The thiospinel group of nickel cobalt sulfides (NixCo3–xS4) are promising materials for energy applications such as supercapacitors, fuel cells, and solar cells. Solution-processible nanoparticles of NixCo3–xS4 have advantages of low cost and fabrication of high-performance energy devices due to their high surface-to-volume ratio, which increases the electrochemically active surface area and shortens the ionic diffusion path. The current approaches to synthesize NixCo3–xS4 nanoparticles are often based on hydrothermal or solvothermal methods that are difficult to scale up safely and efficiently and that preclude monitoring the reaction through aliquots, making optimization of size and dispersity challenging, typically resulting in aggregated nanoparticles with polydisperse sizes.

In this talk, I will discuss our scalable “heat-up” method to colloidally synthesize NixCo3–xS4 nanoparticles that are smaller than 15 nm in diameter with less than 15% in size dispersion, using two inexpensive, earth-abundant sulfur sources. The synthesis leverages the amino acid l-cysteine ethyl ester and elemental sulfur to provide tunable compositional control, yielding gram-scale quantities, and is applicable to multiple ternary metal sulfide systems. Our method provides a reliable synthetic pathway to produce phase-pure, low-dispersity, gram-scale nanoparticles of ternary metal sulfides. This method enhances the current capabilities of NixCo3–xS4 nanoparticles to meet the performance demands to improve renewable energy technologies.

Understanding and Manipulating Rock-Water-Gas Interfaces in Ultramafic Rocks for Novel and Economically Relevant Reactions *Iwnetim I. Abate; Massachusetts Institute of Technology, United States*

Understanding and manipulating heterogeneous rock-water-gas interfaces are essential for discovering new methods of extracting critical minerals and controlling economically relevant reactions. Iron-rich ultramafic rocks in the subsurface are involved in chemical redox reactions, where iron is oxidized and electrons are transferred to reduce molecules such as water, producing hydrogen. This process, known as serpentinization, naturally *produced significant amounts of hydrogen, first discovered in Mali during the 1980s. In addition, the interaction of water with these rocks produces percolated fluid with trace amounts of dissolved critical minerals such as Li, Co and Ni. However, 1) the complex and dynamic nature of the rock-water-gas interface during serpentinization, 2) factors affecting the thermodynamics and kinetics of the reaction, and 3) the optimization of the interface for high-yield and high-rate reactions are not yet fully understood. In this work, we combine computational and experimental methods to develop a chemical, mechanical, and electronic understanding of these reactions, aiming to create a generalizable framework. We explore how these processes can be tuned to produce economically valuable products such as hydrogen. Unlike the naturally occurring hydrogen discovered in Mali, we propose and demonstrate methods to stimulate and actively control the reaction kinetics for hydrogen production under subsurface conditions at rates and yields that are economically feasible if scaled, potentially meeting all our energy needs for the next 250,000 years.*

4:00 PM EN10.07.06

Illuminating the Impact of Hydrocarbon Adsorption on Ru Surface Energetics *Erin E. Dunphy, Samuel Marks and Michael F. Toney; University of Colorado Boulder, United States*

Chemical recycling of plastic waste through hydrogenolysis using Ru/Al_2O_3 *catalysts offers a promising route to sustainable energy infrastructure by producing high-value products. However, the control of product distributions remains challenging due to the elusive nature of polymer adsorption on catalyst surfaces. This study explores the complex interactions between polymers and Ru/*Al_2O_3 *catalysts, which involve solid reactants and oil, liquid, and gas products under relatively high temperature and hydrogen pressure conditions. Our findings reveal a structural hysteresis associated with the adsorption of various hydrocarbons, indicating that polymer adsorption significantly impacts the Ru metal structure at the catalyst interface. We compare real and model systems under relevant conditions by extracting the mean-square displacement of both Ru/*Al_2O_3 *catalysts and single crystal Ru. This work aims to elucidate the fundamental phenomena governing polymer-catalyst interactions, ultimately guiding the design of more robust catalysts with extended lifetimes and improved performance for sustainable plastic recycling processes.*

Turning Discards into Values—Polymeric Membranes with Chelating Properties for Efficient Palladium Recovery from Wastewater *Jamaliah Aburabie, Shabin Mohammed, Anilkumar Kumaran and Raed Hashaikeh; New York University Abu Dhabi, United Arab Emirates*

This study introduces an efficient approach using a novel polymeric membrane adsorber designed specifically for the efficient recovery of palladium ions from dilute solutions. The membranes, fabricated from polythiosemicarbazide (PTSC), present a promising solution by offering high adsorption site density, thus overcoming the limitations commonly associated with traditional adsorbents. This investigation outlines the fabrication process, performance evaluation, and potential applications of these membranes in the context of extracting precious metals, especially palladium, from seawater and other dilute solutions.

The extraction of precious metals, such as palladium, from seawater and wastewater has gained significant attention as a promising method for resource recovery from abundant oceanic environments [1]. Palladium, essential for modern industries like petrochemicals, biomedicine, electronics, and catalysis, is highly valued due to its unique chemical and physical properties. However, challenges remain in palladium recovery, including low selectivity, inefficiency, and limited regeneration of current adsorbents. Addressing these obstacles requires the development of effective adsorbents capable of selective separation and efficient recovery [2].

Up-to-date as of November 14, 2024

This study introduces an innovative polymeric membrane adsorber specifically designed to capture high densities of palladium ions, providing an efficient alternative for recovering palladium from dilute solutions. Utilizing polythiosemicarbazide (PTSC), a polymer known for its singular chelation site per monomer, the membranes are fabricated using a phase inversion technique, creating a porous interconnected structure suitable for liquid-phase applications with excellent flux rates. This approach leverages the inherent adsorption properties of PTSC, eliminating the need for additional agents, thereby overcoming the limitations of traditional adsorbents with low capacities. The robust PTSC membranes enable pressure-driven permeation, bypassing diffusion issues typically associated with packed column adsorption methods.
Batch adsorption tests conducted under ambient conditions with a 10% HCl solution demonstrated a maximum adsorption capacity of 1310 mg/g for a 1000 ppm Pd solution [3]. The membranes showed outstanding palladium adsorption, achieving 90–96% selectivity in dynamic filtration for palladium recovery from 10 ppm solutions in just 6 minutes. Palladium elution was successfully performed using a 0.1 M thiourea solution, allowing the membranes to be reused for at least three cycles without significant performance loss. Additionally, the membranes exhibited high selectivity for palladium compared to other metals such as copper, chromium, and cadmium.

Efficient Geological Hydrogen Production by In Situ High-Throughput System *Yifan Gao, Ming Lei, Lokesh Sangabattula, Hugh B. Smith, Ju Li and Iwnetim I. Abate; Massachusetts Institute of Technology, United States*

Hydrogen plays a vital role in the global energy transition, yet current production methods, such as steam reforming and electrolysis, are CO_2-intensive and expensive, respectively. Geological hydrogen (Geo-H_2), produced through the reaction of water with iron-rich rocks (serpentinization), presents a promising, clean, and cost-effective alternative. The Earth's crust contains enough iron to produce hydrogen to supply the global energy need for over 250,000 years. However, slow natural production rates, the difficulty in locating suitable sites with adequate hydrogen accumulation, and challenges in trapping and collecting hydrogen limit its practical application. Stimulated Geo-H_2 production, which involves enhancing the serpentinization reaction by injecting water into subsurface rocks, offers a more controllable and potentially scalable method by optimizing injection fluids and catalysts, paving the way for economically viable large-scale hydrogen production.

In this study, we present an in-situ high-throughput Geo-H_2 production system that significantly accelerates hydrogen generation from natural rocks. Our system achieves a production rate 200 times faster than previously reported, completing the process in just 8 hours. We show that adding as low as 1 wt% of a catalyst can greatly improve hydrogen production. By examining various ionic species and concentrations, we detail their impact on catalytic performance. To uncover the underlying mechanisms at rock-water-gas interface, we employed characterization techniques such as SEM, XRD, XPS, and XANES, along with DFT calculations. We also optimized experimental conditions, including temperature and pH, to enhance efficiency. Our system supports continuous, high-throughput experimentation with real-time sampling and monitoring, allowing data collection as frequently as *every three minutes. This advancement represents a significant step forward in studying Geo-H_2 production, providing detailed data and improved accuracy in tracking reaction kinetics. By accelerating Geo-H_2 generation and improving data collection, this study sets the stage for future developments that could make Geo-H_2 a more scalable and efficient source of clean energy.*

SESSION EN10.08: Upcycling Critical Materials for Energy Storage II

***Critical Materials and Sustainability for Battery Technologies** Emma Kendrick; University of Birmingham, United Kingdom*

In this paper, the sustainability aspects related to emerging battery technologies and advancements is explored. The understanding of the influence of materials choices, energy, and the impact upon the environment in establishing a complete circular supply chain for battery materials is required. This involves assessing the significance and shortage of materials, the manufacturing process for both materials and batteries, their longevity, and the potential for recycling and reusing materials at the end of their life cycle.

Circular material choices and supply are currently heavily influenced by cost. However, as different minerals and materials are listed as critical on various global lists, it may be necessary to consider alternatives. Lithium, graphite, phosphate, silicon, and cobalt are all included in the EU and UK critical materials lists, highlighting supply chain risks and their high economic importance. By following the principles of sustainability - reduce, reuse, recover, and recycling - we can work towards reducing our reliance on these materials. For instance, sodium-ion batteries are being explored as an alternative, using sodium, iron, and hard carbon in place of lithium, cobalt, and graphite. While this approach leads to significantly lower material costs, it's important to note that initial life cycle assessments (LCAs) show that these batteries have a higher embedded carbon footprint per kWh. Therefore, it is important to consider other sustainability factors such as recyclability and lifespan.
In this paper, we explore design for disassembly considerations for sodium-ion and lithium-ion batteries. Possible recycling routes, materials recovery, and reuse scenarios for these materials. The design of cells and electrodes often affects recovery rates, so we suggest routes for electrode manufacturing, compositions, and design considerations to optimize performance and material recovery rates.

9:00 AM EN10.08.02

***Continuous Lithium Extraction from Brine by Highly Efficient Redox-Couple Electrodialysis** Ge Zhang[1], Rong Xu[2], Xin Xiao[3] and Yi Cui[1]; [1]Stanford University, United States; [2]Xi'an Jiaotong University, China; [3]Zhejiang University, China*

The rapid growth of lithium ion batteries has catalyzed an unprecedented demand for lithium. However, global Li supplies struggle to meet the ever-increasing demand because traditional Li mining processes are slow, expensive, inefficient, and environmentally unsustainable. Here, we introduce a highly efficient redox-couple electrodialysis (RCE) approach for sustainable Li extraction from brines. In our design, the electrodialysis is driven by the same half-cell electrochemical reaction but operated in the opposite directions: hydrogen evolution *reaction and hydrogen oxidation reaction, which consumes minimum energy due to the zero equilibrium full-cell voltage resulted from the nature of the same half-reactions and their low overpotential. Meanwhile, the adoption of solid-state electrolytes as Li-ion selective membranes ensures high selectivity of the Li extraction from brines with mixed ions. We demonstrate a continuous Li extraction from brines for over 100 hours, with an low operating voltage of around 0.25 V, a Faradaic efficiency of 88.87%, and a Li selectivity of 99.54%. Notably, the Li extraction via RCE consumes the specific energy of a mere 1.1 kWh per kilogram of Li, approximately an order of magnitude lower than the energy demands of most reported Li extraction techniques. Techno-economic analysis reveals that Li extraction via RCE offers a substantially reduced cost compared to the traditional Li extraction technique. The efficiencies and cost benefits innate to our RCE approach not only position it as a promising alternative to prevailing Li extraction techniques but also as a potential catalyst to reshape the lithium supply chain.*

9:15 AM EN10.08.03

***Highly Selective Granulation Adsorbents for Lithium Recovery from Gas Field Brine** Muhua Zhao; Sinopec Beijing Research Institute of Chemical Technology, China*

With the rapid development of lithium batteries, the lithium demand is significantly increased. Adsorption with granules have made progress in extracting lithium from salt lake brine. However, Lithium recovery from oil and gas produced water still faces challenges and difficulties due to the high sodium salt content and organic pollutants. Here, we introduce the granules tuning method to synthesize lithium adsorbents with high selectivity and adsorption efficiency. By adjusting the surface/core pore structures, it is possible to promote cyclic service life of the granules. And adjusting powder lithium ion-sieve dispersion could effectively promote lithium adsorption efficiency. Density function theory (DFT) simulations revealed that lithium transport could be promoted and transferred to binding sites by specific co-binders, which accelerated mass transfer efficiency in low concentration brine. The novel designed granules can exhibit more than three times higher distribution coefficient of Li^+ compared to commercial adsorbents. Moreover, it can efficiency recovery of Li^+ (adsorption efficiency 98.4%) from gas field brine with high salt content and organic pollutants, indicating that the designed granules could be used in an appealing and competitive manner for industrial processes.

9:30 AM EN10.08.04

***Recycled Graphite Enabled Superior Performance for Lithium Ion Batteries** Zeyi Yao and Yan Wang; Worcester Polytechnic Institute, United States*

As the conflict between the expanding requirement for energy storage and scarcity of the resources for the current lithium-ion batteries (LIBs) shows up, recycling graphite attracts growing attention. Although various recycling methods have been reported, the recycled graphite cannot reach the strict commercial standards of purity, scalability, efficiency, and capacity, preventing it from battery manufacturing. Herein, a closed-loop graphite recycling process with the surface recovery and modification for the graphite from the end-of-life batteries is demonstrated, and the important roles of defects and functional groups on the graphite surface are deeply studied. The recovered graphite delivers a matchable purity and initial coulombic efficiency with commercial graphite. Fabricated in industrial standard battery testing parameters, full cells with recovered graphite possess enhanced rate reversibility, cycle life,and capacity along with reduced anode material cost. These impressive results not only underscore the transformative potential of surface reconstruction and modification in graphite recycling, but also present economic feasibility and sustainable pathway for significantly improving battery performance and addressing global resource challenges via integration with the hydrometallurgical recycling process.

The Impact of Direct Battery Cathode-to-Cathode™ Recycling and Upcycling on Sustainable Practices *Chao Yan and Jared Liao; Princeton NuEnergy, United States*

The rapid expansion of the electric vehicle (EV) market and the corresponding increase in battery production have intensified the need for sustainable battery recycling practices. This presentation examines the role of direct cathode-to-cathode™ recycling and upcycling in enhancing environmental sustainability and resource efficiency within the lithium-ion battery (LIB) sector. Conventional recycling techniques often lead to significant material loss and high energy consumption. In contrast, direct cathode-to-cathode recycling/upcycling preserves the functional integrity of cathode materials, facilitating their direct reuse in new batteries with minimal reprocessing.

Princeton NuEnergy (PNE), a U.S.-based innovative clean-tech company, initiated its pilot production in 2022 and manufacturing plant in 2024. PNE is revolutionizing the supply chain of critical materials through its patented technology for directly recycling and upcycling cathode materials from spent LIBs and manufacturing scraps. Utilizing an innovative low-temperature plasma-assisted process (LPAS™), PNE efficiently rejuvenates high-value cathode active materials, making them suitable for direct reintroduction into cell manufacturing. PNE's technology is set to significantly disrupt the battery market, representing a major leap forward in sustainable material recovery and recycling.

10:45 AM EN10.08.06

Synthesizing Highly Crystalline Graphite Powder from Bulk Polyethylene Waste for Lithium-Ion Battery Anodes *Ngoc Tien Huynh[1,2], Yuan Gao[1,2], Yun Yang Lee[1,2], Ki-Joong Kim[1,2], Viet Hung Pham[1,2], Congjun Wang[1] and Christopher Matranga[1]; [1]National Energy Technology Laboratory, United States; [2]NETL Support Contractor, United States*

Upcycling plastic waste into graphite can potentially be used, in conjunction with other methods, to manage existing waste materials and diversify graphite supply chains. However, synthesizing large quantities of crystalline graphite powder from plastic waste, particularly polyethylene (PE), remains a challenge because PE decomposes into light gases during thermal processing, and simple methods do not exist at any appreciable size scale to address this challenge. In this work, a method is developed for air processing bulk forms of PE waste to create a stable carbon char that does not readily decompose during high-temperature processing. This method employs solid additives in the form of salts, which are combined with the PE melt during air processing to increase the effective surface area of the melt and improve the oxygen-driven chemistry that stabilizes the PE for high-temperature processing. After removing the solid salt additives from the PE-derived char, it is converted into a highly crystalline bulk graphite powder using a Fe-based low-temperature (<1500 °C) catalytic process. The PE-derived graphite powder showed excellent electrochemical performance as an anode material for lithium-ion batteries (LIBs) with a capacity of up to 302 mAh/g at 0.5 discharge/charge cycles per hour (0.5 C) and capacity retention of 100% after 415 cycles. This method illustrates there are opportunities for upcycling large quantities of PE waste to produce graphite powders suitable for use in LIBs.

11:00 AM EN10.08.07

Recovery and Regeneration of End-of-Life Cathodes Through Selective Leaching Process *Milon Miah; University of Birmingham, United Kingdom*

Large-scale recycling and regeneration of lithium-ion cathode materials are challenged by the complex mixture of chemistries often present in the waste stream. This study outlines an efficient process for separating and

regenerating phases within blended cathodes. We demonstrate the efficacy of this approach using cathode material from an end-of-life NMC and NFM mixture. By exploiting the different stabilities of transition metals in acidic media, we show that ascorbic acid can selectively leach NMC 811 from a mixed cathode electrode (NMC 811/NFM333) in just 5 minutes, allowing both phases to be effectively recovered separately.
This process facilitates the upcycling of the NFM content from the resultant leachate. The remaining nickel-rich NMC 811 can be directly regenerated through a hydrothermal hydroxide process, which also decomposes the PVDF binder, thus avoiding fluorine contamination of the recovered layered oxide. We present electrochemical data for the regenerated NMC 811 phase and demonstrate that the leachate can be upcycled into next-generation materials. Unlike many recycling studies performed on model systems, this method is illustrated on a real end-of-life EV battery.
This approach has significant potential for recycling EV battery waste and other Li/Na-ion battery waste, such as mobile phone batteries, where different cell chemistries are often mixed.

11:15 AM EN10.08.08
A Green Closed-Loop Process for Selective Recycling of Lithium from Spent Lithium-Ion Batteries *Jiahui Hou and Yan Wang; Worcester Polytechnic Insititute, United States*

As the economy started to recover from the COVID pandemic, the price of Li2CO3 skyrocketed to its highest. This situation has aggravated concerns about the supply chain for lithium-ion batteries (LIBs). Recycling spent LIBs is a potential solution to alleviate the bottleneck of the supply chain and prevent environmental pollution and has attracted lots of attention. However, lithium recycling is generally disregarded because of the complex recycling process and its low recycling efficiency. Here, in this work, we developed a sustainable lithium recovery process, which can selectively leach and recover lithium with formic acid before recycling valuable metals. With the reported method, lithium can be 99.8% recovered from layered oxide cathode materials with 99.994% purity. In addition, this lithium recovery process is affordable, compared to the typical hydrometallurgical process, by saving 11.15% per kilogram of spent LIBs. Therefore, this research provided a new solution to eliminating the effects of lithium ions on valuable metal separation and the co-precipitation reaction and precluding the influence of other metal ions on lithium recovery. This simplified lithium recovery process provides new opportunities for sustainable recycling of LIBs and economical restoration of the lithium supply chain.

11:30 AM EN10.08.09
Comparison of Carbothermal and Hydrogen Reduction for Recycling Valuable Materials from Cathode Black Mass of Spent Lithium-ion Batteries *Ankush Kumar, Srinivas Seethamraju and Venkatasailanathan Ramadesigan; Indian Institute of Technology Bombay, India*

The extensive use of lithium-ion batteries (LiBs) for different energy storage applications generates a significant amount of spent LiB waste annually. For sustainable use of the critical materials present in the LiBs, the recycling of spent LiBs is required. The combined pyro/hydro-metallurgy process for recycling spent LiBs is receiving considerable attention over traditional methods because it operates at lower temperatures (< 1000 °C) during the pyro stage and utilizes less harmful reagents in the hydro stage. It includes the thermal reduction of $Li_{1-a}Ni_xMn_yCo_zO_2$ *(NMC) cathode material, followed by multi-step leaching for metal extraction [1]. Thermal reduction is a crucial step that helps avoid harmful inorganic acids during multi-step leaching.*

Thermal reduction is usually performed in the presence of reducing agents such as carbon (carbothermal reduction or CR), H_2 *(g),* SO_4^{2-}*,* NO_3^{2-}*, and* Cl^-*. The CR or* H_2 *(g) reduction has received considerable attention because (a) it avoids anionic interferences like* SO_4^{2-}*,* NO_3^{2-}*, and* Cl^- *during the multi-step leaching and (b) it produces valuable gases which aid in lithium carbonate or hydroxide production.*

The decomposition temperatures of cathode black mass (CBM) components, i.e., binder (PVDF), acetylene black, and NMC, are 380 – 480 °C, 500 - 600 °C, and 850 – 1200 °C, respectively [2]. Thermal reduction in the H_2(g) environment occurs effectively between 400 - 600°C. It is observed that the thermal reduction of NMC at 400°C with 100% H_2(g) and at 500 °C with 10% H_2(g) yields LiOH, MnO, and Ni-Co alloy [3]. Existing literature shows that the product obtained after conventional CR of CBM at 400 - 1000 °C contains undecomposed NMC, Mn_3O_4, MnO_2, MnO, CoO, NiO, Co, Ni, and Li_2CO_3. The reported optimal operating temperature of the CR process for NMC is 600 to 900 °C. Different reaction parameters such as reaction medium, CBM to reductant ratio, catalyst, particle size, and holding period can influence the optimal operating temperature. For example, adding NaOH as a catalyst to the feed mixture (NMC + C) helps lower the reduction temperature to below 600 °C [4]. This literature confirms the feasibility of NMC thermal reduction at less than 600 °C; therefore, a systematic study of thermal reduction at a lower temperature range is required.

In this study, CR of NMC with and without NaOH catalyst is performed at 400 – 600 °C and compared with the result of H_2(g) reduction of NMC. The thermal heating of NMC without C and NaOH at 480 °C and 600 °C yields disordered and spinel NMC, respectively. The thermal heating with 20 wt.% C at 480 °C produces disordered NMC. At 520 – 600 °C, new phases (NiO and Li_2CO_3) apart from undecomposed NMC are obtained. With the addition of 20 wt.% NaOH catalyst with 20 wt.% C, the formation of NiO and Li_2CO_3 is observed even at lower temperatures, i.e., 420 – 480 °C. Further, the analysis of the same system at higher temperatures (520 – 600 °C) results in a strong reduction, yielding Ni-Co alloy in addition to NiO and Li_2CO_3. Therefore, it is essential to note that 480 °C to 520 °C is critical for forming new NMC phases during CR with C or C + NaOH. Thermal reduction of NMC performed with 10% H_2(g) at 380 - 450 °C gives comparable results as CR with 20 wt.% C at 480 °C. However, 100% H_2(g) strongly reduces NMC into Co-Ni alloy and Li_2O/LiOH at 450 °C.

This study demonstrates the feasibility of varying degrees of reduction of NMC at lower temperatures. Further research is needed to investigate thermal reduction using 10 – 100 % H_2(g) at 480 – 600 °C and compare it with CR products to obtain a comprehensive understanding.

Effects of Different Impurities on the Properties of Recovered Cathode Materials by Hydrometallurgical Recycling
Zifei Meng and Yan Wang; Worcester Polytechnic Institute, United States

The escalating demand for lithium-ion batteries necessitates sustainable recycling strategies to limit the cost and mitigate environmental impact. The cathode, a critical component of spent lithium-ion batteries, can be effectively regenerated through hydrometallurgical recycling. This process introduces three categories of impurities: cationic, anionic, and solid impurities, from various battery components. Cation impurities, including Al^{3+}, Cu^{2+}, $Fe^{2+/3+}$, originate from cathode/anode current collector and cell cases, respectively. These cations adversely affect morphology and tap density of cathode materials since they can react with OH^- and influence the nucleation of precursors. However, these cations can merge into the lattice of cathode materials. With a small amount of substitution, they can inhibit cation mixing and improve the electrochemical performance of recovered cathode *materials. As for anion impurities, there are S^-, F^-, and PO_4^{3-} and they are sourced from electrode materials and electrolyte. These anions have less effects on the morphology of recovered cathode materials, but some of them can cause holes inside particles, which can improve the electrochemical performance. Solid impurities, mainly neutral insoluble substances, contain carbon from anode and conductive agents. Carbon impurities can affect the nucleation of precursors and form holes inside particles. This study provides a systematic exploration of how these common impurities affect the morphology, tap density, phase, cation mixing, and electrochemical performance of recovered cathode materials, which can offer valuable insights into the role of impurities in recycling processes, aiding researchers in refining recovery techniques for optimal performance of recycled cathodes.*

SESSION EN10.09: Upcycling Critical Materials for Energy Storage and Reducing Heat in Manufacturing

Substituting Critical Materials in Positive Electrodes for Li-Ion Batteries— Implications for the Electrode-Electrolyte Reactivity *Livia Giordano; University of Milano-Bicocca, Italy*

Nickel-rich layered oxides are promising positive electrode materials for Li-ion batteries, due to their high specific energy on the first cycles and the substitution of the traditionally used Co for the less critical element Ni. Despite these promises, these materials are characterized by striking performance degradation, accompanied by the building of electrode-electrolyte interfacial impendence. Understanding the (electro)chemical reactions at the interface between the positive electrode and the organic electrolyte is crucial for the rational design of sustainable Li-ion batteries with improved safety, capacity retention and cycle life. Density Functional Theory (DFT) calculations demonstrated that solvent C-H dissociation, accompanied by an interfacial charge transfer, occurs for organic carbonates at the surface of Li_xMO_2. The driving force for the interfacial reactivity depends on the oxide composition and increases on oxide surfaces with transition metal ions from left to right in the periodic table and by increasing transition metal oxidation state upon delithiation, with the position of oxide O 2p band center with respect to the Fermi level serving as a reactivity descriptor [1]. These findings were used to identify a design principle for the screening of coating materials which can prevent the dissociation of organic carbonates [2]. Here we use DFT calculations to analyze the stability trends for Li- and Na-batteries positive electrode materials as a function of the transition metal and state of charge, which are used to rationalize the observed degradation mechanisms. These results are leveraged to identify stability descriptors for positive electrode materials that can be used for the design of novel positive electrode materials [3].

Eco-Friendly Sustainable Lithium Ion Extraction from Aqueous Solutions—Lithium Selective Ceramic

Membrane *Seung-Hwan Lee[1,2], So Hyun Baek[1], Jeungjai Yun[1], Hyun-Woo Lee[1], Yongbum Kwon[1], Kee-Ryung Park[1], Yoseb Song[1], Bum Sung Kim[1], Yong-Ho Choa[2] and Da-Woon Jeong[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)*

Global lithium demand is expected to increase from 500,000 tons in 2021 to 2 million tons in 2030, and the lithium shortage is expected to reach 220,000 tons. This dramatic increase in lithium demand is largely due to the widespread use of lithium ion batterie, or electronic devices. In recent years, there has been a global effort to extract lithium ions from dissolved seawater or wastewater. Nevertheless, the extraction of lithium from seawater remains a significant challenge due to its low concentration and abundance of interfering ions. For the selective separation of lithium ions, it is necessary to fabricate membranes with nanochannels that allow only lithium ions to pass through. Our system consist of an anion exchange membrane (AEM) and lithium lanthanum titanium oxide (LLTO) membrane with a perovskite structure. It is a system that consists of three modules and two membranes and selectively extracts only lithium ions by applying a voltage of 5 V. The system produced lithium concentrated solutions with a lithium ion concentration of 10,000 ppm and a lithium selectivity (Li+/Mg2+) of 1000. Lithium phosphate powder with 99.5% purity was fabricated from lithium concentrated solution through a powdering process. The produced lithium phosphate has high purity and can be immediately used for industrial purposes. In addition, it can be fabricated with lithium carbonate and lithium hydroxide by adding an already developed process. It is expected that this system will be used as a supply chain to solve unstable lithium supply.

2:15 PM EN10.09.04

An Electrophoresis Approach for Recycling Black Mass from Spent Lithium-Ion Batteries *Pu Wei Wu, Shun Yu Tsai, Yueh Tzu Ma, Ming Hung Chen and Yu En Zhang; National Yang Ming Chiao Tung University, Taiwan*

The rapid proliferation of lithium-ion batteries (LIBs) has generated significant environmental challenges due to the disposal of spent batteries. Therefore, identifying an efficient recycling method is critical for resource recovery and waste reduction. In our laboratory, we have adopted the electrophoresis technique to enable phase separation in black mass from spent LIBs. Electrophoresis involves imposition an electrical field so the suspended particles can be driven toward the electrode with opposite polarity. Lithium cobalt nickel manganese oxides (NMC) and graphite exhibit different zeta potentials and densities in black mass. Under a suitable supporting solvent, NMC and graphite could be physically separated and collected. Our approach offers distinct advantages over the conventional chemical leaching routes in terms of reduced energy consumption and chemical waste. To enhance the separation efficiency, we use citric acid as a surfactant that firmly adheres to the surface of NMC particles for a more significant negative zeta potential. Our preliminary results demonstrate that leveraging the lateral electrophoresis and vertical gravitational force could phase-separate the NMC and graphite. Our ongoing research is to optimize the phase separation cell design and conduct scaling-up work to validate the translation of this technique to practical industrial use.

Exploring the Potential of Solution-Based Synthesis Towards Material- and Energy-Efficient Oxide Electrodes for Future Energy Storage *Marlies Van Bael[1,2,3], Dries De Sloovere[2,1,3], Ken Elen[2,1,3], Bjorn Joos[1,2,3] and An Hardy[1,2,3]; [1]Hasselt University, Belgium; [2]imec, Belgium; [3]EnergyVille, Belgium*

The ongoing transition from fossil-based to renewable energy sources and the imperative for a carbon-neutral economy are driving research and industry to reassess material choices as well as synthesis methodologies.

Multi-metal oxides, particularly within the domain of oxide electrodes play a crucial role in renewable energy storage applications, including batteries and hydrogen production via (photo)electrocatalytic water splitting. For the synthesis of multi-metal oxides, the preferred choice of solution-based methods is often motivated by their versatility, scalability, and high degree of composition and morphology control. Besides the highly controllable material properties that result from solution-based methods, the specific precursor chemistry can and should also address sustainability, atom economy and energy efficiency. An additional challenge in mentioned applications is related to the rapidly growing demand for more efficient storage of renewable energy, combined with the fast-growing electrification of transport. This surge is leading to a tremendous increase in the need for electrode materials, many of which rely on elements with vulnerable supply chains. Consequently, there is a pressing need to find alternative materials.

In this lecture, we will explore the challenges and opportunities in this field, drawing on our insights in the water-based solution-gel synthesis, e.g., of copper-based oxide electrodes for photoelectrochemical water splitting. Besides, special attention will be given to some innovative chemistries designed to facilitate low temperature and hence energy-efficient synthesis of complex multi-metal oxides. We will discuss approaches such as chemical design of precursor complexes for an adjusted gel-network or UV-assisted precursor decomposition in sol(ution)-gel synthesis, and auto-combustion synthesis.
Addressing the urgent need to find alternatives to cobalt in the currently dominating $LiNi_xMn_yCo_zO_2$ *(NMC) cathodes of lithium-ion batteries, it is key to develop innovative materials with lower cobalt content or even entirely cobalt-free alternatives. Several options exist, among which spinel or layered oxide structures. Unfortunately, their commercialization faces hurdles due to chemical or structural degradation during electrochemical operation. We will highlight the important influence of the synthesis methods on the properties of such materials and provide some of our recent solution-based approaches for element doping or surface engineering showing promise in stabilizing the structure and enhancing their performance.*
As securing a stable and affordable supply of lithium becomes increasingly challenging as well, we will finally discuss our exploration of above discussed solution-based methodologies for the development and improvement of electrode materials for sodium-ion batteries.

LCI Comparison of Silicon and Graphite Anodes Manufactured Using Different Techniques *Mike Lain, Alf Smith, Satish Bolloju, You Wu, Stuart Coles and Louis Piper; Warwick Manufacturing Group, United Kingdom*

Most commercial lithium ion cells contain 5 – 10 wt% silicon in their predominantly graphite anodes, but the *challenge of operating anodes with high silicon contents remains. One promising approach is to use plasma enhanced chemical vapour deposition (PECVD), rather than the standard composite coating approach with binders and solvents. There is a perception that CVD processes consume too much energy to be cost competitive, but this may neglect the large energy consumption associated with graphitisation. The most objective way to resolve this is to use a life cycle analysis comparison for different anode types.*

A life cycle inventory (LCI) has been developed for four anode compositions; graphite, graphite with 10 wt% SiOx, 70 % silicon powder, and PECVD silicon. The first three anodes use binders and conductive carbon, in an aqueous mix. The fourth incorporates new primary data from a PECVD process using hexamethyl disiloxane as reactant, rather than the more common (and pyrophoric) silane. The LCI analysis calculates both the actual energy consumption, and kg CO_2-e values reflecting emissions of greenhouse gases, NOx, and SOx. Initial results suggest that the PECVD process should not be excluded, based on energy consumption and overall emissions.

