inaccessible. We demonstrate measurements of correlated applied noise using spin-to-charge readout of two NV centers and implement a spectral reconstruction protocol for disentangling local and nonlocal noise sources. This novel quantum sensing platform will allow us to measure new physical quantities that are otherwise inaccessible with current tools, particularly in condensed matter systems where two-point correlators can be used to characterize charge transport, magnetism, and non-equilibrium dynamics.*

3:30 PM QT05.10.05

New Telecom Qubit System Based on Er^{3+} in Thin Film CeO_2 on Silicon *Jiefei Zhang[1], Gregory Grant[1,2], Ignas Masiulionis[1,2], Michael Soloman[1,2], Jonathan Marcks[1,2], Jasleen Bindra[1], Jens Niklas[1], Alan Dibos[1], Oleg Poluektov[1], F. J. Heremans[1,2], Supratik Guha[1,2] and David Awschalom[1,2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States*

Trivalent erbium ions (Er^{3+}) are promising spin defects for developing quantum memories in quantum communication networks due to their unique spin-photon interface at telecommunication band. To this end, controlling the local host environment to enable long-lived Er^{3+} electron spins in a technology compatible platform is key. Here, we report on a new qubit system Er^{3+}: CeO_2 (cerium dioxide) epitaxially grown on silicon. The near-zero nuclear spin environment provided by CeO_2 is critical for supporting long-lived spins with predicted long spin coherence[1]. Its silicon compatibility also points to the feasibility of this platform for device integration[2]. We verify the host structure via thorough microstructural study[2] and explore routes towards improvement of the optical and spin linewidths via growth optimization and post-growth treatment of the Er:CeO_2 films. Additionally, we study the optical and spin coherence properties of Er^{3+} in this system and demonstrate narrow homogeneous linewidth of 440 kHz with an optical coherence time of 0.72 μs at 3.6 K[3]. The slow spin-lattice relaxation enables direct observation of spin dynamics at 3.6 K. The Er^{3+} electron spins have a spin relaxation of 2.5 ms and a spin coherence of 0.66 μs (in the isolated ion limit)[3]. Further exploration of spin dynamics at sub-Kelven temperature is undergoing. All these findings indicate the potential of Er^{3+}:CeO_2 qubit systems as a scalable platform for quantum networks and communication applications.

Spin and Optical Properties of ZnO Donors Synthesized via Implantation *Kai-Mei Fu[1,2], Xingyi Wang[1], Ethan Hansen[1], Vasileios Niaouris[1] and Lasse Vines[3]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States; [3]University of Oslo, Norway*

Donors in semiconductors are attractive qubit candidates for quantum information applications. In a direct band *gap semiconductor, the donor spin is optically coupled to the donor-bound exciton providing a means for initialization, readout and control. Here we present recent results on donor and donor-bound excitons in the direct band gap semiconductor zinc oxide (ZnO). We focus on donors that we can create via ion implantation, specifically indium and the I10 donor, both in commercial substrates and high-purity MBE epitaxial layers. The longitudinal spin relaxation times approach 1s, the optical transition linewidth of single donors is approximately three times broader than the fundamental limit, and hyperfine interaction strength with the indium nuclear spin of 100 MHz is observed.*

***Integrating Artificial and Biological Photosynthesis for Microbial Bioproduction** Arpita Bose; Washington University in St. Louis, United States*

Since industrialization, human activity has directly contributed to a 50% rise in atmospheric carbon dioxide (CO_2), which now constitutes over 420 ppm of the Earth's atmosphere. Absent intervention, the International Panel on Climate Change predicts CO_2 levels reaching 550 ppm by 2050. Such an increase would exacerbate the economic, environmental, and social costs of climate change. However, technological innovation promises to not only curb CO_2 emissions and their downstream effects, but also transform how we think about our energy and materials economies. One such innovation is the use of artificial photosynthesis – either through photoelectrochemical or photovoltaic cell systems – to upcycle CO_2 by capturing solar energy and converting it to chemical energy. While these systems are attractive due to the use of efficient light absorption materials, they have largely been restricted *to synthesizing C1 compounds. This is because the mechanistic link between solar energy harvesting and CO_2 conversion remains unclear. Like artificial photosynthesis, microbial electrosynthesis (MES) is also considered a promising CO_2 upcycling technology that integrates the disciplines of electrochemistry, microbiology, and engineering. Unlike artificial photosynthetic systems, MES can sustainably produce multi-carbon compounds from CO_2 using self-repairing, self-replicating microbial biocatalysts. However, MES suffers from low product yields, inefficient solar and electrical energy conversion, and little insight into the biological mechanisms underlying electron transfer processes. Given the strengths and weaknesses of artificial photosynthesis and MES, the two technologies could complement one another well. In that vein, we are exploring the use of metabolically versatile photosynthetic bacteria capable of synthesizing iron-based nanomaterials as platforms for MES-based bioproduction. Our research shows that biogenic, iron-based nanomaterials improve bioplastic production by enhancing electron transfer in our MES systems. While this can pave the way toward industrial-scale applications, our work highlights the need for additional research to elucidate the underlying mechanisms and further improve bioproduct yields.*

9:45 AM SB01.01.02

A Semi-Artificial Photoelectrocatalytic Biohybrid for Efficient and Selective Carbon Dioxide Conversion to Medium Chain Fatty Acids *Cathal Burns[1,2], Elizabeth Gibson[2] and Shafeer Kalathil[1]; [1]Northumbria University, United Kingdom; [2]Newcastle University, United Kingdom*

Converting atmospheric carbon dioxide emissions and water into value-added liquid multi-carbon products (e.g medium-chain fatty acids (MCFA's)) and O_2 remains a difficult undertaking. Here, we present a semi-biological photoelectrochemical (PEC) system consisting of a scalable and cheap $CuBi_2O_4$ photocathode (stabilized by MgO), with Sporomusa ovata grown on the electrode surface, a known CO_2-fixing acetogenic and electrotrophic bacteria[1-3]. The PEC biohybrid effectively produces acetate and ethanol (as well as H_2 and O_2) after 140 hours of stable operation (>5.5 days), without the need for any sacrificial organic additives. The PEC system splits water into its core elements forming O_2 on the anode and providing H_2 and electrons via the photocathode to living S. ovata cells to utilize as reducing equivalents for synthesis of acetate and ethanol from waste carbon dioxide. Chain elongation was then performed on the photosynthesised acetate and ethanol via fermentation using Clostridium kluyveri which produced butyrate (C4) and caproate (C6). Spectroelectrochemistry (cyclic voltammetry and UV-Vis spectroscopy), transient absorption spectroscopy, and attenuated total reflection infrared spectroscopy were also used to probe the biointerface and gain a deeper mechanistic understanding of these biohybrid systems. This semi-artificial photosynthetic approach demonstrates the advantages of synergistically pairing biotechnology with materials science as a promising method to use waste carbon dioxide as a feedstock for solar chemical production.

Biohybrid Systems for H_2 Production and CO_2 Reduction *Nicolas Plumere; Technische Universität München, France*

Biocatalysts have unmatched performance in terms of activity, selectivity and energy efficiency for the conversion *of small molecules such as H_2, CO_2, O_2 or N_2. However, implementation of biocatalysts in devices for energy conversion cannot proceed without solutions that mitigate their intrinsic fragility. Protection strategies using a redox-active polymeric matrices can effectively stabilize biocatalysts such as the hydrogenase and significantly increase their operational lifetime for electrocatalytic H_2 oxidation or production [1, 2]. Mass transport and electron transfer limitations emerge as trade-offs when increasing matrix dimensions for protection considerations [3]. Quantitative analysis supported by kinetic modeling enable to pin-point such bottlenecks and guide the rational design of the immobilization matrix [4, 5] to enable high catalyst utilization that can theoretically provide robustness for non-limiting periods of time even when using highly fragile hydrogenases [6, 7]. Engineering catalytic reversibility [8] into the redox-active films embedding the hydrogenase enables H_2 oxidation and H_2 evolution at minimal overpotential, making the protected hydrogenase energy efficient in fuel cell and electrolyzers [9]. The same redox-active films were also successfully applied to construct energy efficient biohybrid systems based on CO_2 fixating enzyme [10]. We show that fine tuning of the reduction potential of the polymer is a prerequisite for both bidirectionality and protection under intermittent use.*

Alcohol Oxidase and Fe-ZSM-5 Catalytic Coupling for Concerted Methane Fixation at Ambient Condition

Jimin Kim, Daniel J. Lundberg and Michael S. Strano; Massachusetts Institute of Technology, United States

Anthropogenic methane emissions to the atmosphere constitute a technical challenge because they are driven by diffuse and dilute sources. The low temperature and concentration of these emission streams make them ill-suited to be addressed by current routes of methane oxidation, which invariably rely on high temperatures or pressures to drive methane oxidation rapidly and efficiently. Herein, we report the catalytic coupling of alcohol oxidase with an iron-modified ZSM-5 that functions as a synthetic methanotrophic system capable of partially oxidizing methane at ambient temperatures and pressures, producing chemically useful intermediates for concomitant material synthesis. Methane reacts at the Fe-ZSM-5, producing methanol, which is oxidized at the enzyme to formaldehyde and hydrogen peroxide. The latter subsequently reacts back at the Fe-ZSM-5 as the methane oxidizer in a unique catalytic couple. We show that the methane-to-formaldehyde selectivity can exceed 90% at room temperature, surpassing the highest literature values to date. The generated formaldehyde intermediate can be rapidly incorporated into a growing urea polymer, with a material growth rate exceeding 5.0 mg gcat hr-1, commensurate and even exceeding rates for many cultured methanotrophic bacteria systems. The resulting carbon-capturing urea-formaldehyde polymer is shown to be successfully incorporated into nanocomposites, with performance comparable to commercially available resin. This work presents a *sustainable, scalable, and cost-effective route for concerted methane oxidation at ambient conditions to produce high-value polymers, allowing the unique valorization of ambient methane emission streams.*

Improving the Activity and Stability of [FeFe]-Hydrogenase on Electrodes for Electroenzymatic H_2 Production

Ross Milton[1,2]; [1]University of Geneva, Switzerland; [2]National Centre of Competence in Research (NCCR) Catalysis, Switzerland

Over 99% of molecular hydrogen (H_2) produced today originates from fossil fuels ("gray H_2"). While CCUS (carbon capture, utilization and storage) enables H_2 production without releasing carbon dioxide (CO_2) into the atmosphere ("blue H_2"), water electrolysis offers a carbon-neutral route ("green H_2"), although this represents only around 0.1% of H_2 produced today. The use of enzymes on electrodes as electrocatalysts, or bioelectrocatalysts, presents an opportunity for precious metal-independent electrolytic H_2 production. While these "hydrogenases" can rival electrocatalysis using Pt in terms of activity per site (DOI: 10.1039/B201337A), enzymes are not widely considered to be stable for long periods of electrocatalysis.

We recently reported a simple electrode preparation procedure using indium:tin oxide (ITO) nanoparticles and [FeFe]-hydrogenase, where we observed comparatively large current densities for electroenzymatic H_2 production (DOI: 10.1021/jacsau.2c00551). Surprisingly, these enzyme electrodes exhibited high operational stability over multiple days of continuous potentiostatic turnover.

The coupling of a quartz crystal microbalance with enzymatic electrochemistry on electrode surfaces of different morphologies has permitted us to characterize the ITO:[FeFe]-hydrogenase interaction. We conclude that mesostructured ITO electrode surfaces offer improved electrocatalytic activity and stability of [FeFe]-hydrogenase from Clostridium pasteurianum.

SESSION SB01.02: Electryfing Biomaterials for Energy and Sensing

Programming Bioelectronic Bacteria as Real-Time and Multiplexed Sensors & Actuators *Xu Zhang, Robyn Alba and Caroline Ajo-Franklin; Rice University, United States*

Challenged by a changing climate, dwindling natural resources, and a growing global population, we need renewable advanced materials that meld the sustainability of biology materials with the functionality of conventional materials. To help address this need, my research group engineers microorganisms as bioelectronic sensors and actuators by re-programming naturally-occurring pathways from microbes that transfer electrons to and from materials in their environment.

In my talk, I will first report how we have created bioelectronic sensors that convey multiple channels of information. Existing bioelectronic sensors can sense a variety of hazards to human and environmental health, however, these sensors transmit information through only a single electrochemical channel. This severely limits *the amount of sensing information that can be transmitted. To increase this information content, we developed a multichannel bioelectronic sensor in which different chemicals modulate distinct extracellular electron transfer pathways in Escherichia coli. To create an E. coli strain with two reporting channels, we introduced a riboflavin synthesis pathway from Bacillus subtilis alongside the metal reducing (Mtr) pathway from Shewanella oneidensis. We can distinguish whether one or both pathways are active in this strain using amperometric measurements at distinct redox potentials. To demonstrate multi-channel bioelectronic sensing, we regulated the Mtr and riboflavin pathways using arsenic and cadmium responsive promoters. With this strain, we used a series of amperometric measurements at distinct redox potentials to distinguish the presence of the different heavy metals in situ. These accomplishments provide a new platform for multichannel bioelectronic sensors that simultaneously detect and report multiple toxins.*

Next, I will describe how we have utilized the probiotic bacteria Lactiplantibacillus plantarum to sense and actuate via electronic signals. L. plantarum is known to utilize exogenous small molecule quinone mediators to perform extracellular electron transfer, which allows it to produce a detectable current. Different 1,4-naphthoquinone mediators yield significantly different current outputs. Using a library of 30 mediators, we probed the important physicochemical properties and biochemical interactions of quinones that are responsible for extracellular electron transfer in L. plantarum. We find that extracellular electron transfer is correlated most strongly to the mediator's polarity and binding affinity. Furthermore, we identify that amine containing mediators yielded incredibly stable current output over 5 days. These findings increase our understanding of structure-activity relationships for quinone-mediated EET and provide mediators for bioelectronic sensing.

Electrical Access to (Non)-Electroactive Bacteria by Redox Polymer-Based Artificial Molecular Conduits

Shenghan Gu[1], Kuniaki Nagamine[2], Saman Azhari[1], Takeo Miyake[1] and Gábor Méhes[1]; [1]Waseda University, Japan; [2]Yamagata University, Japan

Through extracellular electron transfer (EET), metabolic energy conversion of bacteria has the potential to be harnessed for industrial processes, such as electricity generation, wastewater treatment, bioelectrosynthesis, bioremediation. While electroactive bacteria (EB), such as Shewanella oneidensis, possess natural molecular conduits to transfer electrons to or from electrodes, many other bacteria cannot efficiently interface electrode surfaces, greatly limiting the range of accessible reactions for utilization. To solve this issue, redox polymers (RPs) have recently surfaced to be able to mediate charge transfer between non-EB and electrodes[1].
Here, we report on our investigations of extracting EET-derived electrical currents from both the EB S. oneidensisMR-1 and the non-EB E.coli using a ferrocene-based RP as an artificial molecular conduit. Through the use of mainly standard electrochemical techniques, including chronoamperometry, scanning voltmmetry and electrochemical impedance spectroscopy, we characterize the magnitude and nature of the observed signal. Importantly, by employing EB, our investigations revealed a different mechanism of current extraction between RP-coated and non-coated electrodes. Finally, as a follow-up on our earlier works[2,3], I will show our initial results on combining RP with the well-known conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) aiming at maximizing the extracted EET. Our results intend to stress the yet unexplored possibilities and capabilities of the microbes surrounding us for utilization in processes beneficial for society.

Bioelectronic Biofilm on Chip—Understanding Biofilm Formation Dynamics Through Combined Optical and Electronic Methods *Deema K. Islayem, Nabila Yasmeen, Sagar Arya and Anna-Maria Pappa; Khalifa University of Science and Technology, United Arab Emirates*

Biofilm formation, characterized by the aggregation and irreversible adhesive of diverse microorganisms on both biotic and abiotic surfaces, represents a complex process. Biofilms are held together by a self-produced matrix known as extracellular polymeric substances (EPS), which are the main responsible for the high antibiotic resistant feature of the biofilm. Bacterial infections associated with biofilms are accountable for a significant portion of healthcare-associated infections, emphasizing the need for in-depth research into biofilm development and resistance mechanisms. Current in vitro biofilm model systems lack the ability for continuous online monitoring, as they require the removal of the biofilm from the growth substrate, disrupting its natural behaviour. We have developped a microfluidic platform with integrated electrodesfor real-time, and non-disruptive biofilm formation studies. Moreover, it serves as a reliable tool by mimicking the natural behaviour of the biofilm formation under flow conditions, thereby enhancing understanding of biofilm behaviour and enabling the development of more effective prevention and treatment strategies. The microfluidic chip incorporates a gold electrode array coated with Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)/PEDOT:PSS which has shown to enhance measurement sensitivity due to its low impedance values. Using our combined optical/ electrochemical platform we acquire insights into the biofilm lifecycle—from initial attachment to dispersion. Additionally, we have tested different antibiotic treatments, revealing varying degrees of resistance and responses to specific treatments. By combining and correlating the electrochemical (electrochemical impedance spectroscopy, EIS) and optical (fluoresence microscopy) data we not only acquire mechanistic understanding into biofilm formation and disruption dynamics but we also reveal figures of merit in EIS for characterizing biofilm health in a quantitative manner. This study lays foundation for applications of electrochemical sensing of biofilms in clinical settings, i.e., for detecting the presence of biofilm- related infections as well as evaluating new antibiofilm strategies.