3D Printed Nanoporous Separators Based on Polymerization-Induced Phase Separation for High Cycling Stability Li-Ion Batteries *Jiandi Wan; University of California, Davis, United States*

Separators with controllable microstructures are a crucial component of high-power high-energy Li-ion batteries. The separator microstructure has been linked to battery failure by localized current hot spots. Thus, separator fabrication methods that offer precise control of porosity and morphology at the submicron scale hold promise for increasing the Li-ion battery lifetime and performance. Here, we demonstrate using projection micro-stereolithography and polymerization induced phase separation to manufacture hexanediol diacrylate (HDDA) separators with controlled morphologies (bi-continuous and droplet) and porosities (26.6% - 63.1%). Systematically varying the microstructure of the HDDA separators enables the examination of structure-property relationships with respect to the high-rate performance and cycling stability of $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$/graphite batteries. Compared with a Celgard 2325 separator, the optimized porous HDDA separator increases the 10C-rate capacity by 34% and decreases the capacity degradation rate at 1C-rate by 4.9%. This work not only presents the technology for producing high performance porous separators, but also offers a pathway for future 3D battery fabrication

Exploring the Practicality of Iron as a Sustainable Replacement to Coal *Echo St. Germain, Randall M. Erb and Yiannis Levendis; Northeastern University, United States*

The negative and long-lasting effects of carbon dioxide within our atmosphere has set the clock for the rapid decarbonization of energy. While carbon-free technologies have been developed, many of these solutions require new infrastructure and supply chains to be formed which slows transition away from carbon-based fuels. One modern fuel source that has garnered interest in hastening adoption of carbon-free energy is iron. This solid fuel has comparable ignition and flame temperatures to coal, which would allow iron to assimilate into preexisting infrastructure with minimal modifications. Instead of producing carbon dioxide, iron powder forms various oxides during combustion which resolidify into byproducts that can be recycled back to its original form, completing the "iron fuel cycle". For iron to be a realistic alternative to coal the practicality and details of this "iron fuel cycle" need to be better understood. Current work on iron integration into coal plants has been based on thermodynamic calculations and does not assess how iron combustion would work in real-world application. Characteristics of iron in various furnace environments needs to be collected to update current predictions of iron fuel ignition and combustion to understand how iron particles will interact with each other and how to best utilize the reaction's nanoparticle byproducts. Through scanning electron microscopy and x-ray diffraction we have examined the *effects of various temperatures, flow rates, and oxygen concentrations on the byproducts of iron particle combustion within a drop tube furnace. Within this work, we present experimentally grounded recommendations for optimal particle morphologies and furnace environments, which can be used to further analyze the cost of transitioning from coal to iron in specific industries.*

Sustainable Iron Production via Highly Efficient Low-Temperature Electrolysis of 3D Conductive Colloidal Electrodes

Panya Thanwisai and Yan Wang; Worcester Polytechnic Institute, United States

In order to decarbonize the iron and steel production that generates around 8% of global CO_2 emissions, in this work, we propose a low-temperature electrolysis (100 °C) with 3D conductive colloidal Fe_2O_3 electrodes to produce iron sustainably. As the designed electrodes offer the 3D conductive network to facilitate the electrochemical reduction of Fe_2O_3, high-purity Fe powder (>95%) can be produced with high current efficiency (>95%). There is no direct CO_2 emission from this process, and only O_2 is emitted as a byproduct. In addition to Fe, we also demonstrate the production of metal and alloy powders such as Cu, Ag, and FeNi alloy using the proposed method. Moreover, a techno-economic assessment of the process is performed to evaluate industrial feasibility as well as CO_2 emission analysis. Altogether, our proposed alternative process is green, environmentally friendly, and energy efficient, showing great potential for revolutionizing the conventional process that has a history of significant environmental impact for decades.

Green Ironmaking by Rapid Reduction of Iron Oxide with Ammonia

Sanya Mittal and Luke Davis; Tufts University, United States

Steel will be essential to the energy transition, and decarbonizing steel production will therefore also be critical. Steel is found in electric vehicles, wind turbines, solar panel racking, geothermal plants, and electricity transmission towers—not to mention buildings, ships, and bridges. However, steel production is responsible for 7-8% of annual global CO_2 emissions, with half of this CO_2 coming from converting iron ore into iron.

Ironmaking alone produces ca. 4% of annual CO_2 emissions, some 2×10^9 metric tons/year (2 Gt/a). These CO_2 emissions result from reduction of iron oxides to iron metal with fossil fuel-derived CO, producing CO_2 as a chemical byproduct, and can only be eliminated through new chemistry. Using ammonia instead of coke—releasing only water and nitrogen as byproducts—could be a widely deployable method of decarbonizing industrial ironmaking, because ammonia carries hydrogen and can be transported easily worldwide.

Direct reduction of iron oxide with ammonia has been reported previously,[1-3] but the process suffers from slow reaction kinetics and low utilization of ammonia. To date, the fastest and most efficient reduction of any iron oxide with ammonia was reported in 21 min at 750 °C, utilizing 8.9% of the ammonia on the ~1.7 mmol scale.[3] Because the cost drivers of ironmaking processes are throughput (i.e., capital equipment utilization), ore costs, and fuel costs, the low utilization and slow rate provide critical barriers to the possibility of decarbonizing ironmaking using ammonia.

A thermochemical assessment of the reaction highlighted high temperatures and high flow rates of pure NH_3 as key parameters to explore to enhance utilization; from a simple kinetics perspective, these conditions should also increase the reaction rate. Drawing on this analysis and subsequent experiments, we have reduced iron oxide to iron on the mmol scale in 1 minute while using 64% of the ammonia supplied. These results represent order of magnitude improvements in both rate and utilization. We will also discuss scale-up of the reaction, and translation of the process insights to pelletized ore, a common form used industrially.

Nitric Oxide as a Probe Molecule for Understanding the Nature and Density of Active Sites in Fe-N-C Oxygen Reduction Reaction Catalysts *Deborah Myers[1], Xiaoping Wang[1], Magali Ferrandon[1], A. Jeremy Kropf[1], Yachao Zeng[2], Gang Wu[2], Hanguang Zhang[3], Piotr Zelenay[3], Cong Liu[1] and Jae Hyung Park[1]; [1]Argonne National Laboratory, United States; [2]University at Buffalo, The State University of New York, United States; [3]Los Alamos National Laboratory, United States*

The highest oxygen reduction reaction (ORR) activities in acidic environments for platinum group metal-free electrocatalysts have been achieved for materials derived from iron, nitrogen, and carbon-containing precursors *such as iron-substituted zinc-based zeolitic imidazolate frameworks (ZIF).*[1-3] *These precursors are typically heat treated in an inert atmosphere at temperatures ranging from 900 to 1100°C to form the ORR-active material. In addition to their high intrinsic activity, under certain preparation conditions these catalysts are free of crystalline iron species, with iron atomically dispersed in a nitrogen-doped carbon matrix, as determined through characterization by high-resolution electron microscopy and X-ray absorption spectroscopy. While the exact nature of the active site in these materials is still a matter of debate, the probe molecule, nitric oxide, has been shown, using nuclear resonance vibrational spectroscopy, to bind to Fe and also to poison the ORR.*[4-6] *An in-depth study of the interaction of nitric oxide with a variety of Fe-N-C catalysts can thus provide insight into the nature of the ORR active site in this class of catalysts which can in turn guide the synthesis of catalysts with improved activity and durability. To study this interaction, we have used aqueous electrochemical measurments of the impact of nitric oxide on the Fe redox features and on the ORR activity and we have evaluated the selectivity of the nitric oxide for Fe sites using electrochemical stripping, temperature programmed desorption, and in situ X-ray absorption spectroscopy. The implication of these results on the nature and density of ORR active sites in Fe-N-C catalysts will be discussed.*

Identification of Redox Active Iron Species in FeNC Catalysts by Resonance Spectroscopies *Lingmei Ni; Technische Universität Darmstadt, Germany*

Proton exchange fuel cells (PEFCs) are a clean technology for efficient conversion of chemical into electrical energy and are specifically promising for the decarbonization of heavy duty vehicles [1]. Currently, the drawback of PEFCs is the high cost of Pt-based catalysts used for cathode and anode, which hinders their commercialization. [2] The rapid development of FeNCs holds promise for replacing Pt-based catalysts for the oxygen reduction reaction (ORR). The nature and characterization of the FeNC active sites is a challenging subject, as catalysts typically contain side phases that are superparamagnetic at relevant catalytic conditions, hindering their discrimination from FeN_4 environments. [3-6]

During the past years, we developed in situ and operando measurement options to solve the debate on the structure of active sites.[7] ^{57}Fe Mössbauer experiments were carried out in situ, and operando to identify iron signatures and their changes induced by different conditions. On the basis of our in situ results of three differently prepared catalysts, two transitions between the oxygenated and deoxygenated state were found and assigned to sites involved in the direct and indirect ORR. [8-9] Further in situ Mössbauer studies of a porphyrinic FeNC model catalyst at potentials between 0.9 and 0.2 V (RHE) revealed that there are two different "onset potentials" *originating from different iron environments and associated with different steps in the ORR mechanism. To gain an in-depth understanding of the behaviour of the active sites, operando Mössbauer conditions (thus during ORR) were carried out for one FeNC catalyst that exhibited the strongest change during in situ testing. [7]*

In this work, I will explain our approach to apply in situ and operando Mössbauer spectroscopy and summarize our most recent findings on the electrochemical behaviour of FeNC catalysts including the above mentioned works and more recent ones that combine different techniques to gain a more comprehensive view on FeNCs.

Platinum-Group-Metal-Free Electrocatalysts via N + Ions Implantation and Iron Evaporation on Vertically Aligned Carbon Nanotubes

Valerio C. Ficca[1,2], Ilaria Rago[3], Gianlorenzo Bussetti[4], Elena Stellino[1], Marco Sbroscia[1] and Ernesto Placidi[1]; [1]Sapienza Università di Roma, Italy; [2]Sapienza University of Rome, Italy; [3]Istituto Nazionale di Fisica Nucleare, Italy; [4]Politecnico di Milano, Italy

The continuous research on cost-effective nanomaterials for energy conversion in Fuel Cells, Zinc-Air batteries, and Electrolyzers is characterized by platinum-group-metal-free (PGM-free) electrocatalysts. Such materials are based on C, N, O, and non-noble transition metals and are usually synthesized following a chemical route based on organic and inorganic compounds [1–3]. To maximize the catalytic efficiency, the compounds are mechanically mixed and then pyrolyzed one or multiple times at high temperatures (>900°C) and controlled in a non-oxidative atmosphere. The result is the leveling of differences between C- and N-containing precursors. Moreover, the processes also involve one or more acid-washing steps to remove secondary unwanted species, especially for low pH applications, and to create a porous structure [4]. The chemical route is the most widely used for the synthesis of PGM-free, but a poor level of control is exerted on the final result in terms of oxygen and nitrogen moieties. In *some cases, it was possible to maximize pyridinic nitrogen functional groups over the others by selecting specific reagents [5,6], de facto narrowing the vastness of choices of precursors. To address the problem of product controllability, alternative approaches for carbonaceous structure modification are investigated. Among them, ion beam techniques for selective ion implantation have been investigated as desirable for large-scale production of fine-tuned optical-related materials and semiconductors such as p- and n-doped carbon nanotubes and graphene [7–10]. Aiming at transposing such results to PGM-free, we investigated the feasibility of replicating the active sites formation within the boundary of a cleaner physical approach instead of the pyrolysis-based route.*

The new recipe is thus developed and based on N+ ions implantation via Kaufman apparatus operated at different ion beam energies, followed by iron evaporation from an electron beam evaporator inside an ultra-high-vacuum (UHV) clean chamber. Vertically Aligned Carbon nanotubes (VA-CNT) were chosen as reliable model carbon structures, characterized by an almost total content of sp2 carbon, to avoid spurious contributions from the material and to future transposing the procedure to other common carbonaceous allotropes. The final goal is thus to obtain fine-tuned PGM-free not depending on N-containing compounds.

Upon preparation of five samples at increasing ions beam energies (50 eV, 100 eV, 200 eV, 400 eV, 800 eV), along with control samples, the preliminary investigation based on scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS), and Raman spectroscopy techniques shown similarities of the final product with the chemical route, illustrating that the formation of active sites is indeed a natural phenomenon only due to the presence of nitrogen inside the carbon matrix. Moreover, within the prepared samples, simply tuning the ion beam energy was also possible to maximize the pyridinic N content minimizing all other moieties. Lastly, electrochemical tests performed on a representative sample showed catalytic activity towards the oxygen reduction reaction (ORR), confirming the feasibility of the process. The preliminary results are thus paving the way to the limitless and nitrogen-compound-free synthesis of critical raw material-free nanoelettrocatalysts.

N-Eoped Carbon Nanocatalyst with Zn Single Atom Catalytic Sites from N-Eoped Graphene and Metal-Organic Frameworks *Niladri Talukder[1], Yudong Wang[1], Bharath Babu Nunna[2,1] and Eon Soo Lee[1]; [1]New Jersey Institute of Technology, United States; [2]Weber State University, United States*

Over the past decade, nitrogen-doped carbon materials, particularly nitrogen-doped graphene (N-G), have emerged as highly promising catalysts for various electrochemical reactions. N-G has demonstrated noteworthy catalytic activity for oxygen reduction reactions (ORR), which are crucial for the performance of electrochemical energy systems such as PEM fuel cells, metal-air batteries, supercapacitors, etc. To further enhance N-G's catalytic performance, researchers have integrated it with metal-organic frameworks (MOFs), resulting in N-G/MOF composites. These composites benefit from the combination of N-G's catalytic properties, as well as the micro- and mesoporous structures, and diverse chemically functional sites offered by MOFs, which together promote ORR catalysis. In specific electrochemical conditions, these N-G/MOF composites have sometimes

outperformed benchmark ORR catalysts like Pt/C. Typically, the preparation of these catalysts involves high-temperature treatments that remove most of the metal atoms, creating metal-free porous carbon structures along with N-G-like structures. However, the potential of retaining and utilizing these metal sites within N-G/MOF catalysts for ORR catalysis remains an area that has yet to be thoroughly explored.
In our study, we synthesized a nitrogen-doped carbon nanocatalyst by integrating an N-G catalyst with a metal-organic framework (Zeolitic Imidazolate Frameworks-8, ZIF-8) using a Nanoscale High Energy Wet (NHEW) ball milling process. Initially, we produced the N-G catalyst by wet ball milling graphene oxide (GO) with melamine, serving as the carbon and nitrogen precursors, respectively. This N-G catalyst showed performance close to a 10 wt% Pt/C catalyst. Subsequently, we integrated the N-G catalyst with ZIF-8 through a similar NHEW ball milling process, optimizing the structural and functional properties by adjusting the grinding speed and time. The optimal N-G/MOF nanocatalyst was synthesized at a milling speed of 350 rpm for 16 hours, resulting in the best performance as an ORR catalyst. This N-G/MOF catalyst exhibited a higher ORR current density compared to a 10 wt% Pt/C catalyst in both alkaline and acidic environments, with almost the same ORR onset potential. The calculated electron transfer number indicated a 4e- transfer ORR process on the N-G/MOF catalyst. Moreover, the N-G/MOF catalyst retained over 90% of its ORR current density after 2000 cycles of operation. The N-G/MOF nanocatalyst was thoroughly characterized to examine changes in morphology, elemental composition, and chemical bonds using various analytical techniques: scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), and Fourier-transform infrared spectroscopy (FTIR). The results showed that the N-G/MOF nanocatalyst retained the morphological features of both N-G and ZIF-8. Elemental composition analysis revealed the presence of zinc (Zn) in the material. Detailed XPS analysis of the C 1s and N 1s spectra confirmed the presence of Zn-NC-C type bonds, indicating the formation of Zn single-atom catalytic sites advantageous for ORR catalysis. This finding was further supported by comparing FTIR peaks among N-G, pure ZIF-8, and N-G/MOF. Energy Dispersive Spectroscopy (EDS) analysis showed the atomic-scale dispersion of Zn sites within the nanocatalyst. The N-G/MOF nanocatalyst effectively leveraged the synergistic advantages of combining N-G and ZIF-8, along with the formation of beneficial Zn sites. Hence, this N-G/MOF nanocatalyst performed robustly across different electrochemical environments.

Cobalt Embedded N-Doped Carbon Nanotubes as Bifunctional Catalysts for Zinc–Air Batteries *Sarvesh Kumar and Balaram Sahoo; Indian Institute of Science, India*

A unique architecture features Co nanoparticles covered by carbon shells within a defective carbon framework, enhanced by various nitrogen moieties. This design increases surface area and porosity, exposing numerous active centres for catalytic activities. Our single-step in situ synthesis produces excellent bifunctional electrocatalysts for oxygen evolution, oxygen reduction, and zinc-air battery applications. The abundant active centres and pores result in exceptional ORR performance. Our Co-embedded carbon nanotubes with optimal N-doping show a higher half-wave potential ($E_{1/2}$) of ~0.882 V vs. RHE compared to the standard Pt/C electrode (~0.874 V vs. RHE) in 0.1 M KOH solution, with the same catalyst mass loading. For zinc–air batteries, our samples, as air-reducing catalysts, exhibit a high open-circuit voltage of 1.512 V and an impressive peak power density (150.6 mW cm^{-2}), which surpasses the commercial Pt/C + RuO_2 catalysts (92.4 mW cm^{-2}), as well as many reported bifunctional electrocatalysts. Hence, our samples are potential candidates for the coherent depiction of multifunctional, efficient, and durable electrocatalysts for the straightforward, inexpensive, and scalable fabrication of rechargeable zinc–air batteries.

Precise Manufacturing of Highly Porous Electrode Materials with Exceptional Durability for Use in Large-Scale Salt Water Battery Systems *Manar M. Hazaa and Nageh K. Allam; The American University in Cairo, Egypt*

Salt water battery (SWB) is a promising low-cost water desalting technique for brackish (moderately saline) water. However, the stability and regeneration of SWB electrodes have been major obstacles limiting the large-scale practical application of this technology. One of the key challenges is the oxidation of the electrodes during the repeated adsorption and desorption processes, which degrades their long-term performance. In this work, the researchers demonstrated the ability to design and fabricate SWB Electrodes with exceptionally stable performance. They used a one-step pyrolysis method to produce carbon materials doped with a controlled amount of nitrogen (NDCs). The optimized pyrolysis conditions allowed the fabrication of NDCs with a unique meso/microporous structure, high specific capacitance, and impressive salt adsorption capacity of up to 26.5 mg/g in single-pass desalination mode. Notably, all the NDC electrodes exhibited exceptional stability, retaining 100% of their desalination capacity over 150 consecutive charge/discharge cycles. This was achieved even under harsh operating conditions, such as 1.4 V charging voltage, in both aerated and deaerated solutions. Additionally, the NDC electrodes demonstrated charge efficiencies in the range of 40-60%. Analysis of the potential of zero charge (PZC) for the NDC electrodes revealed minimal shifts after the extensive stability tests, indicating negligible electrode oxidation. In comparison, commercially available activated carbon (AC) electrodes showed a significant decrease in salt adsorption capacity within just a few cycles under the same conditions. In summary, the researchers successfully developed a one-step pyrolysis method to fabricate nitrogen-doped carbon (NDC) electrodes with unprecedented cycling stability and desalination performance, addressing a key challenge in the practical application of SWB technology.

Functional Thin Film Carbon Electrodes as Platform Materials for Fundamental Studies of Interfacial Reactivity *Paula Colavita; Trinity College Dublin, The University of Dublin, Ireland*

Electrochemical systems such as fuel cells, batteries and electrolysers are expected to play a critical role in enabling electrification efforts. However, many of these technologies currently rely on the use of precious and scarce elements as electrocatalysts, which can pose limitations to their deployment at scale. Carbon and nanocarbon materials can play an important role in the development of novel electrodes/electrocatalysts to address this issue. Carbons/nanocarbons are highly versatile and their structural, electronic and chemical properties can span over an impressively wide range. Importantly, effective control over interfacial properties via bulk or surface modifications offers an attractive route to impart and control reactivity, that can potentially be leveraged for the design of electrocatalysts with decreased reliance on critical raw materials.
This presentation will discuss progress in our group on the use of thin film carbon electrodes based on heteroatom modified scaffolds, to understand materials design principles for improving performance in key reactions for energy applications. First, the use of thin-film model electrodes with well-defined composition and N-site distribution for elucidating the role of N-functionalities in key cathodic (e.g. ORR) and anodic reactions (V(+5/+4)) [1-2] will be described. Then, the presentation will focus on how the properties of carbon thin films make them

suitable as platform materials for electrochemistry at the nanoscale via scanning electrochemical cell microscopy (SECCM). SECCM at these carbon thin film electrodes can be used to elucidate structure-function relationships of nanomaterials [3] as illustrated using two case studies of relevance to energy storage/conversion, namely correlative-SECCM work with N-doped graphene oxides and 2D MXenes.

Real-Time Investigation of Reactive Oxygen Species and Radicals Evolved from Fe-N-C Catalysts During the Oxygen Reduction Reaction *Seth Putnam and Joaquin Rodriguez-Lopez; University of Illinois at Urbana-Champaign, United States*

The development of platinum-group-metal-free (PGM-free) oxygen reduction catalysts is critical to improving the economic viability of various energy storage and conversion technologies such as fuel cells. However, the primary barrier to their wider commercialization is a lack of stability. Reactive oxygen species (ROS) and radicals have been proposed in many studies as a root cause for the rapid loss in activity. However, the direct detection and quantification of ROS under catalytic condutions is difficult due to the short lifetimes and dilute amounts of species such as hydroxyl radicals. To overcome this challenge, we have used an operando scanning electrochemical microscopy (SECM) technique to directly and selectively probe the production of radicals in real-time,SECM showed a monotonic production of OH radicals with increasing overpotential. This trend was distinct from that observed for hydrogen peroxide under the same conditions. Additionally, electron spin resonance (ESR) spectroscopy was used to thoroughly confirm our SECM results and confirm that the hydroxyl radical is the dominant radical species produced. Additionally, observing the production of ROS as a function of catalyst degradation also showed a decreased production as the catalytic activity decays, Finally, the structural origins of these damaging radical species was probed using a variety of model systems such as iron phthalocyanine and iron oxide nanoparticles. These results provide a comprehensive insight into the production and role of ROS on Fe-N-C catalyst systems. These experiments open the door for further mechanistic and kinetic investigations involving transient reactive oxygen species and radical intermediates on electrocatalytic systems.

Towards More Durable Fe-N-C Catalysts—Understanding Degradation Mechanisms of Active Sites and Carbon Structure *Kevin Yang and Sanjeev Mukerjee; Northeastern University, United States*

In pursuit of more sustainable materials for energy production, doped-carbon, single-atom catalysts have taken hold as prospective candidates to replace traditional noble metal catalysts for energy conversion technology. Herein, we report on using iron and nitrogen-doped carbon, denoted as Fe-N-C, as a noble metal-free catalyst for oxygen-depolarized cathodes in HCl electrolysis to replace the state-of-the-art noble metal catalyst, Rh_xS_y. While Fe-N-C shows high intrinsic oxygen reduction activity, the durability and degradation of the material in HCl electrolysis devices have yet to be studied.
Fe-N-C has been shown to have high resistance to anion poisoning and improved performance over commercial platinum catalysts in HCl electrolysis. Fe-N-C achieves a current density of 0.5 A/cm^2 at 1.38 V. This surpasses Rh_xS_y by 0.1 V, allowing for lower power requirements while producing the same amount of chlorine. We have

developed a scalable method to bulk synthesize Fe-N-C with high oxygen reduction activity (1). To fully realize its potential, Fe-N-C is subjected to accelerated stress tests (ASTs) in uncontrolled shutdowns to observe the changes in electrochemical performance. In situ Raman spectroscopy, X-ray spectroscopy, and in situ ion probes are used to characterize changes in structure and active site density to elucidate the cause of performance decay. This work contributes to the evaluation of Fe-N-C structure during various stages of degradation. More notably, this process contributes considerably to the commercialization of Fe-N-C as a practical replacement for noble metal catalysts in HCl electrolysis.

An Identical Location STEM Approach for the Study of Degradation in Electrocatalytic Nanoparticles

Francisco Ruiz Zepeda, Ana Rebeka Kamsek, Lazar Bijelić, Armin Hrnjić, Andraz Pavlišič, Milena Šetka, Matija Gatalo, Marjan Bele, Primoz Jovanovič, Goran Drazic and Nejc Hodnik; National Institute of Chemistry, Slovenia

On the verge of climate change, current efforts are being made to mitigate the carbon footprint generated by our high energy consumption, leading to a demand for more sustainable energy technologies. The utilization of hydrogen fuel cells is one of the most promising and emerging solutions to this problem. However, the catalytic nanoparticles inside these fuel cells degrade, primarily due to the harsh environment and potential fluctuations that occur during activation protocols or regular workload cycles. Typically, nanocatalysts, which are usually composed of precious metal-based nanoparticles (e.g., Pt-M) deposited on a conductive support (such as carbon), can face dissolution, dealloying, and other related phenomena that degrade their performance. Activity and stability (among other technical issues) hinder their development as suitable power sources. Therefore, tracking changes arising in nanoparticles (or the support) after an electrochemical process can grant valuable information regarding the structure-stability relationship. Identical location scanning transmission electron microscopy (IL-STEM), which is achieved by comparing STEM data taken from the same spot of the material before and after an electrochemical process, has proven to be an effective method for elucidating specific features appearing at the surface and nanostructure of the electrocatalytic nanoparticles. The modifications registered at the atomic scale are of particular interest, as their analysis can help in the understanding of resulting trends by providing important structural feedback. In this work, we describe how we have used identical location in Pt-based nanoparticles (employed in fuel cells and electrolysers) which have undergone different electrochemical cycling processes, either after an activation protocol or a degradation mechanism. The structural and morphological characteristics are investigated and compared in both states. The findings show that the dissolution of atomic columns and atomic sites, as well as redeposition sites in the catalytic nanoparticles, are an indication that certain facets may be more affected than others. Thus, it is possible to identify regions that have suffered reshaping contributing to degradation. Additionally, other key factors such as the evolution and distribution of strain in the nanoparticles can be examined, usually linked to catalytic activity. These observations can lead to a more comprehensive view of catalyst design when aiming to improve the stability and durability of the material.

Hynes, Level 3, Room 305

*1:30 PM *EN11.03.01*

Nitrogen-Doped Carbon Nanotubes—Bucky Papers and Magnetic Nanotubes as Innovative Electrodes Assisting Advanced Oxidation Processes to Improve Reclaimed Water Quality *Mercedes Oropeza[1], Enrique Contreras-Bernabe[2], Jose M. Romo-Herrera[3], Luis A. Romero-Orellana[1] and Yadira Gochi-Ponce[1]; [1]Insituto Tecnologico de Tijuana, Mexico; [2]University of Illinois at Urbana-Champaign, United States; [3]Universidad Nacional Autónoma de México, Mexico*

Inspired by the ONU sixth sustainable development goal, clean water and sanitation, this paper presents two types of electro-Fenton, EE, advanced oxidation process, AOP, to improve reclaimed water quality produced in a wastewater treatment plant in Tijuana, B.C. Mexico. Fenton-type processes are among the known AOPs that require the supply of H_2O_2 and Fe(II) to create a high oxidant medium. Two cases were studied to address this issue when removing recalcitrant organic pollutants (ROPs) from reclaimed water. Physicochemical characterization of the electrode materials, as well as of the treated water, allows the evaluation of the electro-Fenton efficiency.
For the first case, H_2O_2 is formed through nitrogen-doped carbon nanotubes, N-CNTs, bucky paper, and BP, serving as a membrane and electrocatalyst at the same time for the oxygen reduction reaction (ORR) to form H_2O_2, the Fe(II) was ensured from a BP of MWCNTs@Fe_3O_4 as a composite anode. In this case, the formation of hydroxy radicals, OH°, may depend on the flow through the membrane reactor, since on the cathode, H_2O_2 was generated and went through the anode to find the iron species from Fe_3O_4 on their path. The proof of concept to evaluate the electrocatalyst and reactor performance showed an efficient remotion of recalcitrant pollutants in reclaimed wastewater (obtained from Tijuana's city wastewater treatment plant). Fluorescence spectroscopy, chemical oxygen demand, and total organic carbon were used to evaluate water quality parameters. The success of this concept test is mainly due to the design of BP-N-CNTs in a pyrolytic reactor at a specific temperature to promote the formation of graphitic sites to catalyze ORR into two electron mechanisms.
The second case started with a dispersion of N-CNTs with Fe_3O_4 deposited by electrophoretic deposition, EPD, onto Ti sheets to obtain all-in-one nanocomposite renewable cathodes joining the electrocatalyst for H_2O_2 and Fe(II) supply in the same electrode. The nanocomposite cathode N-CNTs@Fe_3O_4 has inserted the magnetite nanoparticles, ensuring the Fe(II) species supply in the same physical space. In this case, the electro-Fenton reactor was a simple mixed tank. The concept test used a saturated oxygen solution of sulfamethoxazole, a common pharmaceutical found in reclaimed water due to its persistence after traditional wastewater treatment processes.
The new N-doped nanocomposite materials improved water quality in both the membrane reactor and the mixed tank with an all-in-one electro-Fenton cathode. The possibilities are open to design desired nanocomposites to drive a reaction mechanism caring for the environmental and social impact.

Microwave-Assisted Synthesis of Nitrogen-Doped Carbon Catalysts for Efficient Hydrogen Reroxide Production via Electrochemical Oxygen Reduction Reaction *Milena Setka[1,2], Marjan Bele[2], Miroslav Soos[1], José M. Catalá-Civera[3] and Nejc Hodnik[2]; [1]University of Chemistry and Technology, Prague, Czechia; [2]National Institute of Chemistry, Slovenia; [3]Universitat Politècnica de València, Spain*

Hydrogen peroxide (H_2O_2) is among the top 100 most important chemicals, with extensive applications in

industries such as paper and pulp bleaching, water treatment, food processing, electronics, and medical and pharmaceutical disinfection. The electrochemical two-electron (2e$^-$) oxygen reduction reaction (ORR) provides a sustainable method for decentralized H_2O_2 production, offering an alternative to the energy-intensive centralized industrial anthraquinone process [1]. Metal-free, heteroatom-doped carbon-based catalysts have emerged as promising alternatives to expensive, toxic, and scarce noble-metal or alloy catalysts like Pt, Pd, Au, Pt–Hg, and Au–Pd for 2e$^-$ ORR [2].

In this study, nitrogen-doped carbon-based catalysts (NCC) were synthesized from polyaniline (PANI) using a microwave-assisted method (MW). MW heating is an attractive alternative to conventional thermal methods due to its faster heating, improved energy efficiency, and potential for creating nanostructures with unique morphological or structural properties [3]. The MW synthesis of NCC was carried out in a microwave calorimeter equipped with a dual-mode cylindrical cavity, which allowed for simultaneous heating of the sample and measurement of the material's dielectric properties in relation to the carbonization temperature [4].

Heating control in the PANI sample was achieved by adjusting the resonant frequency near 2.45 GHz, which regulated the MW power delivered to the cavity. Oscillations in MW power within the 20±10 W range enabled rapid heating and cooling cycles in the 350-500 °C temperature range, resulting in uniform NCC structures ($NCC_{heating-cooling}$). In contrast, continuous MW power increase caused thermal run-away and localized superheating of the material.

The ORR performance of the synthesized NCC was evaluated using a rotating ring-disk electrode (RRDE) with a Pt ring and glassy carbon (GC) disk in O_2-saturated 0.1 M KOH media. The $NCC_{heating-cooling}$ samples demonstrated 93% selectivity to H_2O_2, diffusion-limited current densities of 2.6 mA cm^{-2}, and an H_2O_2 production current of 3.9 mA cm^{-2}, surpassing the performance of nitrogen-doped carbon-based catalysts synthesized by conventional heating methods reported in the literature.

Understanding the N-Doping Process of Graphene to Optimize Its N Species Proportion

José M. Ruiz-Marizcal[1], Jose I. Paez-Ornelas[2], Héctor H. Fernández-Escamilla[3], Eduardo Antonio Murillo Bracamontes[2], Gabriel Alonso-Nunez[2], Eduardo G. Pérez Tijerina[3], Noboru Takeuchi[2] and Jose M. Romo-Herrera[2]; [1]Centro de Investigación Científica y de Educación Superior, Mexico; [2]Centro de Nanociencias y Nanotecnología, Mexico; [3]Universidad Autónoma de Nuevo León, Mexico

Current global challenges, such as alternative clean energy sources or environmental remediation issues, have turned their attention into electrochemical reactions are important due to their electrical and thermal properties, but their chemical stability represent a task to overcome. Recent advances have highlighted nitrogen-doped carbonaceous materials as an alternative to metallic electrocatalysts, owing to their earth-abundant availability and improved resistance to poisoning effects by side products.

Nitrogen doping introduces modifications to the carbon network causing redistribution of charge locally, creating active sites that facilitate various electrochemical reactions. Nitrogen atoms can be incorporated into the sp^2 *carbon network in several configurations, such as pyridinic, graphitic, pyrrolic nitrogen, or even as oxidized nitrogen species. Each configuration contributes uniquely to the catalytic properties of the material giving place to different pathway selectivity of the electrochemical reactions. For instance, pyridinic nitrogen presents selectivity for the 4-electron pathway for the oxygen reduction reactions (ORR), while graphitic nitrogen yields selectivity for the 2-electron ORR pathway [1].*

In this study, we investigate in detail the nitrogen doping of graphene through post-synthesis methods by heat treatments under an inert atmosphere, using graphene oxide as a precursor. Understanding the nitrogen incorporation process by heat treatments represents a key tool to optimize the Nitrogen species proportion incorporated and aiding on its selectivity as electrocatalyst. We monitored the physicochemical and structural properties of the obtained materials using a range of techniques including X-ray photoelectron spectroscopy (XPS), thermogravimetric analysis (TGA), Raman spectroscopy, X-ray diffraction (XRD), optical microscopy, and atomic force microscopy (AFM). This was analyzed together with DFT calculations to elucidate and propose a N doping process mechanism.

The results indicate that the doping process can be tailored to optimize the Nitrogen species proportion and therefore the materials performance for specific electrocatalytic applications. It is emphasized the potential of nitrogen-doped graphene for applications requiring electrocatalytic activity and stability. This makes nitrogen-doped graphene a highly attractive material for the next generation of Non-Platinum Group electrocatalysts.

Nitrogen-Doped Carbon Materials with Unusual Structural and Electronic Properties Enhancing Electrocatalytic CO_2 Conversion and N_2 Fixation *Jingsong Huang[1], Yong-Hui Tian[2], Mina Yoon[1], Miklos Kertesz[3],*

Yang Song[4], Dale K. Hensley[1], Peter V. Bonnesen[1], Liangbo Liang[1], Rui Qiao[5], Arthur P. Baddorf[1], Timothy J. Tschaplinski[1], Nancy L. Eagle[1], Zili Wu[1], Harry M. Meyer III[1], Miaofang Chi[1], David Cullen[1], Adam J. Rondinone[6] and Bobby G. Sumpter[1]; [1]Oak Ridge National Laboratory, United States; [2]Northwest University, China; [3]Georgetown University, United States; [4]AMETEK, Inc., United States; [5]Virginia Tech, United States; [6]Los Alamos National Laboratory, United States

Nitrogen (N) doping in carbon materials yields carbon nanospikes (CNS) with tip sizes down to 1 nm, which enable electrochemical CO_2 reduction reaction (CO_2RR) selectively to ethanol when coupled with Cu nanoparticles (CuNP),[1] and electrochemical N_2 reduction reaction (NRR) to ammonia if used alone.[2] Through joint experimental and theoretical studies, we uncovered the unusual effects of N doping that induce metallic properties in graphitic materials via unconventional interlayer covalent pi-pi bonding (so-called pancake bonding) and create an ultrastrong electric field at the sharp tips of CNS. In the first case, we identified that N-doped graphene (NGP) with various doping levels can form 2D covalent pancake bonds, significantly reducing interlayer separations.[3] The binding energies can be enhanced by 50% compared to pristine graphene, which relies mainly on van der Waals (vdW) interactions. This unusual chemical bonding results from the covalent pi-pi overlap across the vdW gap, while the individual layers maintain the in-plane pi-conjugation. In NGP-based graphite with the optimal doping level, the NGP layers are uniformly stacked, and the 3D bulk exhibits metallic characteristics in both in-plane and stacking directions, beneficial for enhancing electrode conductivity. In the second case, we found that N doping can afford the unique morphology of CNS, featuring intense folds and sharp spikes.[4] When coupled with electro-nucleated CuNP, CNS can electrochemically reduce CO_2 to ethanol at a rate of 286 $\mu g\ cm^{-2}\ h^{-1}$ with a high selectivity of 84% and an overall Faradaic efficiency of 90%.[1] If used alone without cocatalysts, CNS can electrochemically reduce N_2 to ammonia at a rate of about 100 $\mu g\ cm^{-2}\ h^{-1}$ under ambient conditions.[2] Using multiscale modeling efforts, we found that the strongly positive surface curvature at the sharp tips of CNS can produce an ultrastrong electric field above 10 V/nm, which is 10^4x stronger than that in cloud-to-ground lightning. This ultrastrong electric field activates the otherwise inert and stable CO_2 and N_2 molecules, both characterized by the triple and double bonds, large ionization potentials, negative electron affinities, and relatively small proton affinities compared to solvent water molecules. The field effects also facilitate electron and proton transfers from CNS and solvent molecules, respectively. The insights gained offer valuable guidance for scientists aiming to enhance carbon-based nanomaterials through N doping toward practical technological applications.

Atomistic Understanding of Single Metal Atom in Nitrogen Doped Graphene for Electrocatalysis *Yuanyue Liu; The University of Texas at Austin, United States*

Single metal atoms embedded in nitrogen doped graphene (M-N-C) are promising electrocatalysts for various reactions. However, the atomistic understanding of the catalytic mechanism is often limited due to the use of simplified models. I will present our recent efforts in developing and applying atomistic simulation methods to understand the M-N-C. Particularly, by including the explicit solvation and surface charge into the model, and by calculating the activation energies, we obtain new insights about the active site in Ni-N-C for CO2 reduction, why Co-N-C can reduce O2 to H2O2 rather than H2O, and what is the rate-limiting step of oxygen reduction on Fe-N-C. These insights can guide the design of new electrocatalysts.

Tunable Electrocatalytic CO_2 Reduction Products on Fluorine-Engineered Iron Single Atom Catalysts *Wenyu Zhong and Xunyu Lu; University of New South Wales, Australia*

Electrochemical CO_2 reduction reaction (CO_2RR) provides a promising approach to a carbon-neutral world. In our work, tunable CO_2RR product distribution has been achieved upon the manipulation of Fe atomic centre by fluorine (F) doping. Enhanced electrochemical CO_2-to-CO conversion has been realized through inserting F atoms into the carbon atoms of the Fe-N-C single atom network. More interestingly, the product distribution completely altered to a steady production of 1:1 syngas across a wide potential range after simply modifying the way F is doped. The electronic structure and coordination environment of the Fe atomic centre in different F-doped Fe single atom catalysts (SACs) has been examined by X-ray adsorption spectroscopy (XAS), and density functional theory (DFT) calculations revealed that the tunable CO_2RR products is connected to the varied overall energy barriers on different F-doped Fe SACs. This work highlights the feasibility and flexibility of manipulating single atom catalytic centre in tuning CO_2RR performance, extending the application of SACs and providing new insights for the design of CO_2RR catalysts with desired products.

4:30 PM EN11.04.04

Nitrogen-Doped Carbon Nanosheets Supported Fe-Single-Atom Catalysts for Electrochemical Conversion of Nitrogen to Ammonia *Ahmed M. Agour and Nageh K. Allam; The American University in Cairo, Egypt*

Electrochemical nitrogen reduction reaction (NRR) has been established as a promising and sustainable alternative to the Haber–Bosch process, which requires intensive energy to produce ammonia. Unfortunately, NRR is constrained by the high adsorption/activation of the N_2 energy barrier and the competing hydrogen evolution reaction, resulting in low faradic efficiency. Herein, a well-dispersed iron single-atom catalyst was successfully immobilized on nitrogen-doped carbon nanosheets (Fe_{SAC}-N-C) synthesized from pre-hydrothermally derived Fe-doped carbon quantum dots with an average particle size of 2.36 nm and used for efficient electrochemical N_2 fixation at ambient conditions. The as-synthesized Fe_{SAC}-N-C catalyst records an onset potential of 0.12 V_{RHE}, exhibiting a considerable faradic efficiency of 23.7% and an NH_3 yield rate of 3.47 $\mu g\ h^{-1}\ cm^{-2}$ in aqueous 0.1 M KOH electrolyte at a potential of −0.1 V_{RHE} under continuous N_2 feeding conditions. The control experiments assert that the produced NH_3 molecules only emerge from the dissolved N_2-gas, reflecting the remarkable stability of the nitrogen–carbon framework during electrolysis. The DFT calculations showed the Fe_{SAC}-N-C catalyst to demonstrate a lower energy barrier during the rate-limiting step of the NRR process, consistent with the observed high activity of the catalyst. This study highlights the exceptional potential of single-atom catalysts for electrochemical NRR and offers a comprehensive understanding of the catalytic mechanisms involved. Ultimately, this work provides a facile synthesis strategy of Fe_{SAC}-N-C nano-sheets with high atomic-dispersion, creating a novel design avenue of Fe_{SAC}-N-C that can vividly have a potential applicability in the large spectrum of electrocatalytic applications.

4:45 PM EN11.04.05

Computational Design of Metal-Nitrogen-Carbon Catalysts for Sustainable Energy Conversion *Guoxiang (Emma) Hu; Georgia Institute of Technology, United States*

Metal–nitrogen–carbon (M-N-C) catalysts are emerging as promising candidates for electrochemical reactions (e.g., oxygen reduction reaction) which are critical for clean and sustainable energy devices. However, due to the large chemical design space, myriad possible structural configurations, and dynamic structure evolutions of the metal centers under reaction conditions, the design of these catalysts has been challenging and cost-prohibitive for both experiments and computations. Here, using density functional theory (DFT) combined with explicit solvation models and machine learning, we rapidly and efficiently evaluate over 20,000 dual-atom M1M2-N-C catalysts for oxygen reduction reaction. We first generate a DFT database of a subset of the M1M2-N-C catalysts, and validate our computational predictions of the structure, stability, and catalytic activity with experimental data where available. With this benchmarked database, machine learning models based on neural networks were trained and applied to identify promising catalysts in the search space which possess higher activity than the state-of-the-art Pt catalysts. The computational framework developed in this work can be generally extended to other important electrochemical reactions including carbon dioxide reduction reaction and hydrogen evolution reaction for sustainable energy conversion.

Self-Assemble Alkali Niobate/Carbon Heterostructure by Rapid Precipitation Using the Spray Pyrolysis Method *Silvania Lanfredi[1], Fabiano R. Praxedes[1], Marcos A. Nobre[1] and Juan M. Lale[2]; [1]University of São Paulo State–UNESP, Brazil; [2]Universidad Autónoma de Chile, Chile*

Semiconductors based on the perovskite structure (ABO_3) are promising materials for energy conversion. However, most of these materials are strictly sensitive to the ultraviolet region under solar light because their high band gap energy hinders their light harvesting in the visible region [1]. On this subject, doping the crystalline sites of the perovskite structure with heteroatoms was demonstrated to be an effective strategy for tailoring the electronic structure of semiconductors. Nitrogen doping has been one of the most explored strategies to extend the light absorption of metal oxides to the visible region. However, the synthetic methods available require, besides high temperature, long thermal treatment under ammonia gas flow with no controlled nitrogen content doped [2]. Herein, we propose a strategy to generate an in situ reduced environment to promote fast nitrogen doping into potassium-sodium niobate ($K_{0.5}Na_{0.5}NbO_3$) by means of the spray pyrolysis method. Also, we explored the relationship between nitrogen doping and the amount of nitrogen doped by means of the B-site codoping in the perovskite structure [3]. Accordingly, spherical particles were synthesized from the precursor solution (50 mmol/L) containing the metal salts. The solution, sprayed at 1.7 MHz, was transported under an airflow rate of 5 L/min into the pyrolytic chamber heated at 600°C. Nitrogen doping was dependent on glycine use as a nitrogen source. The physical-chemical property of the precursor solution enabled the tailoring of spherical particles by glycine proportion to the precursor solution. Structural analysis by X-ray diffraction indicated the formation of $K_{0.5}Na_{0.5}NbO_3$ phase of monoclinic symmetry with space group Pm. By transmission electron microscopy (TEM) *and elementary CNH analysis, the content of nitrogen-doped present a strict relation with tungsten doping into the B-site of the Perovskite structure. The results indicate nitrogen-safe generation and in situ nitrogen doping by spray pyrolysis. This methodology reduces the synthesis steps and avoids the generation of toxic gases. Thus, sodium and potassium niobates codoped with tungsten and nitrogen and sensitized with g-*C_3N_4*, obtained by spray pyrolysis, have a prominent bandgap energy (1.46 eV), which makes them potential photocatalysts for energy conversion in the visible spectrum. Further analysis by degrading 1 L of Basic Blue 41 solution (26 micromol/L) under neutral pH indicated high dye loading (16.60 micromol) onto spherical particles alongside the formation of superoxide radicals, yielding a rapid photodegradation of the pollutant model (*136.36×10^{-3} *micromol* m^{-2} min^{-1}*) by the best composition* $K_{0.5}Na_{0.5}(W_{0.03}Nb_{0.97})O_{3-y}N_y|g\text{-}C_3N_4$ *(5% m/V glycine).*

New Insights into Pt Active Sites for Anion Exchange Membrane Direct Ammonia Fuel Cells

SeonYeong Lee and Han-Ik Joh; Konkuk University, Korea (the Republic of)

Ammonia, consisting of a nitrogen atom bonded with three hydrogen atoms, has been considered a prominent hydrogen carrier candidate to realize the carbon-free hydrogen economy due to its carbon-free properties, ease of liquefaction, and already well-equipped infrastructure and market. Beyond its role as a carrier, some strategies to directly use the ammonia itself as a fuel have been widely studied [1]. Direct ammonia fuel cells (DAFCs) generate electricity via electrochemical redox reactions involving ammonia oxidation reactions (AOR) and oxygen reduction reactions (ORR) at the anode and the cathode, respectively. Like other fuel cells that directly use liquid fuel, the DAFCs face significant challenges related to fuel crossover, resulting in mixed potential, electrocatalyst poisoning, and low kinetics. In particular, platinum-group metal (PGM) electrocatalysts, known for their excellent activity and durability for the ORR, have not been widely used in the cathode of DAFCs. This is because the ammonia that crosses over from the anode to the cathode can easily be oxidized or poisoned on the Pt surface, degrading cell performance.

In this study, we propose new insights into Pt atomic active sites with high ORR activity and ammonia oxidation resistance. Ultralow Pt-loaded catalysts (< 0.5 wt.% of Pt) derived from three kinds of metal-organic frameworks (MOFs) were prepared with different active sites: M-N_x *atomic sites, PtFe alloy, and a combination of both by simply varying pyrolysis conditions. Carbon quantum dot additives with abundant N composition were coated on the MOF substrate to maximize metal atomic structure without metal agglomeration. Pt-Fe-NC catalyst_900°C catalyst primarily created Fe and Pt atomic active sites, where a metal atom coordinates with nitrogen atoms in the carbon matrix. In contrast, PtFe metal alloys were formed in Pt-Fe-NC_1000°C catalyst. These catalysts demonstrated high ORR activity in alkaline electrolytes, outperforming commercial Pt/C catalysts. Surprisingly, compared to commercial Pt/C catalysts, the Pt-Fe-NC_950°C catalyst had a mass activity value of 4.266 A/*mg_{Pt} *(@ 0.9 V vs. RHE), nearly 142 times higher than Pt/C (0.03 A/*mg_{Pt}*). To investigate the ammonia oxidation resistance of the catalysts, ORR activity was compared in an ammonia-added alkaline environment. In the presence of ammonia, the ultralow Pt-loaded Pt-Fe-NC catalysts showed a much lower decrease ratio of half-wave potential than that of Pt/C (7.4%). In particular, the Pt-Fe-NC catalyst_900°C catalyst with multiple metal atomic active sites exhibited only a 0.6% decrease ratio. DFT calculations confirmed that Pt atomic active sites had high ammonia oxidation resistance, as ammonia molecules rarely adsorbed to the Pt surface in Pt-*N_x *sites. As a result, we suggest that an ultralow Pt-loaded catalyst with atomic-scale Pt active sites could be a viable cathode catalyst for DAFCs.*

Bubble Release from Tunable Porous Carbons *Nicola Seraphim, Noa Soffer-Lugassy and David Eisenberg; Technion–Israel Institute of Technology, Israel*

Fuel cells (FC) and electrolyzers are considered a promising alterantive for energy storage. Through a redox reaction occuring on an anode and a cathode, we can extract an electric current to extract energy. However, fuel cells are not yet commercial due to many obstacles. Catalysts alternatives and low power density isuues are usually discussed, but another major problem of FC (or electrolyzer) is bubble poisoning, which occurs when gas is generated through an electrochemical reaction, leading to bubble formation and adhesion to the electrode. This continues adhesion lowers the surface area, decreases mass transfer, reduces exposure of active material.

One of the methods to tackle bubble poisoning is by porous structures. Different types of porous strucures can help with mitigating bubbles, each with its own unique pore size distribution, surface area, tortuosity etc. Nevertheless, cracking the link between porous structure and bubble mitigation is not simple, as many variables come to play at the bubble release and dynamics.

In order to understand better the relationship between mitigating bubbles and pore size, we synthesized N-doped carbons with different spherical pores, through hard template method, using acrylonitrile as a precursor and silica spheres as template, changing only the pore size (40, 80, 120, 200 nm). Decoupling pore size from the porous structure parameters, we can understand the relation between bubble release and pore size.

The materials exhibited a trend as pore size increases, bubble size and adhesion increases to lower active surface area as recorded in cyclic voltammetry measurements, while the number of bubbles decreases. This was viewed using photography and a built setup to help record the electrode surface, as well as the bubble dynamics. Together with mathematical analysis based on the materials roughness and characteristics, we discovered smaller pores are preferable for bubble mitigation.

Modulating Oxygen Species Proportion in Graphene Oxide—Towards Influencing the N-Doping Process *José M. Ruiz-Marizcal[1], Jose I. Paez-Ornelas[2], Héctor H. Fernández-Escamilla[3], Gabriel Alonso-Nunez[2], Noboru Takeuchi[2] and Jose M. Romo-Herrera[2]; [1]Centro de Investigación Científica y de Educación Superior, Mexico; [2]Centro de Nanociencias y Nanotecnología, Mexico; [3]Universidad Autónoma de Nuevo León, United States*

Graphene oxide (GO) has emerged as a key precursor for nitrogen-doped graphene due to its unique structure, which includes a variety of oxygen-containing functional groups such as epoxides, hydroxyls, carboxyls and carbonyls among others. These oxygen could be impacting the doping process in a different manner. Understanding the transformation and reorganization of these functional groups should be essential for optimizing the nitrogen doping of graphene.

The oxygen functionalities in graphene oxide are reactive and can undergo significant reorganization under controlled conditions, such as mild thermal treatments or by pH-dependent chemical procedures. This reconfiguration could promote the desired surface chemistry that facilitate the incorporation of nitrogen atoms into the carbon network of graphene. By carefully selecting and tuning these treatments, it should be possible to convert certain oxygen species into configurations that favor the nitrogen doping. Therefore, this approach of modifying the oxygen functional groups in the graphene oxide to be used as the precursor should represent a promising strategy for improving the efficiency of nitrogen doping and optimizing the performance of nitrogen-doped graphene in electrocatalytic applications.

In this study, we explore the redistribution of oxygen species proportion by different post-synthesis treatment of *graphene oxide. Techniques such as X-ray photoelectron spectroscopy (XPS), thermogravimetric analysis (TGA), Raman spectroscopy, X-ray diffraction (XRD), were used to monitor the changes in the chemical and structural properties of the Graphene oxide. This was analyzed together with feasible organic chemistry reactions and DFT calculations to understand in deep the different processes. The ability to control the oxygen species on the graphene oxide surface is crucial, as it could influence the subsequent nitrogen doping efficiency and the nature of the nitrogen incorporation (e.g., pyridinic, graphitic, or pyrrolic nitrogen).*

Platinum-Group-Metal-Free Electrocatalysts Via N$^+$ Ions Implantation and Iron Evaporation Over 2D-Supported Carbonaceous Materials

Valerio C. Ficca[1], Marco Sbroscia[1], Elena Stellino[2], Ilaria Rago[3], Andrea Capasso[4], Naurang L. Saini[1] and Ernesto Placidi[1]; [1]Sapienza Università di Roma, Italy; [2]Sapienza University of Rome, Italy; [3]Istituto Nazionale di Fisca Nucleare, Italy; [4]International Iberian Nanotechnology Laboratory, Portugal

Ion beam methods (IBM) for selective ion implantation are at the basis of large-scale production of fine-tuned optically related materials and semiconductors but also for p- and n-doped carbon nanotubes and graphene [1–4]. Continuous research on cost-effective nanomaterials for energy conversion in fuel cells, zinc-air batteries, and electrolyzers could actually benefit from a precise and scalable approach for the preparation of electrocatalysts. Indeed, platinum-group-metal-free electrocatalysts (PGM-free), specifically designed for those applications, are materials composed of carbon, nitrogen, oxygen, and non-noble transition metals, hence chemically compatible with IBM. Commonly, PGM-free are synthesized through a chemical process involving both organic and inorganic compounds [5–7]. To enhance catalytic efficiency, these compounds are mechanically mixed and subjected to one or more pyrolysis cycles at high temperatures (>900°C) in a controlled, non-oxidative atmosphere. Additionally, acid-washing steps are employed to remove unwanted secondary species, particularly for applications in low-pH environments, while also creating a porous structure [8]. Although the chemical synthesis method is widely used for producing PGM-free materials, it offers limited control over the final product, especially in terms of the distribution of oxygen and nitrogen functional groups.

In an effort to apply IBM methodology to PGM-free materials, we investigated the feasibility of replicating the formation of active sites using a cleaner, physical approach, rather than the traditional pyrolysis-based route. The newly developed method is based on nitrogen ion (N+) implantation using a Kaufman ion source at varying beam energies, followed by iron deposition via electron beam evaporation in an ultra-high vacuum (UHV) clean chamber. After the first investigation performed over vertically aligned carbon nanotubes (VACNT), to pave the way and investigate the feasibility of producing fine-tuned PGM-free electrocatalysts without relying on nitrogen-containing precursors, we implemented the study. With the original recipe developed for VACNT, other carbon nanostructures can be investigated, like graphene grown on copper using chemical vapor deposition (CVD) technology. After preparing a set of samples at increasing ion beam energies (20–50 eV), along with control samples, preliminary analyses using scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM), and Raman spectroscopy revealed that the final product exhibited similarities to those produced by chemical methods. This indicates that the formation of active sites is a natural result of nitrogen being incorporated into the carbon matrix. Moreover, by simply adjusting the ion beam energy, it was possible to maximize the content of pyridinic nitrogen while minimizing other nitrogen moieties. Finally, *electrochemical testing of a representative sample demonstrated catalytic activity toward the oxygen reduction reaction (ORR), confirming the viability of the process. These initial results pave the way for the development of PGM-free electrocatalysts through a nitrogen-compound-free synthesis, offering a sustainable approach to creating critical raw-material-free nano-electrocatalysts.*

Low-Dimensional Nano-Carbons—Form Doped Carbon Nanotubes and Doped Graphene to 3-D Hybrids and Biological Applications

Mauricio Terrones; The Pennsylvania State University, United States

We will describe the synthesis of carbon nanotubes and nanotube networks using different dopants during chemical vapor deposition. In particular, the effects of sulfur, boron and nitrogen will be discussed. For example, sulfur induces the formation of pentagons and heptagons, whereas boron aids the growth of heptagonal carbon rings, and nitrogen promotes the formation of pentagonal cusps. It will be demonstrated that it is indeed possible to assemble/grow carbon nanotube networks if a careful control of dopants is achieved during chemical vapor deposition (CVD) growth. High-resolution electron energy loss spectroscopy (HR-EELS) studies on these nanotube materials will be presented, and the locations of boron, sulfur and nitrogen within nanotubes will also be shown. First principles theoretical calculations on nanotubes containing pentagon, hexagons and heptagons in the presence of these dopants will be discussed. We will also discuss the cytotoxicity and applications as molecular sensors and virus traps of these doped nanocarbons.

This talk will also discuss the synthesis of large-area, high-quality monolayers of nitrogen-, silicon- and boron-doped graphene sheets on Cu foils using ambient-pressure chemical vapor deposition (AP-CVD). Scanning tunneling microscopy (STM) and spectroscopy (STS) reveal that the defects in the doped graphene samples arrange in different geometrical configurations exhibiting different electronic and magnetic properties. Interestingly, these doped layers could be used as efficient molecular sensors in conjunction with Raman spectroscopy. In addition, the synthesis of hybrid carbon materials consisting of interconnected graphene layers (graphene foams) by solvothermal routes will be discussed. These foams are highly conducting, very robust and can operate at temperatures ranging from 77K to 1173K.

Freeze-Burn—Fabrication of Hetero-Doped Porous Carbon Networks via Polymer-Templated Rapid Thermal Annealing *James Nicolas M. Pagaduan and Reika Katsumata; University of Massachusetts Amherst, United States*

RTA typically heats materials to ~1200 °C at 100 °C/sec, a classic and common processing method of semiconductors but far less explored for polymers. Our group has pioneered polymer-assisted RTA in fabricating porous carbon materials by "Freeze-Burn." For porous carbon materials production, there has been an opportunity to bridge the gap between template and template-free methods where structural control and throughput are often trade-offs. We addressed this challenge by utilizing matrix polymer blends that undergo phase separation during heating (freeze) while polymer degrades (burn), termed "Freeze-Burn." The Freeze-burn demonstrated successful templating of a wide range of carbon nanoparticles (Freeze-Burn 1.0; ACS Applied Polymer Materials 2022) and direct pyrolysis of nitrogen and boron-doped porous carbon materials with an excellent performance in microcpacitance and wound healing (Freeze-Burn 2.0; Advanced Functional Materials 2023).

8:45 AM EN11.06.03

Understanding the Rheological Insights for Scalable Fabrication of Catalyst-Embedded Carbon Fibers—Exsolution-Driven Structural Development During Carbonization *Ga-Hyeun Lee[1], Seok-Jin Kim[2,2], Jung-Eun Lee[1], Changbeom Jeon[1], Javeed Mahmood[2], Cafer T. Yavuz[2,2] and Han Gi Chae[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]King Abdullah University of Science and Technology, Saudi Arabia*

The urgent demand for sustainable energy solutions has propelled the development of efficient and stable electrochemical catalysts for hydrogen production via water splitting. While metal-carbon nanocomposite powders have shown promise as electrocatalysts, their scalable fabrication and long-term stability remain significant challenges. The use of polymeric binders to coat these catalysts on electrodes can mask electroactive sites, hinder electron transfer, and cause peeling under high current densities. To address these issues, recent research has focused on designing self-supported catalysts, with carbon fiber-based materials receiving particular attention due to their excellent mechanical properties, high surface area, and good electrical conductivity. However, current approaches suffer from poor interfacial adhesion and limited scalability, necessitating the development of cost-effective and scalable manufacturing routes for high-performance electrocatalytic electrodes.

In this study, we present a comprehensive investigation of the rheological properties and exsolution-driven structural development mechanisms to enable the scalable fabrication of ruthenium-embedded carbon fiber electrocatalysts. By elucidating the rheological behavior of the catalyst-containing precursor solution, we optimized the coating process to achieve a uniform distribution of ruthenium nanoparticles around the carbon fibers, overcoming the challenges posed by increased Laplace pressure on the curved fiber surfaces.

Furthermore, we systematically investigated the exsolution-driven microstructural development of the ruthenium-embedded carbon fiber electrocatalysts during the carbonization process. This was achieved by understanding the exsolution mechanisms with respect to the processing parameters, including carbonization temperature and tension, and optimizing the structural development to achieve good catalytic performance and mechanical integrity. These findings underscore the significance of self-supporting catalysts, offering a general framework for stable, self-supported electrocatalytic electrode design.

The insights gained from this study allowed us to optimize the carbonization conditions to achieve the desired catalytic activity and stability. The scalability of our approach was demonstrated using semipilot-scale equipment, where we established a highly optimized protocol for producing continuous self-supported electrocatalytic electrodes. The resulting electrodes exhibited excellent catalytic activity and stability towards the hydrogen

evolution reaction, with a low overpotential of 11.9 mV at a current density of 10 mA cm^{-2} in an alkaline solution and only a slight overpotential increment (6.5%) after 10,000 cycles.
Our findings underscore the importance of understanding the rheological properties and exsolution-driven structural development mechanisms in the scalable fabrication of high-performance catalyst-embedded carbon fiber electrocatalysts. This work provides a general framework for the design and manufacture of stable, self-supported electrocatalytic electrodes for various energy conversion applications.

9:00 AM *EN11.06.04
Aerogel-Based MNC Electrocatalysts for Oxygen Reduction Reaction in Fuel Cells *Lior Elbaz; Bar-Ilan University, Israel*

Great advancements have been made in the past couple of decades in the development of platinum group metal-free (PGM-free) oxygen reduction reaction (ORR) catalysts based on earth-abundant elements such as nitrogen, carbon, and first-row transition metals (usually Fe or Co, but also Cu and Mn). This work has been mostly inspired by biological systems where some of the catalytic centres are composed of complexes of metallo-porphyrins and phthalocyanines. These molecular catalysts show fair, but not exceptional ORR activity and stability. In order to increase the performance of transition-metal complexes, a new class of high temperature-treated (HT-treated) catalysts, composed of the same elements, i.e., a transition metal, carbon and nitrogen, has been developed. Although some improvements were made, the performance of HT-PGM-free ORR catalysts remains inferior to PGM catalysts, calling for further improvements in order to make them a viable alternative to the state-of-the-art materials. One such direction is the increase of the active site density, and catalyst utilization to mitigate their intrinsically low turnover frequency (TOF).
In this work, we designed, synthesized, and characterized ORR catalysts based on iron and/or copper, carbon and nitrogen in a well-defined, high surface-area covalent framework (COF) of aerogels. Aerogels are ultralight, porous materials, with ultra-low density, and high void volume (> 97%), also known for their unique physicochemical properties such as high porosity, controllable pore size and surface area, just to name a few. The variety of precursors used for aerogel synthesis makes them promising candidates for a wide range of applications in catalysis, capacitors, insulators, absorbents, and many more. In the context of electrocatalysis of fuel cells' reactions, carbon-aerogels have been mostly used so far as catalysts' supports for PGM and PGM-free catalysts. In their inorganic form, aerogels can have ultra-high catalytic site density, high surface area, and tuneable physical and chemical structures - all very important features for a heterogeneous catalyst. In this talk, I will discuss the synthesis and electrocatalytic properties of several transition metal-based aerogels developed in my research group. For example, at the beginning of our work on this topic, we synthesized an aerogel based on 5,10,15,20-(tetra-4-aminophenyl)porphyrin (TAPP) and Fe(II), which was later heat-treated at 600°C to enhance its electronic conductivity and catalytic activity while preserving its macro-structure. The resulting material has a very high concentration of atomically dispersed catalytic sites (4.01x10^{19} sites cm^{-3}), capable of catalyzing the ORR in alkaline solution very well (E_{onset} = 0.93 V vs. RHE, TOF = 0.2 e^{-} site^{-1} s^{-1} at 0.8 V vs. RHE). I will present the work we conducted on this topic and include some of our most recent unpublished results with bi-metallic complexes which show exceptional performance.

9:30 AM *EN11.06.05
Electrifying CO_2 into Chemicals and Fuels with Single Atom Catalysts *Feng-Yang Chen[1,2] and Haotian Wang[1]; [1]Rice University, United States; [2]Stanford University, United States*

Electrochemical conversion of atmospheric molecules (CO_2, O_2, H_2O, N_2) into fuels and chemicals offers a green and sustainable alternative to traditional manufacturing processes. However, this approach faces significant challenges at two systemic levels: the development of electrocatalysts that are active, selective, and stable for *efficient chemical conversions, and the design of innovative catalytic reactors that achieve practical reaction rates and efficient product separation. In this talk, I will discuss the rational design strategies for both single atom catalysts and reactors, using CO_2 reduction reaction as a representative example. These advancements are critical for the practical implementation of electrochemical manufacturing processes for fuels and chemicals, and they highlight the potential for scalable and sustainable energy solutions.*

Doping Carbon Nanotubes with Substitutional Heteroatoms—What To Expect *Paola Ayala; University of Vienna, Austria*

Various functionalization methods for carbon nanotubes have been proposed over the last three decades. One of those is the direct substitution of heteroatoms on the tube's walls but this counts among the most complicated tasks to achieve from the experimental point of view. The incorporation of heteroatoms involves different scenarios. Staying at a very low doping regime would imply that the electronic band structure semiconducting single-walled carbon nanotubes (SWCNTs) would not have a strong modification but it should involve a rigid band shift. The doping levels up to which SWCNTs still keep this model has never been determined. Furthermore, the large incorporation of heteroatoms leads the formation of new stoichiometries with completely new properties. Regardless the scenario, SWCNTs doped with N (or also with B), offer a rich and exciting scope of physical properties that cannot be overseen and there is still a vast playground for research. In this context, using functionalization methods to access the properties of SWCNTs in a controllable manner is of enormous interest. Among those methods, substitutional doping and intercalation will be the focus of this talk as examples since they offer a rich scope of potential applications. The heteroatoms responsible for the functionalization of the tubular structures can induce changes in the physical properties of the tubes, but the greatest challenge in this field is the proper understanding of the heteroatom content and distribution, which should be controlled for the next research phase towards applications. We will discuss the progress towards understanding how the energies of charge carriers and lattice vibrations are modified, among other effects due to the presence of heteroatoms and defects. I will give particular emphasis on establishing the prerequisites for studying the rich low-dimensional physics of substitutionally doped SWCNTs as an example. Furthermore, we will discuss the changes in the site selective electronic structure of other various examples of functionalized SWCNTs.