Biosensing with Ingestible Pill for Gut Health Monitoring *Mohammad Shafiqul Islam, Angsagan Abdigazy, Munia Ferdoushi, Sandra L. Galindo and Yasser Khan; University of Southern California, United States*

Gut health is crucial for overall human physiological well-being, representing digestion, immune functions, early detection of chronic diseases, and mental health. Hence, monitoring gut health is beneficial for the early detection of critical health issues and guided interventions to maintain physical and mental health. Traditional methods for determining gut conditions require hospital-based invasive measurements in the human gastrointestinal (GI) tract. We introduce an ingestible pill to unleash the potential of utilizing information from gut health monitoring for overall health assessment. Our ingestible pill presents convenient, non-invasive measurements through comprehensive real-time data collection in the GI tract. We precisely measure the composition of gases (oxygen O_2, ammonia NH_3) and articulate the variations in pH levels at different segments of the GI tract. We fabricate the gas sensors based on the principle of fluorescence quenching. In our custom-made ingestible pill, the gas-sensitive membrane is excited by a wavelength-specific LED (440nm for O_2, 530nm for NH_3). In response, the membrane produces fluorescence in the red spectrum (580 nm and 640 nm), with the intensity varying according to the target gas concentration. Our gas sensor in the ingestible pill can detect O_2 in 0-20% and NH_3 in 0-100 ppm. We use the 3-electrode sensing mechanism for detecting pH. We fabricate the 3-electrode sensors by inkjet printing the gold (Au) nanoparticle ink in a flexible substrate, while the reference electrode is by direct 3D writing of

Ag/AgCl. We modify the working electrode using an H+ ion selective membrane. Our pH sensor is capable of measuring pH 1 to 7. Our ingestible pill supports bi-directional operation, which is necessary for measuring reduction and oxidation currents in amperometry and voltammetry. We envision this ingestible pill will bridge the gap between gut health and overall health monitoring, providing a powerful tool for personalized healthcare.

3:45 PM *SB01.02.05

Nanomaterials Interfaced to Photosystem I for BioHybrid Energy Conversion *David E. Cliffel, Kane Jennings, Matthew Galazzo and William Lowery; Vanderbilt University, United States*

Photosystem I (PSI) is one of the primary macromolecular machines that drive photosynthesis in green plants and cyanobacteria. Extracted PSI has been employed successfully as a macromolecular photosensitizer within a host of low-cost electrochemical and solid-state photovoltaic architectures. This presentation will also explore our group's recent efforts to integrate PSI with advanced nanomaterials, including carbon nanotubes, carbon quantum dots, and conducting polymers polyaniline (PANI), polypyrrole, polyviologens, and poly(3,4-ethylenedioxythiophene). Our current work is aimed at building new prototypes using PSI in solid state interfaces for scalable solar energy conversion. Finally, the incorporation of PSI into conducting polymer frameworks holds promise for improved conductivity and orientational control in the photoactive layers in these devices.

4:15 PM *SB01.02.06

Living Photosynthetic Bacteria for Sustainable Bio-Photovoltaics *Rossella Labarile[1], Anna De Salvo[2], Federico Rondelli[2], Michele Di Lauro[2], Massimo Trotta[1], Fabio Biscarini[2] and Gianluca Maria Farinola[3]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Fondazione Istituto Italiano di Tecnologia, Italy; [3]Università degli Studi di Bari Aldo Moro, Italy*

Solar energy is the most abundant energy source on Earth and will be the key source of electricity in a low-carbon future. [1] The development of solar power technologies is considered one of the best options to meet the increasing future energy demand. [2] To maximize the potential of solar power, new materials are needed to harvest and convert solar energy alongside the current photovoltaic technologies. [3] As new and optimized material, photosynthetic bacteria can pioneer the cutting-edge novel strategies for environmentally safe and cost-effective energy production. [4]
Rhodobacter (R.) sphaeroides is a versatile photosynthetic purple non sulfur bacteria able to harvest sunlight, and particularly the Near Infrared region, and perform an efficient photochemical energy transduction. Bio-hybrid architectures [5-7] have been designed aiming at photovoltage generation using the light harvesting abilities of photosynthetic components. Here, whole metabolically active photosynthetic cells of the wild type and the carotenoidless mutant strain of R. sphaeroides were implemented in a two electrodes device configuration, obtaining a positive variation of the generated photovoltage upon lighting cycles. The higher photovoltage output and the ability to elicit a constant voltage output in slow lighting conditions of the mutant strain, almost three times higher than the voltage amplitude obtained with wild type cells. Photosynthetic bacterial cells were also implemented in a light-driven three-electrode actual device, as electrolyte-gated organic transistors and in a power cell exposing bacteria to direct sunlight illumination.

Thursday Morning, December 5, 2024
Hynes, Level 2, Room 205

8:30 AM SB01.03.01
A Stretchable, Strain-Limiting and Mechanically Stable Bio-Inspired Microfiber for Wearable Electronics
Adeela Hanif, Junho Park, Dohui Kim, Jaeseung Youn, Unyong Jeong and Dong Sung Kim; Pohang University of Science and Technology, Korea (the Republic of)

Since fiber-based approaches have high stretchability, the devices fabricated on them with limited stretchability cannot fully withstand large stretching, particularly when the wearer participates in vigorous activity. Stretchable systems can replicate the "j-shaped stress-strain or strain-limiting" mechanical behavior of biological tissues under deformations and provide mechanical compliance and comfort to wearers. A network of soft elastin fibers and stiff collagen fibers causes the biological tissues to be stretchable at low strains, and exhibit strain-limiting behavior when deformed at large strains. We developed a combined microfiber and nanofiber (NFs)-based approach to mimic this mechanical behavior of tissues, which involved wrapping soft polyurethane (PU) microfiber with stiff and inflexible poly(vinyldenefluoride) (PVDF) NFs and coating them in polydimethylsiloxane (PDMS). By tailoring the loading ratios of the PVDF NFs it is possible to tame the elastic moduli of the bio-inspired microfibers to match well with those of biological tissues. As shown by confocal imaging during stretching, PU microfibers maintain stretchability and stiff PVDF NFs play a role in strain-limiting characteristics. The stretchable poly(3,4-ethylenedioxythiophene) polystyrene sulfonate/ Polyurethane dispersion (PEDOT: PSS/PUD) coating on the bio-inspired microfiber showed a negligible difference in current-time (I-T) response after static stretching (~ up to 30%- human skin stretchability range) which indicated the efficient absorption of stress by the bio-inspired microfiber. An electrical response of a stretchable temperature sensor was measured by directly attaching it to the fist and stitching it into the bandage to demonstrate microfiber's ability to measure skin temperature and accommodate body movements. A light-emitting diode (LED) ON/OFF test was performed to demonstrate that bio-inspired microfibers could be used as electrodes in the future. Wearable electronics based on mechanically stable and stretchable bio-inspired microfibers have the potential to be the frontier due to their high adaptability for non-planar bodies and ease of sewing in fabrics.

8:45 AM SB01.03.02
Utilizing Piezoelectric Technology for Sensitive Detection of SARS-CoV-2 *Annu Mishra and Ashish Mathur; UPES, Bidholi, India*

The fields of health and biotechnology depend significantly on viral diagnostics, however these analysis might pose difficult analytical problems. Piezoelectric transduction using Quartz Crystal Microbalance (QCM) approach has emerged as a highly reliable technique for the bio-detection of DNA, RNA, proteins, and virus. In contrast, the majority of molecular methods used in clinical laboratories, such as reverse transcription-polymerase chain reaction (RT-PCR) and antigens tests, require long acquisition times and frequently yield unreliable results for COVID-19 virus detection. This is made achievable by the incredibly high sensitivity of QCM sensors to changes in the mass of pertinent biomarkers, making them appropriate for quick, label-free, selective, and real-time monitoring of specific disease(s) in a point-of-care setting.

In this study, we describe the development of a QCM biosensor modified with AuNPs to detect SARS-CoV-2 DNA. Predictably, adding AuNPs to QCM bioelectrodes should make it easier for thiol-modified probe DNA to bind strongly through Au-SH bonding. This could result in a sensitive and durable nano-biosensor that can monitor changes in resonant frequencies to determine the COVID-19 status. Consequently, the use of piezoelectric nano-biosensing devices can efficiently screen prospective patients at the point-of-care, particularly in areas with limited resources, leading to a cost-effective and sustainable healthcare environment.

9:00 AM SB01.03.03

PolyGraph—Biocompatible and Flexible Graphene Composites for Microneedle-Based Neural Interfacing Devices *Jack Maughan[1,2,3], Cian O'Connor[2,3], Oran Kennedy[2,1], Ian Woods[2,3], Eoin Caffrey[1,3], Jose Munuera[1,1], Adrian Dervan[2,3], Fergal O'Brien[2,3,1] and Jonathan Coleman[1,1,3]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Royal College of Surgeons in Ireland, Ireland; [3]Advanced Materials and BioEngineering Research (AMBER) Centre, Ireland*

Brain-computer interfaces (BCIs), specialized electrodes capable of delivering electrical stimulation to and recording signals from the brain, have been used as novel treatments for epilepsy, Parkinson's, and other neurological disorders. Looking beyond medical treatment to biological enhancement, BCIs may allow the integration of prosthetic and communication technologies with neural signaling, making their development an area of investigation with the potential for significant medical and societal impact. However, they are faced with the challenge of balancing biocompatibility, degradation, and neuroinflammation with electrical performance, device design, and stiffness. Optimizing the many facets of these devices involves trade-offs, for example between neurocompatibility and electroconductivity, which compromises the performance of existing BCIs. Therefore, the hypothesis of this study is that by developing a multi-phase material which combines highly electroconductive graphene with a biocompatible polymer, a conductive, non-inflammatory, and flexible microneedle-based neural interface could be developed. To achieve this, polymer-graphene composites were fabricated, and a novel fabrication method was used to manufacture flexible, electrically isolated microneedle arrays capable of delivering electrical stimulation to neuronal cells - key outcomes for successful BCIs.

The graphene (Gr) formulation was first optimized, with polyvinylpyrrolidone (PVP) found to be the optimal stabilizer for liquid phase exfoliation of thin graphene nanosheets with high conductivity (>1000 S/m), yield (>1g) and hydrophilicity. The culture of mouse motor neuron cells in medium containing PVPGr suspensions showed robust proliferation and healthy metabolic activity, indicative of excellent biocompatibility. PVPGr was then further characterized using SEM, AFM and Raman spectroscopy, to establish its optical and morphological properties, before being combined with polycaprolactone (PCL) to form conductive and processable graphene-polymer composites (PolyGraph). Electrode materials require optimal electrical performance, so PolyGraph was enhanced by NaOH treatment to increase specific surface area, followed by coating with a thin AuPd layer to reduce charge transfer resistance. This brought the charge storage capacity (~8.66 mC/cm^2) and charge transfer resistance (~6.3 Ω) into line with requirements for BCI devices. Finally, the stiffness and biocompatibility of PolyGraph were assessed and compared to traditional electrode materials. PolyGraph yielded a tensile modulus of ~92 MPa, *several orders of magnitude lower than metals, and human iPSC-derived neurons grown on the surface of the material exhibited robust axonal extension across the surface. With the graphene and composite materials optimized, electrical stimulation and the fabrication of microelectrode arrays was then investigated. To this end, freestanding electrodes fabricated using custom microneedle molds and by leveraging the material's 3D printability were connected using a bioresorbable collagen-based backing to form a flexible device. This design aims to minimize foreign body response on implantation, while maintaining electrical performance. Finally, to demonstrate the capacity of these PolyGraph microelectrode arrays to interface with neurons, flat PolyGraph electrodes were used to stimulate human neurons in 3D culture in a biomimetic hyaluronic acid-based hydrogel. These data demonstrate the development of biocompatible, flexible and versatile graphene composites for the fabrication of BCI devices, with the capacity to effect neural stimulation and recording, while overcoming key limitations of existing microelectrode designs. Beyond microelectrode applications, PVPGr and PolyGraph composites also have the potential to act as highly conductive, biocompatible materials across a diverse range of applications, such as tissue engineering, implantable electronics, and wearable devices.*

3D Bioelectronic Platforms for Monitoring and Guiding Stem Cell-to-Neuron Development *Achilleas Savva; Delft University of Technology, Netherlands*

Organic electronic materials, notably conducting polymers, enable functional 3D bioelectronic interfaces and bridge the dimensionality mismatch between 2D/static electronics and 3D/dynamic biology. Here, we describe the development of biomimetic 3D platforms for in vitro stem cell cultures by combining organic electronic materials, extracellular matrix materials, and microfabrication techniques. First, we demonstrate the development of electroactive, porous scaffolds based on poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and their integration into an electrode configuration. These 3D bioelectronic devices are used as platforms for 3D human adipose-derived stem cell (hADSC) growth and their differentiation into neuron-like cells. We employed electrochemical impedance spectroscopy to non-invasively monitor these biological processes. Next, we present the development of 3D multifunctional porous scaffolds that exhibit both electrical conductivity and photosensitivity. Water-based solution mixtures of PEDOT:PSS and the semiconducting polymer P3CPT are transformed into 3D scaffolds via freeze-drying. Evidence shows that light can be converted into a bioelectric cue, assisting the differentiation of hADSCs into neurons. Finally, we describe the development of electrically conducting hydrogels and their use in creating 3D neural networks from human induced pluripotent stem cells (iPSCs). We combine PEDOT:PSS with classic hydrogel materials as well as extracellular matrix materials to synthesize biocompatible, conductive, and transparent hydrogels under physiological conditions.

Neuroprotective Therapies with Magnetoelectric Nanodiscs for Parkinsonian Symptoms *Ye Ji Kim, Sharmelee Selvaraji, Emmanuel Vargas, Antoine D. Comite, Polina Anikeeva and Nidhi Seethapathi; Massachusetts Institute of Technology, United States*

Parkinson's disease (PD), the most common neurodegenerative motor disorder in the world, affects 2-3% of the *world's population over the age of 65. PD is characterized by the loss of dopaminergic neurons in the mid-brain region called substantia nigra and symptoms such as resting tremors, bradykinesia, slowed gait, and postural instability[1]. The current gold standard of surgical care for PD patients is subthalamic nucleus deep brain stimulation (STN DBS), which has been shown to bring tremor symptoms under control. However, because of the invasive nature, increased risk, side effects, and exclusive patient criteria for the electrode-based DBS, this treatment option is primarily applied only to late-stage PD patients at an average of 14 to 15 years after diagnosis[2-4]. In this study, we present a promising, less invasive alternative with magnetoelectric nanodiscs (MENDs)-based STN DBS. MENDs are composed of* Fe_3O_4-$CoFe_2O_4$-$BaTiO_3$ *with a double-core-shell structure to generate electric polarization in the piezoelectric shell strained by the magnetostrictive core under biologically benign magnetic fields. The treatment effects of the MEND- and electrode-based stimulations are compared by assessing the motor deficits and locomotion in Parkinsonian mice (6-OHDA mouse model). We have developed deep-learning methods to analyze the locomotion and investigate the characteristic gait properties of the mice with Parkinsonian symptoms. Furthermore, since electrode-based STN DBS potentially delays the progression of PD when performed at an earlier stage[5-8], we examine whether MENDs slow down disease progression possibly with neuroprotective effects. These results indicate that treatment with MEND-based STN DBS for early-stage PD holds the potential to pave the way to novel neuroprotective therapies.*

Biohybrid Thin Film Models of Cardiac Output *John Zimmerman[1], Luke MacQueen[1], James Ikeda[1], Douglas Henze[1], Daniel J. Drennan[1,2], Sean Kim[1], Herdeline Ann Ardoña[1,3], Suji Choi[1], Qianru Jin[1], William Pu[4] and Kevin K. Parker[1]; [1]Harvard University, United States; [2]Texas A&M University, United States; [3]University of California, Irvine, United States; [4]Boston Children's Hospital, United States*

Microphysiological systems (MPS) have recently emerged as a powerful set of tools for modeling cardiac diseases in vitro. Composed of both synthetic and cellular material components, these devices use tissue engineering to mimic the native microenvironment of the heart, thus allowing researchers to recapitulate both healthy and disease cellular phenotypes. This includes systems such as muscular thin films (MTFs) cantilevers, which have previously been used to model features such as cellular contractility and calcium propagation. MPS represent an important steppingstone in improving therapeutic testing, as they can help provide mechanistic insights into disease modeling, while providing reproducible metrics of cardiac performance. The hope is that by building more *realistic in vitro models, these types of systems can help bridge the gap between laboratory and clinical testing, leading to improved clinical outcomes. However, traditionally it has been difficult to obtain similar metrics from both in vitro and in vivo studies, especially in a high throughput manner. For the heart, this includes cardiac output, which serves as a key clinical metric for assessing the health of the heart. To address this challenge, here we demonstrate how existing MTF platforms can be adapted to serve as a simplified model of the left ventricle's native myocardium, In vivo, the left ventricle's myofibril architecture is organized in helically, creating a twist-based mechanism to efficiently pump blood to the remainder of the body. To model this process, here we formed an angled tissue engineered cantilever model which could efficiently pump the surrounding fluid media. Envisioning that these thin films represent a transmural section of ventricular endocardium, we then measured the net flux of media occurring transverse to the longitudinal axis of the cantilever. By measuring the resulting fluid flows using particle imaging velocimetry (PIV), we then quantified how much thrust these biohybrid systems were capable of generating, using this as a basic analog to cardiac output. As the resulting cardiac outputs were angle dependent, we then used both computational simulation, and experimental testing to determine which angles produced the maximal output. Overall, by incorporating fluid-dynamics with a previously known high throughput screening model (e.g. MTFs), this study can help bridge the gap between clinical and in vitro measurements. while suggesting that angled tissue engineered thin films may serve as a simplified platform for studying key features of cardiac health and disease in the laboratory.*

3D Printed Exo-Friendly ECG Sensor Featuring Dry-Attachable Design *Yiting Chen, Jake Non and Woo Soo Kim; Simon Fraser University, Canada*

The healthcare of elderly individuals is an increasingly crucial focus within the global research community. A key tool for monitoring heart health is the electrocardiogram (ECG) sensor, enabling swift diagnosis of cardiac conditions. Current ECG technology often demands the application of electrolyte gel beforehand, leading to messy test areas, complex usage procedures, and time wastage in healthcare settings. Moreover, the reliance on silver/silver chloride electrodes, known for their conductivity and reliability, poses cost and environmental challenges due to mining and disposal processes. Additionally, single-use electrode contacts contribute significantly to landfill waste. There exists a pressing need for a viable alternative to silver-based contacts that integrates similar functionality, swift application, and sustainability. Introducing an eco-friendly origami-structured ECG sensor solution—this design offers dry attachability for clean and rapid use in testing areas. The origami structure reduces mechanical stress on electrical contacts, ensuring precise measurements through repeated usage. The printable polymer filament in the origami structure provides mechanical durability and prolonged functionality, enhancing the sensor's longevity. By utilizing biodegradable materials like carbon, cellulose, and shellac, our sensor upholds high electrical conductivity in an eco-friendly and cost-efficient manner. Overall, this user-friendly and sustainable ECG sensor presents a swift and accurate heart monitoring solution tailored to meet the needs of the aging population.