11:00 AM *EN11.07.02
Atomically Precise Graphene Nanoribbons—The Road Towards Device Integration *Debopriya Dutta[1], Riya Sebait[1], Amogh Kinikar[1], Zafer Mutlu[2], Roman Fasel[1], Mickael Perrin[1] and Gabriela Borin Barin[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]The University of Arizona, United States*

Graphene nanoribbons (GNRs) show exciting properties deriving from electron confinement and related band gap tunability[1]. The ability to tune GNRs' electronic and magnetic properties at the single atom level makes them an *ideal platform for a wide range of device applications, from classical transistors to spintronics. In this talk, I will overview the necessary steps to bring GNRs from ultra-high vacuum (UHV) to device integration, focusing on the main aspects of synthesis, characterization, substrate transfer, and transport measurements. After the on-surface synthesis in UHV, GNRs are transferred using different methods based on wet*[2] *and semi-dry/dry-transfer approaches. Those processes allow the characterization of GNR's fingerprint modes and overall alignment via Raman spectroscopy (in UHV and upon exposure)*[3,4] *and the characterization of their electronic properties on decoupled substrates such as quasi-free-standing graphene on SiC. We integrate different armchair GNRs (5-, 9-, 17-AGNRs) into field-effect transistors with different gate and contact configurations. We demonstrate the highest* I_{on} *current GNR-FET device to date by using a double-gate configuration*[5]*. 9-AGNR-FETs show* I_{on} *currents up to 12μA and* I_{on}/I_{off} *up to* 10^5*. By integrating 9-AGNRs into FET devices using graphene and carbon nanotubes*[6] *as electrodes, we also report tunable multi-gate devices showing quantum dot behavior with rich Coulomb diamond patterns. Finally, I will present recent developments on a fully dry-transfer approach of GNRs in ultra-high-vacuum and the possibilities of their application in quantum devices.*

Bias-Enhanced Growth of NanoCarbon Interlayers Towards Ohmic n-Type Diamond Contacts

Gabriel B. Munro-Ludders, Saurabh Vishwakarma, Franz A. Koeck, David Smith and Robert J. Nemanich; Arizona State University, United States

*Ohmic metal contacts to n-type diamond have historically posed a challenge to the fabrication of diamond devices, due to the formation of a pervasive and rectifying Schottky barrier, which limits the practicality and scope of diamond devices. Nitrogen-doped nanostructured Carbon (nanoCarbon) films have recently been explored as ohmic interface layers, to enable low-resistance ohmic contact with n-type diamond. In this work, control over morphological and electrical properties of ohmic nanoCarbon films is achieved by altering the film growth time and utilizing a negative substrate bias. The films were characterized via TEM, which indicate the composition of the films consist of ~4 nm diameter sp3–bonded diamond grains surrounded by a matrix of sp2 bonded carbon. Monochromatic UV photoemission reveals occupied electronic states in the diamond gap for all growth conditions. The resistivity is determined via Hall effect to logarithmically decrease with bias from 1.7 Ω*cm, to 2.9*10-1 Ω*cm, and 3.1*10-2 Ω*cm, for films grown with 0V, 150V and 300V of bias, respectively. The carbon bonding order within each film is additionally characterized via Raman spectroscopy, for which the Raman sp2 "G" peak position increases with both growth time and bias voltage. A correlation is observed between the Raman sp2 "G" peak position and film resistivity on a logarithmic scale, thus the carbon sp2 bonding order is found to be a critical material parameter which alters the electrical properties of nanoCarbon films.*

11:45 AM EN11.07.04

Polymer Fragmentation Analysis for Effective Nitrogen Doping of Graphene via Rapid Thermal Annealing

Claire Senger[1]*, Shao Zhuze*[2]*, Shogo Kumagai*[2]*, Toshiaki Yoshioka*[2]*, Casey Burdett*[3] *and Reika Katsumata*[1]*;*
[1]*University of Massachusetts Amherst, United States;* [2]*Tohoku University, Japan;* [3]*University of North Georgia, United States*

As defect introduction in graphene from synthesis and characterization processes is unavoidable, it is crucial to establish a new defect-healing method for graphene in post-silicon device fabrication. Current healing methods, such as conventional thermal annealing, are time-consuming, highly specialized, or tedious. To this end, we developed a new time- and energy-efficient healing approach for graphene, utilizing polymer-assisted rapid thermal annealing (RTA). In this method, a nitrogen-rich, polymeric "nanobandage" is coated directly onto graphene and processed via RTA at 800 °C for 15 seconds, successfully doping nitrogen into graphene. Utilizing a polymer layer opens up opportunities for patterned doping and doping in elements other than nitrogen for graphene and other 2D materials in the future. To understand more deeply the mechanism behind this method, we further investigate the degradation of the nanobandage polymer and how the fragmentation changes in the presence of graphitic carbon via complementary techniques. We utilize both in-situ mass spectrometry attached to the RTA processor for real-time data and pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS) of the polymer to obtain more detailed data on what gases the sample breaks down to. Advancing our knowledge of how the polymer breaks down will inform future molecular design of other polymers, allowing for more types of doping and improving efficiency.

SYMPOSIUM EN12

Scientific Basis for Nuclear Waste Management
December 2 - December 3, 2024

Symposium Organizers
Dan Gregg, ANSTO Synroc
Philip Kegler, Forschungszentrum Juelich
Josef Matyas, Pacific Northwest National Laboratory

Blast Furnace Slag (BFS) Composite Cement for the Immobilisation of Sulphate Bearing Nuclear Wastes—Development So Far *Hajime Kinoshita; The University of Sheffield, United Kingdom*

We have been developing blast furnace slag (BFS) composite cement with a barium hydroxide $Ba(OH)_2$ activator to _safely accommodate sulphate bearing nuclear wastes._

Sulphate bearing nuclear wastes are usually difficult to immobilise effectively via the conventional vitrification or cementing processes. In the vitrification, the presence of soluble sulphate causes phase separation in borosilicate glass [1], while in the cementation, it causes the internal sulphate attack in the long term, leading to the microstructural changes [2,3] such as expansion and cracking.

The use of $Ba(OH)_2$ _is interesting because it can, while simultaneously activate the slag, capture the sulphate ions contained in the waste stream to form stable_ $BaSO_4$ _as shown in reaction 1._
$Ba(OH)_2 + MSO_4$ _(Waste) à_ $BaSO_4 + M(OH)_2$ _(1)_
where M denotes cations which may be forming sulphates in the waste streams. The high density $BaSO_4$ _has a high radiation attenuation coefficient and has been studied as a radiation shielding material [4]. Thus, it could be advantageous to form_ $BaSO_4$ _as a part of cement matrix for nuclear waste encapsulation. The key technical findings so far are:_

* _The immobilisation of soluble sulphate-bearing aqueous wastes is achievable in BFS composites with addition of_ $Ba(OH)_2$_, promoting the simultaneous formation of_ $BaSO_4$ _and the activation of the BFS [5]._
* _Mixing of_ $Ba(OH)_2$ _with sulphate waste (simulant), prior to addition of BFS favours the formation of hydrotalcite and C-S-H, typically identified in NaOH-activated BFS systems, while the direct inclusion of_ $Ba(OH)_2$ _with BFS and sulphate waste resulted in ettringite, barium carbonate and portlandite [5]._
* _Both_ Na_2SO_4 _and_ $Ba(OH)_2$ _appear to be acting as alkaline activators in the system with direct inclusion of_ $Ba(OH)_2$ _[6]._
* _An increased addition of_ $Ba(OH)_2$ _is beneficial, promoting a higher extent in the reaction of BFS, and a 30 % excess of_ $Ba(OH)_2$ _over_ Na_2SO_4 _appears to be sufficient to prevent the presence of free_ Na_2SO_4 _in the system [6]._
* _The extent of reaction increased with the presence of heat and irradiation, including ettringite, resulting in a higher compressive strength compared with the unexposed control samples [7]._
* _The BFS composite system was stable under the irradiation of 2.9 MGy over 256 h without showing any cracks or structural modifications after irradiation [7]._

The direct inclusion of $Ba(OH)_2$ _with the BFS and sulphate appears to be beneficial, providing extra alkalinity to the system for the reaction of BFS, and more formation of C-S-H products, along with the formation of_ $BaSO_4$_. The irradiation tests also show that the formation of_ $BaSO_4$ _with a high attenuation of gamma radiation might be playing an important role in providing radiation resistance. In the presentation, the progress made so far are summarised here and discussed to further develops the system for practical application of the technique for the immobilisation of sulphate bearing nuclear wastes._

Disposal MOX—A Potential Immobilization Route for Separated Plutonium *Jack Rolfe[1], Colin Boxall[1], Richard Wilbraham[1], Dave Goddard[2] and Hayley Green[3]; [1]Lancaster University, United Kingdom; [2]National Nuclear Laboratory, United Kingdom; [3]Sellafield Ltd, United Kingdom*

The United Kingdom possesses the world's largest civil stockpile of separated plutonium (Pu), ≈140T, accumulated from an extensive history of spent fuel reprocessing. Due to associated nuclear proliferation and security risks, it is imperative that this Pu is disposed of in a wasteform that renders it permanently inaccessible, such as by immobilising it within a ceramic wasteform. One candidate wasteform currently under assessment is Disposal MOX (dMOX), a variation of MOX fuel designed for direct Geological Disposal Facility (GDF) disposal instead of irradiation. Key differences between the two include: the incorporation of a neutron poison (Gd) for criticality purposes, an increased density, and potentially a higher Pu loading.

The resistance of dMOX wasteforms to oxidative dissolution under GDF groundwater relevant conditions needs to be understood. Specifically, how the introduction of both Pu and Gd dopants alter the corrosion behaviour of the bulk UO_2 matrix needs to be explored. This may indicate ideal dopant concentration levels for dissolution inhibition and could help underpin the deployment of dMOX.

Using Ce as a non-active Pu surrogate, a series of homogenous Gd and Ce doped UO_2 powders have been manufactured from the thermal decomposition of mixed-metal oxalate precursors, containing 1-10mol% of the metal ion dopant. Dopants were successfully homogenously incorporated, with no evidence of phase segregation. These powders were cold pressed, sintered into pellets, and cast in epoxy resin to form electrodes. Electrochemical investigation has indicated that the introduction of the lanthanide dopants inhibits the oxidation of UO_2 to soluble UO_2^{2-} when in excess of ≈ 7 mol%, evidenced by a reduction in current density when an overpotential of 0.4V is applied (vs a saturated calomel reference electrode). This has been attributed to the clustering of defects at grain boundaries, reducing overall grain boundary conductivity. This observed inhibition in UO_2 corrosion is advantageous for the deployment of dMOX.

Additionally, the effect of new novel sintering routes, namely Spark and Plasma Sintering (SPS) on the corrosion behaviour of UO_2 and the lanthanide doped UO_2 has been explored. Sintering via SPS allows higher final pellet densities to be achieved, at the expense of smaller grains. While a higher density may lead to more dissolution resistance, smaller grains will likely cause an increased rate of corrosion. The overall effect of these competing factors is currently under investigation, with the results to be reported at the conference.

11:15 AM EN12.01.03

HIPed Pollucite Glass-Ceramics as Advanced Wasteforms for the Immobilization of Cs-Loaded IONSIV Wastes *Ghazaleh Bahman Rokh[1], Jess Degeling[1,2] and Dan Gregg[1]; [1]Australian Nuclear Science and Technology Organisation, Australia; [2]UNSW Sydney, Australia*

A promising novel candidate glass-ceramic wasteform based on pollucite for the immobilization of Cs-loaded IONSIV® with high Cs selectivity and retention has been developed. Inorganic ion exchangers have proven to be the most effective technology for sequestering radionuclides from liquid waste streams in the nuclear industry. The wasteform was designed to target pollucite, srilankite, and rutile phases where pollucite formation was a function of Cs loading on the IONSIV®. This provides effective control over the phase formation as well as elimination of soluble Cs-rich phase(s) that may otherwise form during processing. The tailored pollucite glass-ceramic provides *chemical and processing flexibility through the addition of small amounts of glass formers. Caesium was determined to be partitioned predominantly to the ceramic phase, thus taking advantage of pollucite's relatively high chemical durability. Glass was included to provide chemical and processing flexibility and to increase the tolerance of the design to variations in Cs-loading on the IONSIV®. Importantly, the wasteform design and tailored additives ensure the production of a consistent phase formation in the wasteform, irrespective of Cs-loading on the IONSIV®.*

Highly stable and durable wasteforms were produced via sintering and hot-isostatic pressing (HIP) with waste loadings of up to 70 – 80 wt.%. HIPing was employed to enhance the densification of the glass-ceramic and to ensure prevention of Cs-release via volatilisation to the off-gas during final consolidation within the HIP canister. The amount of glass in the formulation was further tailored to balance the processing benefits with the waste loading reduction. In addition, the properties of the HIPed wasteforms were compared with samples densified via sintering, to examine the impact of HIPing on its effectiveness for waste immobilisation.

The waste loading, extent of densification, phase stability of the wasteform, the HIP canister-wasteform interaction and aqueous durability of pollucite glass-ceramic wasteform were examined after densification via the HIPing process. The designed glass-ceramic wasteform provides an excellent wasteform candidate for permanent storage and final disposal of international Cs-loaded IONSIV® wastes.

11:30 AM EN12.01.04

Interactions of Silicon Carbide and Stainless Steel in Cermet Wasteforms *Malin C. Dixon Wilkins and John S. McCloy; Washington State University, United States*

The development and deployment of Gen IV reactors using TRISO and related fuels is on-going, both for large-scale and small modular reactors. The back-end of a TRISO fuel cycle poses new challenges to waste immobilization science, with the complex TRISO particle structure comprising layers of porous carbon, pyrolytic carbon and silicon carbide present alongside the fuel kernel (UO_2, UC, UCO, etc.) being unique among fission fuels. Cermets, composites of ceramic components dispersed throughout a metallic matrix, have been proposed as high-density, durable wasteforms, with the utilization of metallic waste streams (e.g. contaminated stainless steels, Ni-based alloys) as components resulting in extremely high waste loadings and lowering the amount of non-active feedstock materials necessary. In this work, characterization of the interactions between SiC and 316L stainless steel in cermets prepared by hot uniaxial pressing (HUP) will be presented. Cermets with 50:50 volume loadings of SiC and 316L stainless steel were produced (HUP cycle of 1000 °C, 30 mins, 39 MPa), and the impact of a range of SiC sources and particle sizes was examined. Processing routes for the production of bulk SiC from relevant forms of C have been appraised for their applicability to TRISO immobilization, with simple high temperature reactions being the most feasible given the need for scale-up.
Low porosity was observed in the final products; however, significant interaction between SiC and steel was observed in all materials, resulting in formation of regions of C and metal silicides of approximately the same size as the initial SiC particle size. The produced microstructures were characterized by Raman spectroscopic mapping and electron microscopy techniques, with both giving complementary information with respect to identifying regions containing C, steel, SiC, and a range of metal silicides and carbides. Segregation of the metallic components was observed, with Cr and especially Ni appearing to form separate phases, rather than mixed Fe/Ni/Cr silicides or carbides. The observed fractions of C and SiC varied as a function particle size, with larger initial particle sizes resulting in less reaction with the stainless steel matrix, forming relatively lower fractions of metal silicides and carbides. The source of SiC (or C used to synthesize it) was less important to the produced phase assemblage, other than effects attributable to particle size. A preliminary sample comprising a 50:25:25 volume ratio of 316L:SiC:UO_2 has also been prepared as a better simulant of a wasteform for a TRISO fuel mix.

11:45 AM EN12.01.05

Structural Characterization of Novel Tin Fluorophosphate Nuclear Salt Waste Forms *Peyton McGuire, Matthew Page, Bethany Sparks, Nancy Birkner and Kyle S. Brinkman; Clemson University, United States*

Recently, phosphate glass, specifically tin fluorophosphate glass/glass-ceramics (TFPG/TFPGC) or SnF_2*-SnO-*P_2O_5*, has gained attention as a potential vitrification medium for chloride-based nuclear salt waste. Greater chemical durability and density along with lower melting temperatures imparts TFPG/TFPGC distinct advantages in stability, waste volume, and synthesis ease/cost relative to industry-standard borosilicate waste forms. The tendency of phosphate glass/glass-ceramic systems to succumb to hygroscopicity in ambient conditions, however, impedes further implementation of TFP compounds as waste forms unless their structural matrices can be improved to combat this. The discovery in this work of crystalline phase formations of stronadelphite (*$Sr_5F(PO_4)_3$*), cerium phosphate (*$CePO_4$*), and neodymium ultraphosphate (*NdP_5O_{14}*) within novel 30 mass-% chloride salt waste-loaded TFPG samples, which were observed to resist hygroscopicity, was used as a basis to modify TFP chloride salt waste forms which did not naturally form these structures through artificial phase incorporation. Initial XRD and SEM-EDS analysis has revealed that the inclusion of 3 mass-% single-phase fluorapatite [2(*$Ca_5F(PO_4)_3$*)], of which stronadelphite is a structural analog, into specific 30% waste-loaded TFPGs resulted in higher chlorine retention rates and structural phase-stability than both non-included and other phase-included TFPGCs. Further structural testing of Nd-Ultraphosphate phase-inclusion and CaO substitution of TFP waste forms, along with additional chemical and thermal analyses, is ongoing.*

SESSION EN12.02: Spent Nuclear Fuel

A Tribute to Rodney C. Ewing *William J. Weber; The University of Tennessee, Knoxville, United States*

The scientific community lost a scientific leader and spokesman with the passing of Rodney C. Ewing on July 13, 2024. Rod was instrumental in founding this symposium series on the Scientific Basis for Nuclear Waste Management, a contributor since the first symposium in the series, an organizer and proceedings editor, and a program committee member for most of his career. While well known for his contributions and leadership in nuclear waste management, Rod made many fundamental scientific advancements and contributions to materials science, mineralogy, and geology. Rod was a member of the National Academy of Engineering, former chair of the US Nuclear Waste Technical Review Board, co-director of Stanford University's Center for International Security and Cooperation, and a professor of Earth Sciences at Stanford at the time of his passing. This tribute will highlight several of Rod's many scientific contributions and accomplishments, as well as the legacy he leaves behind.

2:00 PM EN12.02.02

Spent Nuclear Fuel Experiments During the Last 20 Years Performed at JRC-Karlsruhe *Joan de Pablo[1,2], Albert Martínez-Torrents[2], Javier Gimenez[1], Frederic Clarens[2], Miguel Angel Cuñado[3] and Daniel Serrano Purroy[4]; [1]Universitat Politècnica de Catalunya, Spain; [2]Eurecat, Centre Tecnologic Catalunya, Spain; [3]ENRESA, Spain;*

[4]European Commission Joint Research Centre, Germany

Twenty years ago, Enresa initiated an ambitious research program aimed at exploring the behavior of high burn-up spent nuclear fuel within the expected conditions of a deep geological repository. This research has been conducted within the hot cells at the Joint Research Center, Karlsruhe (JRC), in the frame of a collaboration agreement between Enresa, JRC, Eurecat and UPC-Barcelona Tech.

The primary aim of this investigation was to gain insights from leaching experiments regarding various factors, including the characteristics of the spent fuel such as Burn-up, Linear Power Density, and sample type (powder, segments), alongside the diverse experimental conditions such as redox conditions and leaching solutions (bicarbonate water, cement water and bentonitic groundwater). The radionuclide segregation during irradiation was also a factor studied. From a radial point of view comparing internal and external powder samples, and from an axial point of view, determining the effect of the interpellet space, and using cladded segments from different positions of the pin.

Seven specimens of spent fuel have been studied in total, with four originating from PWR reactors and the remaining three from BWR reactors. Burn-ups varies from 45 to 63 MWd/kgU.

In this work, we present results on spent fuel characterization as well as on leaching experiments in terms of Instant Release Fraction for significant fission products such as Rb, Sr, Cs, Mo and Tc and matrix dissolution rates based on uranium release.

Leaching data have been modelled by using Segregated Radionuclide Identification and Quantification Model (SERNIM). The main advantages of SERNIM is its capacity to separate the release of a radionuclide from the different locations in the fuel at any time, including the gap, dishing and fractures; pre-oxidized fuel surface; internal grain boundaries and finally UO_2 matrix dissolution.

2:15 PM *EN12.02.03

Influence of Additives (Cr-, Cr/Al- and Gd) on UO_2 Dissolution Behaviour *Nieves Rodríguez-Villagra[1], Sergio Fernández-Carretero[1], Abel Milena-Pérez[2], Laura Bonales[1], Sofía Durán[1], Luis Gutiérrez-Nebot[1], Joaquín Cobos[3] and Hitos Galán[1]; [1]Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas, Spain; [2]Studsvik Nuclear AB, Sweden; [3]Estación Biológica de Doñana, Spain*

Extensive work has been devoted to the conventional UO_2 fuel stability under representative conditions of a deep geological repository (DGR). Currently, there is an international interest to use the so-called "improved fuels", specially designed to enhance fuel properties and its performance compared to traditional UO_2 fuels. Additive-based UO_2 fuels involved the incorporation of small amounts of metal oxides such as chromia (Cr_2O_3) or chromia-alumina (Cr_2O_3-Al_2O_3), which are the two main considered type of accident tolerant fuel (ATF) pellets to be extensively used for near-term designs. The improvements on UO_2 doped fuels with additives are related to higher densification, greater pellet-cladding interaction (PCI) resistance, higher creep rate, lower fission gases release during irradiation and higher resistance to post-failure degradation. Other types of additives as Gd_2O_3, widely used in light water reactors, are added to UO_2, since Gd is a burnable neutron absorber and because of it appropriate solid solubility in UO_2.

Leaching results of a new type of fuel with additives (Cr-doped UO_2, Al/Cr-doped UO_2 and Gd-doped UO_2) are presented. Doped UO_2 pellets with 0.06 wt%Cr_2O_3, 0.05 wt% Cr_2O_3/0.02 wt% Al_2O_3 and 4.5 wt%Gd_2O_3 are firstly prepared (by dry route) and characterized. In order to investigate the influence of leachant nature (i.e. pH, anion complexing agents) and the doping effect on the leaching behavior, the dissolution of uranium is analyzed on these three type of freshly prepared doped UO_2 pellets under synthetic groundwater solutions, without and with HCO_3^-. Static dissolution experiments with the prepared doped UO_2 samples are run under three simplified aqueous leachants: PC (sodium perchlorate, pH 7.2, 136 days), BC (bicarbonate water, 0.019 M $NaHCO_3$- 0.001M NaCl, pH 8.9, 168 days) and YCW (young cementitious water, pH 13.5, 379 days). Overall, the addition of Cr, Cr/Al and Gd *does not lead to a significant change of the U dissolution behavior at pH 7.2 (PC, ~10^{-9} mol●L^{-1}) and 13.5 (YCW, 4●10^{-8} – 2●10^{-7} mol●L^{-1}), however differences between in U behavior for these three types of additives were found at high carbonated water. At pH 8.9 (BC), higher final U concentrations are quantified for Cr-doped UO_2 (~10^{-6} mol●L^{-1}) and Cr/Al-doped UO_2 (10^{-7} mol●L^{-1}) when compared to those at pH 7.2. The high U concentration values observed in the tests, close to those found under oxidizing redox conditions, suggest that the presence of potential traces of atmospheric oxygen (possibly introduced as residual dissolved oxygen), is a result of an oxidative dissolution process at the pellet surface promoted by carbonates. The analyses of the leached samples surfaces show the absence of precipitated secondary phases containing uranium. These results provide added knowledge into the influence of doping and leachant nature on the dissolution behavior of modern spent light water reactor fuels under the post-closure conditions expected in a DGR.*

3:15 PM *EN12.02.04
Fast Release of Radionuclides from a Spent Nuclear Fuel (UOX, 50.4 GWd/tHM) Under High Alkaline Solution and in Presence of Hydrogen *Thierry Mennecart[1], Christelle Cachoir[1], Karel Lemmens[1], Roberto Gaggiano[2], Katrien Meert[2] and Tomas Vandoorne[2]; [1]SCK CEN, Belgium; [2]ONDRAF/NIRAS, Belgium*

Many countries consider the direct disposal of the Spent Nuclear Fuel (SNF) in a deep geological repository as the safest long-term waste management option. However, regardless of the design, the groundwater intrusion through the engineered barriers and the contact with the SNF are unavoidable, leading to SNF alteration and release of radionuclides into the environment. Consequently, it is crucial to understand and to identify the dissolution mechanisms of the SNF under deep geological disposal conditions and to quantify the release of the radionuclides which is a combination of two processes: a fast short-term release of segregated radionuclides occurring once the clad has failed and water reaches the SNF, and a slow long-term release associated with the dissolution of the SNF matrix. These processes might be influenced by the surrounding environment and the characteristics of the engineered barriers. In Belgium, the current long-term management strategy for spent nuclear fuel relies on the "Supercontainer design", leading to a highly alkaline environment caused by the presence of concrete. The corrosion of iron-based materials present in the engineered barriers will generate hydrogen imposing reducing conditions.

A first leaching experiment with a total duration of 1600 days was carried out with SNF samples originating from the pressurized water reactor Tihange 1, with a burn-up of 50.4 GWd/tHM, in contact with a high pH solution (YCWCa, pH 13.5) and a bicarbonate solution (pH 7.4 – 8.2) commonly used as reference for such leaching experiments. To impose reducing conditions and to monitor the fission gas release, the experiments were performed using autoclaves under 40 bar total pressure with two mixtures of H_2/Ar, resulting in a hydrogen partial pressure of 0.3 or 1.6 bar. Regular samplings of the gas phase and the leaching solution were done as a function of time. This study presents the results obtained during the first period of about two years when the process of fast radionuclides release dominates.
We have observed that there is no (significant) effect of hydrogen partial pressure (0.3 or 1.6 bar) or leaching medium on the fast release of fission gasses and of the fission products iodine and cesium.

More recently, a second leaching experiment was initiated with SNF samples from the same fuel rod, leached in YCWCa either with 0.3 bar hydrogen partial pressure or in absence of hydrogen (pure Ar atmosphere). The experiments are performed in duplicate. Even if some differences appear when comparing the two leaching experiments likely attributed to the SNF samples themselves, the previous results in YCWCa are confirmed, increasing the confidence in the values and conclusions of the first experiment.

3:45 PM EN12.02.05

The Corrosion of UO2-Based Spent Nuclear Fuel Under Storage and Disposal Conditions—A Comparison of Real Irradiated Fuel and SIMFUEL Studies *Colin Boxall[1], James Goode[2], David Hambley[2], Elizabeth Howett[1], Nigel Huang[1], Lucy Kissick[2] and Nadya Rauff-Nisthar[1]; [1]Lancaster University, United Kingdom; [2]National Nuclear Laboratory, United Kingdom*

Historically, UO2-based spent nuclear fuel (SNF) in the UK was reprocessed at Sellafield's Thermal Oxide Reprocessing Plant (THORP). THORP closed in 2018 and current UK policy is that SNF will be send to a GDF due to open ~2075. Until then fuel will be kept in storage ponds at Sellafield.

Internationally, the vast majority of UO2-based SNF is from LWRs and a significant amount of research has been carried out to support both the wet storage and direct disposal concepts in terms of the physical and aqueous durability of cladding and irradiated UO2. However, in the UK, the vast proportion of SNF is from indigenous Advanced Gas-cooled Reactors (AGRs). AGRs, whilst also using UO2-based fuel, employ CO2 as coolant and are graphite moderated. Further, the fuel assembly cladding is comprised of 20/25/Nb steel (20% Cr, 20% Ni) rather than zircalloy as is the case in PWRs. Consequently, AGR fuel has unique characteristics that need to be evaluated in order to satisfy safety case requirements for both extended pond storage and geological disposal.

In the UK, the very high radiation fields arising from real SNF prohibits their study in all but a few specialised "hot cells" operated by Sellafield or NNL, a resource that is necessarily constrained. One way to obviate this problem is to work on simulated SNF (SIMFUELs

Thus, we have been studying a series of novel SIMFUELs designed to replicate SNF discharged from a UK AGR at a range of simulated burnups. AGR SNF destined for long term wet-storage could face pond water ingress through the fuel cladding as a result of damage to that cladding. Similarly, in a GDF, at some point after repository closure, it is expected that the canisters within which the SNF is sealed will fail, allowing the ingress of groundwater. In either scenario, the pond/groundwater may come into contact with the UO2 fuel pellets initiating their corrosion and dissolution.

Consequently, our studies have focussed on understanding both the materials properties of these SIMFUELs and their corrosion behaviour as a function of electrolyte compositions and conditions relevant to pond storage and geological disposal. This presentation will present the key findings from those studies, with an emphasis on those conducted electrolyte systems designed to simulate storage pond waters and granitic and evaporite groundwaters.

Features to be presented include: the role of each of the main classes of additives to the SIMFUEL (the trivalent lanthanides, the so-called grey phases, the epsilon-particles) play in determining the behaviour of the fuel matrix and the effect of galvanic coupling of the SIMFUEL to the stainless steel cladding on their corrosion behaviours (inc. the sacrificial protection afforded to the fuel in some groundwaters).

This SIMFUEL data is compared with recently obtained novel data gathered from electrochemical corrosion studies of UK legacy AGR spent nuclear fuel and conducted in the "hot cell" facilities at the UK National Nuclear Laboratory (NNL) Windscale Facility. In these studies of real fuel, a range of electrochemical techniques have been deployed on a cross-sectional segment of real irradiated AGR spent nuclear fuel, under electrolyte conditions of different solution pHs and chloride concentrations in order to mimic certain aspects of pond storage conditions. This data provides both (i) the first ever insight to the electrochemical corrosion behaviour of a SNF sample consisting of irradiated uranium dioxide coupled directly to similarly-irradiated 20/25/Nb stainless steel and (ii) confirmation that the non-active SIMFUEL studies provide an excellent surrogate for the study of real irradiated fuel.

*4:00 PM *EN12.02.06*

The Complexitiy and Intricacy of the Materials Chemistry in Additive Doped-UO_2 Fresh and Spent Nuclear

Fuel *Gabriel Murphy[1], Philip Kegler[1], Martina Klinkenberg[1], Daniil Shirokiy[1], Andrey Bukaemskiy[1], Elena Bazarkina[2], Kristina Kvashnina[2], Maximilian Henkes[1], Andre Rossberg[2], Christoph Hennig[2], Peter Kaden[3], Dirk Bosbach[1] and Nina Huittinen[3]; [1]Forschungszentrum Jülich GmbH, Germany; [2]European Synchrotron Radiation Facility, France; [3]Helmholtz-Zentrum Dresden-Rossendorf, Germany*

Additive doped-UO$_2$ nuclear fuels have become increasingly popularised due to the enhanced operational safety benefits they possess over traditional non-doped forms. The addition of additives such as Al, Nd, Mg, Mn and particularly Cr among others into UO$_2$ during fuel fabrication has been demonstrated to result in significantly enhanced grain growth that enables enhanced fission gas retention during reactor operations. Subsequently, this enables the fuel to remain within the reactor for extended burnup periods and better enable it to respond to transient events leading to these fuel variants to fall under the accident tolerant (ATF) class. Despite the prolific interest in such fuel varieties from industry and researchers alike, significant gaps exist in the fundamental materials chemical understanding of these fuels. For instance, a description of the chemical-redox states that occur within Cr-doped UO$_2$ has remained contentious until only recently [1]. Such a lack of basic knowledge arises through the complexity of chemical states that additives can adopt within the fuel matrix. This complexity is further exacerbated when one considers the complex chemistry that arises when additive doped-UO$_2$ fuel varieties are discharged from reactors as spent nuclear fuel (SNF). Studying SNF is challenging due to the heightened radioactivity of these materials, restricting their investigation to few specialised nuclear laboratories. Our group has devoted significant efforts to investigating additive doped-UO$_2$ materials using model system studies involving the synthesis of representative specimens that are relevant to industry standards and subjecting them to high resolution spectroscopic investigation. Our experimental investigations, often performed synergistically with simulation methods, have enabled a precise and detailed chemical description of additive doped-UO$_2$ materials as fresh fuels and further provided insight into their behaviour as SNF. Accordingly, this presentation will discuss these recent endeavours in a "cradle to the grave" approach including (i) the role of secondary phases in facilitating or inhibiting grain growth during sintering (ii) comparative analysis of extracted single crystal grains against bulk material to deconvolute chemical states in fresh fuel and (iii) formation of additive specific solid phases in SNF and their response to radiation damage through experimental and simulation methods.

The Safe Storage of Plutonium Dioxide *Daniel Mabon; Lancaster University, United Kingdom*

At 140te, the UK currently possesses over half of the world's stockpile of civil plutonium, which is stored as calcined powder in sealed stainless steel canisters at Sellafield. The powder is strongly α-active & generates helium at a rate dependent on factors such as nuclear fuel enrichment, burn-up, and age. This work, co-funded by UKRI and Sellafield Ltd, aims to investigate helium release from plutonium powders.

Up-to-date as of November 14, 2024

Due to the issues involved with working with plutonium, structural analogues have been used instead, with the surrogates used including cerium dioxide, yttria-stabilised zirconium dioxide, and thorium dioxide. As helium isn't radiogenically produced in the first two of these surrogates and only in minute amounts in the third, a main area of focus during this project has been investigating methods of introducing helium into the surrogates. Two main routes of doing so have been explored: thermal infusion of helium, and helium ion beam implantation.

Thermal infusion of helium involves using a high-temperature and high-pressure helium atmosphere to promote helium diffusion into the surrogate powder. Ion beam implantation involves using an ion beam to bombard a sample with helium ions of sufficient energy to implant the ions into the sample. Ion beam implantation requires specialist facilities, such as those in the Dalton Cumbria Facility operated by the University of Manchester.

A range of analytical techniques have been used to characterise the as-received/fabricated surrogate powders and resultant samples produced by either thermal infusion or ion beam implantation. These techniques include inter alia: Raman Spectroscopy, XRD (X-ray diffraction) analysis, SEM/EDX (Scanning Electron Microscopy with Energy Dispersive X-ray Spectroscopy, and TGA-MS (Thermo-Gravimetric Analysis with Mass Spectrometry).

Thus, work has been split into three areas: the characterisation and analysis of the baseline surrogate powders, the production and analysis of thermally infused surrogate powders, and the production and analysis of ion beam irradiated surrogate powders. The characterisation of the baseline powders included thermally annealing the powders at a range of temperatures up to 1100°C to determine the impact temperature has on both the powder and crystalline structure.

Notable findings during the characterisation of the thermally annealed powder indicate that, for all three samples, there is a three-stage water desorption process, with a physisorption and two chemisorption phases, matching that of plutonium[1].

A notable discovery during the helium ion beam irradiation of cerium dioxide samples was the discolouration of the cerium dioxide samples post-irradiation. Literature [2] suggests that oxygen vacancies are being formed, which is supported by Raman Spectra of the irradiated samples. This is notable as simulations [3][4] suggest that oxygen vacancies in a plutonium dioxide lattice are an energetically favourable location for helium ions to occupy.

Experiments in progress include; the characterisation of thermally infused samples, helium desorption experiments for both infused and irradiated samples, and further water desorption experiments.

Effective Buffers to Measure Elemental Release from Low Activity Waste Type Glasses as a Function of pH

Lucy Mottram[1], Rachel Crawford[1], Ramya Ravikumar[1], Clare L. Thorpe[1], Claire L. Corkhill[2], James Neeway[3], *Carolyn Pearce[3], Albert A. Kruger[4], David Kosson[5], Jose Marcial[3] and Russell J. Hand[1]; [1]The University of Sheffield, United Kingdom; [2]University of Bristol, United Kingdom; [3]Pacific Northwest National Laboratory, United States; [4]U.S. Department of Energy, United States; [5]Vanderbilt University, United States*

Project GLAD (Glass Leaching Assessment for Disposability) investigates the US Environmental Protection Agency (EPA) 1313 Standard Method for assessing the durability of Low Activity Waste (LAW) glasses destined for disposal at the Integrated Disposal Facility (IDF). The EPA 1313 test measures elemental release as a function of pH over a pH range relevant to subsurface conditions in the IDF expected to be circumneutral to mildly alkaline. To fix the pH, and counteract the rapid increase in pH observed when LAW glass is initially exposed to water, the EPA 1313 test can be performed in buffered solution providing the buffer does not affect the glass dissolution rate. Alkali-metal-free buffers are desirable as the presence of alkali metals in solution can lead to ion exchange reactions with the glass surface. Two alkali-free buffers, TRIS ($NH_2C(CH_2OH)_3$) and ammonium chloride – ammonia (NH_3/NH_4Cl), were investigated to perform the EPA 1313 test in the alkaline regime (pH 8.5 – 10.5) at varying temperatures (RT, 40 °C, and 60 °C). Both buffers were shown to effectively maintain the desired pH at room temperature, and up to 40 °C, but the effectiveness of TRIS decreased at 60°C. Previous studies have shown the presence of a TRIS-boron complex and raised concerns that it could lead to increased boron release. Here, although ^{11}B NMR showed evidence of TRIS-B complexation, its effect on the rate of elemental release was found to be negligible under the test conditions. On the other hand, the ammonium buffered systems showed increased release of cations indicating that NH_4^+ may participate in ion exchange.
The TRIS buffer was therefore selected for further work and the EPA 1313 test was conducted on a set of LAW glasses for comparison to parallel tests using only acid addition to control the pH. The test response as a function of time (typical EPA 1313 tests are conducted over 48 hours) to ascertain how a range of glass compositions behave between 1- 8 days.

5:00 PM EN12.02.09
Effects of Containment Materials on the Dissolution Behaviour of Vitrified Wasteforms *Rachel Crawford[1], Lucy Mottram[1], Claire L. Corkhill[2], Carolyn Pearce[3], James Neeway[3], Jose Marcial[3], David Kosson[4], Albert A. Kruger[5], Russell J. Hand[1] and Clare L. Thorpe[1]; [1]The University of Sheffield, United Kingdom; [2]University of Bristol, United Kingdom; [3]Pacific Northwest National Laboratory, United States; [4]Vanderbilt University, United States; [5]U.S. Department of Energy—Office of Science, United States*

Vitrification is used in many countries to immobilise high activity waste liquors and is increasingly considered for low and intermediate activity waste streams. Radioactive elements are chemically incorporated in the glass structure and, therefore, will be released as the glass dissolves. As such, investigating the impact of the localised environment on durability and long-term behaviour is vital to the development of the safety case for disposal. Many studies conducted focus on the effects of environmental factors (e.g., pH, temperature and groundwater chemistry), however, within the disposal environment, a series of natural and engineered barriers will also be in place to isolate wasteforms from groundwater. These barriers will influence groundwater compositions prior to contact with wasteforms.

Iron is known to influence the rate of dissolution of silicate glasses [1]–[3]. The impact of steel corrosion in close contact to nuclear waste glasses has been shown to influence glass corrosion and must be considered in the safety case although the type and steel to be used is specific to a nations disposal policy. United Kingdom (UK) High-Level Waste (HLW) is to be disposed of in canisters comprised of 309 stainless steel, with potential overpack material of S355 steel. Intermediate-Level Waste (ILW) within the UK is to be disposed of within 304L stainless steel, which is also under consideration for the containment of ILW. At the US Hanford site, mild steel grades are also under consideration for wastes disposed of at the Integrated Disposal Facility (IDF).

Here preliminary studies have been performed on the influence of canister and overpack materials using conditions relevant to the safety case for the disposal of HLW in the UK, using MW25, 309 stainless steel and a saline groundwater currently under investigation. Alongside this data, long term tests set up, through the GLAD (Glass Leaching Assessment for Disposability) project, will explore the influence of steel corrosion on the dissolution rates of Low-Activity Waste glasses destined for disposal at the IDF. Container materials and simulant wasteforms are corroded with an average gap of 200 um between materials to determine the localised effect of steel on glass alteration, in repository relevant conditions.

Understanding Ruthenium Volitility in Nuclear Fuel Recycling *Bibi Shehrbano[1], Colin Boxall[1], Richard Wilbraham[1] and Joshua Turner[2]; [1]Lancaster University, United Kingdom; [2]National Nuclear Laboratory, United Kingdom*

Until the closure of reprocessing two years ago, spent nuclear fuel management at the UK's Sellafield plant involved spent fuel reprocessing by the PUREX (Plutonium Uranium Redox Extraction) process. This produced a Highly Active (HA) aqueous waste predominantly comprised of the fission products and activation products formed in spent fuel, a significant fraction of which are platinum group metals (PGMs) such as palladium, rhodium, and ruthenium. Using evaporators, this HA raffinate is concentrated into storage tanks in the Highly Active Liquor Evaporation and Storage (HALES) facility. From there, it is fed to the Waste Vitrification Plant (WVP) where the resultant Highly Active Liquor (HAL) feed is calcined and combined with glass to produce an immobilised HA waste form.

Amongst the PGMs in the HA raffinate, Ru has two relatively long-lived isotopes: Ru-103 and Ru-106, with half-lives of 39.8 days and one year, respectively. While the volatilisation of fission products in nuclear waste typically occurs at high temperatures, Ru is an exception, as its volatilisation can occur at lower temperatures, including during the early stages of the three-stage vitrification process. These stages are:

The HAL is evaporated to dryness - completed at 150°C.

The solid residues are calcined (inc. denitration to oxides) at 500-600°C.
The calcined oxides are fused into a glass melt, at 1000-1100°C.

Due to its volatility and high specific radioactivity, Ru presents significant challenges in waste management. Indeed, vitrification at Sellafield has been scrutinised following the accidental release of 3.1 GBq of volatile Ru-106 (specific activity = 1.239 x 10^{14} Bq/g) from the Waste Vitrification Plant (WVP) in 1997. To prevent future incidents, understanding the complex solution and thermal chemistry of Ru is crucial. It is widely accepted that the volatilisation of Ru occurs due to a redox state change from Ru(III) to Ru(VIII), forming RuO_4. However, the effects of different atmospheric conditions and intermediate chemical steps in this process are not well understood.

One possible route for this volatilisation involves the conversion of soluble Ru(III) in the nitric acid based HA raffinate to particulate RuO_2 during stage one of the drying/calcination/vitrification process described above. This is followed by atmospheric oxygen-driven oxidation of the solid RuO_2 to volatile RuO_4 at the same temperature or slightly higher. The work described here focuses on this latter process of the volatilisation of RuO_2.

The work described here is focused on the oxidation of solid RuO_2 to RuO_4. In this, RuO_2 volatilisation has been studied as a function of temperature using ThermoGravimetric Analysis (TGA) employing a range of temperature vs time profiles under both nitrogen and oxygen atmospheres. Using commercially available RuO_2 powders, mass losses due to dehydration are observed during TGA runs up to 1000°C. This has resulted in the development of a 3-cycle pretreatment of the samples during TGA runs so as to dry the material before detailed analysis of volatilisation at a range of hold temperatures. When held at 1000°C in nitrogen atmospheres, the amorphous as-received RuO_2 simply recrystalises into larger RuO_2 crystals with a well-defined rutile structure. However, when held at 1000°C for 1650 min in an oxygen atmosphere, total mass loss is observed, with all the RuO_2 sample being volatilised. At 950°C for 1650 min in an oxygen atmosphere, slow mass loss is observed, with half of the RuO_2 sample being volatilised. These mass loss studies have been carried out at range of temperatures, including, 400°C, 600°C, 760°C, 860°C and 950°C. During these experiments, mass loss, and thus volatilisation, is observed at all temperatures including as low as 400°C. Experimental data shows that rate of mass loss increases with temperature, which allows Arrhenius parameters to be calculated and these results to be reported at the conference.

The Design Pathway for Developing Iodine Sorbents—Metal-Functionalized Silica Aerogels *Josef Matyas, Brian Riley and Joshua Silverstein; Pacific Northwest National Laboratory, United States*

The effective capture and immobilization of iodine, particularly the radioactive isotope iodine-129 (I-129) with a half-life of 15.7 million years, is a significant challenge in nuclear waste management due to its high volatility and mobility in the environment. Solid sorbents are preferred for this purpose due to their high efficiency, stability, and ease of handling. However, a systematic design pathway is essential to enhance their effectiveness. This pathway ensures that all critical factors are considered, from material selection to practical application and long-term stability. For example, the choice of support affects the overall sorption performance, and its functionalization increases the loading capacity and selectivity of the sorbent toward specific elements of interest and improves uptake kinetics. The support has to be chemically stable and compatible with targeted environments and process conditions, and it has to provide a high surface area with a high density of sorption sites. The pore structure plays a crucial role as well, because pores of different sizes and structures affect the sorption kinetics and capacity. Another factor is mechanical and chemical stability under radiation and in complex off-gas streams. The support can also contribute to the increased selectivity of the sorbent for iodine over other species present in the gas streams. Lastly, practical considerations such as the cost and availability of the support impact its suitability for *large-scale applications. An intriguing option is to develop sorbents with a hierarchical structure or architecture at multiple length scales. They would consist of multiple levels of porosity and different metal chemistry than silver, e.g., Cu and Bi, and allow for increased surface area, improved mass transfer, and enhanced selectivity. This combination of pore sizes and chemical functionality would enable effective capture of iodine from complex off-gas streams. The presentation will discuss the design pathways, synthesis, and sorption performance of metal-functionalized silica aerogels and different strategies to sequester iodine. This will include results from durability tests.*

Iron Sulfide Particles for Capturing Radionuclides *Nabil Ashraf Shuvo and John S. McCloy; Washington State University, United States*

There is an urgent need to remediate volatile radioactive contaminants like ^{129}I at nuclear cleanup locations such as Hanford. These elements are found in radioactive tank waste and may be found in the soil and groundwater. Along with established techniques, new separation techniques could improve the way purpose-designed waste forms containing these components are separated and stored. Most disposal plans explored for ^{129}I containing low-activity waste involve storage in underground repositories after processing. In these settings, iodine's high mobility and radiotoxicity necessitate careful management to mitigate long-term environmental impacts. Additionally, methods used to capture iodine during reprocessing are not suitable for direct disposal, requiring conversion into suitable waste forms. These waste forms aim to chemically immobilize or physically encapsulate iodine to minimize the leaching of iodine by groundwater. This study presents the synthesis and sorbing action of iron sulfide particles with forms of iodine in an aqueous environment. Iron-based magnetic nanoparticles can sorb iodine and metals from contaminated water sources, and their magnetic properties allow novel separation operations of target contaminants (e.g., I, Tc, Hg). This discussion will examine the potential of iron sulfide particles as a sorbent for capturing pollutants, such as ^{129}I, and investigate the efficiency of the methods to assess the feasibility of adding magnetic separation techniques into aqueous waste processing flowsheets. The used sorbents can in principle be stripped and reused or collected for a purpose-designed waste form.

9:30 AM EN12.03.04

Mechanisms of Capture of Radioactive Cs^+ by Zeolite Analcime by Density Functional Theory *Jinyi Liu; University of Florida, United States*

Zeolites, naturally porous materials, possesses unique adsorption and ion exchange characteristics, making them highly promising for the treatment of effluents containing nuclear fission products, specifically radioactive Cs^+. Among them, zeolite analcime, a naturally abundant mineral, stands out as a possible candidate for Cs^+ entrapment. However, due to the complexity of the ANA framework that analcime belongs to, the Cs^+ site and diffusion mechanism is still not well understood. In this work, density functional theory (DFT) calculations are employed to characterize the transport mechanisms of Cs^+ throughout analcime structure. Two diffusion pathways, the 6-member-ring and 8-member-ring, are identified, and the energy barriers for each pathway are calculated using the nudged-elastic band (NEB) method. The calculation shows that the 8-member-ring pathway is more energetically favorable than the 6-member-ring. Additionally, the transport mechanisms of smaller Na^+ ions are determined. The combined transport mechanisms of Cs^+ and Na^+ provide a deeper atomic-level understanding of analcime's Cs^+ adsorption capabilities.

This work was supported by the Center for Hierarchical Waste Form Materials (CHWM), an Energy Frontier Research Center (EFRC) funded by the United States Department of Energy Office of Basic Energy Sciences through Award DESC0016574.

Current Understanding and Modeling of The Aging of Cementitious Waste Forms—A Hanford Site Perspective *Matthew Asmussen; Pacific Northwest National Laboratory, United States*

Cementitious waste forms, or waste forms produced in ambient conditions (termed grout in the U.S.) play a crucial role in nuclear waste management strategies. These waste forms allow for incorporation of a number of different waste types (e.g., solids, liquids), overcome volatility challenges, provide low-cost production methods and allow the tailoring of final waste form properties through formulation design. With the hydration or polymeric reactions that make up this class of waste forms the matrix continues to age and evolve with time. Depending on the disposal site location for a cementitious waste form, being able to track and predict these evolutions is crucial to evaluating the waste form performance within the disposal facility in a performance assessment. A wide range of mechanisms and processes are possible for cementitious waste forms and the dominant and passive ones change with the disposal environment As such, site- and material-specific R&D is required to provide a technical underpinning to support long-term disposal modeling. This presentation will cover recent efforts at the U.S. Department of Energy Hanford site to further both the understanding of key mechanisms and processes to cementitious waste form aging at the site (e.g., oxidation, carbonation, Ca leaching) and approaches to capture these processes in long-term models. Several multi-institute reviews in the U.S. have highlighted a need to update and harmonize the modeling approach for grout materials at the Hanford Site to account for time-dependent processes (e.g., carbonation) that control bulk mechanisms (e.g., cracking). This presentation will also cover an overview of a U.S. Department of Energy Office of Environmental Management project using a multi-organization expert team to produce conceptual models for grout aging at Hanford that can be applied in PAs using a Hanford Grout Modeling Framework.

10:45 AM *EN12.04.02

Microbes, Minerals and Material Heterogeneity—The Limitations of Laboratory Glass Dissolution Tests *Clare L. Thorpe[1], Garry Manifold[1], Daniel Parkes[1], Rachel Crawford[1], Jenny Ayling[1], Claire L. Corkhill[2] and Russell J. Hand[1]; [1]The University of Sheffield, United Kingdom; [2]University of Bristol, United Kingdom*

Glass dissolution mechanisms have been well described as far as they relate to nuclear waste type silicate or borosilicate glass exposed to simple solutions. Successive stages of glass alteration are understood to progress from initial ion exchange, inter-diffusion and network hydrolysis, to the formation of secondary alteration phases leading to a rate drop and either a long-term reduction in glass alteration or eventual rate resumption. However, with countries now engaged in site selection for near surface or deep geological disposal facilities for vitrified waste, there is increased interest in understanding glass alteration in more complex systems. This talk will focus on the extent to which complex environments can be replicated in laboratory experiments and the limitations of standardised dissolution tests.

Recent studies of glass alteration in dynamic, open, natural environments highlight the role that external elements, sourced from groundwater and surrounding mineralogy, play in secondary phase formation. In particular, multiple studies show that externally sourced elements are sequestered into alteration layers as they form and have significant effect on alteration layer chemistry. Glasses exposed to aqueous environments for between 20 and 220 years offer insight into the processes by which alteration layers grow and evolve over time, the phenomenon of chemically distinct lamellae/banding and vermiform features. Similarly, studies performed in more complex systems provide evidenced that microorganisms can affect glass alteration indirectly by controlling the local chemical environment, particularly the speciation of Fe and the availability of P. Finally, where glasses produced under laboratory conditions are usually relatively homogeneous whereas those produced at scale may contain crystalline phases associated with cooling, phase separation, or incomplete vitrification. Recent work has shed light on how mineral phases that are either more or less durable than the bulk glass matrix can affect the measured test response in closed system laboratory tests and how these challenges can be overcome.

11:15 AM EN12.04.03

An Exploration of the Contamination of AISI 304L Stainless Steel when Corroded in Nitric Acid Based Spent Nuclear Fuel Reprocessing Dissolver Simulant *Hannah C. Lane[1,2], Anne Callow[2], Thomas Carey[2], Christina Hofer[3] and Colin Boxall[1]; [1]Lancaster University, United Kingdom; [2]National Nuclear Laboratory, United Kingdom; [3]University of Oxford, United Kingdom*

Nuclear fuel reprocessing plants require effective decommissioning technologies in order to reduce the hazardous inventory prior to dismantling and minimise the waste volume generated at the end of facility life. As fuel is dissolved in nitric acid during the reprocessing process, corrosion of the dissolver, which is primarily made from AISI 304L and Nitric Acid Grade (NAG) 18/10L [1], occurs. During this corrosion of stainless steel that makes up components of nuclear reprocessing facilities, radioisotopes originating in the dissolved spent fuels become entrenched within the protective Cr-rich oxide that forms on the surface of the steel. This contamination poses a significant hazard during decommissioning due to the high radiation levels and limited accessibility of some components. An effective decontamination strategy would mean safer decommissioning, significant financial savings per cubic meter of waste, and could allow for recycling and reuse of some components [2] which will mean lower waste volumes will require permanent disposal.

To create an effective decommissioning strategy, an accurate picture of both the chemical and radiological contamination of the stainless-steel vessel and pipework must be known. Access is limited by the high radiation field inside process cells and vessels [3], meaning the condition of inner surfaces is not directly known. This has created a need to simulate environments by deliberately contaminating stainless steels under conditions as similar as possible to those found on plant so the resulting surfaces can be characterised. In this series of work, this simulated contamination has been achieved through two methods – boiling and electrochemistry. The boiling tests involved both submerging and suspended AISI 304L coupons above 105 °C 3 M nitric-acid based dissolver simulant for 10 to 110 days, whereas the electrochemical test involved using an AISI 304L coupon as the working electrode in a 3-electrode cell and holding the system at 80 °C and an elevated potential for ≈2.5 days. Simulant reprocessing liquor was supplied by the UK National Nuclear Laboratory. The coupons generated during this work were first analysed using Scanning Electron Microscopy and Raman spectroscopy in Lancaster University's UTGARD laboratory. Following this, they were taken to the Materials Research Facility (MRF) in Culham to use the Focussed Ion Beam (FIB) to make atom probe specimens which were analysed at the University of Oxford using their Nuclear Materials Atom Probe (NuMAP) facility.

From the six samples taken to the MRF, 24 usable atom probe tomography tips were generated, of which 19 successfully generated data. Analysis of all 19 data sets is still ongoing, however preliminary analysis shows the presence of heavy metal contamination within the oxide layer of the coupons submerged during the boiling tests, *including V, Mo, Rb, Cs, Gd, Ce, Tc, and Nd. These contaminants all appear to be engrained within the oxide layers, and do not penetrate past the native nickel enriched region close to the metal-oxide interface. These results are significant, in particular the presence of V and Ce which are common surrogates for the highly radioactive Np and Pu respectively. The entrenchment of these radioactive contaminants could be responsible for the high contamination levels of the facility, despite previous attempts at decontamination.*

A Thermodynamic Analysis on the Swelling Stress of Ca-Bentonite Under Various Solution Conditions
Kosuke Ichikawa and Haruo Sato; Okayama University, Japan

Buffer material, one of the engineered barrier elements in the geological disposal of a high-level radioactive waste, develops swelling stress due to groundwater penetration from the surrounding rock mass. The swelling stress of bentonite is strongly dependent on water chemistry such as saline water. The authors have developed a thermodynamic model for calculating the swelling stress of bentonite, based on the thermodynamic data of interlayer water in Na-montmorillonite and Ca-montmorillonite obtained in earlier studies. In previous studies, the swelling stress of Ca-bentonite was calculated as a function of montmorillonite partial density in the distilled water condition, based on the thermodynamic data of interlayer water of Ca-montmorillonite. In this study, the swelling stress (pressure) of water-saturated Ca-bentonite was calculated for various montmorillonite partial densities and solution conditions for sodium chloride concentration, and compared with the measured data. Swelling stress versus montmorillonite partial density was estimated for solutions containing sodium chloride ([NaCl] = 0-6 m, m: molality) and compared to data measured for bentonites with various montmorillonite contents and silica sand contents. The calculated swelling stresses generally decreased with increasing [NaCl] for the same montmorillonite partial density. The trend of the calculated swelling stress versus [NaCl] was quantitatively in a good agreement within the scattering of the measured data.

Measurements of Thermodynamic Data of Interlayer Water in Na-Bentonite by Relative Humidity Method
Haruo Sato; , Japan

Buffer material (compacted bentonite) composing engineered barrier in the geological disposal of a high-level radioactive waste develops swelling stress by penetration of groundwater from the surrounding rock mass after the closure of the disposal tunnels. In the past studies, we measured the activity and the relative partial molar Gibbs free energy of interlayer water in Na-montmorillonite which is the major component of Na-bentonite used as a buffer material by vapor pressure method, and proposed a thermodynamic model to analyze the swelling stress of bentonite based on thermodynamic theory. However, the thermodynamic data of interlayer water in bentonite are quite limited. In this study, we determined the thermodynamic data of interlayer water (activity and relative partial molar Gibbs free energy) by measuring relative humidity (RH) and temperature for water in Na-bentonite and Na-montmorillonite. We also analyzed the swelling stress of Na-bentonite based on the thermodynamic model and the thermodynamic data of interlayer water, and compared to the measured data.
The Kunigel-V1® and Kunipia-F® bentonites (provided from Kunimine Industries Co. Ltd.) were used as a Na-

bentonite. The Na-montmorillonite contents of both bentonites are approximately 51% and 99%, respectively. Bentonite powder which was dried at 105 °C over 24 hours was placed in a polyethylene bottle in an amount of 3.00g each (repeatability n=3), and slowly adsorbed water vapor with 100 % in RH and -99 kPa or less in a vacuum chamber (polycarbonate desiccator) for about 9 months. Next, RH and temperature sensors and polyethylene bottles with moisturized bentonite powder were placed in the vacuum chamber, and the chamber of which inside pressure was reduced to -95 kPa (6.3 kPa with absolute pressure) or less was submerged in a water bath at 25°C. The RH and temperature in the chamber were measured after 24 hours and the weight of the bentonite was measured. This operation was repeated every about 24 hours. Thus, RH and temperature in the chamber were measured as a function of water content (ca. 10-100 %).

The activities and the relative partial molar Gibbs free energies of interlayer water in both bentonites decreased with decreasing water content in water contents lower than approximately 40 %. This trend is the same as in the past studies. The swelling stresses of Na-bentonite calculated using the thermodynamic data of interlayer water obtained in this study were generally in good agreement with the measured data of swelling stress over the montmorillonite partial density.

SESSION EN12.05: Experimental Tools

Fluorine K-Edge X-Ray Absorption Spectroscopy for Glasses, Minerals and Salts *John S. McCloy, Malin C. Dixon Wilkins and John Bussey; Washington State University, United States*

Very little data exists in the literature for absorption spectra at some low-energy X-ray edges, particularly the fluorine K-edge (~690 eV). Though it is not possible to obtain extended X-ray absorption fine structure (EXAFS), considerable information is contained in the X-ray absorption near edge structure (XANES). Over 100 materials were measured at the Canadian Light Source Spherical Grating Monochromator beamline at the F K-edge at room temperature. This presentation describes the lessons-learned for obtaining high-quality XANES at the fluorine edge using both total electron yield (TEY) and fluorescence modes. A number of materials of interest for nuclear waste management were measured, including F-containing oxide glasses, molten salt relevant pure fluoride glasses and compounds, and F-containing minerals with potential as waste forms. Specifically, findings on more than 40 oxide glasses (silicate, borosilicate, aluminosilicate, phosphate, borate, etc.), >30 metal fluorides binaries and ternaries including rare earth fluorides and oxyfluorides, and >20 F-containing natural minerals are presented. Preliminary insights and trends are offered for binary fluorides, mineral phases and environments, and glasses. Possible future uses of this promising technique are also discussed.

Real-Time Tracking of Oxidation States of Nano Particulate UO_2 Electrode Using HR-XANES at Uranium M_4 Edge and a Microfluidic Technique *Tonya Vitova[1], Jennifer Yao[2], Bianca Schacherl[1], Bruce K. Mcnamara[2], Eugene Ilton[2], Jaeoyoung Heo[2], Christian Vollmer[1], Sven Schenk[1], Shalini Tripathi[2], Harry Ramanantoanina[1] and Edgar Buck[2]; [1]Karlsruhe Institute of Technology, Germany; [2]Pacific Northwest National Laboratory, United States*

Studying redox reactions in actinide chemistry presents a significant challenge, which can be addressed by *designing and utilizing innovative in-situ cells that combine electrochemistry with spectroscopy. This approach is particularly advantageous when advanced high-resolution X-ray emission and absorption spectroscopic techniques, which are highly sensitive to actinide oxidation states and binding environments, are employed.*[1]

We will present the first synchrotron application of such an in-situ cell. The experiments were conducted at the ACT station of the CAT-ACT beamline at the KIT Light Source in Germany. High-resolution X-ray absorption near-edge structure (HR-XANES) spectroscopy at the uranium (U) M_4*-edge was utilized to monitor the oxidation states of a uranium dioxide (*UO_2*) working electrode within a microfluidic electrochemical cell. The study observed that U(IV) oxidized to U(V) and subsequently to U(VI) with increasing redox potentials, and the process reversed back to U(IV) with decreasing redox potentials.*

Coupling a microfluidic electrochemical cell with HR-XANES opens new avenues for investigating the electronic structure of redox-sensitive materials. This methodology requires only micrograms of sample, making it possible to conduct research that would be otherwise inaccessible with highly radioactive bulk materials such as spent nuclear fuel.

Irradiation Effect on Noble Metal Particles in Water Using In Situ Liquid Cell Transmission Electron Microscopy *Jaeyoung Heo, Bruce K. Mcnamara, Dongsheng Li and Edgar Buck; Pacific Northwest National Laboratory, United States*

Noble metal particles (NMP) in spent nuclear fuel (SNF) play a key role as catalysts to suppress the oxidative dissolution of SNF in the presence of hydrogen gas generated from iron corrosion. Therefore, to predict SNF degradation rate which is described in Fuel Matrix Degradation (FMD) model, the stability of NMP in a radiation environment is important. Herein, we analyzed NMP extracted from SNF using transmission electron microscopy (TEM) and found that NMPs became significantly degraded after nearly decade of intact storage. Furthermore, we investigated the stability of NMPs under irradiation environment using in-situ liquid cell TEM experiments. We synthesized Pd NMPs and Pd-Ru NMPs to study the irradiation effect on NMPs in water for in-situ liquid cell TEM experiments. Dissolution of both types of particles in water was observed owing to the formation of radiolytic species in water. In this regard, we confirmed that higher electron dose rate accelerates the dissolution rate. Also, we have checked the irradiation effect on NMPs without water environment. Instead of dissolution, Pd-PdO core-shell structure was formed with higher dose rate in the absence of water in the system. In addition, after the system reaches super-saturation of Pd^{2+} *ions in water due to Pd NMPs dissolution and evaporation of water, Pd dendrite formation was observed by reducing* Pd^{2+} *ions with electron beam. This confirms that Pd NMPs dissolves and* Pd^{2+} *ions still exist in water solution. From these in-situ observations, the stability of NMPs under irradiation environments is a potential concern, which, in turn, may impact the ability of these particles to limit SNF degradation.*

On the Use of Ion Beams to Simulate Alpha-Decay Damage in Crystalline Ceramic Phases *William J. Weber; The University of Tennessee, Knoxville, United States*

The principal source of radiation damage in ceramics for immobilization of actinide-containing nuclear waste is alpha-decay of the actinides, which occurs over geologic timescales due to the long half-lives of the actinides and their daughter products. Alpha-decay produces energetic alpha particles (4.5 to 5.5 MeV) and recoil nuclei (70 to 100 keV) that result in radiation damage and the accumulation of helium. Historically, the evolution of radiation damage due to alpha-decay has been studied using short-lived actinides; however, ion beam irradiations have become nearly the only approach currently employed to study radiation damage in relevant materials due to decreased costs, shorter irradiation timescales and the non-radioactive nature of the irradiated materials. While ion irradiations can be performed over a wide range of irradiation conditions, most studies are performed over a narrow range of irradiation conditions, which can complicate the interpretation and relevance. For example, ion irradiation studies on relevant materials may predict that a phase transformation (e.g., amorphization) occurs, but cannot predict the dose or temperature regime for the phase transformation under alpha-decay damage rates in a repository. In general, all ion irradiation experiments are conducted at relatively high dose rates compared to alpha-decay damage rates. Many experiments, such as in situ irradiation in an electron microscope or swift heavy ion irradiations, do not provide data suitable for predictive modeling, such as the dose, appropriate kinetics, and swelling associated with such phase transformations. Too often the dose and kinetics for phase transformation are dominated by processes related to the mass and energy of the ions used for irradiation (e.g., ratio of electronic to nuclear energy loss); in actuality, it is thermally dominated processes that will control the dose and kinetics of phase transformation over the timescales of radiation damage in actual waste forms. Fortunately, several collaborative studies over the years employing MeV heavy-ion irradiations have provided experimental data on a few relevant materials (pyrochlore, zirconolite, and silicate apatite) that are in good agreement with results from identical samples doped with short-lived actinides. Such benchmarking of ion irradiation results against alpha-decay damage results demonstrates that bulk-like irradiation with MeV heavy ions, such as Au, can provide the best approximation to damage accumulation from alpha decay, yielding swelling and phase transformation behavior that agree well with results from alpha-decay damage. However, radiation damage kinetics must be considered when predicting behavior for materials with low defect recovery and recrystallization temperatures, as in monazite and fluoroapatite, which amorphize under MeV heavy ion and swift heavy ion irradiations, but not from alpha-decay damage.