Nanotechnological Approach for Sustainable Agriculture—Plant Health Monitoring and Efficient Delivery to Plant System *Seonyeong Kwak; Seoul National University, Korea (the Republic of)*

Nanotechnology is an important driver in the agri-tech revolution. It promises more sustainable and efficient agricultural systems by providing methods for managing stress and delivering necessary inputs more efficiently. This presentation will discuss plant health monitoring nanosensors and briefly introduce our current efforts to enhance plant engineering efficiency at the end. Plants produce chemicals to activate defense systems when they encounter stress. Therefore, identifying these stress-related plant endogenous molecules can help us recognize stress conditions and develop strategies to prevent disease development through timely management. Recently, we have developed a nanosensor platform for the optical monitoring of stress-related plant molecules in living plants. The sensor can detect the onset and type of plant stress in real time using surface-enhanced Raman spectroscopy (SERS) technology. By attracting plant signaling molecules to the silver nanoshell surface using polymers, the sensor enhances Raman scattering of the analytes by more than 10^7 *times. The nanosensor was designed to be placed in a specific location depending on the plant signals being monitored, and it can be adjusted to be optically active in the near-infrared region to minimize interference from plant chlorophyll fluorescence. Under abiotic or biotic stress, the nanosensor can successfully monitor multiple stress-related molecules, indicating the possible onset of plant stress. This plasmonic nanoprobe platform will guide us in understanding plant signaling better under various environmental stresses and contribute to sustainable agriculture through improved management practices.*

11:30 AM SB01.04.02

Uncovering the Neuromodulatory Potential of Organic Semiconducting Oligomers in Hydra Vulgaris *Martina Blasio[1], Silvia Santillo[1], Giuseppina Tommasini[2], Mariarosaria De Simone[2], Vittorio De Felice[1], Claudia Zenna[1], Giuseppe Coppola[1], Daniele Mantione[3], Angela Tino[1], Eleni Stavrinidou[4] and Claudia Tortiglione[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]CSIC-Universidad de Zaragoza, Spain; [3]University of the Basque Country, Spain; [4]Linköping University, Sweden*

Functional materials offer a valid alternative to traditional techniques for modulating neuronal function. By observing the behavioural patterns induced by neuroactive substances in simple animal models, valuable clues can be obtained on their modes of action and their potential to unlock new therapeutic applications. In this context, the nervous system of the small freshwater polyp Hydra, organized as a net of hundreds to thousands of neurons, provides a manageable yet complex framework to uncover fundamental interactions between neurons and neuromodulatory compounds, avoiding the issues raised by more complex nervous systems. The organic semiconducting oligomer ETE-S has already been shown to act as neuromodulator in Hydra vulgaris inducing precise behavioural responses. Here we present the results obtained by challenging Hydra with other thiophene-based trimers [2]. Through electrophysiological recordings and functional calcium imaging we expanded the knowledge on the neuromodulating effects of this class of semiconducting oligomers. These findings have the potential to shed light on fundamental chemical and physical phenomena in organic bioelectronic interfaces for neuromodulation, ultimately paving the way to innovative methods that could accelerate the development of this technology for clinical applications.

11:45 AM SB01.04.03

Large Polyurethane/PEDOT: PSS Porous Electrodes for Real-Time Monitoring of Ion-Driven Communication in Filamentous Cyanobacteria *Francisco Cotta[1], Diogo Correia[1], Raquel Amaral[1], Felipe Bacellar[1], Peter Zalar[2] and Paulo R. Rocha[1]; [1]Universidade de Coimbra, Portugal; [2]Holst Centre, Netherlands*

Cyanobacteria play a vital role in shaping evolution and ecological transformation throughout earth's history. Over *the last decades humanity has witness an increase in frequency and magnitude of poor water quality events associated with cyanobacteria strains capable of producing Taste and Odour (T&O) metabolites and toxins making them a global concern for human health and the drinking water industry.*

In this talk we will show that the T&O producer Oscillatoria sp. a debilitating cyanobacteria species for the drinking water industry demonstrate electrical excitability, which is mostly governed by diffusion of Ca^{2+} *ions. The breakthrough is realized by means of an ultra-sensitive electrophysiology system based on porous polyurethane (PU) foams dip-coated with poly (3, 4-ethylenedioxythiophene): polystyrene sulfonate (PEDOT: PSS) exploiting ultra-large-area electrodes of 199* cm^2*, which maximizes the double-layer capacitance and concomitant detection sensitivity. The measured paracrine signal of Oscillatoria sp. results from the sum of all individual cell contributions and scales with electrode area, hence indicating correlation with productivity and biomass. We further suggest that when Oscillatoria sp. operate cooperatively, the signal appears as intra- and inter-filamentary* Ca^{2+} *Waves (benchmarked with fluorescence probes) which are suppressed with the specific ion channel inhibitor gadolinium chloride. Overall, the analysis and hypothesis proposed pave the way for preventative water quality management through quantitative electrogenic assessments of* Ca^{2+} *signalling in cyanobacteria populations.*

Electrifying Biomaterials—Protein-Based Polymers as a Test Bed to Explore Energy and Charge Transfer and as Functional Electronic Materials *Nadav Amdursky[1,2]; [1]The University of Sheffield, United Kingdom; [2]Technion–Israel Institute of Technology, Israel*

I will discuss the use of proteins to make large-scale free-standing biopolymers capable of supporting charge transport. Our inspiration is the natural role of proteins in mediating charges. Our approach is based on identifying waste proteins available in bulk quantities from raw feedstocks and using them in a green polymerization to create conductive biopolymers. We show that we can form large-scale highly-elastic polymers on the macroscale. Due to the water uptake of our protein-based polymers and the presence of oxo-amino-acids, our protein-based polymers show excellent proton conductivity. Using various post-polymerization modifications (PPM) and physical modifications allows us to enable electronic transport and optoelectronic properties. We can achieve it by: 1) binding electron mediating groups into the protein matrix via molecular doping; 2) binding long-lived chromophores into the protein matrix that enables to harvest energy; 2) using PPM, where we can chemically decorate with common conjugated mono-/oligo-/poly-mers used in the conductive polymers field, thus making a mixed ionic-electronic conductor. From an application point of view, our new protein-based biopolymers have several attractive properties; they are environmentally friendly, they possess inherent biodegradability and biocompatibility, they have good mechanical properties, and their formation obeys most principles of green chemistry. Moreover, due to the low price tag of our chosen proteins and the simple formation process, the cost of the biopolymers is very low. Currently, our main targeted application for our new family of polymers is for biological interfaces, and we show their use in biosensing applications, while other lines of applications include the use of our biopolymers for biomedical and energy applications.

1:45 PM SB01.05.02

Hydrovoltaic Properties of Self-Assembled Protein Nanowires *Joffrey Champavert[1], Julien Hurtaud[1], Patrice Rannou[2] and Vincent Forge[1]; [1]CEA Grenoble, France; [2]LEPMI (CNRS/Grenoble-INP/UGA/USMB), France*

Recently, a new, versatile, and promising source of renewable energy from water has been proposed: hydrovoltaics [1-3]. This emerging technology makes it possible to generate energy directly from the interaction between water vapour and functional nanomaterials. Due to the power output (a few tens of $\mu W/cm^2$), potential applications are mainly in low-consumption electronics, such as sensors and IoT devices. Although hydrovoltaics is garnering significant attention, the underlying mechanisms remain a topic of debate [4].
In this study, we demonstrate the potential use of self-assembly proteins, i.e. amyloid fibers, as hydrovoltaic biogenerators. These amyloid fibers, composed of protein nanowires with a diameter of 10-20 nm and an average length of several μm, are non-pathological. The hydrovoltaic properties of these bionanowires have been observed in various forms: as a film or as a macro-wire. In the case of macro-wires form, a potential difference forms naturally and spontaneously when the amyloid fibers align and dry. In fact, an open-circuit voltage (OCV) appears when humidity exceeds 40% relative humidity (RH). This OCV is directly correlated to the humidity levels ans increases as the humidity rises. For a single macroscopic wire, an OCV of 1.5 V was recorded at 85% RH.
In the case of the film form, we demonstrated hydrovoltaic properties using protein films placed between two glassy carbon electrodes, taking advantages of a gradient of immobile charges. Electrochemical modifications are required on one of the electrodes (oxidation at the anode) to establish this gradient. Water oxidation at the anode induces chemical changes in the protein side chains, leading to the appearance of an OCV of around 0.4 V at 85% RH and a power output of around 50 $\mu W/cm^3$. In both cases, water adsorption on the material's surface is crucial and determines the moisture content required to generate electricity.
Our work paves the way for further advancements in the 'fusion' of desirable features, bringing the concept of a true biogenerator for electronics closer to reality.

Photosynthetic Bacteria Do It Better *Rossella Labarile[1], Danilo Vona[2], Matteo Grattieri[2], Paolo Stufano[1], Melania Reggente[3], Fabian Fischer[4], Ardemis Boghossian[3] and Massimo Trotta[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Bari Aldo Moro, Italy; [3]École Polytechnique Fédérale de Lausanne, Switzerland; [4]University of Applied Sciences and Arts, Switzerland*

One of the most investigated photosynthetic anoxygenic microorganisms [1] is the purple non-sulfur bacterium Rhodobacter (R.) sphaeroides, recently reclassified as Cereibacter sphaeroides [2], belonging to the family Paracoccaceae in the class α-proteobacteria. We are interested in exploiting molecules, enzymes, isolated inner structures and the whole metabolically active cells, as active components in photoconversion processes to be exploited in optoelectronic devices, photoelectrochemical cells, and sensory systems with a particular focusing on the interfaces of all these components with electrodes.
Based on the promising evidences of their photo responses, we explore the developing of biohybrid

photoelectrochemical systems exploiting adhesivity and conductive properties of polydopamine (PDA) [3] starting from the biocompatibility of the polymer and its monomer [4] to the assemble of conductive coatings as biotic-abiotic interfaces in biohybrid photoelectrochemical devices by encapsulating of the bacterial cells of R. sphaeroides [5] and R. capsulatus [6] to ensure electronic communication.
Our group is also involved in other applications that span from photosynthetic bio-inspired sunlight pumped laser to biohydrogen generation. An account of these running research projects will be also presented.

This work was funded by the Fonds National Suisse de la Recherche Scientifique, project Phosbury - Photosynthetic bacteria in Self-assembled Biocompatible coatings for the transduction of energy - (Project Nr CRSII5_205925/1)

Observation of Six Orders of Magnitude Photoconductivity in DNA-MoS_2 Hydrogel Nano-Biocomposite

Chandan Biswas[1,2]; [1]The University of Texas at Austin, United States; [2]Sungkyunkwan University, Korea (the Republic of)

The advancement of bio-optoelectronic materials promises innovative systems and devices that can enable advanced optical bio-sensing, imaging, diagnostics, and treatment technologies. The materials choice and integration approach of an appropriate nanomaterial into a biomaterial matrix remains an open question towards achieving highly photoconductive nano-biocomposite materials. A nano-biocomposite film with ultrahigh photoconductivity remains elusive and critical for bio-optoelectronic applications. A uniform, well-connected, high-concentration nanomaterial network in the biological matrix remains challenging to achieve high photoconductivity. Wafer-scale continuous nano-biocomposite film without surface deformations and cracks play another major obstacle. In recent years, deoxyribonucleic acid (DNA) has emerged as a promising material for the development of hydrogels. However, natural DNA hydrogels are weak in mechanical strength and electrical conductivity due to their negatively charged phosphate backbone. However, poor charge transport and limited device performance were often observed due to an inadequate integration approach of 2D nanomaterials (such as MoS_2) in the DNA matrix. An appropriate integration approach of the well-connected MoS_2 network with a high

concentration in the DNA matrix is deemed necessary for high-performance DNA-MoS_2 nano-biocomposites. Here we observed ultrahigh photoconductivity in DNA-MoS_2 nano-biocomposite film by incorporating a high-concentration, well-percolated, and uniform MoS_2 network in the ss-DNA matrix. This was achieved by utilizing DNA-MoS_2 hydrogel formation, which resulted in crack-free, wafer-scale DNA-MoS_2 nano-biocomposite films. Ultra-high photocurrent (5.5 mA at 1 V) with a record-high on/off ratio (1.3×10^6) was observed, five orders of magnitude higher than conventional biomaterials ($\sim 10^1$) reported so far. The incorporation of the Wely semimetal (Bismuth) as an electrical contact exhibited ultrahigh photoresponsivity (2.6×10^5 A/W). Such high photoconductivity in DNA-MoS_2 nano-biocomposite could bridge the gap between biology, electronics, and optics for innovative biomedicine, bioengineering, and neuroscience applications.

Functionalized Polar Polythiophenes for Electroactive Cellulose Composites *Renee Kroon; Linköping University, Sweden*

Conjugated polymer:cellulose composites have been used for a multitude of hybrid electronic applications such as energy storage, thermoelectrics and pressure sensors. The electroactive component must rely on water-processability to create intimate mixtures with cellulose or facilitate the ingression of the electroactive component into the cellulose scaffold for optimal mechanical and electronic performance. For most devices, the electroactive component needs to be fixated to resist exposure to an aqueous environment, which otherwise leads to delamination or dissolution.
We recently have demonstrated that incorporating physical crosslinking moieties in polar polythiophenes is a tool to both reinforce these materials as well as tune active swelling when operating in OECT's. In this talk, we will present how polar polythiophenes can be enhanced with carboxylate functional groups, and what properties are attainable with such materials. By functionalizing polar polythiophenes with carboxylate groups, we can make them water-processable, create hybrid materials with cellulose derivatives through induced hydrogen bonding, and are able to recover the separate components at end-of-life.

3:45 PM SB01.06.03
Exploring Natural Polar Molecules Applicable to Organic Electronics *Kouki Akaike[1], Takuya Hosokai[1], Yutaro Ono[1,2], Ryohei Tsuruta[2] and Yoichi Yamada[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]University of Tsukuba, Japan*

The drive for sustainability in organic electronics is imperative to mitigate the adverse environmental and health impacts associated with the disposal of organic devices [1]. Achieving biodegradability and biocompatibility in electronic devices is a solution to reducing electronic waste. From this point of view, employing natural molecules as device components is straightforward because biomaterials can be carbon neutral and disposable in an eco-friendly way. A goal of pursuing sustainability of organic devices is the replacement of fossil-fuel-derived electronic materials with bio-based counterparts as much as possible, ideally without deteriorating device performances, which will save the use of fossil fuel and lower the environmental impact of the disposed devices.
The abovementioned motivation prompts us to explore natural molecules applicable to organic devices. As the first step of replacing device components with biomaterials, this study investigates two natural molecules

applicable to an electrode modifier and self-assembled electret [2], where the formation of the dipole layer and the ability of spontaneous orientation polarization are necessary, respectively. The first example is the application of caffeic acid (CfA), a polar phenylpropanoid, to a surface modifier for a hole-injection electrode. We demonstrated that CfA molecules formed a dipole layer at electrode interfaces by exposing the carboxyl group to the outermost surface by vacuum-deposition or spin-coating. The preferential orientation of CfA molecules increases the work function of various electrodes used in organic electronics by up to 0.7 eV [3]. Consequently, single-layer devices incorporating the CfA modifier show improved hole injection in forward bias by a factor of 10^1*-*10^2*[3].*

We are also seeking natural molecules that decrease the work function of electrodes. In the course of that study, baicalein, a flavonoid compound found in natural products, was found to exhibit a giant surface potential (GSP) exceeding 5500 mV at a film thickness of 100 nm with a slope of 57 mV/nm [4]. This performance is comparable to the well-known organic semiconductor tris(8-hydroxyquinoline)aluminum(III) (Alq_3*). Additionally, baicalein films exhibit superior photostability compared to* Alq_3 *films [4].*

In this contribution, we will discuss the mechanisms driving the preferential orientation of CfA and spontaneous orientation polarization of baicalein based on spectroscopic analyses.

Partially Reduced Graphene Oxide as a Promoter of Thrombin Activity and Fibrinogen Clot Formation

Jennifer Gao[1,2], Emily Zhang[3,2], Rebecca Isseroff[2] and Miriam Rafailovich[2]; [1]Shanghai Pinghe School, China; [2]Stony Brook University, The State University of New York, United States; [3]Roy C. Ketcham High School, United States

Approximately 40% of trauma-related deaths worldwide are due to bleeding, highlighting the need to create a topical dressing that would enhance the rapid clotting of deep cuts and/or wounds. Reduced graphene oxide has been studied extensively for its electronic properties; partially reduced graphene oxide (pRGO) contains fewer oxygen-containing functional groups than graphene oxide (GO), which increases its electrical conductivity but maintains some of the functional groups that still keep it water-soluble. Previously it was shown that pRGO enhances the ability of the enzyme microbial transglutaminase to crosslink gelatin. Since thrombin is an enzyme that catalyzes fibrinogen clot formation, we sought to examine whether pRGO would also enhance thrombin's enzymatic activity and speed the formation of clots.

A 1 mg/mL GO solution was reduced with sodium borohydride (NaBH4) to obtain 10, 12, 15, 20 and 25 mM reductions of pRGO. Fibrinogen (4 mg/ml) was clotted with thrombin (1 u/ml) and a thromboelastograph quantified the viscoelastic properties of the sample including the R value, which is the time it takes to begin forming the clot to an amplitude of 2mm; the angle of the tangent to the clotting curve, which indicates the rate of clot formation; the time it takes to fully form the clot; and the maximum amplitude (MA), which shows the strength of the clot.

The addition of pRGO significantly enhances thrombin's activity in all aspects. Although GO improves the initial clotting rate (indicated by the tangent of the angle) by 17%, pRGO boosts it by 63%. Whereas GO reduces overall clotting time by 27%, pRGO reduces the overall clotting time by 60% . However, compared to the control, pRGO improves the maximum amplitude of the clot by 71%, while GO decreases it by 6%.

Testing the various reduction degrees of prGO demonstrated that 20mM exerts the most significant enhancement, increasing the initial clotting rate by 147%, enhancing the clot strength by 154%, and decreasing the overall clotting time by 60%. To derive the optimal reduction degree for a pRGO promoter, the mean of the extremums of *the values as far as angle to the curve, maximum amplitude, and total clotting time for each pRGO reduction was determined to be 19 mM.*

Halving the amount of thrombin in the control to 0.5 u/mL results in roughly half the initial clotting rate as compared to the full 1 u/mL thrombin control. However, halving the amount of thrombin while adding 20 mM pRGO nearly triples the initial clotting rate of halved thrombin and even speeds the clotting rate 56% faster than the full 1 u/mL thrombin control.

Increasing the amount of pRGO while keeping the amount of thrombin constant at 0.75 u/mL was shown to progressively increase the angle of the tangent (thereby decreasing the initial clotting time) but eventually reached a maximum plateau.

Hence, partially reduced graphene oxide shows significant promise as a promoter of thrombin's activity to clot fibrinogen, with far-reaching implications for healthcare as prGO's ability to enhance thrombin's clotting efficiency could be a major breakthrough in managing severe wounds and improving survival rates for trauma patients.

Mechanism of Phenylalanine-Induced Charge Transport Enhancement in PEDOT:PSS Films *Ramesh Adhikari, Jonathan Van Magness, Divyansh Chamria and Ege Kutlubas; Colgate University, United States*

Conducting polymer complex poly(3,4-ethylenedioxythiophene) doped with poly(styrenesulfonate) (PEDOT:PSS) is used for a wide range of electronic applications due to ease of processability, water dispersibility, chemical stability, and commercial availability. The PEDOT:PSS complex is composed of hydrophobic conducting PEDOT globules enclosed by hydrophilic nonconducting PSS strands. Therefore the charge transport through a PEDOT:PSS is limited by charges having to hop over PEDOT globules separated by PSS. This results in lower conductivity of PEDOT:PSS compared to other conducting polymers. Various groups have demonstrated that the use of polar molecules such as ethylene glycol, dimethyl sulfoxide, and sulfuric acids as dopants that screen the charge interaction between PEDOT and PSS units and therefore induce phase separation to create PEDOT-rich regions which significantly improves the transport through PEDOT:PSS films. Here, we will present our finding that introducing the natural aromatic amino acid Phenylalanine in PEDOT:PSS can improve the conduction while increasing the transmittance of the resulting film [1]. We will present our study on the charge transport mechanism on these films based on DC and AC characterization, optical spectroscopies, SEM, and conducting probe AFM (C-AFM) to elucidate the relationship between film morphology and charge transport in these composite films. The use of bioderived materials such as amino acids along with conducting polymers to create transparent conducting composite films could open up avenues for developing and integrating bio-based materials in future electronics, help improve the environmental footprint of electronic devices, and potentially allow for the development of materials with a higher degree of biocompatibility for their application in bioelectronics.

Highly Stretchable Dynamic Hydrogels for Next Generation Bioelectronics *Stephen J.K. O'Neill, Jade A. McCune and Oren A. Scherman; University of Cambridge, United Kingdom*

Addressing the mechanical mismatch between biological tissues and traditional electronic materials has long posed a challenge in bioelectronics and soft robotics. Recent advancements in supramolecular polymer networks (SPNs) present a promising solution, offering materials that harmoniously interface with biological tissues on account of their softness, stretchability, and high-water content. Herein, an electrically conductive SPN that not only mimics the mechanical properties of biological tissue, but also simultaneously exhibits electronic and ionic conductivity, will be introduced. Through rational guest design, ultrahigh-affinity host–guest ternary complexes with binding affinities exceeding 10^{13} M^{-2} are accessed and embedded as dynamic crosslinks within polymer networks to achieve tissue-mimetic properties. The SPNs demonstrate remarkable stretchability (>500%), rapid *self-recovery, and high-water content (>84%), making them ideal for fabricating intrinsically stretchable bioelectrodes capable of precise electromyography monitoring.*

In parallel, the development of supramolecular poly(ionic) networks that extend the capabilities of hydrogel-based devices for soft robotics will be outlined. These networks achieve ionic conductivities up to 0.1 S cm^{-1} while maintaining extreme stretchability (>1500%) and compressibility (>90%). The introduction of dynamic crosslinks facilitates superior inter-layer adhesion, paving the way for the creation of multi-layer tissue-mimetic devices including a stretchable, stand-alone hydrogel power source. Together, these innovations represent significant progress toward the next generation of bioelectronic interfaces and soft robotic systems, offering new opportunities for human–machine interfacing and soft power generation.

Unraveling the Mechanisms of Biogenesis of Thiophene Based Microfibers *Claudia Tortiglione; Consiglio Nazionale delle Ricerche, Italy*

The unmatchable capability of living cells to fabricate complex structure starting from simple building blocks offers new paradigms to seamlessly integrate new electronic structures into the living matter, creating new hybrid devices. We have previously shown the capability of both cells and Hydra to produce fluorescent and conductive interface embedded into the animal tissues, starting from thiophene-based compounds, demonstrating the feasibility to biofabricate novel biocompatible and conformable bioelectronic interfaces. Here we show that the potential of biofiber production is broadly valid in other biological systems, and performed a systematic chemical engineering approach to identify the chemical groups involved in the spontaneous fiber assembling in vivo. Several approaches were followed to decipher the biosynthetic process and to characterize these conductive materials, whose potential as innovative material for electrical devices and therapeutics will be presented and discussed.

SESSION SB01.07: Poster Session: Frontiers of Electrified Biomaterials

Soft Folding Skeletal Muscle Biobot Fabricated with a Conducting Hydrogel, PEDOT:PSS *Maheera Bawa; Massachusetts Institute of Technology, United States*

Muscle for actuation in robotics, or biohybrid robotics, is a growing field combining biological and synthetic materials in centimeter-scale soft robots. While prior studies have leveraged the contraction of 2D cardiac monolayers to power swimming robots, culturing skeletal muscle in this form has proven challenging and has led to delamination of cells from their substrates due to the passive and active tension forces generated by skeletal muscle fibers during development and stimulated contraction. Given that skeletal muscle offers significant advantage over cardiac muscle in robotics, such as on/off control and adaptation to gain-of-function (exercise) and loss-of-function (damage) cues, there is a need to develop methods to control skeletal muscle contraction in 2D formats. We have developed a method for culturing C2C12 murine myoblast-derived muscle on a conducting polymer hydrogel, namely, poly(3,4-ethylenedioxythiophene): poly(styrene sulfonate or PEDOT:PSS) coated with extracellular matrix hydrogels known to promote muscle differentiation, Matrigel and fibrin. These conductive hydrogels exhibit robust mechanical and electrical properties and enable targeted stimulation of skeletal muscle. Unlike previous studies in which electrical stimulation triggers contraction of entire tissues, our platform enables the control of muscle activation precisely and spatiotemporally in specific regions of the gel substrate. Our method of differentiating skeletal muscle on conductive substrates can be used as a building block to create complex, controllable soft robots.

Since cell cultures with direct cell seeding on PEDOT led to minimal cell growth, we have developed a method to layer fibrin gel on top of PEDOT:PSS. PEDOT beams were sterilized and placed in growth medium for 1 day to drive swelling and protein adsorption that functionalized the gel surface for the binding of fibrin. Post swelling, a solution of 8mg/ml fibrinogen mixed with serum-free media, mixed with 4ul of thrombin was added to the PEDOT beams and left to polymerize with a weighted stamp to produce a thin gel layer. After the bilayer was created, 500,000 cells per well were seeded. After 2 days, growth medium was switched to differentiation medium and in 4 more days they were optically/electrically stimulated. Different concentrations of PEDOT:PSS were also tensile tested for stiffness prior. For concentrations of 2.3%, 3.5%, and 7%, preliminary Young's Moduli were measured in the range of 200-800 kPa.

Light vs electrical stimulation of optogenetic cells shows that both methods generate muscle contraction, indicating our ability to grow contractile muscle on PEDOT and maintain them in culture. Leveraging our open-source computational framework to map muscle displacement in 2D, we saw no significant difference in contractile strain (6-7%) between optical/electrical stim, indicating no negative effects of PEDOT on muscle function. While preliminary data shows no significant difference in contractility between stimulation setups, as might be expected given the conductivity of PEDOT, we predict studies where we align muscle fibers unidirectionally via grooved stamps on fibrin/PEDOT, and electrically stimulate directly through PEDOT, will provide a more controlled comparison. Concurrent with experiments, we've generated computational models for rapid in silico iteration of biohybrid robot design. Experimentally determined values of beam geometry, PEDOT/fibrin mechanical properties, and muscle force were input into our custom model. In our current configuration, the muscle layer applies a unidirectional shear force of 0.7 mN to the bilayer beam, generating a maximum deflection of 700 um, corresponding to about 5% strain in the muscle layer. This shows that the conducting substrate allows for significant beam deflection via muscle contraction, showcasing our platform's ability to create soft robots powered by 2D skeletal muscle monolayers.

SB01.07.02

Nanostructured Plasmonic Biosensors Incorporated with Graphene for Early Diagnosis of Alzheimer's Disease *Juiena Hasan and Sangho Bok; University of Denver, United States*

Alzheimer's disease (AD) is the most common form of elderly dementia and for early diagnosis, it is critical to *utilize very sensitive biosensors. Various technologies have been employed for ultrasensitive sensors including plasmonic sensors. The goal of this research is to further improve the sensitivity of plasmonic sensors for the detection of biomarkers such as tau-protein and amyloid-beta 42 in very low concentrations for early diagnosis of AD and dementia.*

The plasmonic sensors in the research utilize various structured Au nanoparticles including star-shaped Au nanoparticles (S-Au) and graphene oxide (GO). S-Au was synthesized by reducing HAuCl4 with hydroxylamine solution in high alkaline condition. Anti-tau-protein antibodies acted as the primary antibody with two secondary antibodies: an Alexa Fluor 594 (AF-594) labeled antibody and a S-Au labeled antibody. Tau-protein was labeled with graphene oxide by the carbodiimide conjugation. GO-labeled tau-protein (GO-tau) was used as a quencher. The competitive immunoassay was performed in three steps: (1) the three antibodies were mixed together to form plasmonic-enhanced fluorescence conjugates (S1); (2) GO-tau and unlabeled tau-protein (or the patient samples) were mixed together (S2); (3) S1 and S2 were mixed. The mixture was observed for fluorescence changes over various periods of time.

The shape of S-Au (diameter: 60±5nm) was highly dependent upon the pH of the reaction. The star shape was caused by a rapid reduction at a high pH causing non-spherical particle formation. Its absorption showed a broad peak at 610nm. The fluorescence conjugate with three antibodies demonstrated strong fluorescence enhancement from AF-594 due to S-Au with 10.5 folds fluorescence enhancement compared to the fluorescence of AF-594 without S-Au. The fluorescence conjugate was mixed with GO-tau (1:1 ratio) and different concentrations of unlabeled tau-protein were added. Because the GO-tau and unlabeled tau-protein competed for the primary antibody in the fluorescence conjugate, the fluorescence was less quenched with more unlabeled tau-protein. In other words, the fluorescence increased when the concentration of the unlabeled tau-protein increased. This research demonstrated promising initial results and detection limits of tau-protein will be studied. Multiple biomarkers, including amyloid-beta 42, will be studied in future research.

SB01.07.03

Fabrication and Characterization of Multidimensional PLA-BaTiO3-MXene Electroactive Composites—Novel Additive Manufacturing for Biomedical Sensing Devices

Jelizaveta Chern[1], Derek Xiong[1], Aidee Gonzales[1], Saquib Ahmed[2,2] and Sankha Banerjee[1,3]; [1]California State University, Fresno, United States; [2]Buffalo State College, United States; [3]University of California, Davis, United States

Additive manufacturing has emerged as a powerful tool for materials fabrication in semiconductor and biomedical industries. This study explores an innovative process for the customized fabrication of these multifunctional composites, focusing on the development of multidimensional electroactive structures for biomedical implantable and wearable sensing devices. The research investigates the fabrication of two- and three-phase multidimensional polymer matrix-based electroactive composites, specifically PLA (3D) -BaTiO3 (0D inclusions) - MXene (2D) systems. These custom architectures are designed to enhance the sensitivity and functionality of lab-on-wafer devices.

The composites are characterized using a comprehensive suite of techniques. Profilometry is employed to assess surface topography and thickness uniformity. Piezoelectric measurements quantify the electromechanical response of the composites, crucial for their application in sensing devices. Impedance spectroscopy is utilized to analyze the electrical properties across a wide frequency range, providing insights into charge transport mechanisms within the multidimensional structures. The integration of 2D MXene structures within the 3D PLA matrix, complemented by BaTiO3 nanoparticles, is expected to yield superior electroactive properties compared to traditional composite systems. This approach paves the way for the next generation of highly sensitive, flexible, and biocompatible sensing devices for medical and wearable applications.

SB01.07.04

Development of Genetic Engineering Tools for The Iridescent Bacteria Cellulophaga Lytica *Shreya Fadanavis, Jillian Pompei Wilson, Janicemar Rullan, Nathaniel Keighley, Mehul Puri, Jordan E. Pagliuca and Milana C. Vasudev; University of Massachusetts Dartmouth, United States*

The study of Flavobacteriacae, a genus consisting of gram-negative, rod-shaped bacteria, has garnered increased interest, particularly in the field of synthetic biology, for their ability to break down complex organic matter as well as their gliding motility mechanisms. The primary focus of our group is to deepen our understanding of one such bacterium, Cellulophaga lytica (C. lytica). Native to the rocky shores and mudflats of Costa Rica, this marine bacterium is capable of withstanding extreme variations in light, temperature, and salinity. One distinct feature of C. lytica is its unique, glitter-like, iridescence, which is believed to be due to the bacterium's ability to self-assemble into microstructures that reflect light at different wavelengths. The strain utilized in this project displays predominantly green iridescence, but red, orange, and purple can be observed as well. The genetic mechanisms governing displayed iridescence, however, remain understudied. It is suspected a specific cassette of genes (gld) is responsible for this observation. This study intends to display whether deletion of the GldB gene in C. lytica can disrupt the formation of uniform colonies, impacting biofilm formation and allowing us to control the iridescence patterns of the bacteria. This gene of interest was chosen for its known role in encoding proteins associated with gliding motility and cellular membrane morphology. If successful, this research will enable the construction of a genetic engineering platform using synthetic biology techniques that can disrupt, control or modify the gliding motility of C. lytica. Being able to harness this mechanism will allow for the incorporation of C. lytica into novel iridescent biomaterials and colorimetric biosensors for future military applications including soldier protection, promoting operational readiness and efficiently executing operations. This genetic toolbox could also be optimized for other marine bacteria as well.

Although biparental conjugation was also attempted, preliminary findings from our team support the use of electroporation as a transformation mechanism to deliver extraneous genetic material into C. lytica to interact with gldB. Testing and standardization of electroporation conditions were conducted with shuttle vectors pYT172 and pYT247, both of which contain the gene for erythromycin resistance (ermF). The growth of the C. lytica colonies on media plates supplemented with erythromycin was confirmed through sequential colony PCR and gel electrophoresis. Future modification of these shuttle vectors will be accomplished through Gibson/Golden Gate assembly, introducing an inducible promoter to regulate expression of a reporter protein (GFP). Alternatively, we also aim to design a suicide vector for target gene knockout of GldB. Essentially, by modulating genetic products that influence cellular communication, protein expression, and adhesion, controllable assembly and iridescence can be demonstrated in our model bacteria, C.lytica.

This foundation allows for further exploration into the feasibility of synthetic spatial patterning of the flavobacterium via 3D-bioprinting technology. Currently, our team is investigating the efficacy of exponential-phase liquid cultures encapsulated within varying concentrations of gelatin and sodium alginate as a form of “bioink”, leading to the formation of hydrogels upon crosslinking with 100 mM calcium chloride. Thus far, the idealized parameters for bioprinting and crosslinking while maintaining maximum cell viability have been achieved. Future endeavors aim to optimize the iridescence visibility within the hydrogel via genetic modification and altering precursor component ratios, unpacking the physiochemical characteristics of the hydrogel itself, and producing increasingly complex structures that are capable of being mobilized for use as colorimetric biosensors.

SB01.07.05

Sepia Melanin Bio-Inks on Paper-Based Laser-Induced Graphenic Electrodes for the Low-Cost, Sustainable Electrochemical Detection of Dopamine *Joaquin Isasmendi[1], Marina Castrillo Fernández[1,2], Lucien Weiss[1], Raphael Trouillon[1] and Clara Santato[1]; [1]Polytechnique Montréal, Canada; [2]Institut National des Sciences*

Appliquées, France

Electrochemical methods allow for rapid, high-sensitivity detection of neurotransmitters. Unfortunately, the redox activity of dopamine, and many other neurotransmitters, can trigger polymerization reactions that are associated with the fouling of most electrode materials. Fouling degrades sensor performance by passivating its surface, which decreases signal quality and strength with sensor use. To mitigate this, novel antifouling coatings are being investigated [1].

With the aim to find antifouling coating materials for the in vitro detection of dopamine, we considered Sepia melanin, an ubiquitous, bio-sourced eumelanin pigment that can be extracted from the ink of the common cuttlefish (Sepia Officinalis). Sepia melanin, made up of 200 nm-sized granules, has been studied for its biocompatibility [2] and sustainable electronic applications [3]. It results from the polymerization of (5,6)-dihydroxyindole and (5,6)- dihydroxyindole-2-carboxylic acid building blocks, which makes its molecular structure analogous to that of polydopamine. We hypothesize that this chemical similarity could limit electrode fouling by facilitating the reduction of oxidized dopamine and minimizing its polymerization at the surface of the electrode.

Laser-induced graphenization (LIG) of filter paper is a straightforward technique that can yield high-performance paper-based electrodes for low-cost bioanalytical quantitation [4]. While our ongoing research focuses on the antifouling properties of Sepia melanin coatings for in vitro sensing of neurotransmitters with live cell cultures, preliminary voltammetric data indicate that LIG paper electrodes, modified using the Sepia melanin, have an increased faradaic response to multiple analytes in solution (ruthenium hexaamine, dopamine) when compared to the unmodified LIG paper electrodes. We hypothesize that the Sepia melanin nano-granules enable redox cycling at the graphene-Sepia melanin interface, thanks to high electron transfer speeds between the analyte and the Sepia melanin.