Modeling Feed-to-Glass Conversion in Electric Waste Vitrification Melters *Pavel Ferkl[1], Pavel Hrma[2], Victor C. Leite[3], Donna P. Guillen[3], Mark Hall[1], Albert A. Kruger[4] and Richard Pokorný[5]; [1]Pacific Northwest National Laboratory, United States; [2]AttainX, United States; [3]Idaho National Laboratory, United States; [4]U.S. Department of*

Energy, United States; [5]University of Chemistry and Technology, Prague, Czechia

This study focuses on modeling the feed-to-glass conversion process in waste vitrification melters, specifically those used for the vitrification of legacy nuclear waste at the Hanford site. It explores modeling approaches and feed characterization methods developed for understanding feed-to-glass conversion and predicting glass production rate in electric melters.
The conversion process involves mixing nuclear waste with glass-forming and modifying additives, which are introduced into the melter as a feed. This feed forms a reacting material layer, known as the cold cap, that floats on the molten glass surface. The endothermic conversion processes within the cold cap, including water evaporation, conversion reactions, and sensible heating, consume thermal energy primarily supplied by the molten glass below. Thus, efficient heat transfer from the glass melt to the cold cap is crucial for optimizing the glass production rate.
Using the developed models, we evaluate various strategies to enhance the melting rate such as increasing bubbling rates to boost melt convection, adjusting glass formulations to lower viscosity or increase thermal conductivity, and optimizing melter feed to prevent stable high-temperature foam formation in laboratory-scale, pilot-scale, and full-scale melters.

Experimental Determination of Gibbsite Solubility in Concentrated Mixtures of NaOH + $NaNO_3$ and NaOH + $NaNO_2$ at Elevated Temperatures—Applications to Hanford Tank Waste

Yongliang Xiong[1], Vanessa Mercado[1], Jessica Kruichak[1], Guangping Xu[1], Yifeng Wang[1], Phillipe Weck[1] and Scott Wood[2]; [1]Sandia National Laboratories, United States; [2]Geochemagine LLC, United States

At the Hanford Site, there are approximately 56 million gallons (MGal) of hazardous radioactive waste (Page et al., 2018). Of the total 56 MGal waste, about 21 MGal are liquid supernatant, along with approximately 23 MGal being soluble saltcake, and approximately 12 MGal are insoluble sludge (Colburn and Peterson, 2020). Aluminum (Al) is the second most prevalent component in the sludge phase, after sodium (Na) (Colburn and Peterson, 2020; Westesen and Peterson, 2022; Westesen et al., 2023). The Hanford supernatants are characterized with high pH, high concentrations of sodium, nitrate, nitrite, and aluminate [$Al(OH)_4^-$]. Therefore, a fundamental understanding of aluminum chemistry under the conditions relevant to Hanford Tank Waste provides the key knowledge basis for development of a scientifically sound and effective pretreatment approach. Such an approach will be advantageous both for aluminum dissolution and removal from HLW sludge, and for prevention of precipitation of aluminum phase(s) from supernatants.

In this work, we report our experimental results regarding the solubility of gibbsite in mixtures of NaOH + $NaNO_3$ and NaOH + $NaNO_2$ at elevated temperatures starting from 60°C. In our experiments, equilibrium is primarily approached from the direction of undersaturation. NaOH concentrations range from 1.0 mol:kg^{-1} to 3.0 mol:kg^{-1} in the mixtures. The concentrations of both $NaNO_3$ and $NaNO_2$ are in a range from 1.0 mol:kg^{-1} to 5.0 mol:kg^{-1} in the mixtures. In the supernatant liquid from Tank 241-AN-105, the nitrate and nitrite concentrations are 4.08 and 4.58 mol:kg^{-1} (McCoskey et al., 2015), respectively. Therefore, the nitrate and nitrite concentrations in our experimental matrices cover their respetive concentrations present in the supernatant liquid. Based on our previously evaluated Pitzer parameters for Na^+—$Al(OH)_4^-$ (Xiong, 2014), our current experimental data will be used to calculate the Pitzer interaction parameters for NO_3^-—$Al(OH)_4^-$ and NO_2^-—$Al(OH)_4^-$.

Structural Role of U and Th in Different Glass-Forming Systems *John Bussey, Malin C. Dixon Wilkins, Gavin McCloy and John S. McCloy; Washington State University, United States*

Vitrification is a critical technology for long-term immobilization of nuclear waste. While most U from used nuclear fuel is not planned for immobilization in glass, there are certain situations where U and/or Th-rich waste streams may be vitrified. One example is the 56 million gallons of nuclear waste at the Hanford Site in Washington State, where some actinides remain in certain tanks. When planning for vitrification efforts, understanding the structural impact of different waste constituents is essential for efficient and successful deployment. This review explores existing literature on U and Th incorporation into silicate, aluminosilicate, borosilicate, and phosphate glasses. Additionally, novel insights into less-studied glass systems (for example, titanate, aluminate, borate, and sulfate) as well as waste relevant complex systems are discussed based on structural characterization techniques including Raman spectroscopy. In addition, the potential of complementary X-ray absorption spectroscopy and X-ray total scattering measurements for probing U/Th incorporation are introduced. Crystalline products resulting from devitrification processes are probed with X-ray diffraction. These findings not only advance the fundamental understanding of U and Th incorporation into non-crystalline matrices but also provide guidance for future vitrification endeavors.

4:00 PM *EN12.06.04
Machine Learning the Chemistry, Structure and Properties of Molten Salt Across the Fuel Cycle *Stephen Lam; University of Massachusetts Lowell, United States*

A central challenge to deploying molten salt nuclear technologies lies in our ability to accurately characterize, predict, and monitor the chemistry of molten salts throughout the fuel cycle. In synthesis, dissolved species can *exist in multiple oxidation states, whose ratio must be adjusted to control purification processes, volatilization and corrosivity. Similarly, during operation, the fuel salt composition evolves continuously with generation of numerous fission products, which produces significant changes in the thermophysical and thermochemical properties of the melt. Finally, in back-end fuel recycling processes, lanthanides and impurities must be separated from the salt while retaining fissionable actinides. Each of these steps requires the study of an enormous array of evolving chemical and thermodynamic conditions in the solution phase. Here, current experimental and computational approaches are not sufficiently accurate and expeditious for assessing the large design spaces demanded across the fuel cycle. As such, it is unlikely that we will achieve the robust chemical understanding required for commercial deployment and regulatory approval under conventional research paradigms employed in the study of molten salts. This talk will discuss our latest advances in applying artificial intelligence to overcome these challenges for studying the chemistry-structure-property relationships in molten salt, which include 1) machine learning-assisted atomistic simulation for speed and accuracy, 2) chemistry-informed machine learning for interpolating thermophysical and thermochemical properties across the periodic table, and 3) machine learning-enhanced characterization and online monitoring with spectroscopic methods. We will show how state-of-the-art methods have been applied for uncovering structure-property of molten salts with unprecedented speed and resolution and discuss future opportunities for improvement in each of these areas.*

4:30 PM *EN12.06.05
Utilizing Ab Initio Molecular Dynamics to Determine Thermophysical Properties of Molten Salts *Benjamin Beeler[1,2], David Andersson[3] and Kai Duemmler[3]; [1]North Carolina State University, United States; [2]Idaho National Laboratory, United States; [3]Los Alamos National Laboratory, United States*

Molten salts are critical to advanced nuclear systems, playing a role as the fuel, coolant, and recycling medium. However, a significant knowledge gap exists for the fundamental properties of nuclear-relevant salts that must be narrowed in order to expedite the technical readiness level of advanced nuclear reactor concepts. Experimental efforts on molten salts are often expensive and difficult, due to the high temperatures required, as well as the volatility, corrosivity, toxicity, and radioactivity of some salts. With the rapid development and improvement of computational materials science, computational methods such as Density Functional Theory (DFT) calculations and ab initio Molecular Dynamics (AIMD) simulations are widely used as an effective and reliable tool to investigate the atomic interaction in materials. This work will outline recent efforts at predicting the thermophysical properties of molten salts, including the least-explored group of salts: actinide-halides. Where possible, comparison and validation with experiments are shown, and the power of computational materials science in exploring a wide swath of compositions and temperatures is demonstrated. The fundamental questions of DFT-based explorations of molten salts, such as how to describe dispersion forces, will be discussed, providing guidance on implementation. Finally, the next steps for AIMD in the world of molten salt properties will be discussed.

EN12.07.01
Surface Sites Characterization of UO_2—A Comparison Between Caesium Sorption and Potentiometric

Titration *Nieves Rodríguez-Villagra[1], Úrsula Alonso[1], Sofía Durán[1], Lorena Serrano[1], Joaquín Cobos[2] and Hitos Galán[1]; [1]Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas, Spain; [2]Estación Biológica de Doñana, Spain*

The back-end of the nuclear fuel cycle includes, at least, 1) on-site pool storage, 2) either on-site or off-site dry or wet interim storage, and 3) long-term waste disposal. The purpose is that both the temperature and radioactivity of radioactive wastes gradually decrease, while containing and isolating from human's environment, and for future generations, until their radiotoxicity has decayed to non-hazardous levels for hundreds of thousands to millions of years. To demonstrate the safety of disposal in a deep underground repository, the selected location should be justified through the use of predictive modeling calculations and experimental evidences, to confirm that the potential release rate of radionuclides will be slower than their rate of radioactive decay. An important component of a safety case is the long-term predictive modeling of Spent Nuclear Fuel (SNF) based on theoretical and semiempirical models, and based on dissolution rate data as function of environmental variables [1]. Alteration rates for reactions between groundwater and the solid surface of SNF (mainly UO_2 or pre-oxidized layer) are typically based on the surface area of the solid material, in most cases determined by the BET isotherm, and/or based on site density. The specific surface area, the density of reactive surface sites (NS) or sorption sites and other geometric parameters are directly involved in the dissolution of the SNF [2] and are a key input parameters that are still not well defined by means of systematic studies. Most models neglect the solubility of the non-oxidized matrix while reducing conditions are expected. The improvement of these input data and methods for determining sorption and site densities would significantly enhance the knowledge for predictive models by providing the reactive surface area of solids.

In this work, we have experimentally studied the characteristics of UO_2(c) surface sites by two approaches: potentiometric titration and ^{137}Cs sorption isotherm, varying Cs concentration. The sorption of Cs^+ ions from aqueous solutions at 0.1 M ionic strength by powdered UO_2(c) surface, as the main component of the SNF, was evaluated in order to simulate the removal of radioactive Cs released from irradiated fuel. It is known that the fission product caesium is representative element of the instant release fraction.

The maximum sorption capacity of Cs^+ onto the UO_2 surface (particle size: 20-32 µm, BET surface area: $0.357 \pm 0.007\ m^2 \bullet g^{-1}$) obtained from the sorption isotherm (0.1 mol L^{-1} $NaClO_4$ at 25°C and pH=6.3) was $6.3 \bullet 10^{-5}$ mol$\bullet g^{-1}$, value that can be considered as an estimate of UO_2(c) surface site density. The surface acidity constants and site density were also determined by potentiometric titrations. Modelling the titrations data collected in 0.1 mol$\bullet L^{-1}$ $NaClO_4$ with the double diffuse layer model, using Chess code [3], led to acidity constants of pKa1= 3.2 and pKa2=-10.8. The experimental solubility of the UO_2 in 0.1 mol$\bullet L^{-1}$ $NaClO_4$ system (m/v ratio of 40g$\bullet dm^{-3}$) at different pHs was previously determined as $pK_{s,0} = -(3.2 \pm 0.2)$, in agreement with UO_2(am, hydr.) [4]. From our experiments, it can be concluded that there is a large effect of dissolution on surface charge determination for $pH<4$ and $pH > 12$.

Gamma Radiation Effect on UO_2—Set-Up Flow-Through Dissolution Experiments *Nieves Rodríguez-Villagra[1], Laura Bonales[1], Sofía Durán[1], Lorena Serrano[1], José Cobo[1], Luis Gutiérrez-Nebot[1], Joaquín Cobos[2] and Hitos Galán[1]; [1]Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas, Spain; [2]Estación Biológica de Doñana, Spain*

In most countries, the long-term disposal of spent nuclear fuel (SNF) into a deep geological repository (DGR) is a radioactive waste management policy. Assuming a container failure, once groundwater contact with SNF, the potential radionuclide release is a key issue to understanding. Solubility and dissolution rate of radionuclides are strongly dependent on UO_2(s) matrix dissolution since upon water exposure. The SNF solubility depends on a variety of factors (intrinsic and extrinsic): redox, pH, temperature, radiolysis, aqueous system composition among others. Equally, the U dissolution behavior is clearly determined by its redox state. In this scenario, oxidized U in aqueous systems will be stabilized as UO_2^{2+} (hexavalent U), as a consequence of tetravalent U oxidation, e.g. oxidizing species as radiolytic H_2O_2. Uranyl cationic species in different speciation forms are expected to be found at a wide pH range. The importance of solubilized UO_2^{2+} lies in its potential incorporation of trace radioelements onto secondary uranyl phases. The influence of radiation emitted by the fuel is an additional parameter that directly affects the dissolution rate of the fuel matrix. When groundwater is subjected to radiolysis by ionizing radiation particles (α-particles, β and γ) from nuclear fuel, generate H_2O_2 and H_2 at much higher rate than that of other radiolysis byproducts [1]. Moreover, the yield of the various radiolytic products varies with the radiation type, its energy, and time [2]. Gamma radiation emitted from the fission and neutron activation products will go across long distances from the fuel surface and even go through the cladding and the inner surface of cask [2]. In young spent fuel, γ radiation plays a significant role in the total dose rate under temporary or final disposal because of short-lived decay products of irradiated SNF.

In order to know the effect of this radiation in the fuel stability at DGR conditions, leaching experiments were performed on UO_2 pellets in the presence of an external gamma irradiation source using well-controlled flow-through dissolution experiments at different low flow velocities under oxidizing conditions. Firstly, in order to verify the set-up (the design of the flow-through reactor) and different flow rates (3.2 ± 0. 2; 30 ± 10 and 90 ± 20 $\mu Lxmin^{-1}$) and residence times of the leachants in the flow cell, single-pass flow-through experiments are performed at room temperature in the absence of a radiation at I = 0.02 M of ionic strength as a function of bicarbonate concentration (0, 0.001M $NaHCO_3$ and 0.019 M $NaHCO_3$). Ionic strength was stablished by using $NaClO_4$ (no bicarbonate) or NaCl (bicarbonate). A good agreement of data and trends (U concentration vs pH, $[HCO_3^-]$, residence time and flow rates) is obtained for the experimental set-up and procedure. The results show the expected impact of carbonates on the dissolution rate of U, i.e. the concentration of dissolved U(VI) increased with increasing $[HCO_3^-]$ at oxic conditions [3]. Then, experiment in presence of intense γ-radiation field (dose rate of 3.9 $mGyxs^{-1}$), equivalent to a cooling time of 30 years for a 40 $MWdxkg^{-1}$ fuel, was carried out in absence of bicarbonates (I = 0.02 M, $NaClO_4$ solution) at 95 ± 20 $\mu Lxmin^{-1}$ flow velocity. It was observed the formation of H_2O_2 in the leachate as well as the formation of a secondary phase identified as metastudtite, on the surface of the UO_2 pellet. This uranyl secondary phase was identified by both, XRD and Raman spectroscopy.

Thermal and Radiation Stability of Am-241 Doped Zironcate Materials—Updates from the RISE-241 ActUsLab

Up-to-date as of November 14, 2024

Joint Research Centre EU Project *Gabriel Murphy[1], Sara Gilson[2], Octavian Valu[3], Olaf Walter[3], Karin Popa[3] and Nina Huittinen[4]; [1]Forschungszentrum Jülich GmbH, Germany; [2]Oak Ridge National Laboratory, United States; [3]European Commission Joint Research Centre, Germany; [4]Helmholtz-Zentrum Dresden-Rossendorf, Germany*

The thermal and radiation stability of Zircaloy cladding material that houses spent nuclear fuel (SNF) is an important factor when considering the storage and eventual disposal of SNF in a geological repository. It is known that on the surface of the cladding, oxidised zirconia (ZrO_2) phases are inherently present. Following fuel swelling and rim contact, the zirconia layer on the interior surface can interact with SNF elements, leading to the formation of phases such as pyrochlore and zirconates among others. These phases act as the first intermediate barrier between SNF and the metallic cladding and consequently are important to consider in safety design, particularly for release of radionuclides (RNs). A pertinent RN that contributes significantly to the radiological hazard of SNF, is the isotope Am-241. The chemistry of Am is largely unique, being able to readily dissociate between its tetravalent and trivalent states in oxides, making it difficult to investigate via surrogate studies. Furthermore, Am-241 has a relatively short $t_{1/2}$ of 432 years and decays via alpha emission (5.486 MeV), resulting in significant ensuing radiation damage in host materials. Consequentially, understanding the thermal and radiation stability of host material phases incorporating Am-241 is pertinent for safe disposal of SNF. As a part of the national project “AcE” funded by the German Federal Ministry of Education and Research (BMBF) and through the European Commission ActUsLab program, we have investigated several zirconium oxide polymorphs, including but not limited to Nd-pyrochlore and zirconia, doped with 5 mol% Am-241. The particular focus of the investigation is to understand the thermal and radiation stability of the different oxide polymorphs when Am-241 is incorporated. This presentation will highlight some on-going results from this research program including high-temperature phase transformations, radiation induced lattice swelling, phase separation, and associated apparent redox activity induced by the presence of Am-241. The experimental data used in this research were generated through access to the ActUsLab/FMR under the Framework of access to the Joint Research Centre Physical Research Infrastructures of the European Commission (RISE-241, Research Infrastructure Access Agreement N°36344/02).

Scalable and Chemical Free Activation Synthesis of High-Performance Microporous Carbon Adsorbents for Nuclear Waste Capture *Changbeom Jeon, Ga-Hyeun Lee and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Radioactive wastes, the byproduct of nuclear energy generation, need to be urgently captured due to their high volatility and well-established adverse effects on human health. Among the radioactive waste adsorbents, conventional activated carbon materials, which are used as industrial adsorbents, nevertheless exhibit low adsorption capacities. On the other hand, MOFs, COFs, and POPs are emerging as new effective adsorbents. However, due to their low production volume and complex manufacturing processes, they remain at the laboratory scale. One of the primary challenges associated with effective adsorption in practical applications is achieving both high processibility and adsorption performance.

Herein, we present an effective activation method for generating a carbon-based pore structure in a scalable and low-cost absorbent. Specifically, compared to conventional activation methods for high porosity, we adopted a chemical-free physical activation method (carbon dioxide utilization), ultimately reaching a high specific surface area and total pore volume than conventional activated carbon. Furthermore, the adsorption capacities of iodine, one of the nuclear wastes, are comparable to those of MOFs, COFs, and POPs but also demonstrate higher adsorption rates.

Our work makes several critical contributions: 1) These fiber types of large-scale sorbents can be used as a sorbent themselves without substrates due to their self-standing characteristics. 2) This processing method proposes a proper way to utilize captured carbon dioxide and even capture nuclear wastes, byproduct of low-

carbon energy, for a carbon-neutral society. The nano/microstructure evolution of PAN-based activated carbon fiber during physical activation was investigated, and its correlation with radioactive waste adsorption performances will be discussed in detail.

EN12.07.05

Electrogravimetric Studies of 20Cr-25Ni Austenitic Stainless Steel to Characterize Spent Nuclear Fuel Cladding Corrosion *Stephen Byrne[1], Colin Boxall[1] and Angela Jackson[2]; [1]Lancaster University, United Kingdom; [2]National Nuclear Laboratory, United Kingdom*

Corrosion processes are inherently electrochemical in nature. The economic costs and risk to human health as a result of corrosion induced failure can be catastrophic [1]. Current policy calls for UK spent nuclear fuel (SNF) to be sent to a geological disposal facility (GDF) for its permanent disposal. However, it may be up to 100 years before a UK GDF becomes available [2]. Consequently, all spent fuel arisings for the foreseeable future will be sent to interim wet pond storage at Sellafield. SNF is comprised of cylindrical UO_2 *pellets, encased in 20Cr-25Ni-Nb austenitic stainless-steel (SS) cladding. Consequently, cladding plays a major role in the containment of SNF. A loss in cladding integrity, due to in-situ corrosion processes, would result in pond or ground (in the cases of interim storage or ultimate disposal respectively) water becoming contaminated with water soluble radioactive fission products – such as,* ^{137}Cs*,* ^{90}Sr*,* ^{99}Tc*,* ^{3}H*. A cladding failure scenario greatly increases the costs and severity of protection measures necessary for the safe handling and storage of SNF.*

Using the electrochemical techniques of open-circuit potentiometry (OCP) and linear-sweep voltammetry (LSV), this paper presents studies on the corrosion susceptibility under wet storage conditions of as received cladding manufactured at Springfields. Corrosion mechanisms imply mass changes at the cladding surface and the quartz-crystal nanobalance (QCN) is a gravimetric analysis technique, that can be coupled with electroanalytical methods, to measure electrochemically induced material mass changes with nanogram sensitivity [3]. Thus, quartz-crystals coated in 20Cr-25Ni austenitic steel were specially manufactured to replicate SNF cladding composition. As a result, novel electrogravimetric analysis has also been performed, with 20Cr-25Ni coated QCN crystals (cladding simulant) as working electrode in the electrochemical cell.

LSV experiments were conducted on cladding as a function of temperature in pH 11.4 dosed storage water simulant with [Cl] = 20uM. Observed corrosion potentials, passive ranges and cathodic shifts in pitting potential with increasing temperature were in agreement with literature studies on 20Cr-25Ni-Nb and other austenitic stainless steels [4]. The effect of increasing chloride concentration was also investigated. This indicated that whilst corrosion inhibition is maintained up to 1mM chloride at ambient temperature 298K, a greatly increased corrosion susceptibility was observed for at the same 1mM chloride concentration at the predicted pond operating temperature of 318K. This suggests that either an alternative cladding corrosion inhibition strategy is necessary under these conditions, or that chloride content of the storage ponds needs to be carefully controlled.
Finally, QCN experiments were performed on cladding simulant material in order to better determine the effect of pH 11.4 dosing on passive layer behaviour, and the nature of trans-passive corrosion under these conditions. Previous studies on 316 SS in 3.6M HNO_3 *have revealed that no net growth in the passive layer occurs below an applied overpotential of ~400mV, above which the steel of the QCN crystal is catastrophically stripped. In contrast, analogous QCN studies of a 20Cr-25Ni-Nb SS simulant layer in simulant pond water at T = 298.15K°, pH =11.4, and [Cl] = 20uM, reveal that significant mass/passive layer growth occurs when held at the open-circuit potential, with no mass loss indicated in the trans-passive region at overpotential > ~1000mV. This highlights the advantages of using the QCN - which essentially combines conventional coupon testing with electrochemical corrosion experiments - as a means to better characterise the effect of pond dosing strategies on cladding corrosion inhibition. Accordingly, studies are now ongoing at elevated temperatures and chloride concentration in*

order to determine the envelope of protection afforded by the current strategy.

Evaluation of Retardation Effect for the Migration of Cesium Under Unsaturated Conditions

Taiji Chida, Hirotaka Kawakami, Tsugumi Seki, Noriaki Watanabe and Yuichi Niibori; Tohoku University, Japan

Radioactive waste generated with the use of nuclear power, which is relatively low-level radioactivity, is disposed of in shallow subsurface. In addition, after the accident of Fukushima Daiichi nuclear power plant, there are a numerous amount of soils contaminated by radionuclides, mainly Cs, with the decommissioning works in Fukushima prefecture. These contaminated soils will also be disposed of in the shallow subsurface after their temporal storing in an interim storage facility. In the shallow subsurface, the migration of radionuclides in the unsaturated layer is one of the key issues.

A typical shallow subsurface of about 10 m depth consists of soil particles, water, and air. The migration of radionuclides varies significantly depending on the degree to which the porous media are filled with groundwater. Under saturated conditions, such as in deep underground, the migration of radionuclides through the liquid phase is retarded by interaction with the solid phase. On the other hand, when the porous media are unsaturated, the retardation effect for radionuclides is influenced by the gas phase. That is, the migration of radionuclides would be retarded by decreasing the permeability of the liquid phase with the clogging of pores by the gas phase. In addition, the retardation effect would be reduced by inhibiting the sorption of radionuclides to the solid phase because the gas phase limits the contact between the liquid and solid phases.

Conventional radionuclide-migration assessment only corrects for the influence of the unsaturated condition by reducing the pores filled with the liquid phase. In this case, the retardation effect under the unsaturated condition is estimated to be greater due to reduction of pores through which radionuclides can migrate. However, for the actual evaluation, it may be also necessary to consider other factors of the unsaturated condition, such as the reduction of the contact surface area between the liquid and solid phase. Therefore, in this study, the migration behavior of radionuclides was investigated by column flow experiments under unsaturated conditions. In addition, based on the experimental results, the retardation coefficients were estimated by an analytical model reflecting the unsaturated conditions.

In the flow experiments, the column was packed with sand particles and placed horizontally to avoid the saturation distribution in the flow direction while considering the flow direction of groundwater in the actual environment. As a tracer, a 1 mmol/L CsCl solution was continuously injected into the packed column under constant pressure conditions. The concentration of Cs in the effluent at the outlet of the column was measured by an atomic absorption spectrometry to obtain breakthrough curves of Cs. Besides, the distributions of the liquid and gas phases in each packed column were obtained by X-ray CT images. Then, assuming that there are two kinds of flow paths in the packed column, one of which is easy to flow (saturated layer) and the other is difficult to flow (unsaturated layer), this study combined the numerical solutions of the two advection-diffusion equations and estimated the retardation coefficient for Cs in the column.

In the results, the retardation coefficients were estimated to be smaller than those obtained in the conventional assessment. In other words, these differences indicate that the retardation effect is likely to be overestimated by the conventional assessment. Furthermore, based on this analysis, an approximate equation between the retardation coefficient and the water saturation was presented in this study. This equation is consistent with the conventional definition of the retardation coefficient, when the water saturation is unity, i.e., the pores in soil are perfectly saturated with water. These results would help to clarify the retardation effect under unsaturated conditions that may occur in shallow soil layers.

Sampling Complex Energy Landscapes in Materials Science Using Data-Driven Force Fields *Clovis Lapointe and Mihai-Cosmin Marinica; Université Paris-Saclay, CEA, France*

Statistical methods, such as Machine Learning (ML) trained on physical data, can be invaluable when traditional approaches are limited or when their direct application is hampered by challenges like high computational costs. In materials science the interaction and transformation of crystal defects networks give rise to an extraordinarily diverse range of defect morphologies [1]. Additionally, accounting for chemical disorder presents another layer of complexity that is often overlooked in the emerging field of machine learning approaches. By utilizing the recently open-sourced MiLaDy (Machine Learning Dynamics) package [2] combined with accelerated Molecular Dynamics based on the Bayesian adaptive biasing force method [2], we aim to sample the intricate energy landscapes of defects by: (i) using methods that can identify complex networks of minima and saddle points at zero K; (ii) offering reliable force fields that handle intricate defects such as interstitials and dislocation loops; (iii) probing the atomistic free energy landscape of metals with ab initio accuracy up to the melting temperature [3]; (iv) examining chemical disorder in high entropy alloys (HEA); and, finally, (v) proposing surrogate models that sidestep traditional approaches to access challenging properties, like vibrational entropies [4].

Environment-Adaptive Machine Learning Potentials for Atomistic Simulations of Materials Under Extreme Conditions *Ngoc-Cuong Nguyen; Massachusetts Institute of Technology, United States*

This talk focuses on the development of machine learning potentials for atomistic simulation of materials under extreme conditions. We present a unified framework for constructing internal coordinate descriptors and atom density descriptors, and develop an efficient algorithm to compute these descriptors. We develop a novel methodology for creating descriptors that dynamically adjust to the unique local environments surrounding each central atom. This involves conceptualizing the atomic energy at every central atom as a probabilistic distribution across various clusters within the reduced-dimensional descriptor space. This procedure is facilitated by employing dimensionality reduction and clustering techniques, thereby enabling a more nuanced and environment-specific representation of atomic interactions. We employ these newly developed machine learning potentials to perform property calculations and atomistic simulations of several elements and compounds. We compare them with density-functional-theory and experiments for a wide range of observable properties, including crystal, liquid, and amorphous bulk phases, as well as defects and phonon dispersion. We demonstrate that these new potentials enable accurate atomistic simulations of Aluminium, Hafnium, and Hafnia under extreme temperature conditions.

2:15 PM MT01.01.03

Description of Metavalent Bonding in Chalcogenide System—A Comparative Study of Machine Learning Potential Models *Minseok Moon, Seugwoo Hwang and Seungwu Han; Seoul National University, Korea (the Republic of)*

Metavalent bonding (MVB) is a unique and important bonding mechanism that differs from traditional ionic, covalent, and metallic bonds. Materials with MVB found in certain chalcogenides exhibit distinctive properties such as high electrical conductivity, low thermal conductivity, and enhanced electronic polarizability. These attributes make MVB materials suitable for various applications like thermoelectrics, phase-change memory, and topological insulators. Understanding MVB would be essential for designing and optimizing next-generation functional materials.

Previous studies using density functional theory (DFT) have analyzed the structural and electronic properties of MVB at the atomic level. However, the size limitations of DFT pose challenges in accurately representing the competition between electron delocalization found in metallic bonding and electron localization seen in covalent or ionic bonding. The localized states in MVB materials, which are critical for functional electronic devices, can be larger than the tight periodic boundary conditions used in DFT calculations, potentially misrepresenting them as delocalized states. Additionally, the high computational cost of DFT makes it difficult to observe the dynamic properties of MVB, such as the crystallization behavior in phase-change memory devices. These challenges highlight the need for alternative approaches to study MVB properties.

Recently, there has been increasing interest in using machine learning potentials (MLPs) as an alternative to DFT. MLPs can compute energy and atomic forces much faster than DFT while maintaining similar accuracy. However, replicating the distinct structural characteristics resulting from the complex nature of MVB remains a challenge for MLPs. This study investigates the feasibility of describing MVB in the chalcogenide GeSe system using different MLP models: Behler-Parrinello type neural network (BPNN) with atom-centered symmetry functions via the SIMPLE-NN package,[1] the moment tensor potential (MTP) using the MLIP package,[2] and the equivariant graph neural network (GNN) with the SevenNet package.[3] We compared the amorphous structures produced by these MLP models to the amorphous structures generated by DFT. The amorphous structures generated with MLPs exhibit subtle differences in local structures, such as radial distribution functions (RDFs) and angular distribution *functions (ADFs). The MTP and GNN models showed higher accuracy in describing ring-topology compared to the BPNN model by considering higher-order many-body interactions. Interestingly, only the GNN model succeeds in describing fine details in Peierls-like structural distortions that characterize MVB in amorphous chalcogenides. We confirmed that GNN models can overcome the limitations of atom-centered descriptor models and effectively reproduce the characteristics of MVB by transferring the neighboring environment through message-passing. Additionally, the electronic structures of the amorphous structures were calculated using DFT single-point calculations, revealing that only the structures generated with the GNN potential accurately reproduced the energy gap and density of states (DOS) characteristics, while the other models exhibited the gap closing. To understand how GNN models can capture MVB characteristics, we also test various hyperparameters, including the maximum degree of spherical harmonics for graph nodes and edges, the number of interaction layers, and the maximal correlation order of tensor products.*

***Deterministic and Probabilistic Descriptor Models for Complex Atomic Simulations** Thomas D. Swinburne; Centre National de la Recherche Scientifique, France*

I will discuss how descriptors (high-dimensional, many-body order parameters) can be used to coarse-grain atomic simulations of materials. These are typically used in a deterministic setting, i.e. to predict energy and forces given atomic positions. Capturing model uncertainty in this regime requires proper treatment of model misspecification which is entirely neglected when training with the expected loss, but the true generalization error can be approximately minimised[1]. Deterministic models can also capture important microstructural features such as dislocation densities, correlation functions, or vibrational entropies, offering many efficiencies when deploying at scale. Descriptor timeseries extracted from simulation trajectories can be used to make probabilistic forecasts of simulation futures; in this setting, ideas from active learning are very useful to quantify and qualify prediction uncertainty[2]. The opportunities provided by descriptors for data-driven analysis of extreme defect dynamics will be illustrated through application to nanoparticles and plastic deformation of metals.

3:30 PM *MT01.01.05
***Structural Signatures of Mechanically and Thermally Activated Dynamics in Glassy Materials** Joerg Rottler, Siavash Soltani, Christoph Ortner and Chad Sinclair; The University of British Columbia, Canada*

Structural relaxation in glassy materials is spatially and dynamically heterogeneous, with regions of fast particles coexisting near slow ones when the material evolves through spontaneous thermal activation. In sheared glasses at low temperature, where the activation is purely mechanical, deformation proceeds via localized shear transformations. Substantial efforts have been directed towards establishing whether such local dynamics also has a local structural origin. This talk will discuss two ML based approaches that contribute to this goal. In the first *part, we employ the atomic cluster expansion (ACE) to obtain a systematic set of local descriptors, and use them to predict regions of high and low mechanical or thermal activity in the glass via linear regression. We find that for both modes of activation, most of the predictive power is already obtained at the two-body order, while higher order terms provide only modest improvements. Dimensionality reduction is then employed to construct minimal sets of descriptors.*

In the second part, we turn to unsupervised learning and construct a Markov-State model by coarse-graining the molecular dynamics trajectories into a low-dimensional feature space using graph neural networks in combination with the variational principle for Markov processes (VAMP). The transition timescale between states is larger than the conventional structural relaxation time, but can be obtained from much shorter trajectories. The learned map of states assigned to the particles reveals a form of heterogeneity, and corresponds to local excess Voronoi volume. These results resonate with classic free volume theories of the glass transition, singling out local packing fluctuations as one of the dominant slowly relaxing features.