In Situ Soft Plant Wearable System for Long-Term and Quantitative Monitoring of Live Plant Stresses

Qin Jiang[1], Xin Zhao[1], Tiyong Zhao[1], Kefan Wu[2], Xingxing Dong[1], Han Ding[1] and Zhigang Wu[1]; [1]Huazhong University of Science & Technology, China; [2]Olin College of Engineering, United States

Our work presents a soft plant wearable system (SPWS) that can in-situ, quantitatively, and long-termly monitor *various essential abiotic/biotic stresses of live tomato plants, e.g., heat, drought, nutrient deficiencies, and mite attacks. Being intimately attached to the abaxial surface of live tomato leaf, the presented SPWS enables us, for the first time, to simultaneously monitor temperature, humidity, and spectral information of leaf, which can directly indicate the plant stresses. Using a machine learning framework, the SPWS can achieve high prediction accuracy (98.4%) and early-stage diagnostic of stresses (2 days earlier than visual detection). We further applied the SPWS to continuously monitor the plant health fluctuation under stresses, providing a potential solution for noninvasive phenotyping and precision agriculture.*

Tomatoes are cultivated worldwide for their naturally healthy and high nutritional value, becoming one of the most produced agricultural products. However, tomato cultivation faces substantial challenges due to various biotic stresses (e.g., diseases and pests) and abiotic stresses (e.g., unsuitable temperature, drought, and nutrient deficiency). These stresses significantly lead to production overcosts, pesticide overuse, and crucial yield losses. Consequently, timely and precise tomato stress monitoring is significant for optimizing pesticide applications and fertilization, improving yield, and protecting the ecosystem. Although some soft sensors can be directly attached to plant surfaces for monitoring their physiological data, a key challenge associated with plant soft sensors is establishing quantitative relationships between sensing data and actual biotic/abiotic stress levels in plants.

In this work, by coupling multi-modal sensing components (e.g., spectral, temperature and humidity (T&H) sensor) with flexible liquid metal circuits, the PSWS can be directly attached to the lower epidermis of tomato leaf for conformal, quantitative, and long-term stresses monitoring. The PSWS introduced a novel in-situ spectral detection method that can collect transmission spectrum of leaves to comprehensively reflect variations in plant pigments. When the plant experiences various stresses, such as essential nutrient deficiency (e.g., nitrogen (N), phosphorus (P), and potassium (K)) and spider mites attackes, leaf pigment composition undergoes significant changes. By analyzing these spectral changes, we can establish a quantitative correlation between specific spectral features and the respective stress factors. Moreover, the PSWS can continuousely detect the leaf surface's T&H information to indicate transpiration rate and water content of plant for over 10 days. We have also developed a machine learning framework to couple these sensors' information and classify plant health statuses with high diagnostic accuracy (> 98.4%). The real-time data can be collected and wirelessly transmitted to a mobile user interface, providing instantaneous diagnostic feedback on plant stress conditions..

Finally, two demonstrations of our PSWS have been presented to explore its practical potential for tomato plant cultivation and breeding. 1) Using the PSWS, we continousely monitored health status flactuations of live tomato plants that experienced drought, nutrient deficiency, and timely replenishment for over 31 days. 2) The PSWS can be practically applied in a greenhouse setting, where it was employed to select suitable grafting rootstock by detecting nutritional statuses of various tomato plants.

SB01.07.07

pH-Sensitive Functionalized Single-Walled Carbon Nanotubes for Plant Genome Engineering

Hyuna Kwak, *Woojin Jeong, Yeong Yeop Jeong, Hongwoo Lee, Seonyeong Kwak and Pil Joon Seo; Seoul National University, Korea (the Republic of)*

Global warming and the growing global population present significant challenges to food security, highlighting the urgent need for innovative strategies to boost crop productivity and resilience to changing environmental conditions. The advancement of novel plant genome engineering techniques, particularly through the use of single-walled carbon nanotubes (SWNTs) as nanomaterial carriers, offers a promising solution to these challenges. SWNTs possess remarkable properties such as a large surface area, high aspect ratio, and superior mechanical strength, making them ideal for delivering biomolecules, including genetic materials, into plant cells. In this study, we demonstrate that utilizing the penetrating capabilities of SWNTs allows us to overcome genetic barriers in plant tissue culture and regeneration processes, thereby maximizing the potential of genome engineering for crop improvement. We introduce pH-sensitive SWNTs utilizing histidine, enabling the *internalization of genetic materials and their cytosolic release in plant cells. This nanocarrier exhibits a sufficient surface charge for interacting with nucleic acids and dimensions suitable for penetrating plant cell membranes, leading to more efficient nucleic acid release at the intracellular pH conditions of plant cells. By delivering cargos to plant tissues, it successfully controls genetic barriers, promoting regeneration through genetic regulation. Highlighting the role of Histidine-functionalized SWNTs in efficiently controlling tissue culture-based plant regeneration mechanisms aligned with sustaining food production emphasizes the urgency of developing innovative solutions that keep pace with the evolving dynamics of our planet and population growth.*

SB01.07.08

Integrated Proteomics and Metabolomics Reveal Altered Metabolic Regulation of Xanthobacter Autotrophicus Under Electrochemical Water-Splitting Conditions *Zachary Schuman and Yongchao Xie; University of California, Los Angeles, United States*

Biological-inorganic hybrid systems are a growing area of study seek to combine microorganisms with abiotic materials for purposes such as chemical synthesis, environmental remediation, and energy generation. Recently, hybrid systems have been developed toward the sustainable generation of value-added chemicals from only electricity, water, and air. These hybrid systems typically consider microorganisms as catalysts that perform only the reaction of interest, however unaccounted for metabolic activity may influence that reaction and the overall system output. The investigation of biological responses to the hybrid environment is thus critical to future system development and optimization. The present study investigates this phenomenon in a system that uses electrochemical water-splitting to provide reducing equivalents to the nitrogen-fixing bacteria Xanthobacter autotrophicus for the reduction of N2 to biomass that may be used as fertilizer. Using integrated proteomic and metabolomic methods, we have found differentiated metabolic regulation under electrochemical water-splitting conditions. We further report an increased expression of certain key proteins, including those responsible for nitrogen fixation and assimilation, that indicate increased rates of nitrogen fixation and support previous findings of accelerated biomass accumulation under electrochemical water-splitting conditions. This work presents a challenge to an inert catalyst view of microorganisms in biological-inorganic hybrid systems while demonstrating the power of multi-omics analysis as a tool for detailed analysis of those systems.

SB01.07.09

Integrated Omic Analysis Reveals Unexpected Metabolic Rewiring of CO_2 Fixation in H_2-Mediated Materials-Biology Hybrids *Yongchao Xie, Zachary Schuman, Thomas Wu, Junyoung O. Park and Chong Liu; University of California, Los Angeles, United States*

A hybrid approach combining water-splitting electrochemistry and H_2-oxidizing, CO_2-fixing microorganisms offers a promising solution of producing value-added chemicals from sunlight, water, and air. The classic wisdom without thorough examination to date assumes that the electrochemistry in such a H_2-mediated process does not affect microbial behavior. Here we report unexpected metabolic rewiring induced by water-splitting electrochemistry in H_2-oxidizing acetogenic bacterium Sporomusa ovata that challenges such a classic view. We found that the planktonic S. ovata in the materials-biology hybrids is more efficient in utilizing reducing equivalent for ATP generation and hence CO_2 fixation to acetate than in cells grown with H_2 supply, supported by integrated metabolomic and proteomic studies. These observations unravel previously underappreciated materials' impact on microbial metabolism in seemingly simply H_2-mediated charge transfer between biotic and abiotic components. Such a deeper understanding at the materials-biology interface will foster advanced design of hybrid systems for sustainable chemical transformation.

SB01.07.10

Electrochemical Neurotransmitter Detection with Parylene-C Neural Probes *Mona Abdelmonem, Ali Soleimani, Farbod Amirghasemi, Sina Sina Khazaee Nejad, Abdulrahman Al-Shami, Haozheng Ma and Maral Mousavi; University of Southern California, United States*

Catecholamines are a focus of extensive research due to their crucial role in the brain's reward system, yet their precise function remains elusive. Quantifying catecholamines including dopamine is essential for regulating cognitive processes, aiding in early detection, diagnosis, monitoring, and therapeutic interventions for intricate neural disorders.
Implantable neural interfaces are indispensable for advancing practical applications of clinical neurotechnologies. Electrochemical sensors, known for high sensitivity, selectivity, rapid response time, minimal sample preparation, non-invasiveness, and portability, play a key role in catecholamine measurement.
Parylene C is chemically inert and features a low Young's modulus (~2-3 GPa), aligning closely with the mechanical properties of biological tissue. We propose the use of a label-free Pt electrode known for durability during long-term implantation using Parylene C. The electrodes are constructed using thin-film Parylene C, a biocompatible polymer classified as USP class VI. The flexibility of parylene is pivotal as it allows implanted devices to adapt to the brain or muscle shape, ensuring movement without harming surrounding tissue. To achieve the detection of dopamine at low concentrations, we applied gold-palladium nanoparticles and a graphene oxide, poly(3,4-ethylenedioxythiophene)/ poly(styrene sulfonate) (PEDOT/PSS) electrode coating and optimized square wave voltammetry (SWV) waveform for selective dopamine measurement.
Our approach holds promise for prolonged, reliable in vivo sensing. The introduction of parylene electrodes is crucial for understanding the context of our work. Our electrodes are crafted through a process involving the integration of gold-palladium nanoparticles and a graphene oxide PEDOT: PSS film onto flexible parylene C sensors. This novel combination aims to enhance sensitivity and durability for precise catecholamine determination in vivo.
The novelty of our work lies in the development of a modified sensor with improved sensitivity and durability for in vivo catecholamine determination. This modification involves the strategic use of gold-palladium nanoparticles and a graphene oxide PEDOT:PSS film on a flexible parylene C sensor. This innovative approach addresses challenges related to biofouling and degradation, ensuring a prolonged sensor lifespan during long-term implantation.

SB01.07.11
Recyclable and Sustainable PLA-Based Substrates Designed for Printed and Flexible Electronics *Nikos Bikiaris, Rafail Ioannidis and Nikolaos Nikolaidis; Aristotle University of Thessaloniki, Greece*

Printed electronic (PE) technologies have experienced significant and ongoing growth over the past few decades. In 2020, it was estimated that 30 billion devices were connected to the Internet, encompassing a wide range of applications from smart cities to smart wearables, and extending from domestic environments to industrial settings. This expansion has been fueled by numerous advancements in electronics, polymer processing, and printing technologies. [1] Currently, printed electronics (PE) are transitioning into their commercial phase, compelling academic research teams to address new challenges and issues that have only recently emerged. [2] Flexible hybrid electronic devices are typically manufactured on substrates made from various thermoplastic polymers, such as poly(ethylene terephthalate) (PET), poly(ethylene naphthalate) (PEN), and thermoplastic polyurethane (TPU). These conventional plastics provide distinct performance benefits, including high flexibility and low cost. However, they are derived from rapidly depleting non-renewable petroleum resources and often necessitate incineration or landfilling at the end of their lifecycle.[3] Using greener materials and fabrication processes will promote sustainability and help meet the Eco-design directive regulations and the objectives of the European Green Deal. Among bio-based polymers, poly(lactic acid) (PLA) has recently been explored as a *potential candidate for thin film printed electronics (PE). [4] Nevertheless, commercial PLA exhibits poor heat resistance and inherent brittleness, but its copolymerization with biobased aliphatic monomers may overcome this challenge. Such a polymer is poly(ethylene azelate) (PEAz) produced from biobased ethylene glycol and azelaic acid.*

In the current work a series of biobased and recyclable PLA-PEAz flexible copolymers were successfully synthesized by a combination of the two-stage melt polycondensation procedure for PEAz synthesis, followed by a ring opening polymerization (ROP) reaction in the presence of lactide. The recyclability of the prepared polymeric substrates was evaluated using a microwave assisted hydrolysis and ^{1}H NMR spectroscopy. Enzymatic hydrolysis and UV degradation were also tested for the evaluation of the polymers degradability in the environment.

A Soft and Stretchable Platinum Nano Particle Based Electrode for Real-Time In Vivo Monitoring of Hydrogen Peroxide

Jiawei Tan, Yichao Zhao, Kaiji Zhang, Mahammadreza Bahramian, Xuanbing Cheng, Jialun Zhu, Junjie Fang, Zoe Pepper, Andre Li, Murtadha Al Msari, Katherine Lim, Eva Shlyakhovaya and Sam Emaminejad; University of California, Los Angeles, United States

Hydrogen peroxide (H2O2) plays a crucial role as a signaling molecule in tissue environments, influencing oxidative stress responses, immune functions, and cellular signaling pathways. Real-time monitoring of H2O2 levels within tissues is essential for understanding oxidative dynamics implicated in diseases such as neurodegenerative disorders, cardiovascular diseases, and cancer. For example, in neurological studies, monitoring H2O2 provides insights into oxidative damage mechanisms in brain tissues, enhancing our understanding of diseases like Alzheimer's and Parkinson's. Similarly, in cardiovascular contexts, real-time H2O2 monitoring helps assess oxidative stress levels in vascular tissues, crucial for managing inflammation and promoting cardiovascular health. Additionally, in oncology, monitoring H2O2 in tumor microenvironments aids in understanding tumor progression and responses to therapies.

Here, we have developed a soft and stretchable platinum-nanoparticle (PtNP)-based electrode for in-vivo H2O2 monitoring. The sensor employs a multi-layered architecture, featuring a brittle interfacial platinum-nanoparticle-based layer electrically connected to an underlying stretchable conductive layer through a vertically conductive film. The sensor's silicone-based conductive stretchable trace is sealed with a silicone-based vertically conductive layer. The interfacial layer is fabricated through e-beam deposition of Cr/Au, followed by PtNP electrodeposition. Even under strain and fracturing of the PtNP layer, the fractured surfaces remain electrically connected to the bottom stretchable traces, thereby preserving the sensing capability unaltered under 100% strain.

To assess its robustness for in vivo applications, the stretchable H2O2 sensor can be tested across various biological systems, including human stem cell-derived neurons and cardiomyocytes, primary neurons and astrocytes, and ex vivo and in vivo mouse brain models. Implanted in the brains of mice, the sensor adheres smoothly to brain tissues, providing stable, real-time recordings of H2O2 dynamics in response to pharmacological stimuli and pathological conditions. Future enhancements will integrate wireless modules for unrestricted movement measurements, further advancing its utility in studying and treating oxidative stress-related diseases.

SB01.07.13

Improved Adhesion of Electrically Conjugated PEDOT: Bf4 Film by Modifying Flexible Electrode Surfaces

Alexandra Boyadzhiev and Huanan Zhang; The University of Utah, United States

Improved adhesion of electrically conjugated PEDOT: Bf4 film on flexible Conjugated polymer poly(3,4-ethylenedioxythiophene) (PEDOT) is widely favored in various applications due to its thermal stability, high conductivity, biocompatibility, and accessibility. Despite its numerous advantageous characteristics, PEDOT faces challenges, primarily related to surface adhesion. Repeated exposure to electrochemical and mechanical stress can compromise the integrity of the PEDOT surface, resulting in abrasions and diminished performance over time. While recent studies have focused on enhancing PEDOT adhesion on solid substrates, less attention has been given to improving adhesion on flexible substrates.
Using manufactured Au/Ni flexible electrodes is extremely convenient. They are efficiently designed, accessible, and affordable and have various applications, like biosensors. However, these electrodes present challenges for PEDOT deposition due to their smooth surface, limiting adhesion. Electrochemically deposited PEDOT can significantly enhance biosensor performance by reducing impedance and enabling more precise signal recording at lower frequencies. Nonetheless, PEDOT's inherent poor adhesion to metal substrates, compounded by the physical strain from electrode flexion, often leads to premature device failure.

Our approach focuses on texturing manufactured electrodes' smooth Au/Ni surfaces to address these issues. Introducing surface roughness enhances the effective surface area and promotes nucleation sites for improved polymer adhesion. We compared the adhesion of the unprocessed manufactured electrodes with an etched substrate and a substrate with electrochemically deposited Au nanoparticles. The etched surfaces were prepared using a top-down approach to remove the top layer of Au on the electrode surface, performing multiple potential scans in an HCl solution. Au nanoparticles were electrochemically deposited onto the electrodes potentiostatically at -2V in a HAuCl electrolyte. Subsequently, we electrochemically deposited PEDOT doped with tetrafluoroborate (BF4) onto our surfaces. We performed a series of comprehensive adhesion tests and electrochemical, thermal stability, and morphology characterization to show the improved performance of our modified samples.

In conclusion, our study highlights improved mechanical adhesion, electrochemical performance, and stability of PEDOT on flexible metal electrodes compared to unprocessed counterparts. This methodological enhancement holds promise for flexible biosensors, offering improved device longevity where PEDOT interfaces with moving components.

Electrochemical Control of Protein Assembly by Direct Charge Neutralization *Eloise Masquelier[1], Yin-Chen Lin[2], Sheng-Ping Liang[1], Seren Tochikura[1], Sabrina Fojut[1], Mike J. Gordon[2,1], Daniel E. Morse[1,1] and Lior Sepunaru[1]; [1]University of California, United States; [2]University of California, Berkeley, United States*

Electrochemistry is a viable tool for (i) studying the thermodynamics and kinetics of a chemical system, (ii) converting chemical energy to electrical energy and vice versa, and (iii) manipulating a ***material structure and function through*** *charge or discharge events. The latter phenomenon is well documented when an intercalation process within a battery is examined. In the case of biomolecules, the idea of using electrochemical potential differences to control their structure and function has been much less explored. In this talk, I'll share our collaborative efforts and discoveries related to the electrochemical triggering of protein assembly processes. We will explore how applying a sufficient reductive potential with a suitable electrode can directly neutralize charged amino acids, peptides, and even proteins. By coupling the electrochemical triggering with spectroelectrochemical measurements such as dynamic light scattering, circular dichroism, and UV absorption, we are able to track, in real-time, the assembly state of the protein caused by the electro-reductive heterogeneous process. The insight from our newly proposed method offers an innovative way to study early intermediates responsible for biological assembly process and opens the possibility for rapid drug screening for neurodegenerative diseases.*

8:45 AM SB01.08.02

Non-Centrosymmetric Single Crystalline Biomolecular Nano-Arrays for Responsive Electronics *Jun Li, Chad A. Mirkin, Zhiwei Li, Yi Xie, Tong Cai, Donghoon Shin and Chaojian Chen; Northwestern University, United States*

Non-centrosymmetric biomolecular crystals, with optical and electrical properties arising from symmetry breaking, hold promise for applications in energy conversion, storage, computing, and biomedicine. However, the synthetic methods used to prepare these crystals are difficult to control and lack reproducibility due to the constraints of working with biomolecules, such as their sensitivity to temperature and the presence of weak intermolecular interactions. Herein, we report a novel strategy for synthesizing ten types of single crystalline amino acid (AA) nanocrystals with control over size (50 nm to 3 μm), anisotropy (particle to rod to wire), and polymorphism (α, β, γ crystalline forms) by leveraging dip-pen nanolithography (DPN) and recrystallization via solvent vapor annealing. This leads to isotropic high-quality crystals that are non-centrosymmetric with strong piezoelectric (g_{33} coefficients >1000 mV m/N), ferroelectric, and non-linear optical properties. Furthermore, recrystallizing arrays of isotropic AA nanodot features with a binary solvent (water and ethanol) leads to arrays of one-dimensional piezoelectric nanorods with their long axis coincident along the polar axis. To demonstrate the potential of these materials in electronic applications, a mechanically responsive device was fabricated by synthesizing arrays of aligned AA nanorods onto micro-interdigital electrodes. These as-fabricated devices are highly sensitive, responding to ultrasonic stimulation in the form of a piezoelectric response. This work is significant as it opens up opportunities for investigating the fundamental properties of AA nanocrystals, particularly their nanoscale polarization behavior. In addition, it allows one to rapidly assemble and study stimuli-responsive electronics based upon soft biomolecular structures, making them promising candidates for developing biomolecular tools spanning sensors, energy harvesters, and implantable medical devices.

9:00 AM SB01.08.03

Fabrication and Characterization of Flexible PVDF-TrFE-BaTiO3-Ti3C2 MXene-Based Composite Multi-Morphs: Towards Advancing Electroactive Materials for Wearable Biomedical Technologies *Derek Xiong[1], Jelizaveta Chern[1], Aidee Gonzales[1], Saquib Ahmed[2,2] and Sankha Banerjee[1,3]; [1]California State University, Fresno, United States; [2]Buffalo State College, United States; [3]University of California, Davis, United States*

Lead-based perovskite oxides have been used as sensors, actuators, and transducers, for sound generation, mechanical detection, optical instruments, microscopes, and many more technologies. Electro-polymers such as PVDF, and PVDF-TrFE-based structures have also been used in several applications towards the development of flexible electroactive multi-morph systems for biomedical applications, but these systems have lower *piezoelectric strain coefficients as compared to those of their lead-based piezoceramics. Though lead-free-based ceramic and electroactive polymer composites have been explored, their property-performance characteristics are not comparable to those of electro-active ceramics. The following work investigates the developments of non-toxic PVDF-TrFE-BaTiO3-Ti3C2 MXene-based lead-free alternatives to perovskite oxide applications by including the MXene phase to combat the weaker piezoelectric strain coefficients. Effective bulk electrical property optimization was achieved by varying the volume fractions of the MXene phase. The MXene phase's volume fraction will have a 1% to 5% variance and the PVDF-TrFE phase will also vary to accommodate the change of the MXene phase, while the volume fraction of the BaTio3 phase will be kept constant at 30%. The dielectric constant, capacitance, impedance, and piezoelectric properties of the samples were measured using an impedance analyzer, and a piezometer. The results were analyzed based on the volume fraction of MXene compared to control values of only PVDF-TrFE and 70% PVDF-TrFE to 30% BaTiO3 to evaluate the change in electrical and dielectric properties. The impedance and dielectric spectra of the nanocomposites were measured across a frequency range of 20 Hz to 10 MHz. The microstructural properties and cross-sections of the thin films were examined using a Scanning Electron Microscope to measure porosity to see if it correlates with any electrical property. The composite's high sensitivity and electron transport properties suggest potential applications in biomedical devices operating at both low and high frequencies without the risk of using any lead-based materials.*

9:15 AM SB01.08.04
Fully Printed High-Performance Flexible OECTs with Sub-Micron Channel Length for Bioelectronics

Mohammad Shafiqul Islam, Sangwon Cha and Yasser Khan; University of Southern California, United States

Organic Electrochemical Transistors (OECTs) modulate the electrical conductivity of an organic channel through ion movements from an electrolyte to the channel, making it suitable for applications in bioelectronics and chemical sensing. Due to high conformality, high transconductance, inherent signal amplification, and stable operation in the aqueous environment, OECTs have gained interest in applications of in-vivo bioelectronics. Most wearable bioelectronics applications require a flexible platform. The printed fabrication process paves the way for implementing OECTs on a flexible substrate. Since the channel volumetric capacitance of OECTs is inversely proportional to the operating frequency, geometry scaling of OECTs is needed for high-frequency applications. However, miniaturization of the planar OECT remains a challenge, which hinders the application of these devices in fast biological events like neuronal signaling and neuromorphic application. In this work, we present a fully printed fabrication method of high-performance OECTs with sub-micron channel length on a flexible substrate. We fabricate the OECT source and drain contacts using gold (Au) nanoparticle ink. After inkjet printing the source electrode, we modify the metal surface with a hydrophobic surface coating, and then inkjet-print the drain metal electrode. Hence, the drain electrode self-aligns with the previously printed source electrode with sub-micron resolution. Next, we use direct 3D printing to fabricate silver/silver chloride (Ag/AgCl) gate electrodes. After that, we inkjet print the organic poly(3,4-ethylene dioxythiophene): poly(styrene sulfonic acid) (PEDOT: PSS) as the channel material for this sub-micron channel length OECTs. We conclude the fabrication process by inkjet printing a protective dielectric layer on the metal electrodes to prevent direct contact of the liquid electrolyte with the metal electrodes. Reducing the volumetric capacitance increases the cut-off frequency of these OECTs, improving their performance and making them suitable for high-frequency bioelectronics.

10:30 AM *SB01.09.01

Living Materials for Photoconversion from Photosynthetic Microorganisms and Biopolymers *Gianluca Maria Farinola; Università degli Studi di Bari Aldo Moro, Italy*

Photosynthetic microorganisms have developed a diverse array of micro/nano structures over billions of years of evolution, finely tuned for interacting with sunlight. Utilizing these specialized structures combined with customized molecules and polymers opens up novel avenues for creating sustainable materials for optoelectronic and photoelectrochemical devices devices for photoconversion [1].

The following examples will be discussed in the lecture:
i) Photoconverters with photosynthetic bacterial enzymes. Chemical modifications are introduced to boost the performance of hybrid constructs vis-à-vis the native proteins [2] and biocompatible interfaces enable to assemble photoenzymes onto electrodes resulting in active materials for optoelectronics [3].
iii) Intact photosynthetic bacteria [4-6] or microalgae [7] cells used as living materials in photoelectrochemical cells for solar energy conversion.
The lecture will discuss the logic behind designing and synthesizing the biohybrid micro/nano assemblies, highlighting the challenges raised by the controlled functionalization and integration in devices. New concepts for photoresponsive materials and devices can be envisaged by combining the biotechnological production and modification of photosynthetic microorganisms with tailored functional molecules and polymers.

11:00 AM *SB01.09.02

Development of Bio-Photo Anodes Using Ulvophyceae Macroalgae *Sergio Choque[1], Cesar Zuñiga[1], Lo Gorton[2], Donal Leech[3] and Federico Tasca[1]; [1]Universidad de Santiago de Chile, Chile; [2]Lund University, Sweden; [3]National University of Ireland, Galway, Ireland*

Three different macroalgae i.e. U. lactuca, U. linza, and U. compressa have been studied for biological photovoltaic energy system (BPVE), using edge plane pyrolytic graphite as the supporting working electrode. The *studied biophotoanodes were evaluated in terms of direct electron transfer (DET) and mediated electron transfer processes (MET). Osmium Polymer (OsP), Ferrocyanide (FeCN), p-benzoquinone (BQ), and 1,4-naphthoquinone (NQ) were used as a mediator during biophotovoltaic experiments in the presence and in the absence of applied light. The electrochemical characterization was performed by cyclic voltammetry (CV) and chronoamperometry. The results show that using BQ during the MET process, the electron transfer to the graphite electrode drastically increases, during light conditions, where the most promising biophotoanode, was in the presence of BQ and U. linza with a current density of 72.1 ± 9.1 μA cm^{-2}, which represents an increase of almost 2000 times over DET results. Similar results were obtained with U. lactuca and U. compressa. The high performance in the presence of BQ for the three macroalgae has been attributed to favorable penetration of the quinone molecule to the cytoplasmic membrane allowing direct exchange of electrons with the photosystem II in the thylakoid structure. Good results were also obtained in the presence of OsP but those results were not comparable to BQ most probably because of the inefficacy of OsP to penetrate the cytoplasmic membrane.*

11:30 AM *SB01.09.03

Enhancing Microbe-Electrode Interactions for Bioelectrochemical Devices *Melania Reggente; École Polytechnique Fédérale de Lausanne, Switzerland*

Microbial metabolisms offer large reaction networks that can be exploited for both energy and chemical production in bio-electrochemical devices. These systems rely on extracellular electron exchange between microbes and electrodes. Catabolic processes can fuel electron transfer from microbes to electrodes for bioelectricity generation, while anabolic processes can benefit from an electron influx for intracellular regeneration of reducing equivalents. This versatility enables a wide range of applications, including bioremediation, biosensing, and chemical production. However, electron transfer between electrodes and microbes is often limiting, thus negatively impacting device performances [1].

We address this bottleneck from both biological and electrode engineering perspectives. Our work focuses on engineering microbes and electrodes using nanoparticles [2], biosynthetic and conductive polymers [3-5], as well as the heterologous expression of extracellular electron transfer pathways [6]. These advances in improving the electrode-microbe interactions increase energy production in microbial fuel cells for wastewater treatment and in bio-photovoltaics for solar energy conversion. The combination of these cross-disciplinary advances thus pushes forward the development of efficient microbial bioelectronic technologies.

Infection-on-a-Chip—Recreating the Biological Steps of Viral Infection on a Bioelectronic Platform to Profile Viral Variants of Concern <u>Susan Daniel</u>; Cornell University, United States

Viral infection begins when a virus particle breeches the host plasma membrane and successfully delivers its genome into that cell. Though these processes must occur for every viral pathogen that infects a host cell, the entry route can vary markedly depending on the viral pathogen, the host cell type, and the local microenvironmental conditions. Virus particles are responsive to their environment and use cues from it to adapt and successfully time the entry process into the host cell. Thus, it is a continual evolutionary battle between the host and the virus to thwart infection and disease. The best-known example of our time is SARS Coronavirus-2 (SARS-CoV-2), where viral mutation rates frequently outpace the development of technologies used to detect and identify emerging variants of concern (VOC). Given the continual emergence of VOC, there is a critical need to develop platforms that can identify the presence of a virus and readily identify its propensity for infection. We present an electronic biomembrane sensing platform that recreates the multifaceted and sequential biological cues that give rise to distinct SARS-CoV-2 virus host cell entry pathways and reports the progression of entry steps of these pathways as electrical signals. Within these electrical signals, two necessary entry processes mediated by the viral Spike protein, virus binding and membrane fusion, can be distinguished.
Most infection 'on-chip' devices employ live cells, miniaturized cell cultures or organoid-like structures, which essentially replicate established virology assays in a smaller format. While these platforms have certain advantages, they do not significantly expedite the assay process, as cells still necessitate time to grow and respond, and typically rely on the delivery of an encapsulated reporter gene, making these systems somewhat cumbersome to operate. Consequently, they are too slow (taking days) for promptly evaluating emerging VOC and recommending timely action. Additionally, cell-based devices are not conducive to studying entry functions at the scale of the plasma membrane, where cell entry initiates. Our device, in contrast, focuses on the activities occurring at a single-cell membrane interface, which is a different “scale” of infection (the onset of entry). Our device has no living cells and can be performed without necessitating reporter-gene encapsulation. Unique to this work, our assay design faithfully replicates the biological cues governing virus response and the selection of distinct entry pathways, mirroring natural occurrences. We demonstrate that our device has this resolution for the

fusion function, a critical step in infection that leads to the delivery of the viral genome across the host cell membrane barrier. Significantly, we have demonstrated functional assessment and used it to differentiate SARS-CoV-2 VOC (Wuhan-Hu-1, Omicron BA.1, and BA.4) – a milestone, to our knowledge, as it marks the first application of a cell-free, virus-free, and label-free system for this purpose. Remarkably, we find that these closely related VOC exhibit distinct fusion signatures that correlate with trends reported in cell-based infectivity assays, allowing us to report quantitative differences in fusion characteristics among them that inform their infectivity potentials. With this design and the electrical approach to interpreting responses, we can swiftly (in tens of minutes) assess and differentiate the functional traits of VOC. This speed is pivotal for determining societal responses as VOC continue to emerge.

11:00 AM *SB02.01.02
***3D Printing of Organic Bioelectronics** Mohammad Reza Abidian; University of Houston, United States*

In recent years, 3D printing of electronics have received growing attention due to their potential applications in emerging fields such as nanoelectronics and nanophotonics.
Multiphoton lithography (MPL) is considered the state-of-the-art amongst the microfabrication techniques with true 3D fabrication capability owing to its excellent level of spatial and temporal control.
Here we introduce a homogenous and transparent photosensitive resin doped with an organic semiconductor material (OS) compatible with MPL process to fabricate variety of 3D OS composite microstructures (OSCMs) and microelectronic devices. Inclusion of 0.5 wt% OS in the resin enhanced the electrical conductivity of the composite polymer about 10 orders of magnitude and compared to other MPL-based methods, the resultant OSCMs offered high specific electrical conductivity. As a model protein, laminin was incorporated into these OSCMs without a significant loss of activity. The OSCMs were biocompatible and supported cell adhesion and growth. Glucose oxidase encapsulated OSCMs offered a highly sensitive glucose sensing platform with nearly 10-fold higher sensitivity compared to previous glucose biosensors. In addition, this biosensor exhibited excellent specificity and high reproducibility. Overall, these results demonstrate the great potential of these novel MPL-fabricated OSCM devices for a range of applications from flexible bioelectronics/biosensors, to nanoelectronics and organ-on-a-chip devices.

11:30 AM SB02.01.03
***Magnetic Hydrogels for Bioelectronic Medicine** Dekel Rosenfeld; Tel Aviv University, Israel*

Cell signaling can be mediated by heat stimulation in the presence of magnetic nanoparticles (MNPs) that dissipate heat efficiently when exposed to alternating magnetic fields (AMFs). Our lab develops novel approaches for remote AMF-based activation of deep organs in the body via implantable, biocompatible magnetic hydrogels designed with controlled magnetic and mechanical properties and tailored to different organ tissues. The AMF-driven activation targets heat-sensitive ion channels, such as the transient receptor potential vanilloid 1 (TRPV1), with a temperature threshold above 42 Celsius.
The magnetic hydrogels accommodate both MNPs and cells and thus serve as a three-dimensional culture model and as bioelectronic implants. We characterize and compare synthetic and biological polymers that can support magnetic nanocomposites in terms of mechanical, magnetic, and biocompatibility properties. Moreover, we develop comprehensive heat transfer models to predict the heat distribution inside and from the magnetic implants.
The magnetic hydrogels achieve wireless, on-demand control of cell signaling. This control is crucial for cell excitability, making our work highly relevant to the fields of neuroscience, tissue engineering, and drug delivery.

11:45 AM SB02.01.04

Tunable High-Quality Nanoporous Gold Electrodes for Bioelectronic Applications *Jialun Zhu, Tsung-Yu Wu, Xuanbing Cheng, Bintao Hu, Yifu Li, Connie Ho, Joshua Ng, Anthony Sung, Zongqi Li and Sam Emaminejad; University of California, Los Angeles, United States*

The nanoporous gold (np-Au) electrode, created through the oxidative dissolution of less noble elements in gold alloys, features a network of nanometer-sized metallic struts and interconnected pores. This structure enhances electrode surface area, making it highly suitable for various bioelectronic applications. Controlling pore morphology allows for a broad investigation of mechanical and surface properties, laying the groundwork for the development of diverse biosensing and stimulation interfaces. However, precise control over np-Au electrode morphology is challenging due to the rapid dealloying process and the lack of robust characterization tools to monitor the evolution of the material's matrix.
Here, we investigated the impact of different fabrication techniques and key process parameters on np-Au electrode morphology, then leveraged the findings to devise a simple method for fabricating high-quality np-Au electrodes with tunable features. In our approach, the master alloy matrix was initially formed through gold/silver sputtering at a 1:2 ratio. The dealloying process was conducted via either electrochemical or direct acid treatment, monitored by electrochemical quartz crystal microbalance (EQCM) and analyzed post-dealloying using Scanning Electron Microscopy (SEM). The speed of dealloying significantly influenced morphology, with electrochemical dealloying proving more controllable and programmable through various applied voltage profiles, resulting in a high-quality np-Au surface.
To demonstrate the practicality of these high-quality electrodes, they were further functionalized with a thiol-based aptamer probe for electrochemical sensing. The sensors exhibited enhanced antifouling capabilities and an improved signal-to-noise ratio (SNR) due to the optimized controlled dealloying process. The resultant concave features acted as physical sieves to enhance antifouling properties. Additionally, the high catalytic activity of the gold surface was confirmed through oxygen reduction reaction cyclic voltammetry, indicating the superior quality of the dealloyed electrode surface.
To evaluate the robustness of the electrode interfaces for in vivo applications, the fabricated sensor was implanted in a rat model for antibiotic monitoring. The sensor delivered high-SNR in vivo drug concentration data within hours of operation and exhibited a significant reduction in signal drift compared to other reported nanostructured in vivo electrochemical sensors. This confirmed the suitability of the np-Au electrodes for in-vivo biosensing applications. The scalability and adaptability of this fabrication process make it ideal for creating high-quality np-Au interfaces on various substrates for diverse bioelectronic device-level integrations.