Machine-Learned Potentials for Studying Corrosion, Embrittlement and Phase Transitions in Zirconium

Garrett Tow, Volker Eyert, David Reith and Erich Wimmer; Materials Design, Inc., United States

Zirconium alloys are used as cladding for nuclear fuel rods due to the low absorption cross-section of thermal neutrons of zirconium in addition to favorable mechanical properties. In nuclear reactors where water is used both as a coolant and as a neutron moderator, the interaction of water with the zirconium alloy can cause oxidative corrosion. This oxidation produces hydrogen gas which can diffuse into the zirconium alloy cladding, react to form zirconium hydrides, and ultimately cause undesirable hydrogen embrittlement of the cladding. Such degradation can increase the susceptibility of the cladding to react with high temperature steam in the case of loss-of-coolant accidents. To better understand the initiation and propagation of corrosion and hydrogen embrittlement, atomistic simulations can be used to conveniently examine various compositions, microstructural features, and atomic-level defects that are possible. One limitation of classical atomistic modeling is that the traditional potentials used for describing the interactions of atoms are often limited to a particular oxidation state and are not adaptive to changes in the local chemical environment. Quantum mechanical (QM) simulations resolve this issue and are flexible in describing changing chemical environments but are simply too time-consuming to simulate the large systems needed to effectively model the propagation of corrosion and embrittlement. To bridge this gap between capabilities and cost of QM simulations and classical simulations, it is possible to parametrize flexible, machine-learned potentials (MLPs) from a training set of data from QM simulations. These MLPs have the flexibility of describing multiple oxidation states for a given element, the accuracy of quantum mechanical simulations, and approach the computational cost of classical simulations using traditional potentials. In this work, an MLP with elemental coverage for Zr, O, and H has been developed in an automated framework. The MLP was found to successfully reproduce several experimental observables for Zr, ZrH_{2-x}, and ZrO_2 including lattice parameters, elastic constants, and even solid–solid phase transitions as a function of temperature. These validation efforts increase confidence in the behavior of the MLP when performing large-scale studies on corrosion and hydrogen embrittlement effects for which direct comparison with experimental results is more difficult.

Enhancing Machine Learning Interatomic Potentials with Multi-Fidelity Training

Jaesun Kim[1], Jisu Kim[1], Jaehoon Kim[1], Jiho Lee[1] and Seungwu Han[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Advanced Study, Korea (the Republic of)

Machine learning interatomic potentials (MLIPs) leverage machine learning techniques to approximate energy, *force, and stress values obtained from ab initio calculations. The MLIPs are particularly valued for their ability to provide quantum mechanical precision at significantly lower computational costs. As a data-driven approach, the fidelity of MLIPs is dictated by the choice of the exchange-correlation functional used in building the ab initio training set. While the semilocal functional such as GGA is favored for its high speed and decent accuracy in many physical properties, some applications require higher-fidelity functionals for predictive simulations. For example, in studies of ion conductivity in solid-state electrolytes, meta-GGA is preferred because conventional GGA functionals overestimate lattice parameters, resulting in exaggerated ion conductivities. However, constructing a high-fidelity dataset for an MLIP is challenging due to the high computational costs.*

A viable strategy to address this is to utilize abundant low-fidelity data, benefiting from the high correlations in data between different exchange-correlation functionals. In this presentation, we introduce an MLIP framework capable of training on multi-fidelity databases simultaneously, which allows for learning high-fidelity potential energy surfaces (PES) using only a small set of high-fidelity data. We implement the multi-fidelity framework into SevenNet [1] an equivariant graph neural network. Specifically, it employs shared parameters to capture the general trends of PES that exist across datasets, alongside fidelity-specific weights that capture finer details in PES variations between the functionals.

We demonstrate the multi-fidelity training with examples of the $In_xGa_{1-x}N$ *alloy and the argyrodite* Li_6PS_5Cl *systems. We generate a low-fidelity database from configurations of strained crystals and ab initio molecular dynamics (MD) simulations using the PBE functional. Then, we select a small portion of structures in the low-fidelity database and perform one-shot calculations employing the* r^2*SCAN functional. We find that chemical environments not directly sampled in the high-fidelity database can be effectively inferred from the low-fidelity data. For example, in the* $In_xGa_{1-x}N$ *system, the interactions between In and Ga captured in the low-fidelity dataset can be transferred to enhance the high-fidelity MLIP, resulting in accurate predictions for the ternary alloy even when using only binary crystals for the high-fidelity database. In the* Li_6PS_5Cl *system, the incorporation of high-force configurations from the low-fidelity data significantly improved the MD stability and lithium-ion conductivity predicted by the high-fidelity MLIP.*

Furthermore, we develop a multi-fidelity universal MLIP, utilizing both PBE and r^2*SCAN databases in the Materials Project. Our approach significantly enhances the accuracy of the MLIP for the high-fidelity channel, enabling accurate predictions of properties such as polymorph energy ordering, equilibrium volumes, and bulk moduli of crystal systems. However, the multi-fidelity MLIP has shown a tendency to underestimate forces, leading to softer phonon spectra. This is attributed to the narrow range of forces around zero in the high-fidelity dataset. We believe that the present methodology holds promise for efficiently creating highly accurate, universal MLIPs by effectively expanding the high-fidelity dataset.*

Symbolic Regression Based on Physics Informed Neural Network for Learning Interatomic Potentials *Aditya Koneru[1,2], Adil Muhammed[1,2], Troy Loeffler[2] and Subramanian Sankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States*

Molecular dynamics is a powerful technique for understanding system dynamics and relies on force-fields to describe the interatomic interactions. These force fields are trained to experimental or quantum mechanical data and over the years have evolved from simple pairwise potentials to the complex Neural Networks. There are two *important aspects to evaluate quality of the force-fields - First, the accuracy of the models, and second the computational cost. While simple classical models can perform fast dynamics, they do so at the cost of accuracy. Neural Networks (NN) are more flexible and can capture a wide range of configurations, but that comes at a cost of interpretability. To address these challenges and bridge the gap between physics-based and ML models, we have developed a reinforcement learning workflow that trains Physics Informed Neural Networks to learn the symbolic relation between the atomic positions and energy. We compare the performance of our PINN models with state-of-the-art physics-based and ML models using a representative example of 10 metallic systems. This evaluation includes aspects like global structural characteristics, surface energies, elastic constants, and phonon dispersions. Compared to conventional NN models, we demonstrate a significant improvement in both speed of convergence and solution quality by integrating physics guided layers with NN.*

4:45 PM MT01.01.09

Scalable Message Passing Neural Network Interatomic Potentials for Designing and Validating Radiation Resistant V-Cr-Ti-W-Zr Alloys *Myles Stapelberg[1,2], Sara Ferry[1,2], Kevin B. Woller[1,2], Markus Eisenbach[3], Rafael Gomez-Bombarelli[1] and Michael P. Short[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Plasma Science and Fusion Center, United States; [3]Oak Ridge National Laboratory, United States*

The deployment of fusion power plants is limited by the insufficient performance of existing structural materials under high temperatures and radiation environments. Historically, Ni and Fe based alloys have shown insufficient high-temperature stability in the presence of neutrons. V-Cr-Ti based alloys have shown enhanced radiation stability, yet do so at the cost of lower strength and susceptibility to gas embrittlement [1]. New materials systems are needed to enable the timely development of commercial fusion energy, yet designing these materials is challenging as it is difficult, expensive, and time-consuming to access neutron irradiation facilities to validate performance. Prior molecular dynamics research found that Ni-Fe compositions with more heterogeneous potential energy landscapes (PEL) contain fewer and smaller defects following primary damage cascade simulations [2]. Their damage resistance is attributed to enhanced recombination by restricting 1D diffusion of crowdion interstitials. Therefore, if we can infer the heterogeneity of the PEL associated with a given material composition, we can then design materials with high radiation damage resistance via composition selection. We can infer PEL heterogeneity by calculating the standard deviation of migration energy barriers for defects, thus enabling us to use it as a tool for composition optimization. However, this is currently hindered by the lack of interatomic potentials for fusion-relevant vanadium alloys. Our goal is to develop an interatomic potential in the V-Cr-Ti-W-Zr space to see if the addition of additional chemical complexity can demonstrate similar PEL heterogeneity as compared to highly concentrated vanadium alloys such as V-20Ti, which are known to have exceptional radiation damage but which are not practical for deployment in fusion applications due to their higher neutron activation and insufficient ductility [1].

In this work, we address the lack of a V-Cr-Ti-W-Zr interatomic potential by training an equivariant message passing neural network interatomic potential from ab-initio molecular dynamics simulations using the Allegro package [3]. Our model achieves quantum-accurate predictions for energies, forces, and stresses in systems exceeding 4096 atoms. This advancement removes limitations on the efficient design of radiation-tolerant structural materials within the V-Cr-Ti-W-Zr composition space. Due to its improved scalability over conventional Graph Neural Network based machine learning interatomic potentials (MLIP), our (MLIP) is suitable for primary damage cascade simulations, phase stability assessments, and estimating short-range ordering in Vanadium and Tungsten-based alloys for fusion power plants. Quantum-accurate energy, force, and stress calculations in systems large enough to model the aforementioned properties provide a remarkable opportunity for potential links between atomistic simulations and macroscopic properties in more complex systems.

SESSION MT01.02: Accelerated Composition Search and Discovery of Novel Materials
Session Chairs: Nithin Mathew and Thomas Swinburne
Tuesday Afternoon, December 3, 2024
Hynes, Level 2, Room 205

1:30 PM MT01.02.02
SODAS—Autonomous Characterization of Defects in High Entropy Materials Under Extreme Conditions via Graph Neural Networks *Bamidele Aroboto and James Chapman; Boston University, United States*

High entropy alloy processing often occurs under extreme dynamic conditions leading to a multitude of unique structural defect environments. These structural environments generally occur under rapid temperature changes, and therefore non-equilibrium conditions, which results in drastic changes in the material's structure over time. Computational techniques such as molecular dynamics simulations can help probe the atomic regime under these extreme conditions. However, characterizing the resulting atomistic structures has proved challenging due to the intrinsic levels of disorder present. Here, we leverage our SODAS platform, a graph neural network framework that can map global state information onto local atomic environments in an autonomous manner. This paradigm represents a powerful tool to encode global information, such as the level of disorder, onto local atomic environments, providing a pathway to characterize atomistic simulations in an intuitive and interpretable manner. In this work we showcase the power of SODAS at characterizing the time-evolution of defects in high entropy alloys during simulations representing additive manufacturing processes, providing experiments with detailed information regarding how processing conditions drive defect formation.

1:45 PM MT01.02.03
A Novel Crystal Plasticity FEM Framework and a Machine Learning Approach to Estimate Material Parameters and Dislocation Densities Under High Stress *Alvaro Martinez Pechero[1,2], Eralp Demir[1], Chris Hardie[2], Yevhen Zayachuk[2], Anna Widdowson[2] and Edmund Tarleton[1]; [1]University of Oxford, United Kingdom; [2]United Kingdom Atomic Energy Authority, United Kingdom*

The Crystal Plasticity-based Finite Element Method (CPFEM) is a well-established tool for modeling the microstructure of materials under deformation. Supported by Oxford and the UKAEA, we have developed an innovative crystal plasticity framework incorporating two different solvers (semi-implicit and explicit) that alternate their activity depending on the slip increments and Cauchy stress. This structure improves flexibility in addressing convergence issues compared to other codes and supports a comprehensive range of material constitutive laws to model slip, creep, strain hardening, and back stress [1].

Furthermore, our CPFEM code incorporates Machine Learning techniques to determine material properties by minimizing an objective-function. This function compares the results of experiments with simulations under *different parametrizations of the material. As we incorporate more experiments, the precision of our model in characterizing the material improves. Among various optimization methods, we chose Nelder-Mead due its simplicity as it does not require mathematical derivatives of the objective function, and its fast convergence given the high time consumption of FEM simulations.*

The length scale dependence of strength is governed by Geometrically Necessary Dislocations (GNDs). The GND densities are computed using the Nye's tensor that reveals a rank-deficient coefficient matrix which is solved by a new method that restricts the GND solution to only the active slip systems. This method improves other alternatives such as: L2 minimization [Arsenlis Parks], slip gradient [Gerken Dawson] and other rate forms [Ma Roters]. Our approach gives consistent results across different simulations, including simple shear, uniaxial tension, and four-point bending [2].

Finally, using this framework, we have simulated the Bauschinger effect observed in copper monocrystal cantilever experiments during initial bending/straightening cycles [3]. The modified Orowan-Sleeswyk model revealed the best match between the micro cantilever Bauschinger experiments, suggesting non-ideal reversibility and storage of a fraction of GNDs as Statistically Stored Dislocations (SSDs) upon load reversal.

Segmentation and Classification of Lower Bainite and Tempered Martensite High Strength Steels Using Deep Learning

Jun Song, Xiaohan Bie, Juan Li and Manoj Arthanari; McGill University, Canada

Because of their superb mechanical properties, high-strength steel (HSS) is a crucial structural metal for many industries, and has seen great use in applications under extreme environments. However, they are very susceptible to hydrogen embrittlement (HE), a phenomenon where the ingress of H leads to the material's ductility loss and abrupt failures. The susceptibility of HSS to HE has been demonstrated to be strongly dependent on the microstructure therein. Two common microstructure types within HSS are lower bainite (LB) and tempered martensite (TM). It has been reported that LB shows more resistance to HE than TM, attributed to difference in the distribution and morphology of carbide precipitates. However, the characterization and comparison of microstructures in LB and TM have been mainly qualitative, and often ad-hocly relying on highly localized features, thus prone to uncertainties particularly in situations when there is no prior knowledge of the heat treatment. Employing deep Learning, we have established a workflow for efficient segmentation and classification of microstructure images of HSS. The workflow enables streamlining of quantitative analysis of carbides in terms of the aspect ratio, size, alignment and density. Our results showed that, despite difference in local regions, LB and TM exhibit little or marginal difference in global characteristics of carbides. Meanwhile, our deep learning *approach has been shown to accurately differentiate the LB and TM microstructures, with an impressive 96.81% accuracy. Our findings demonstrate the potential of deep Learning as a powerful tool in quantitatively analyzing and distinguishing complex microstructures in HSS.*

Effect of Stress, Temperature and Langevin Friction on the Rate of Reaction in Dislocation Dipoles

Mohammadhossein Nahavandian[1], Liam Myhill[1], Soumit Sarkar[1], Nikhil Chandra Admal[2], Giacomo Po[3] and Enrique Martinez[1]; [1]Clemson University, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]University of Miami, United States

Thermal activation of dislocations is critical to predict the mechanical response of materials under common experimental conditions. According to transition state theory (TST), the rate for the system to overcome free energy barriers is a function of an attempt frequency, activation free energy, and temperature. Using Molecular Dynamics (MD), we have computed the power spectrum of a dislocation dipole at different temperatures to relate it to the attempt frequency. For small Langevin frictions, the power spectrum remains the same, but if the friction is strong, there is a change in the power spectrum. We have also computed the rates from MD, both dynamically and statically. Dynamically, we observed a strong dependence on the Langevin friction. As the friction becomes weaker, the rate increases, and we observe an increase in the number of correlated events. Statically, we computed the minimum energy path and activation free energy relying on Schoeck's formalism to compute the activation entropy and observed a significant entropic effect. We have also extended the equations of motion in Dislocation Dynamics (DD) to add stochastic forces, and we have computed the rates for similar configurations and compared them with MD results. We have analyzed the effect of discretization of the dislocation in the results for different temperatures and applied stresses. We discuss here the agreements and differences between the two methods, MD and DD.

High Throughput Nanomechanical Response of Rolled Homogenous Armor (RHA) Steel *Niraj Pramod Atale, Kevin Jacob, Ethan Shimak and Sid Pathak; Iowa State University of Science and Technology, United States*

Rolled homogeneous armor (RHA) steels have been used extensively in vehicle armor due to their high strength, high resistance to ballistic impacts, and penetration coupled with ease of fabrication. These steels are initially cast into required sizes and undergo various thermomechanical treatments to achieve desired properties. Subsequently, they are hot rolled to homogenize the grain structure across the plate and reduce thickness. Existing literature on these steels has primarily focused on compositional variations or thermal history adjustments aimed at enhancing strength or toughness. However, a comprehensive understanding of the microstructure and elastic-plastic damage properties of the microscale constituents of these steels has been lacking despite its critical role in the ballistic response and the processing-structure-property-performance relationship.

The martensitic RHA steel microstructure constitutes the hierarchy of the parent prior austenite grain boundary (PAGB), further divided into packets, blocks, and laths. This hierarchy is associated with the variants resulting from the transformation of parent austenite to martensite. During the diffusion-less transformation process, 24 possible martensitic variants can form, each sharing specific orientation relationships (ORs). If the resulting martensite laths share a common Bain orientation and originate from the same habit plane, the misorientation angle between adjacent laths will be low, typically between 2-3°. In contrast, a significantly higher misorientation angle, ranging from 50-60°, occurs if the laths arise from different Bain orientations. Laths within a specific block exhibit the same *crystallographic orientation. The presence of only small misorientations between laths indicates that these structures are transparent to dislocation motion and, as a result, do not serve as strong barriers. Since the lath boundaries are the only low-angle boundaries, the blocks can be effectively considered as single grains within martensitic microstructures. The 24 possible orientation relationships (ORs) for the parent austenite allow for the formation of four distinct blocks within a given austenite grain. Blocks are separated by high-angle grain boundaries (HAGBs), which act as significant barriers to dislocation motion. Consequently, the size of these blocks is crucial in determining the overall strengthening of the material. The subsequent building unit in this series is a packet, which is formed by a collection of blocks sharing the same habit plane. To achieve a comprehensive understanding of the RHA steel microstructure, a detailed microstructural characterization using XRD, EBSD, and TEM has been carried out to outline the hierarchical microstructure of this material.*

The complex microstructural details in MIL-DTL-12560K RHA steel, where the length scales of interest can span from the nm to µm ranges, require specialized small-scale mechanical tools for testing and characterization. We utilized high throughput nanoindentation techniques coupled with the HR-EBSD technique to probe local nanomechanical response at various strain rates. Our current work provides nanoindentation properties as a function of orientation and strain rate from a single block without the influence of nearby high-angle grain boundaries. The indentation yield (Y_{ind}) surface map indicates a distinct orientation dependence for RHA steel at a strain rate of 10^{-2} s^{-1}. The linear strain hardening co-efficient, however, showed an inverse correlation to Yind. The hardness and change in hardness with strain rate showed less sensitivity compared to yield to capture the orientation effect. Further analysis demonstrated that the block boundary misorientation, distance, and block size also affected the nanomechanical properties apart from block orientations themselves.

3:30 PM MT01.02.09

Role of Ripplocations and Ripplocation Boundaries on the Uniaxial Compression and Bending in Graphite

Kaustubh Sudhakar; Drexel University, United States

Graphite is considered to be the best refractory due to its high melting point, chemical inertness, thermal and electrical conductivity, resistance to thermal shock, and lubricity. The mechanical behavior of graphite remains intriguing due to its anisotropic bonding. This talk focuses on the mechanical response of graphite via deformation simulations using molecular dynamics. First, the interatomic potentials to simulate the graphite structure will be gleaned, this is carefully evaluated using the DRIP-REBO potentials. Using these potentials, 60 graphene layers were loaded uniaxially (UA) along the zig-zag configuration, or by double indentation (DI), normal to the basal planes. Following this, the talk discusses how uniaxial compression simulations reveal the nucleation and motion of ripplocations and ripplocation boundaries (RBs). Notably, the simulations demonstrate a novel phenomenon where tensile and compressive strains nest on the RBs during deformation under DI. Next, our results will be discussed where it is seen that in the linear elastic regime, the total energy, primarily reflects straining of the carbon-carbon bonds, with a modulus of 800 GPa. Following linear elasticity, both deformation mechanisms form RBs spontaneously. Consistent with buckling, the energy per atom required to nucleate RBs in the uniaxial compression configuration is nearly twice that of the double indentation case. The total remote strain for buckling is found to be 0.3% in the DI configuration, and 0.5% for the UA case. In the DI case, a local minimum correlated with face-centered stacking of the graphite layers is observed. Following this, loading-unloading will be discussed, where it is found that cycling significantly reduces the energy per atom to nucleate RBs, endowing a memory effect. The deformation indicates that nucleation of RBs is more challenging than their movement. Finally, our findings are corroborated by TEM evidence in the literature showing remarkable resemblance to experiments at extreme strains of 30 %. The resulting atomistic response is novel, in that, tensile and compressive strains nest at the RBs. This talk offers valuable insights into the mechanical properties of graphite, crucial for various applications.

Challenges and Advances in the Modeling of Activated Processes—A Special Focus on Methodological Developments and Application of the Kinetic Activation-Relaxation *Normand Mousseau and Eugène Sanscartier; Université de Montréal, Canada*

Understanding processes underlying the evolution of materials (aging, defect formation, chemical reactions, catalysis) requires a precise description of atomic interactions in complex environments and on time scales that exceed, sometimes by a lot, the nanosecond. Faced with these challenges, modellers have long been forced to choose between precision, with heavy quantum computations, and time scale, with much lighter empirical potentials, but that are unable to truly describe the complexity of chemical environments. Even with these more than approximate potentials, traditional simulation methods, such as molecular dynamics, do not allow to exceed the microsecond, considerably limiting the relevance of models to understand experimental phenomena. A more efficient coupling of accelerated dynamics approaches, such as kinetic ART, an off-lattice kinetic Monte Carlo algorithm, with ab initio approaches and potentials developed by machine learning, gives hope that it will soon be possible to remove many of these barriers. In this seminar, I will present an overview of the recent developments we are pursuing around these methods.

The work presented here was carried out in collaboration with, among others, Gilles Adjanor, Charlotte Becquart, Laurent Karim Béland, Othmane Bouhali, Romain Candela, Christophe Domain, Fedwa El-Mellouhi, Simon Gelin, Renaude Girard, Miha Gunde, Anne Hémeryck, Antoine Jay, Aynour Koshravi, Carl Levesque, Joseph Lefeevre Loopez, Ruggero Lot, Sami Mahmoud, Layla Martin-Samos, Matic Poberznik, Nicholas Salles, Alecsandre Sauvé Lacoursière, Mijanur Rahman, Oscar Restrepo, Nicholas Richard, Nicolas Salles, Eugène Sanscartier and Mickaël Trochet.

2:00 PM MT01.03.02
Impact of Short-Range Order (SRO) on Thermodynamic Properties of Point Defects *Ziang Yu[1], Benjamin Beeler[2] and Yongfeng Zhang[1]; [1]University of Wisconsin-Madison, United States; [2]North Carolina State University, United States*

U-Mo alloys, particularly with Mo ranging around 10 wt.% (U-10Mo), are crucial as high-density, low-enrichment nuclear fuels in high-performance research and test reactors (HPRRs) and fast reactors. A significant challenge with U-Mo fuel is its unpredictable and excessive swelling under high-temperature irradiation, primarily due to fission-product gas accumulation in bubbles resulting from point defect formation, diffusion, and subsequent microstructural evolution and property degradation. Consequently, understanding the fundamental properties of point defects is essential to addressing these issues and improving fuel performance. However, the thermodynamic and kinetic properties of point defects depend on chemical ordering, i.e., the distribution of Mo atoms, which may not necessarily be random. This study systematically calculates the equilibrium ordering of Mo in U-10Mo in the temperature range from 300 K to 1500 K using hybrid molecular dynamics and Monte Carlo

(MDMC) simulations and identifies non-random, short-range ordering (SRO) of Mo, which alters the thermodynamic and kinetic properties of point defects. Formation energies, diffusivities, and migration energies are determined as a function of SRO parameters and temperatures. Importantly, our findings reveal that interstitials play a significant role in self-diffusion at thermal conditions, which is abnormal in metals. The results provide more accurate atomistic data for basic defect parameters to upper-scale modeling, thereby facilitating a more comprehensive understanding of the thermal properties of point defects and the impact of SRO in U-Mo alloys.

2:15 PM MT01.03.03

The Local Compositional Dependence of Vacancy Diffusivity in 316 Stainless Steel by Gaussian Process Regression *William T. Yorgason[1,2], Andrea M. Jokisaari[2] and Christopher L. Muhich[1]; [1]Arizona State University, United States; [2]Idaho National Laboratory, United States*

316 stainless steel (316 SS) has a long history as a critical structural material in nuclear power plants but has a propensity for radiation swelling. Swelling can be lifetime-limiting and is attributed to vacancy diffusion within the material, meaning accurate quantification of vacancy diffusion is crucial. However, the local compositional effects on vacancy diffusion have not been studied in this material, but initial compositional heterogeneity and radiation-induced compositional segregation is common. The diffusivity of vacancies depends on their vacancy migration energy barriers (VMEB). There are several methods to calculate VMEB, such as using classical force fields or quantum mechanical calculations. Classical force fields are not sufficiently accurate to consistently match qualitative trends in experiment, necessitating the greater accuracy, and greater computational expense, of quantum mechanical calculations such as density functional theory. However, $5x10^4$ VMEB calculations are required to cover the compositional space local to a vacancy, which accordingly multiplies the already computationally expensive quantum mechanical calculations. Therefore, we implement a Gaussian process regression (GPR) trained on a subset of NEB calculations to predict VMEB values in less than one second. The GPR predicted VMEB values have greater accuracy than four molecular dynamics embedded atom potentials and are at least 10^3 faster to calculate as the migration pathway does not need to be traced. To calculate diffusivity, these GPR predicted VMEB values are deployed in a kinetic Monte Carlo (KMC) simulation of a Fe-Cr-Ni solid solution near the compositional ranges of 316 SS. Incorporation of GPR predicted VMEB values into the KMC simulation shows Cr diffuses fastest opposite vacancy diffusion, followed closely by Fe, with Ni moving much slower. Despite Cr diffusing fastest opposite vacancies, the associated VMEB values vary the greatest for this element, showing the importance of other factors that influence VMEB values, such as composition local to the diffusing vacancy. Using these models, we investigate the effects of composition, defect concentration, and temperature on vacancy diffusivity of 316 SS. This methodology can be applied to any other ternary (or more complex) system for which local composition effects on vacancy diffusion are of interest, especially solid solution alloys used as fuel cladding or structural materials in nuclear power plants.

3:30 PM *MT01.03.04

Data-Driven Upscaling—Applications to Multi-Scale Modeling of Extended Defects *Nithin Mathew; Los Alamos National Laboratory, United States*

Nucleation, propagation, and interaction of extended defects, such as dislocations and grain boundaries, play a critical role in controlling the mechanical response of polycrystalline materials. Multi-scale modeling, primarily based on mechanistic and phenomenological models, has played a key role in understanding these phenomena and predicting material response. Advent of exascale computing and advanced machine learning algorithms *opens up new venues of data-driven upscaling where physics-informed machine learning models, in conjunction with physics-based descriptors, can effectively bridge between different computational scales with minimal constitutive and/or phenomenological assumptions. In this talk I will discuss data-driven upscaling applied to modeling of extended defects, primarily focusing on atomistic simulations and discrete dislocation dynamics. It is shown that uncertainty-driven active learning can efficiently learn the underlying physics, where the only assumptions are based on well-grounded physical constructs such as mean-free paths, thermal activation, and configurational forces.*

4:00 PM MT01.03.05

Modelling Point Defects at Finite Temperatures with Machine Learning Force Fields *Irea Mosquera-Lois and Aron Walsh; Imperial College London, United Kingdom*

Point defects control the properties of most functional materials. Their identification is addressed by combining experimental measurements with theoretical models. Most ab-initio studies are limited to a 0 K description due to the high computational cost. In this study, we move beyond this idealised model and explore the effects of finite temperatures on defect formation, using Te_i in CdTe as an exemplar. By including the main entropic contributions, like configurational (structural, spin) and vibrational, we find that thermal effects increase the predicted concentrations by three orders of magnitude. Further, to study the defect dynamics over longer time and length scales we use a machine learning force field (MLFF). These simulations reveal that Te_i rapidly exchanges between configurations and sites already at room temperature, where the accessible low-energy configurations act as stepping stones that promote diffusion. Finally, we assess the interpretability of our MLFF, observing strong correlation between the atomic energies and the defect-induced distortion. Overall, our study underscores the importance of finite-temperature effects and the potential of MLFFs to accurately model complex defect processes.

Accurate Models of Solute-Defect Interaction from First-Principles and Machine-Learning *Anirudh Raju Natarajan and Deepak Somani; École Polytechnique Fédérale de Lausanne, Switzerland*

Defects play a crucial role in determining material properties. In multi-component materials, the interactions between solute elements and defects can be related to material properties such as strength, kinetic transport coefficients, and microstructural stability. Phenomenological models, such as Labusch-type models of dislocations or Mclean segregation theory for grain boundaries provide a bridge between atomistic models and the properties of materials that are subject to extreme environments. However, ab-initio inputs to such phenomenological theories are often difficult or too expensive to compute from accurate electronic structure calculations. For instance, determining the interactions of dilute concentrations of solute elements with a dislocation often requires large simulation cells containing hundreds of atoms. The lack of an accurate model that can rapidly predict the spectrum of interaction energies between a solute and an arbitrary defect severely limits our ability to design new alloys for deployment at elevated temperatures and harsh environments. In this talk, we will describe a new method that leverages recent advances in machine-learning and atomistic modelling to rigorously compute solute-defect energy spectra for a wide-range of material classes. We will show that our theory accurately predicts the properties of materials ranging from complex refractory alloys to lightweight alloys made of aluminum and magnesium. High-throughput calculations together with our physics-based model helps elucidate the relationships between alloy chemistry and material properties. Our model provides an important design tool for the discovery of new material compositions for deployment in harsh environments.

4:30 PM *MT01.03.07

Incorporating Detailed Balance and Uncertainty Quantification in Machine Learning-Based Models of Defect Transport in Alloys *Anjana Talapatra[1], Danny Perez[1], Matthew Wilson[1], Ying Wai Li[1], Anup Pandey[1], Ghanshyam Pilania[1], Soham Chattopadhyay[1,2], Dallas Trinkle[2] and Blas P. Uberuaga[1]; [1]Los Alamos National Laboratory, United States; [2]University of Illinois at Urbana-Champaign, United States*

With the increasing interest in so-called high entropy, multi-principal component, or compositionally complex alloys, there is a greater need to understand how transport is affected by the complex chemistry of these materials. As compared to a simple elemental solid, in which every lattice site is identical and transport can be described by a handful of saddle points, these materials exhibit a very rugged potential energy surface in which every site has a unique chemical environment. This means that every site exhibits a different defect formation energy and corresponding migration barriers for motion to neighboring sites. As the number of elements in these systems increases, it becomes increasingly challenging, and soon impossible, to enumerate the energetics of every site in the system. Alternative approaches are necessary.

Machine learning has become the choice du jour to describe the chemistry-dependent properties of defects in these alloys. Using atomistic data as their foundation, machine learning models can then quickly and accurately predict the migration barriers for defects as a function of the local chemical environment, eliminating the need to determine all possible barriers a priori. As the basis of kinetic Monte Carlo simulations, these models then allow for long-time simulations of transport through the alloy. However, for such simulations to inspire confidence, they must obey detailed balance. Further, it would be beneficial to have some metric of the uncertainty in the predicted barriers and an approach to systematically improve them.

Here, we describe approaches to address both questions. First, we describe how detailed balance can be rigorously implemented in machine learning models of defect energetics. Specifically, we theoretically derive the conditions under which detailed balance will be strictly satisfied and demonstrate that machine learning models based on this derivation do indeed obey detailed balance. We further show that less rigorous treatments lead to systematic errors that can lead to energy drift as the simulation proceeds. We conclude that detailed balance must be considered to obtain valid trajectories and that implementation of detailed balance is straightforward.

We then use the machine learning model to determine the kinetic properties of defects. Using a recently-developed approach in which the complex correlated+uncorrelated kinetic Monte Carlo problem is mapped rigorously onto an uncorrelated surrogate, we then use this to identify which atomic scale events are most critical in describing the trajectory of the defect. This provides a route to close the loop, so to speak: to build an autonomous workflow in which the events that the trajectory is most sensitive to are further refined to improve the description of the material. We demonstrate the elements of this workflow, highlighting how we can then quickly determine the diffusion tensor for defects in complex alloys when given appropriate computational resources.