***Novel Ionic Transistor Architecture for Real-Time Detection of Biological Ionic Signals** Reza Montazami, Fatemeh Hassanpour, McKayla Kling and Hailey Negley; Iowa State University of Science and Technology, United States*

Most living microorganisms communicate through ionic interactions. The ability to nondestructively detect, monitor, and decode these interactions in real-time could significantly enhance our understanding of microbial functions and potentially influence their behavior. However, such a capability has not been realized to date. In this talk, we present a comprehensive study on the early-stage development and characteristics of a novel ionic transistor architecture. This architecture employs the dynamic manipulation of ionic species to facilitate the rapid and reversible formation and decay of ionic double layers, serving as a gating mechanism analogous to n-channel MOSFETs in enhancement mode. This innovative design may enable the real-time detection of biological ionic signals. We will delve into the structural design and operational principles of these transistors, exploring their potential applications in biotronics. Early-stage proof-of-concept findings will be demonstrated, showcasing the promising capabilities of this novel technology for real-time biological ionic signal detection

***Hydrogel-Assist Direct Writing of Organic Semiconductors for Biosensors and Bioelectronics** Omid Dadras-Toussi, Anthony Kitsucky, Anto Sam Crosslee Louis Sam Titus, Sheereen Majd, Chandra Mohan and Mohammad Reza Abidian; University of Houston, United States*

Development of cost-effective fabrication techniques has become a pressing topic for manufacturing of flexible organic electronic circuitry and bioelectronics. To date, construction of organic electronics in micron-scale have mostly relied on conventional patterning techniques such as photolithography, and electrochemical patterning (through selective removal / deposition). The challenges associated with these approaches include minimal control over geometry, the need for sophisticated / expensive instruments, and multi-step / labor-intensive fabrication procedures. Here we present an innovative additive manufacturing technique, referred to as GEL-PEN, using agarose hydrogel, for direct writing of organic semiconductor devices. We demonstrate their capability for a host of applications ranging from electronic circuitry to biosensors and bioelectronics.
In GEL-PEN setup, a wet agarose hydrogel cartridge tip encounters the electrode surface and precisely delivers the solution precursor containing monomer pyrrole, dopant polystyrene sulfonate, and bioactive proteins (i.e. laminin and glucose oxidase), at the interface in form of a meniscus. As high precision motorized stages move based on a pre-defined geometric design, polypyrrole is electrodeposited on a conductive substrate. Processing parameters such as hydrogel concentration, ambient humidity, current density, and stage velocity were optimized at 50%, room temperature, 2 wt%, 1 mA cm^{-2}, and 10 µm s^{-1}, respectively to form high-quality structural features. Materials Confocal Microscopy demonstrated layer-by-layer deposition in a linear fashion, with average width and thickness of 77.6 ± 5.5 nm and 488.7 ± 16 µm per layer, respectively. 3D microdevices with various geometries were successfully fabricated and electrical and electrochemical properties were characterized. Laminin-incorporated microstructures were biocompatible and supported cell adhesion and proliferation. Furthermore, glucose oxidase was incorporated in GEL-PEN fabricated microstructures and amperometric detection of glucose at low activation

potential of 300 mV vs Ag/AgCl reference electrode was successfully achieved with a sensitivity of 4.82 ± 0.36 μA mM^{-1} cm^{-2}, lower limit of detection of 0.01 mM, response time of 11 s, and linear range of 0.1-1.5 mM. GEL-PEN additive manufacturing sets the sights high for development of next-generation and cost-effective bioelectronics and biosensors.

3:00 PM *SB02.03.01

Solid-State Electron Transport Through Proteins Beyond Known Tunneling or Hopping Limits *David Cahen; Weizmann Institute of Science, Israel*

A central puzzle of bio-molecular electronics is how electron transport (ETp) through more than several nm thick solid-state junctions, can be so efficient, often without thermal activation. Such behavior does not fit known transport mechanisms. As proteins lack extended conjugation and thus are low charge carrier density molecules (with low DOS[#]), the experimental ETp results are, well, weird. Starting from a wide range of ETp results within the QM tunnel limit (~2, ~5 or ~7 nm for saturated, conjugated, or multiheme molecules), currents should decrease exponentially with junction width. This decrease should limit detection for non-conjugated polymers, such as proteins, beyond the above (junction) widths. But we measure conduction across up to 60 nm wide protein films, with weak width, and near-complete lack of temperature independence. While the results can be modeled, they exclude known transport mechanisms, adding to ETp results via bacterial nanowires (mm-s) and cable bacteria (£1 cm). We can rationalize the data, assuming ETp is limited by injection (via tunnelling) through one of the contacts, followed by much more efficient charge propagation across the proteins, the mechanism of which is as yet unknown. Discussion will also include, as unintended consequence, insight in biological electron transfer.

The Influence of the Bipolaron Formation Rate on the Charge Transport Properties of Chemically Doped Oligoetherized Polythiophene *Maximilian M. Horn[1], Eva Röck[1], Christina Kousseff[2], Iain McCulloch[2] and Natalie Banerji[1]; [1]University of Bern, Switzerland; [2]University of Oxford, United Kingdom*

In the last decades, organic semiconductors have attracted significant attention due to their biocompatibility, mechanical flexibility, solution processability, and lightweight nature. A recent achievement brought the engineering of side chains in polymer films to enhance ion intercalation, as demonstrated by the newly developed polymer P($g_3$2T-T). This derivative of P3HT, featuring oligoether instead of aliphatic side chains, emerges as a promising candidate for chemical doping because of the affinity of its side chains to dopant anions as well as potential applications in bioelectronic devices. Chemical doping of the P($g_3$2T-T) has been found to achieve an up to fourfold increase in macroscopic conductivity compared to P3HT. However, this enhanced conductivity is highly *dependent on specific doping conditions. While general principles of doping are now well-understood, the precise effects of various doping parameters on the charge transport properties of doped thin films still need to be investigated.*

Our study employs in-situ absorbance spectroscopy as well as THz spectroscopy to investigate the effects of differing dopant and electrolyte concentrations on the conductivity of chemically doped $P(g_32T\text{-}T)$ *films. We reveal that the early kinetics of the doping process have a significant influence on the final thin film conductivity. The results demonstrate that the bipolaron-to-polaron ratio is a rather weak indicator of favorable charge transport properties and that instead the bipolaron formation rate is a superior predictor. We presume that the bipolaron formation rate is entangled with the swelling of the polymer film, the intercalation of the dopant anions, and thus the packing of the polymer film as well as its charge transport properties. We explore two distinct doping methods—immersed doping and anion exchange doping—and use two different dopants,* F_4TCNQ *and Magic Blue, to rule out the impacts of specific doping techniques. Especially for the anion exchange doping method, our results offer for the first time an explanation for the dependence of the electrolyte concentration on the film conductivity. Moreover, we report an excellent restoration of long-range charge transport in chemically doped* $P(g_32T\text{-}T)$*, compared to the short range (100 nm) derived from THz spectroscopy. Overall, our results shed light on the underlying principles of chemical doping and the revealed dependencies on specific doping conditions can help facilitate the development of the next generation of organic semiconducting polymers that can be employed at the interface between biological and electronic systems.*

3:45 PM SB02.03.03

Mechanotransductive Materials for Remote Modulation of Cell Signaling *Jacob Beckham[1], Alexis van Venrooy[2], Ye Ji Kim[1], Soonyoung Kim[2], Florian Koehler[1], Jacob T. Robinson[2], James Tour[2] and Polina Anikeeva[1]; [1]Massachusetts Institute of Technology, United States; [2]Rice University, United States*

Nearly every cell in the body possesses a mechanism to transduce mechanical force into a biochemical signaling cascade. This suggests that mechanotransductive materials, materials designed to exert a mechanical force of controllable magnitude, have the potential to remotely control cell signaling and downstream function in diverse types of tissue. Recent advances have shown that neuronal activity can be remotely controlled with mechanical force, but the overwhelming majority of cells in the body which are not neurons remain comparatively underexplored in this context. Here, we report results demonstrating two different classes of mechanotransductive nanomaterials that can be used to drive cell signaling across several in vitro and in vivo model systems. Our results show that both small molecule-based, light-activated molecular motors (MMs) and larger (~200 nm) magnetically activated magnetite nanodiscs (MNDs) can drive calcium transients even in non-excitable HEK293T cells without the introduction of a mechanoreceptor transgene. MMs rotate in the MHz frequency regime upon activation with visible light. Similarly, MNDs align themselves with externally applied magnetic field, an effect which can be leveraged to exert torque on their surroundings using a quasistatic, low frequency alternating magnetic field. The calcium transients elicited by these systems receive slightly different contributions from intracellular and extracellular calcium in a manner that suggests a dependence on the localization of the transducer. Further, our results demonstrate that mechanically elicited calcium waves can initiate distinct downstream effects depending on the available protein machinery in the activated tissue. In cardiac myocytes and the cnidarian organism Hydra vulgaris, the calcium transients induced by MM drive action potential firing and muscle contraction. In hippocampal glia and immune cells, MNDs drive intracellular and store-operated calcium signaling cascades. Future work aims to identify additional downstream signaling events activated by mechanical stimulation. These results reveal cell populations amenable to remote mechanical modulation and inform the design of tools to study and control calcium signaling in unexplored systems.

4:00 PM SB02.03.04

Long-Term Molecular Monitoring in Complex Biological Environments *Yang Song, Huijie Li and Yi Zhang; University of Connecticut, United States*

Long-term molecular monitoring in complex biological environments is crucial for understanding, preventing, diagnosing, and managing human diseases. Aptamer-based electrochemical biosensors hold promise due to their generalizability and high degree of selectivity. However, existing aptamer-based biosensors face challenges in complex biological environments due to the monolayer loss, aptamer degradation, and biofouling. To address this, we present a surface coating designed to improve the longevity of aptamer-based biosensors in such environments. We demonstrate the application of these surface coatings to various aptamer-based biosensors for detecting drugs (e.g., fentanyl) and neurotransmitters (e.g., dopamine) in undiluted whole blood samples. MTT analysis of forebrain spheroids cocultured with these coatings and in vivo immunohistochemistry studies indicate their biocompatibility for use in real-time, in vivo molecular monitoring. The results establish the potential for chronic aptamer-based molecular monitoring platforms.

4:15 PM SB02.03.05

Design and Fabrication of a Flexible Opto-Electric Biointerface for Multimodal Optical Fluorescence and Electrical Recording *Nathaniel Quirion; The George Washington University, United States*

Optical fluorescence and electrical monitoring of cell activity are two powerful approaches to study organ functions. Simultaneous recording of optical and electrical data types will provide complementary information from and take advantage of each approach. However, devices that can concurrently record optical signals from the same cell population underneath the microelectrodes have not been widely explored and remain a grand technical challenge. This work presents an innovative flexible opto-electric device that monolithically integrates transparent gold nanogrid microelectrodes directly above microscale light-emitting diodes, photodetectors, and optical filters to achieve co-localized crosstalk-free optical fluorescence and electrical recording. The optimized gold nanogrid microelectrodes show an excellent optical transparency (>81%) and a low normalized 1 kHz electrochemical impedance (6.3 Ω cm^2). The optical recording subsystem offers high wavelength selectivity (>1,300) and linearity ($R^2 > 0.99$) for exciting and capturing green fluorescence from various fluorescent reporters in measurement ranges relevant for in vivo applications with minimal thermal effects. The opto-electric device exhibits remarkable durability under soaking for 40 days and repetitive mechanical bending for 5000 cycles. The work may provide a versatile approach for constructing mechanically compliant biointerfaces containing crosstalk-free optical and electrical modalities with widespread application potentials in basic and clinical research.

4:30 PM SB02.03.06

From Conducting Hydrogel to Semiconducting Hydrogel *Shiming Zhang; The University of Hong Kong, Hong Kong*

Thin-film semiconductor-based devices have revolutionized the field of microelectronics. Conducting hydrogels have rapidly gained prominence for bioelectronic applications due to their great similarities with biological systems. The realization of semiconducting hydrogel materials holds significant value in advancing bioelectronics for developing advanced biologics[1]. Further moving towards flexible and stretchable semiconducting hydrogels can enable direct applications at the interface of soft biological systems [1]. However, the development of semiconducting hydrogels presents material challenges, primarily due to the thin-film nature of semiconductors. In contrast, hydrogels tend to have greater thicknesses and struggle to achieve good semiconductor properties.

The advent of organic electrochemical transistors (OECTs) has introduced a new paradigm that can be a powerful testbed to evaluate the performance of a semiconducting hydrogel. In this report, we will trace back the history of the development of the semiconducting hydrogel and its first use in the development of transistors (OECTs) [2]. Moreover, we provide our insight on how to define a semiconducting hydrogel when using OECT as a testbed. Finally, we delve into the development of stretchable semiconducting hydrogels [2] and explore how they can revolutionize applications for tissue-compatible biomedical research.

***Biomimetic Conducting Polymer Devices to Study the Gut-Brain Axis** <u>Roisin Owens</u>; University of Cambridge, United Kingdom*

The gut-brain axis (GBA), has emerged as an incredibly important, but complex, part of human physiology. Dysregulation or disruption of the GBA is implicated in a host of pathologies that affect brain and gut (e.g. Autism Spectrum disorder, Crohn's disease) but also whole body disorders where inflammation and metabolism are affected. Physiologically relevant in vitro human models, as well as advanced tools to study in vivo animal models, are urgently required to elucidate mechanisms in GBA. In this talk I'll discuss a new generation of electronic tools, based on conducting polymers, for understanding the GBA. First, I'll discuss our progress towards generating a complete platform of the human GBA with integrated monitoring and sensing capabilities. We use tissue mimetic conducting polymer scaffolds to build human-based models of the gut and brain which can then be used to study different aspects of GBA in health and disease. Second, I'll discuss conformable electronic devices we've developed for both ex-situ measurements of GI tissue from rats, as well as in vivo experiments in live rats. These devices allow highly sensitive monitoring of gut permeability and motility, as well as the enteric nervous system.

9:30 AM +SB02.04.02
***On-Scalp Printing of Personalized EEG E-Tattoos** <u>Nanshu Lu</u>; The University of Texas at Austin, United States*

Electroencephalography (EEG) is a non-invasive method essential for diagnosing neurological conditions and enabling brain-computer interfaces (BCI). Traditional EEG setups, which rely on wet conductive gels and cumbersome cables, are often labor-intensive, uncomfortable, and prone to signal degradation. Although e-tattoos—soft, skin-conformable wearable devices—have advanced various biomedical applications, they have struggled with EEG compatibility due to hair interference. Here, we report a significant advancement in EEG e-tattoo technology through the automated, on-scalp but non-contact printing of biocompatible and electrically conductive inks. Our PEDOT:PSS-based inks are specially designed for low-skin-contact-impedance electrodes and highly conductive interconnects, can be jetted through hair, dampen the scalp, and rapidly self-dry into ultrathin, skin-soft, and stretchable films. This innovation markedly enhances breathability and longevity compared to traditional gel electrodes, as well as hair compatibility and skin adhesion compared to transferred e-

tattoos. Our manufacturing system employs an automated sensor layout design algorithm, customized for individual head shapes, in conjunction with a 5-axis printing robot to achieve safe and precise sensor placement. These printed e-tattoos successfully capture critical EEG markers, such as motion imagery (MI) and error-related potentials (ErrP), representing a transformative step towards personalized, comfortable, and long-term EEG monitoring.

***Leveraging Soft Microelectrode Arrays for Brain Organoid Electrophysiology** Eleonora Martinelli, Outman Akouissi, Scott Erickson and Stephanie P. Lacour; École Polytechnique Fédérale de Lausanne, Switzerland*

Traditional two-dimensional microelectrode arrays (MEAs) fall short in capturing the complexity of three-dimensional brain organoids. This study introduces two innovative MEA designs to address this limitation, enhancing the study of brain organoid electrophysiology.

The first design features a stretchable MEA tailored to monitor the electrophysiological activity of brain spheroids under varying mechanical loads. These MEAs are fabricated using thin-film technology, comprising a platinum layer sandwiched between polyimide films. Stretchability is achieved through a Kirigami-based patterning technique, incorporating Y-shaped motifs that facilitate out-of-plane deflections. The soft MEAs can sustain strains up to 10% without a notable increase in electrode impedance. Additionally, PEDOT coating on the electrodes enhanced both their electrical and mechanical performance, making them ideal for prolonged neural activity recording from brain spheroids.

Another compliant MEA design integrates soft actuation with flexible MEAs. We developed the e-Flower, a flower-shaped MEA that can envelop sub-millimeter brain spheroids. Inspired by soft micro-grippers, the e-Flower uses the swelling properties of a polyacrylic acid hydrogel grafted onto a polyimide substrate hosting electrical interconnects. Upon the addition of cell culture medium, the e-Flower actuates to envelop the spheroid, achieving a tunable curvature for comprehensive neural signal recording across the spheroid surface. This actuation mechanism requires no additional equipment or solvents and is compatible with standard electrophysiology recording systems.

The e-Flower demonstrated the ability to detect spontaneous neural activity across the entire surface of brain spheroids, highlighting its potential for detailed electrophysiological studies. Meanwhile, the stretchable MEA's capacity to record neural activity under mechanical strain opens new avenues for studying the effects of mechanical loading on neural tissues, mimicking conditions such as traumatic brain injury.

11:00 AM ^SB02.04.04

***Bioinspired Electronics for Brain-Machine Interface** Xiao Yang[1,2]; [1]Stanford University, United States; [2]Johns Hopkins University, United States*

Bioelectronic devices have been very important both as fundamental research tools and as therapeutic avenues for treating brain disorders and injuries. I will talk about how I drew inspiration from biological systems and art forms to design and develop a series of bio-inspired and art-inspired bioelectronics with distinctive biomedical applications. I have introduced bioinspired neuron-like electronics, a biomimetic brain-machine interface designed such that the key building blocks mimic the subcellular structural features and mechanical properties of neurons. I have developed multifunctional vasculature-like electronic scaffolds that guide and longitudinally track neural migration following brain injury. Moreover, we devised flexible kirigami-inspired electronics that transition from a 2D pattern to a 3D basket-like configuration to enable long-term integration and interrogation of human brain organoids and assembloids. Our studies advance bioelectronics in fundamental studies and therapeutic *applications, encompassing neural probes for brain-machine interface, electronic scaffolds for brain repair, and platforms for detecting human genetic diseases and tracking human neural development.*

11:15 AM SB02.04.05

Implantable Organic Semiconductor Devices and Deep-Red Light Excitation for Transcutaneous Stimulation of the Central and Peripheral Nervous Systems *Eric D. Glowacki and Marie Jakesova; Central European Institute of Technology, Czechia*

Great demand exists for minimally-invasive neuromodulation technologies to enable next-generation bioelectronic medicine. We report on our developments of ultrathin (opto)electronic devices for neurostimulation. These devices transduce modulated light impulses into charge-balanced electrolytic currents capable of stimulating excitable tissues. All of these devices rely on far red/near infrared irradiation in the tissue transparency window to actuate nanoscale organic semiconductor components. Our flagship technology is the organic electrolytic photocapacitor (OEPC), a microfabricated thin-film platform that can be integrated onto arbitrary substrates. These devices are not only wireless, but also 100-1000 times thinner than existing technologies. We will discuss examples of chronic implants capable of stimulating peripheral nerves, the cortical surface, as well as deeper brain structures. Light power can be safely and effectively transmitted to implants up to 15 mm below the skin surface, and effectively penetrates the scalp and skull. We believe that the combination of deep red light and ultrathin photovoltaic devices can account for a new paradigm in wireless bioelectronic medicine.

11:30 AM SB02.04.06

3D-Printed All-Polymer Implantable Intracortical Neural Electrode Array for Chronic Brains Neural Recording *Seoyeon Won and Huanan Zhang; The University of Utah, United States*

Implantable intracortical neural electrode arrays have been introduced as promising bioelectronics, detecting electrophysiological signals with high precision. Investigating neural activity in the brain using neural electrodes is crucial for understanding how the brain controls body movement, ultimately contributing to the development of treatments for patients with motor impairments. However, most commercial electrode arrays have a large mechanical mismatch with the brain tissue, leading to neuroinflammatory responses that hinder chronic neural signal recording. Their configurations are also limited by material choices and conventional semiconductor fabrication processes. The development of next-generation neural electrode arrays for in vivo brain neural recording requires the convergence of advanced fabrication processes and novel bioelectrically active materials. In this study, we propose a novel approach that integrates advanced two-photon 3D printing technology and tailored conductive polymer electrodeposition to develop the first functional and vertically templated electrode arrays. The advanced two-photon 3D printing technology is used to create vertical microchannels, and tailored conductive polymer electrodeposition functionalizes the 3D-printed microchannels as neural signal-detectable electrodes. Poly(3,4-ethylenedioxythiophene) doped with tetrafluoroborate (PEDOT:BF_4) as a bioelectrically active material is used to construct vertical templated electrodes inside 3D-printed microchannels. These self-assembled PEDOT:BF_4 all polymer neural electrodes can reduce the mechanical mismatch between electrodes and brain tissue. Moreover, the electrochemical properties of our intracortical neural electrode arrays exhibit outstanding low impedances and stability under physiological conditions. A chronic animal study was also conducted to record brain neural activity in rats. In-vivo brain neural recording was performed for 6 weeks, and the experiments demonstrated stable recording of single-unit action potentials over 6 weeks. This is the first demonstration of all-polymer-based intracortical neural arrays for chronic neural activity recording. The result indicates that our intracortical neural array is a promising bioelectronic platform for next-generation neural electrode arrays to record electrophysiological signals. Furthermore, the 3D-printed and tailored polymer electrode array fabrication process allows numerous design possibilities, offering opportunities to advance *beyond current neural array technology.*

11:45 AM SB02.04.07

Biodegradable Brain Stimulation Electrodes to Promote Translation Towards Stem-Cell Based Neural Repair Strategies *Tianhao Chen, Kylie Sin Ki Lau, Cindi Morshead and Hani E. Naguib; University of Toronto, Canada*

The delivery of electrical stimulation to the brain through implantable electrodes, referred to as brain stimulation, has been recognized as a clinically effective strategy for treating neurological disorders. Endogenous brain neural precursor cells (NPCs) have been shown to be electrosensitive cells that respond to electrical stimulation by (i) expanding in number, (ii) undergoing directed cathodal migration and (iii) differentiating into neural phenotypes in vivo, supporting the application of electrical stimulation to promote neural repair. In this study, we present the design of a flexible and biodegradable brain stimulation electrode for temporally regulated neuromodulation of NPCs. Leveraging the cathodally skewed electrochemical window of molybdenum and the volumetric charge transfer properties of conductive polymer, we engineered the electrodes with high charge injection capacity for the delivery of biphasic monopolar stimulation. We demonstrate that the novel electrodes are biocompatible and can deliver an electric field sufficient for NPC activation for 7 days post implantation before undergoing resorption in physiological conditions, thereby eliminating the need for surgical extraction. The biodegradable electrode demonstrated its potential to be used for NPC based neural repair strategies.

SESSION SB02.05: Brain and Neural Interfaces II

1:30 PM *SB02.05.01

Multimodal Bioelectronics to Probe Brain-Body Physiology *Polina Anikeeva; Massachusetts Institute of Technology, United States*

Probing physiological signals underlying communication between the brain and peripheral organs is essential to the study of organ contributions to the central nervous system function and to the diagnosis and treatment of metabolic, affective, and neuroimmune conditions. Although numerous physical and genetic approaches have been developed to probe brain physiology, the complex anatomy of peripheral organs and the substantial immunosurveillance outside the central nervous system impede direct translation of brain neurotechnologies to the periphery. In this talk, I will discuss our group's strategies to interface with peripheral organs such as the gastrointestinal tract at the scale of circuits, and then illustrate how nanomaterials can be employed as wireless transducers of physical signals to specific cells and receptors.

2:00 PM SB02.05.02

Multifunctional Fibers for Volumetric Imaging and Electrical Recording of Neuronal Activity In Vivo *Taylor M. Cannon, Aylin Baca, Ethan Frey, Pema Maretich, Lee Maresco and Polina Anikeeva; Massachusetts Institute of Technology, United States*

While electrophysiology has traditionally been used to capture neuronal firing dynamics via electrodes implanted in the brain, optical sensing methods leveraging genetically-encoded fluorescent indicators offer unique *advantages for neural sensing, including the ability to monitor specific cell types and detect neurotransmitter release. Endoscopic optical imaging also enables longitudinal tracking of many individual neurons within a wide field of view, but temporal sensitivity remains poor compared to electrophysiology, thus motivating the complementary usage of these techniques in tandem. However, expanding the functionality of neural implants stands to increase damage to surrounding tissue; large, stiff devices provoke inflammatory responses, attenuating recording capabilities and limiting long-term use of devices in vivo. Recent advances using thermal drawing to fabricate multifunctional fibers have yielded soft, flexible, polymer-based probes potentiating bidirectional electrical and optical sensing and stimulation in the brain, while minimizing foreign body response. Optical sensing capabilities of these probes have so far been limited to fiber photometry, which uses a single waveguide channel to relay a bulk fluorescence readout, and lacks the spatial signal discrimination offered by implantable endoscopic lenses. In this work, we advance the optical capabilities of multifunctional fibers to incorporate multicore waveguide bundles capable of relaying spatially-resolved fluorescent signals as analogues of neural activity. Our thermally-drawn fiber bundles feature hundreds to thousands of individual waveguide cores, each acting as a single pixel of an image with customizable resolution and field of view depending on the bundle design. We demonstrate imaging through polymer optical fiber bundles at a spatial resolution of 3 microns, sufficient for visualizing individual neurons. We further apply signal processing methods to leverage spatially-variant light modes captured within each individual waveguide core to achieve 3D imaging without demanding additional hardware. Finally, we show preliminary deployment of our multifunctional devices in vivo, interfaced with custom, miniaturized, head-mounted microscopes to capture fast calcium transients in the mouse brain. Compared to conventional endoscopic brain imaging, multifunctional imaging fiber bundles offer superior materials compatibility with surrounding brain tissue, volumetric imaging capabilities, and complementary electrical stimulation and recording. Overall, our fiber-based platform offers unique opportunities to probe neural signaling across spatiotemporal scales and diverse experimental paradigms.*

2:15 PM SB02.05.03

Next Generation of Selective and Biocompatible Neural Interface—Cleanroom-Free Carbonized Parylene C Electrodes for Neurotransmitter Detection *Farbod Amirghasemi, Abdulrahman Al-Shami, Ali Soleimani and Maral Mousavi; University of Southern California, United States*

Laser engraving is progressively becoming popular for creating porous graphitic carbon structures known as Laser-Induced Graphene (LIG), used in various sensing applications. LIGs are produced by directing a laser beam onto carbon-rich polymers, causing localized heat reactions that transform the SP_{3} carbon atom hybridization into a three-dimensional porous graphitic structure. This method is maskless, scalable, reproducible, cost-effective, and rapid, producing graphite layers with high electrical conductivity and excellent electrocatalytic properties. These features make LIGs superior to graphene created by traditional methods such as chemical vapor deposition (CVD) and wet chemistry.

Traditionally, perylene has been the primary material for developing neural interfaces and probes, and it has been validated in the bioelectronic community. We chose perylene C due to its pinhole-free surface, high flexibility, mechanical strength, and biocompatibility, making it ideal for constructing implantable neural interfaces. However, fabricating electrodes from perylene can be time-consuming and typically requires cleanroom facilities. In this work, we use laser power to carbonize the perylene C substrate, simplifying the complex process of neural electrode microfabrication.

We selected acetylcholine and dopamine as representative neurotransmitters essential to brain activity and requiring distinct detection mechanisms to highlight the versatility of our platform. Our proof-of-concept platform comprises two modules: (1) an acetylcholine (ACh) potentiometric sensor and (2) a voltammetric dopamine *sensor. The ACh sensor includes a working electrode with an ACh-specific sensing membrane and a reference electrode with a reference membrane. Similarly, the dopamine sensor features carbonized parylene C working and counter electrodes and an Ag/AgCl reference electrode.*

The parylene C substrate is carbonized through laser ablation, producing electrode arrays with individual working areas that have a 500–600 μm radius. This one-step fabrication process eliminates the complexities of the multilayer photolithography approach. In the acetylcholine (ACh) sensing module, the electrical potential (emf) between the ACh sensor and the reference electrode corresponds to the activity of ACh in the biofluid, following the Nernst Equation: emf=E^0+(RT/zF) log (aACh). A theoretical slope of 61.5 mV/decade is expected at body temperature, known as the Nernstian slope. The ACh-sensing membrane will be applied to the working electrode area. Due to the electroactive nature of dopamine, we utilized square wave voltammetry (SWV) techniques to measure physiologically relevant concentrations for dopamine detection.

The ACh sensing module showed a Nernstian slope of 54.9 ± 0.8 mV/decade and a 42 nM detection limit. Additionally, our sensor successfully differentiated dopamine from other common interfering substances in the brain, including serotonin, ascorbic acid, and uric acid, within physiologically relevant concentrations.

Advances in neural interface technology require innovative materials and fabrication techniques to improve sensing performance and in-vivo applicability. In this work, we present a transformative approach to neural probe fabrication and neurotransmitter sensing, which promises enhanced performance in neural interfaces. Future research will focus on optimizing sensor integration to in-vivo applications and expanding the range of detectable neurotransmitters.

2:30 PM SB02.05.04
Soft Electronics and Engineered Nerve-on-a-Chip—Developing a Biohybrid Neural Interface *Léo Sifringer[1], Alex Fratzl[2], Blandine F. Clément[1], Parth Chansoria[1], Leah Mönkemöller[1], Jens Duru[1], Stephan J. Ihle[1], Simon Steffens[1], Anna Beltraminelli[1], Eylul Ceylan[1], Benedikt Maurer[1], Sean Weaver[1], Christina M. Tringides[1], Katarina Vulić[1], Srinivas Madduri[3], Marcy Zenobi-Wong[1], Botond Roska[2], Janos Vörös[1] and Tobias Ruff[1]; [1]ETH Zürich, Switzerland; [2]Institute of Molecular and Clinical Ophthalmology Basel, Switzerland; [3]University of Geneva, Switzerland*

In this work [1], we introduce a novel nerve-on-a-chip model designed as a neural interface for deep brain stimulation. Termed as a "biohybrid" approach, it aims to overcome the limitations of standard deep brain implants such as low stimulation resolution. The biohybrid concept leverages on-chip grown retinal neurons to convert electrical signals from a stretchable 2D microelectrode array into synaptic stimulation of a neural target tissue.

The device consists of two primary components: a soft, stretchable multi-electrode array (MEA) and an axon-guiding microstructure [2]. The MEA, fabricated using a transfer stripping method [3], comprises a PDMS substrate and microstructured platinum tracks. The PDMS microfluidic axon guidance structure is aligned and bonded onto the microelectrode array. Spheroids of living retinal neurons labeled with a viral vector are then seeded into 16 seeding wells and cultured under standard cell culture conditions before implantation.

We describe the fabrication of the biohybrid neural interface and characterize the device electrically and mechanically. We demonstrate how the retinal ganglion cells seeded into the implant form an artificial optic nerve of up to 3 mm in length. Moreover, we demonstrate how axons transit from the biohybrid implant into a nerve-forming bioresorbable collagen tube that will guide axons from the implant towards a neural target structure for *sensory reinnervation and synaptic stimulation of the visual thalamus in vivo. We show that retinal spheroids can be stimulated using the stretchable microelectrode array with functional calcium imaging. To assess stimulation-induced signal transmission in the biohybrid implant we present in vitro data on how spikes propagate within the axon guidance channels using CMOS [4] multielectrode arrays. Lastly, we demonstrate that neurons cultured in the device grow axons in the microstructure, and exhibit spontaneous activity for over 3 weeks when implanted in mice.*

With this work, we show that this biohybrid approach has the potential to serve as a new kind of neural interface technology. Although further experiments are necessary for in vivo synapse formation and deep-brain stimulation, previous work has shown the feasibility of this approach in vitro [5], and the findings presented in this work pave the way for a new kind of neural interface.

Microscale Optoelectronic Devices for Advanced Neural Interfaces Xing Sheng; *Tsinghua University, China*

Bio-integrated high performance inorganic optoelectronic devices will provide new insights on interactions between light and bio-systems. Here we present unconventional strategies to design and fabricate microscale, thin-film optoelectronics devices including micro-LEDs and photodetectors that can be formed via epitaxial liftoff and transfer printing techniques. These microscale devices can be heterogeneously integrated on flexible and stretchable substrates and interact with biological systems for biomedical applications. In particular, we produce multifunctional neural probes that can be directly implanted into the deep brain of freely moving animals, modulating and detecting neural activities in vivo.

Magnetogenetic deep brain stimulation (MG-DBS), utilizing nanoscale magnetic actuators, has recently emerged as a promising strategy for treating motor disorder of Parkinson's disease (PD). This innovative approach offers extended recovery durations, while providing cell-specific, fully wireless treatment, addressing the limitations of conventional electrical deep brain stimulation (E-DBS). In this study, we employed a phase-changeable soft neural probe, based on a liquid-metal electrode, to collect electrophysiological signals from the cortico-basal ganglia-thalamic (CBT) circuit in PD mouse brain. This probe minimizes disruption to the neural network within the CBT circuit, enabling precise and comprehensive electrophysiological analysis. By monitoring neural activity changes across six major regions of the CBT circuit, we thoroughly explored the therapeutic effects of MG-DBS. Our electrophysiological analysis not only supports the effectiveness of MG-DBS but also provides valuable insights into the underlying mechanism of DBS therapies. These findings significantly contribute to advancements in the field of neuroscience and neuromodulation therapies.

Flexible Gallium-Based PEDOT: BF4 Coated Electrodes for Chronic Neural Recording and Biocompatibility

Alexandra Boyadzhiev and Huanan Zhang; The University of Utah, United States

Implantable microelectrode arrays are crucial tools in neuroscience to study neural functions as well as disorders like Parkinson's disease, epilepsy, and spinal cord injuries. Despite advancements in neuro-device technology, challenges persist with rigid-metal-based arrays. These devices often cause mechanical mismatches with brain tissue, leading to chronic inflammation, tissue damage, and compromised performance. There is increasing interest in developing flexible electrodes to mitigate these issues.

Our approach to bridging the mechanical mismatch gap involves utilizing gallium-based electrodes for flexible neural implants. Gallium-based materials offer several advantages, including soft mechanical properties, minimal cytotoxicity, and excellent electrical conductivity. Gallium electrodes are initially rigid for implantation but phase into a liquid state post-insertion due to their low melting point, reducing the mechanical mismatch with neural tissue. Though the potential of gallium in neuro-device fabrication is being studied, further research into chronic biocompatibility and recording capabilities is necessary to validate the material's performance.

We electrochemically deposited conductive polymer poly(3,4-ethylenedioxythiophene) PEDOT doped with tetrafluoroborate (BF4) to contain the liquid gallium, preserve its' electrochemical properties and enhance the device biocompatibility. PEDOT: BF4 demonstrates excellent electrochemical and thermochemical performance, low impedance, and good biocompatibility.

This study presents a flexible neural array coated with PEDOT: BF4 on gallium electrodes for chronic in vivo applications. Our findings indicate that these gallium-based, PEDOT: BF4-coated neuro devices exhibit superior biocompatibility compared to traditional rigid metal arrays. After eight weeks, reduced neuron death around the electrode site in rat brains demonstrates improved biocompatibility.

We extensively characterize the electrochemical properties, thermal stability, and morphology of PEDOT: BF4-coated gallium electrodes, demonstrating their structural integrity and chronic electrochemical stability over a five-week in vitro study. Acute in vitro and in vivo experiments confirm the action potential recording capabilities of these flexible gallium-based neuro devices.

Moreover, our chronic implantation study in rats shows promising results, with devices maintaining functionality over eight weeks. Analysis of neural tissue post-implantation reveals reduced inflammation markers (GFAP) and closer proximity of neuronal markers (NeuN) to the electrode site compared to conventional rigid metal implants, suggesting enhanced biocompatibility and reduced tissue damage with our gallium-based, PEDOT: BF4-coated neural implants.

Our research marks a significant advancement in developing chronic implantable neuro-electronics with improved *biocompatibility and longevity. Future research will optimize electrode density and explore advanced fabrication techniques, such as polymer 3D printing, to further enhance device performance and compatibility. Flexible gallium-based neuro-electronics are promising for advancing research and clinical applications in neuroscience.*