5:00 PM MT01.03.08

Energetics of Triple Junctions in Polycrystalline Materials *Nutth Tuchinda[1] and Christopher A. Schuh[2,1]; [1]Massachusetts Institute of Technology, United States; [2]Northwestern University, United States*

In nanomaterials, defects can govern bulk thermodynamics and properties under dynamic conditions. Specifically, at the finest grain sizes in nanocrystalline alloys, triple line density can reach well above typical dislocation density in polycrystalline materials, and thus can play a significant role in bulk properties as a whole. Hence in this work, we study ensembles of triple junctions in nanocrystalline face-centered cubic metals. The line *density is found to correlate with high-angle grain boundary energy and dislocation line energy, although with a negative correlation: triple junctions are thermodynamically favorable defects. In essence, triple line energies are found to be of order -10^{-10} J/m which is close to the magnitude of dislocation core energy around ~ $-Gb^2/12$. The method is also demonstrated by the extraction of defect energy from previously published experiments on Se nanocrystals.*

5:15 PM MT01.03.09

Impact of Grain Boundary Structure on Defect Evolution of Polycrystal Aluminum Under Irradiation Through Molecular Dynamics Simulations *Alhassan S. Issaka, Assel Aitkaliyeva, Michael R. Tonks and Simon R. Phillpot; University of Florida, United States*

High-energy atomic interaction processes are fundamental to a wide range of advanced material technologies, including semiconductor processing, electron microscopy and nuclear power generation. In this study, we employ Molecular Dynamics (MD) simulations to investigate the impact of the primary knock-on atom (PKA) approach on aluminum, focusing on defect evolution resulting from radiation damage. We provide insights into the high-temperature behavior of radiation cascade in aluminum and quantify the extent of damage as a function of the deposited energy using the Norgett−Robinson−Torrens displacements per atom (NRT-dpa) model. We also evaluate defect formation energies for systems containing various grain boundaries and characterize defect evolution and migration. Additionally, we quantify the impact of the distance of the PKA from the grain boundary on microstructure evolution. Our findings provide valuable insights into the effects of radiation damage on aluminum.

1:30 PM *MT01.04.01

Graph Attention Networks for Microstructural Understanding of Abnormal Grain Growth *Elizabeth Holm[1] and Ryan Cohn[2]; [1]University of Michigan–Ann Arbor, United States; [2]Carnegie Mellon University, United States*

Polycrystalline microstructures can be represented as graphs, which capture both grain geometry and connectivity. A number of machine learning (ML) algorithms operate on graph data, raising the question of whether they can be used to predict microstructural evolution in polycrystals. Operating on a data set of Monte Carlo grain growth simulations, we find that a simple graph convolution network outperforms a computer vision approach for predicting the occurrence of abnormal grain growth (AGG) in a model polycrystalline system. Based on this successful proof-of-concept, we extend the data set and enhance the data structure. A graph attention network significantly outperforms simple graph convolution, achieving a 20% reduction in error rate. In addition, feature importance analysis identifies the grain characteristics associated with AGG. Taken together, these results show the promise of ML for both predicting microstructural outcomes and supporting microstructural science.

2:00 PM *MT01.04.02

Data-Mining and Prediction of Alloys for Functional Applications *Jacqueline M. Cole; University of Cambridge, United Kingdom*

Artificial intelligence is increasingly able to predict successfully new materials that possess a targeted functionality. The success of such materials discovery approaches is nonetheless contingent upon having the right data source to mine, and machine-learning approaches that suitably encode structure-function relationships that can be used to predict a lead material for a given application.
This talk shows how to meet the data requirements for uncovering the properties of existing alloys [1] and how to employ machine-learning to predict new alloys for functional applications.[2]
The presentation describes new versions of our home-built 'chemistry-aware' software toolkits, ChemDataExtractor[1,3-5] that have been adapted for stress-strain engineering [1], and language models that have been customised for these engineering applications.[6]

2:30 PM *MT01.04.03
Nucleation Phenomena in Liquid Metals—What Can be Gained from Machine Learning? *Johannes Sandberg[1,2], Thomas Voigtmann[2,3], Remi Molinier[4], Emilie Devijver[4] and Noel Jakse[1]; [1]Grenoble INP, UGA, France; [2]German Aerospace Center, Germany; [3]HHUD, Germany; [4]Université Grenoble Alpes, France*

Nucleation phenomena are commonly observed in our everyday life, manifesting in various forms such as the formation of clouds, the crystallization of sugar in candy making, the bubbling of carbonated beverages, the freezing of water into ice, and the casting of steels and aluminum alloys in transportation industries [1]. Focusing here on crystal nucleation in liquid metals [2], the early stages where the liquid-to-solid transition occurs upon undercooling initiate at the atomic level on nanometer length and sub-picosecond time scales that can still hardly be observed experimentally. To reveal their structural features, atomistic simulations have to be conducted and need at least two important features. Firstly, realistic simulations require the knowledge of interactions with high accuracy, which can be achieved within the Density Functional Theory (DFT) [3]. Secondly, molecular dynamics have to be carried out on a sufficiently large scale so that a reasonable number of nucleation events can be observed [1], often involving millions of atoms. Combining these two ingredients seems at first sight incompatible given the size achievable by DFT-based simulation (AIMD). Recent advances in machine learning interatomic potentials (MLIP) allow overcoming this difficulty and addressing crystal nucleation by means of classical molecular dynamics (MD) simulations at DFT accuracy. A well-established high-dimensional neural network potential trained on a set of configurations generated by AIMD, containing various crystalline structures and liquid states at different pressures, including their time fluctuations over a wide range of temperatures, was shown to be relevant for solidification phenomena [4, 5]. Subsequently, tracking relevant structural information from a nucleation pathway produced by such large-scale MD simulations can be performed without a priori using an unsupervised learning approach founded on topological descriptors borrowed from persistent homology concepts. The translational and orientational ordering of the liquid prior to nucleation, as well as the morphology of nuclei when homogeneous nucleation starts, were studied for various monatomic metals [6, 7]. Results reveal the specificity of the nucleation pathways depending on the element considered, with features beyond the hypothesis *of Classical Nucleation Theory.*

3:30 PM *MT01.04.04
Composition and Temperature Dependence of Point-Defect and Elastic Properties in Multi-Component Alloys for Fusion Applications by Machine-Learning Simulations *Jan S. Wróbel[1], Anruo Zhong[2], Alexandra M. Goryaeva[2], Mark Fedorov[1], Duc Nguyen-Manh[3], Manuel Athenes[2] and Mihai-Cosmin Marinica[2]; [1]Warsaw University of Technology, Poland; [2]Université Paris-Saclay, CEA, France; [3]United Kingdom Atomic Energy Authority, United Kingdom*

In nuclear fusion technology, there is a need for microscopic models for defects as nonlinear sources of stresses and strains since the information about eigenstrains of radiation defects is crucial for the simulations using the finite element method. One of the methods that enable to compute the eigenstrains of defects effectively is molecular dynamics (MD). The primary challenge in atomistic simulations is the availability of realistic interatomic potentials for the alloy systems. An interesting alternative to the conventional interatomic potentials is the use of machine learning (ML) approaches.
In this work, we demonstrate the advantages of ML interatomic potentials using two distinct groups of materials relevant for fusion applications: bcc Fe-Cr-He alloys and Ta-Ti-V-W high-entropy alloys. Accurate and fast ML potentials for both alloy systems were developed based on thousands of density functional theory (DFT) calculations performed on representative structures with varying alloy compositions and different atomic configurations. Various ML approaches, including linear ML and kernel models, along with different types of atomic descriptors, were systematically tested to achieve a good balance between accuracy, speed, and predictive power [1]. The root-mean-square errors between the forces computed using DFT and ML potentials are consistently below ~0.2 eV/Å.
The developed ML potentials were applied in MD simulations to study selected properties, including elastic and point defect properties of Fe-Cr-He and Ta-Ti-V-W alloys as a function of composition. The results obtained were compared with available DFT results. Importantly, MD simulations with ML potentials enabled the study of alloy properties at elevated temperatures and their melting temperatures, which is nearly impossible using the DFT technique. Our study highlights the influence of temperature on the formation free energy of point defects, with vibrational entropy playing a significant role.

Tuning Chemical Distribution in Complex Concentrated Alloys via Thermo-Mechanical Processing

Mahmudul Islam, Killian Sheriff, Yifan Cao and Rodrigo Freitas; Massachusetts Institute of Technology, United States

Thermo-mechanical processing of metallic alloys often involves severe plastic deformation (SPD), which modifies the microstructure and, consequently, the material properties. While recent research has highlighted the role of chemical distribution on the properties of complex concentrated alloys (CCAs), the feasibility of tuning their chemical distribution via SPD remains unclear. Here we employ high-fidelity large-scale atomistic simulations of dislocation-mediated plastic deformation combined with information theory and machine learning to investigate the influence of dislocation-mediated SPD on chemical distribution in CCAs. Our findings reveal that the interaction between dislocations and local chemical configurations can induce nonequilibrium chemical distributions in CCAs, with strain rate and temperature being critical driving parameters governing the evolution and final distribution. Our work suggests that controlled SPD can be leveraged to tune chemical distribution in CCAs, thereby optimizing their materials properties.

Energy of Defects in Metallic Materials in Controlled Recrystallization of Soft Magnetic Steel *Nam Hoon Goo; Pohang University of Science and Technology, Korea (the Republic of)*

Recrystallization in solid metal is a process of releasing stored energy related to various metallic defects. These defects include vacancy, dislocation, grain boundary, precipitate or inclusion particles, and surfaces opened to the external environment.

The metallic materials we have selected for our study are not just any materials, but significant ones due to their unique microstructural features. These features, primarily represented by grain size, grain orientation (texture), and grain shape, play a crucial role in the properties of the material after recrystallization. A prime example is the soft magnetic steel sheet, or electrical steel, a material whose properties are entirely dependent on the grain structure after recrystallization. The alignment of the easy magnetic axis along the crystallographic <001> direction is a key factor for efficient magnetization reversal.

Our study takes a unique approach to understanding recrystallization, viewing it as a necessary annealing procedure following severe plastic deformation. This process is not just about obtaining newly grown and defect-free grains but also involves a sophisticated process of selecting grain orientation through precise control of plastic deformation and subsequent annealing.

This study presents the quantitative analysis of defect structures with plastic deformation, pinned grain boundaries by particles, and exposed surfaces. Plastic deformation is a source of fresh grains, and the pinning particles and surface drag enhance the grain's boundaries. The momentum of mobile grain boundaries is assessed with various situations involving surrounding defects. The molecular dynamic (MD) approach helps evaluate and quantify the energies of boundaries and interacting defects. We introduce the hybrid force fields mixed with Lennard Jones and embedded potentials. LJ potential helps characterize the heterogeneity of atomic configuration, while the embedded atomic model is appropriate for rigid matrix-supporting defect structures. In addition to the selection of hybrid potentials, the combined deep learning algorithm to MD provides a much more accurate force field among metallic atoms and facilitates predictions close to actual experiments. The formation of cube and goss textures, which are rarely produced in the conventional cold rolled and annealing, are described

in terms of the momentum of grain boundaries with peripheral energetic defects. By quantifying the energy of various kinds of defects, we can devise a tool to stabilize the defects and make them useful for the desired microstructure in terms of grain sizes, shapes and orientation.

Shaping Deformation—How Interface Roughness and Alignment Drive Bimetal Mechanics *Avanish Mishra, John S. Carpenter and Saryu Fensin; Los Alamos National Laboratory, United States*

The microstructural characteristics of multi-phase materials, particularly bimetal interfaces, play a critical role in governing their deformation and failure mechanisms under extreme conditions. At high strain rates or during shock interactions, these interfaces significantly influence the evolution of dislocations and twinning, directly impacting the material's overall strength and resilience. Despite this importance, a substantial knowledge gap remains between the observed material behavior and the effects of interface roughness and alignment, limiting the ability to design robust, high-performance components used in sectors such as defense, energy, aerospace, and infrastructure. Current experimental approaches often lack sufficient microstructural insight, and traditional metrics like grain size and distribution fail to capture the complexities of atomic arrangements at bimetal interfaces. To address this, we conducted large-scale Molecular Dynamics (MD) simulations of various Al-Ti bimetal interfaces to explore their role in deformation mechanisms. This study investigates how interface roughness (flat vs. waveform interfaces) and alignment affect material behavior under high-strain rate deformation. In addition to defined interfaces, we also simulated atom deposition to mimic welding processes, further exploring the influence of interface formation on material behavior. Furthermore, by rotating these interfaces relative to the loading direction, we clarify how alignment influences deformation mechanisms, providing valuable insights for optimizing bimetal microstructures. | LA-UR-24-29709

Machine-Learning Molecular Dynamics Simulations of Defects and Domain Walls in Ferroelectric Potassium Niobate *Hao-Cheng Thong[1], Ben Xu[2] and Ke Wang[1]; [1]Tsinghua University, China; [2]China Academy of Engineering, China*

Ferroelectrics are important piezoelectric materials extensively used in actuators and sensors. Among these, lead zirconate titanate (PZT) stands out as a commercially available piezoelectric material known for its excellent performance. However, due to increasing concerns about the environmental and health impacts of lead, there is a significant demand for developing high-performance lead-free piezoelectric materials. Various lead-free systems, including potassium sodium niobate (KNN), barium titanate, bismuth ferrite, and bismuth sodium titanate, have been explored. Among these, the KNN system exhibits relatively good comprehensive performance, making it a focal point in lead-free piezoelectric material research.

Developing high-performance lead-free piezoelectric materials is highly challenging because the performance of ferroelectric piezoelectric materials is closely related to interactions among microstructures at different scales, such as phase structure, domain walls, defects, and grain boundaries. Understanding these complex interactions is crucial for designing high-performance piezoelectric materials. However, due to limitations in experimental characterization methods, it is difficult to distinguish the contributions of various microstructures to the performance directly. Theoretical simulation methods can potentially elucidate the physical mechanisms behind these phenomena. First-principles density functional theory calculations can simulate various properties of ferroelectric materials, but due to the complexity of this computational method, calculations are limited to the electron and atomic scales. Under current computational resources, this method still cannot effectively simulate microstructures on a large spatial scale and their evolution over a long time scale. On the other hand, molecular dynamics simulation is a very useful method for studying the macroscopic properties of ferroelectric materials, but

it requires a high-precision interatomic potential.
This study used a machine learning deep neural network model to construct an interatomic potential energy function for the lead-free ferroelectric material. By incorporating first-principles calculation data into the training dataset, the accuracy of the interatomic potential was ensured with approximate quantum mechanical precision. The results show that molecular dynamics simulations based on the machine learning interatomic potential maintain good consistency with first-principles calculations, accurately predicting multiple basic properties of the material, such as atomic forces, energy, elastic tensor, and phonon dispersion. Additionally, the method demonstrates satisfactory performance in the domain walls, defects, and phase transition simulations. This approach holds promise for constructing interatomic potentials for other ferroelectric systems, contributing significantly to research in the field of ferroelectric materials.

SESSION MT01.05: Poster Session

MT01.05.01
Investigation of Thickness Dependence in Crystallization of Thin Films Using Phase Field Modeling *Jungin Park[1], Hwanwook Lee[1], Donghwan Ahn[2], Seongjae Cho[3], Kyung Song[4] and Yongwoo Kwon[1]; [1]Hongik University, Korea (the Republic of); [2]Kookmin University, Korea (the Republic of); [3]Ewha Womans University, Korea (the Republic of); [4]Korea Institute of Materials Science, Korea (the Republic of)*

Polycrystalline thin films are widely used in nanoelectronics. Recently, the importance of controlling microstructure keeps growing in the cutting-edge nodes of integrated circuit technology. Two representative examples are the polysilicon channel of 3D NAND and the dielectric film of the DRAM capacitor. In both applications, the grain size is important because grain boundaries act as the resistance for the channel and the leakage path for the dielectric. It has been experimentally observed that thicker films have larger grain size in the case of the polycrystalline film prepared by solid-phase crystallization (SPC), i.e., annealing following depositing an amorphous film. However, the origin of the thickness was unclear.
In this study, the relation between film thickness and grain size was investigated experimentally and theoretically. 10, 20, 40 nm thick poly-germanium films were prepared by the SPC process and their grain sizes were obtained by analyzing images from transmission electron microscope. The results clearly show the thickness dependence of the grain size. We successfully reproduced the experimental trend using phase-field simulation. The densities of heterogeneous and homogeneous nuclei, which are main model parameters, were calibrated to fit the experimental results because they are extremely difficult to measure in such thin films. The thickness dependence of the grain size can be explained by the difference between the growth velocity of 3D and 2D grains with the same radius. The grain size is much smaller than the film thickness in the initial stage of annealing where the grain is three-dimensional. Conversely, the grain size is much larger than the film thickness in the late stage of annealing where the grain is two-dimensional. Thinner films reach the 2D grain stage earlier, implying that the grain growth becomes slower at a smaller grain size. Our results may provide process engineers a good insight and our calibrated model can be utilized in the design of thin film process.

MT01.05.02

Exploring Indium Distribution and Phase Stability in Epitaxially Grown $In_xGa_{1-x}N$ with Machine Learning Potential *Jaehoon Kim[1], Youngho Kang[2] and Seungwu Han[1]; [1]Seoul National University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)*

There is a growing need for high-resolution displays that can support virtual and augmented reality (VR/AR) effects. Among various display technologies, microLEDs based on $In_xGa_{1-x}N$/GaN have emerged as promising technology owing to various appealing characteristics such as high brightness, high-energy efficiency, short response time, and good durability. In addition, unlike LCD displays, microLEDs can show broader variation in color and brightness from one pixel to another because they include individual light emitters and do not require a backlight. Despite many advantages, microLEDs still have several technical problems that should be resolved for actual realization. In particular, the internal quantum efficiency (IQE) decreases significantly below 60% with increasing indium concentration, hindering the development of green and red LEDs. Compositional fluctuations and structural inhomogeneities in $In_xGa_{1-x}N$ quantum wells have been suspected to be the cause of this efficiency reduction. However, the solubility of InN to GaN and cation distribution in $In_xGa_{1-x}N$ quantum wells have not been satisfactorily elucidated so far. Moreover, the impact of strain and temperature, which are important process conditions, on the material quality of $In_xGa_{1-x}N$ remains unverified.

In this presentation, we investigate the phase stability and spatial cation distribution for epitaxially grown $In_xGa_{1-x}N$ via neural network potential (NNP), which drastically accelerates molecular simulations compared to authoritative density functional theory calculations without losing accuracy. To this end, we develop a Behler-Parrinello type NNP using SIMPLE-NN package [1] for $In_xGa_{1-x}N$ and perform semi-grand canonical ensemble Monte Carlo simulations using thousands-atom supercells to determine equilibrium phases for various compositions and temperatures. Our results show that strain-free $In_xGa_{1-x}N$ has a wide miscibility gap even at high temperatures over 1000 K. On the other hand, compressive strains, applied to epitaxial $In_xGa_{1-x}N$ thin films in LEDs due to the lattice mismatch between $In_xGa_{1-x}N$ and the GaN substrate, make InN-GaN mixing thermodynamically favorable over a wide range of x. In epitaxial $In_xGa_{1-x}N$, indium atoms tend to be aligned along the c-axis of the wurtzite structure near x=1/3 at low temperatures (< 350 K), as this arrangement is advantageous in terms of internal energy. However, the ordering gradually disappears with an increase of temperature to increase configurational entropy. This implies that $In_xGa_{1-x}N$, which is equilibrated sufficiently during the growth process using chemical vapor depositions (T~1000 K), can exhibit uniform cation distribution. Our simulations also reveal that $In_xGa_{1-x}N$ phases can still form despite slight relaxation of the epitaxial strain, which may be too severe to avoid the creation of threading dislocations. This fact offers useful insights for strain engineering to achieve high-performance $In_xGa_{1-x}N$ microLEDs.

Phase Stability and Alloy Performance—The Role of CALPHAD and VASP in Fusion Power Material Development *Alexandra J. Montes[1], Myles Stapelberg[1,2], Sara Ferry[1,2], Kevin B. Woller[1,2] and Michael P. Short[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Plasma Science and Fusion Center, United States*

Fusion power plants are a top candidate for clean, renewable energy. However, the nature of the fusion process still holds many challenges including those pertaining to the materials being used for the power plants. Materials that can be used for fusion power plants are constantly in development. The materials need to be able to withstand the extreme heat present during the fusion process as well as the radiation damage that occurs as most tend to become too brittle or degrade quickly. Vanadium-chromium-titanium (V-Cr-Ti) alloys in particular have proven to be promising candidates due to the properties they exhibit. This study builds upon the framework *established by Samuel McAlpine in his work on predicting single-phase stability and segregation in alloys, confirming the robustness of simulation-based approaches for material property prediction [1]. This research investigates whether the Computation of Phase Diagrams (CALPHAD) and Vienna ab-initio Simulation Package (VASP) can accurately predict phase stability and thermomechanical properties for V-Cr-Ti alloys. The focus will be on alloys containing 85 at% vanadium (V85%), 92 at% V (V92%), and other highly concentrated alloys in the V-Cr-Ti space. These compositions serve as a validation step for our phase stability predictions prior to tackling V-Cr-Ti-W-Zr alloys in the future. Once our predictions are established we will move on to the V-Cr-Ti-W-Zr system as high alloyed vanadium alloys are likely to suffer from phase instability due to prevalence of Laves Phases between each element in our system [2]. Key findings include the identification of single-phase stability regions critical for ensuring the material's performance in fusion environments. These results validate the effectiveness of integrating CALPHAD and VASP simulations for the predictive modeling of alloy properties. For the broader scientific community, including the aerospace, energy, and nuclear communities, this research has direct implications on the design of concentrated alloys in the BCC refractory space. These findings provide a pathway for the systematic design and optimization of advanced materials, which supports the realization of efficient and durable fusion reactors. The integration of CALPHAD and VASP simulations proves to be a powerful tool in predicting phase stability and thermomechanical properties of V-Cr-Ti alloys, specifically V85% and V92%.*

From Specialist to Generalist Models: Boosting Microscopy Analysis in Materials AI *Stefan Sandfeld[1], Binh Duong Nguyen[1], Marc Legros[2] and Peter Wellmann[3]; [1]Forschungszentrum Jülich GmbH, Germany; [2]Centre National de la Recherche Scientifique, France; [3]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany*

The shift from specialist to generalist models marks a pivotal transformation in materials AI, redefining how we tackle complex challenges in microscopy analysis. Traditionally, specialist models are designed for narrowly focused tasks within specific domains, leveraging domain-specific knowledge and curated datasets to achieve high accuracy. While effective within these confines, such models are often limited in flexibility and scalability. In contrast, the emergence of foundation models - such as transformers - has unlocked new possibilities for generalist models that can address diverse tasks without extensive customization. This presentation delves into this evolution with a focus on electron microscopy. We first illustrate the strengths of specialist models in uncovering "invisible" information within microscopy images. For instance, we demonstrate how in-situ TEM, combined with specialist models, can automatically track dislocation dynamics, capturing the "jerky" motion of dislocations in high-entropy alloys, enabling detailed avalanche statistics. Transitioning towards generalist *approaches, we then explore self-supervised and unsupervised analysis, e.g., on HR-TEM datasets of nanoparticles, highlighting the potential for broad adaptability. Finally, we introduce the transformative promise of generalist foundation models in materials science. These models pave the way for breakthroughs in microscopy and beyond, offering unprecedented flexibility, scalability, and insights for next-generation materials discovery*

Active Learning of Microstructure-Property Relations in Hybrid Materials *Milica Todorović; University of Turku, Finland*

Hybrid organic/inorganic materials play an important role in electronic technologies, where their functional properties are critically determined by the atomistic arrangement between compounds. The interface microstructure can be explored with first principle simulations at considerable computational cost. This procedure can be accelerated with active learning algorithms, by sampling configurations on-the-fly in the search for optimal structures. We encoded such a probabilistic algorithm into the Bayesian Optimization Structure Search (BOSS) Python tool for materials optimisation [1]. BOSS relies on a statistical surrogate model of materials properties to make smart decisions on sampling relevant microstructures. This makes it an effective tool for global exploration of materials energy and property spaces.

We combined BO with first-principles simulations to learn global energy landscapes and perform atomistic structure search [1]. This facilitated studies of hybrid functional materials such as ligand-protected clusters [2], surface adsorbates [3], thin film growth [4] and solid-solid interfaces [5] with modest dataset sizes. We also applied BOSS to map the energetics and dynamics of structural fluctuations inside halide perovskite lattices, and related them to changes in functional properties [6]. With recent multi-objective and multi-fidelity implementations for active learning, BOSS can make use of different information sources to learn materials properties at considerably reduced computational costs.

Inverse Defect Design Using AI and Machine Learning *Subramanian Sankaranarayanan[1,2]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Chicago, United States*

Defect dynamics and design in materials are of central importance to a broad range of technologies from catalysis to energy storage systems to microelectronics. Material functionality depends strongly on the nature and organization of defects—their arrangements often involve intermediate or transient states that present a high barrier for transformation. The lack of knowledge of these intermediate states and the presence of this energy barrier presents a serious challenge for inverse defect design, especially for gradient-based approaches. Using representative nanoscale materials, we will discuss our work on addressing this challenge – this involves utilizing AI/ML algorithms, including symbolic regression, active and transfer learning, multi-objective evolutionary optimization, and reinforcement learning (RL). Mechanistic understanding of the dynamics and design of defective *materials can leverage such multi-fidelity models but often involve multi-objective, multi-dimensional search problems and learning domains that often have continuous search spaces. Conventional approaches rely on human intuition and metaheuristic searches, exhibiting issues like sluggish convergence and scalability concerns. Departing from traditional evolutionary, swarm, random sampling, and gradient-based methods, we will present our work on developing machine learning approaches to efficiently navigate high-dimensional search landscapes, significantly improving search quality, convergence speed, and scalability in material discovery and defect design.*

10:30 AM MT01.06.04
Predicting the Carbon Melting Line Under 100 GPa with the ChIMES Machine-Learned Interatomic Potential
Yanjun Lyu[1], Sorin Bastea[2], Sebastien Hamel[2] and Rebecca K. Lindsey[1]; [1]University of Michigan, United States; [2]Lawrence Livermore National Laboratory, United States

Investigating the carbon melt line is important in diverse research areas, including planetary science, detonation science, and high-throughput high T/P production of nanocarbon materials. Precise experimental determination of the carbon melt line is difficult since platforms capable of creating these conditions can only maintain them for very short timescales (e.g., < 1 μs), making characterization of ensuing temperature exceedingly difficult. As experiments are confronted with these challenges, simulations could help fill the gap. First principles methods have been used to predict the carbon melt line, but the high computational expense precludes their application to the relevant spatiotemporal. Others have attempted to overcome this limitation by using classical interatomic potentials. However, their underlying functional forms preclude accurate description of the intricate behavior of complex molten carbon phases. Recently, machine-learned interatomic potentials have emerged as an effective solution for closing the gap between the accuracy of first principles simulations and the efficiency of classical interatomic potentials. In this work, we have applied ChIMES, a physics-informed machine-learned interatomic potential, to revisit the prediction of the carbon melt line. We will present our melt line predictions and discuss our results within the context of available experimental data and prior simulation predictions. We will also discuss the evolving structures at the interface between solid and liquid phases of carbon.

10:45 AM MT01.06.06
Simulation and Modeling of Prompt Electrical Tree Formation During Dielectric Breakdown in Space-Charged Dielectrics *Thomas J. Montano[1,2], Carolyn Chun[1], Kathryn Sturge[1], Noah Hoppis[1], Ariana Bussio[1] and Timothy Koeth[1]; [1]University of Maryland, United States; [2]NASA Goddard Space Flight Center, United States*

This talk outlines the development and validation of a simulation model to depict nanosecond-scale electrical tree formation and discharge within a dielectric. Electrical treeing is a principal degradation mechanism in polymeric insulation materials that culminates in catastrophic failure in high-voltage equipment. Dielectric materials have advantageous insulating properties and are lightweight, making them useful in aerospace applications. However, the possibility of discharge failure due to electrical treeing poses a substantial risk and can lead to a shortened operational lifetime. This can lead to mission-critical malfunctions, jeopardizing not only expensive equipment but also the overall mission objectives and, in crewed missions, the safety of astronauts onboard. Due to this inherent increase in risk, more complex construction methods of antennas and electronics must be used, leading to increased mission costs. This motivates the development of a simulation environment that can characterize dielectric performance in radiation environments. The simulation results, including discharge current waveforms and electrical tree growth parameters, are compared to experimental results produced under identical conditions to the simulation. By implementing an RLC framework and pulse-forming network to model the electrical characteristics of the breakdown, the simulation produces results that qualitatively agree very well with the experiment. The model shows the promising predictive power of electrical treeing in space-charged dielectrics, essential for mitigating this detrimental effect in dielectrics in charged particle radiation environments, such as *satellites and spacecraft.*

"Accelerating Materials Solutions to Meet National and Global Challenges" Summary of the 2024 Workshop in Support of the Materials Genome Initiative (MGI) 2021 Strategic Plan *Lisa Friedersdorf[1], Cosima Boswell-Koller[2], James A. Warren[3], Charles Yang[4] and Benji Maruyama[5]; [1]White House Office of Science and Technology Policy, United States; [2]National Science Foundation—Division of Materials Research, United States; [3]National Institute of Standards and Technology, United States; [4]U.S. Department of Energy, United States; [5]Air Force Research Laboratory, United States*

The Materials Genome Initiative Subcommittee on Autonomous Materials Innovation Infrastructure (AMII) held a workshop in May 2024 with 80+ participants across academia, industry, and over 15 Federal Agencies for "Accelerating Materials Solutions to Meet National and Global Challenges," in support of the Materials Genome Initiative (MGI) 2021 Strategic Plan.

Over the first decade of the MGI, significant attention has been paid to the ever-increasing predictive power of materials models and their role in accelerating materials design. Now, profound changes are being realized to further accelerate materials experimentation (both synthesis and characterization) through human-enhanced artificial intelligence, integration of modeling & simulation, and application of robotics via autonomous experimentation.

Building on a series of prior federal government-sponsored workshops, this workshop focused on: The current infrastructure landscape for accelerated materials experimentation within the context of the broader Materials Innovation Infrastructure (MII), framing of National and Global Challenges, and identifying gaps in the AMII that must be filled to achieve the goals and targets.

SESSION MT02.01: AI for Microscopy and Spectroscopy I

Beyond the Hype—Navigating the Promise and Pitfalls of Multi-Modal Models for Materials Science *Steven R. Spurgeon; National Renewable Energy Laboratory, United States*

Multi-modal models offer great potential for accelerating discovery in materials and chemical systems, but their adoption raises crucial questions: What materials science challenges are best addressed by multi-modal approaches? How do we weigh the benefits against the resource investment required for multi-modal data acquisition? And critically, how can we optimize experimental workflows to leverage these models effectively? In this presentation, I will delve into the development of multi-modal characterization and analytics, focusing on their application in the demanding fields of next-generation microelectronics and energy storage materials. I will share challenges encountered in designing these workflows, highlighting lessons learned and posing questions that *remain unanswered.*

11:00 AM MT02.01.02

Integrating Chemical Insights and Experimental Parameters into Deep Learning Models Through Feature Engineering for Scanning Transmission Electron Microscopy Data *Jiadong Dan[1], Cheng Zhang[2] and N. Duane Loh[1]; [1]National University of Singapore, Singapore; [2]City University of Hong Kong, China*

Automatic and high-throughput defect identification from scanning transmission electron microscopy (STEM) is crucial for establishing the structure-property relationships in materials. Identifying point defects in monolayer transition metal dichalcogenides (TMDs) is particularly challenging, as existing models often focus on a limited number of samples with distinct contrast features in their atomic columns.

In this study, we discovered that relying solely on imaging data, even advanced deep learning models struggle to accurately identify point defects. To address this limitation, we integrated chemical insights and experimental parameters into our Zernike feature encoder. This integration of domain-specific knowledge enables the classification of point defects across all 1H monolayer TMDs.

Our findings also reveal that with appropriate feature engineering, simple deep learning models like multi-layer perceptrons (MLPs) can achieve high accuracy in defect identification. This research has the potential to significantly expand current automated experimental workflows to a wider range of materials, enhancing the efficiency and scope of defect identification in various material systems.

11:15 AM MT02.01.03

Real-Time Machine Learning Aided Feature Characterization in Scanning Transmission Electron Microscopy (STEM) Images of MoS_2 *Zijie Wu, Matthew G. Boebinger, Kevin Roccapriore and Rama K. Vasudevan; Oak Ridge National Laboratory, United States*

This abstract has been authored by UT-Battelle, LLC, under contract DE-AC05-00OR22725 with the US Department of Energy (DOE). The US government retains and the publisher, by accepting the article for publication, acknowledges that the US government retains a nonexclusive, paid-up, irrevocable, worldwide license to publish or reproduce the published form of this manuscript, or allow others to do so, for US government purposes. DOE will provide public access to these results of federally sponsored research in accordance with the DOE Public Access Plan (http://energy.gov/downloads/doe-public-access-plan).
Recent advances in application of machine learning techniques towards materials science has attracted significant interest in autonomous experiments (AE) on microscopy. However, the incorporation of AE in microscopy often requires fast and automated identification of features/regions of interest and subsequent operations on these features/regions. In this talk, using monolayer MoS_2 as the material of example, we showcase a machine learning-based, automated workflow of atomic feature identifications and structural manipulations via electron beam irradiation on scanning transmission electron microscopes (STEM). Based on High-Angle Annular Dark Field (HAADF) image of MoS_2 acquired real-time on STEM, we first use convolutional neural networks (CNN) trained from the Ensemble Learning Iterative Training (ELIT) approach to identify locations of atoms. We then apply graph-based encoders to classify elements, anomalies, defects, and nanostructures, which allows the final step of atomic fabrications with precise beam control on or near desired atoms and nanostructures. Through this example, we show how machine learning techniques can be combined with advanced instrument control and domain knowledge to create automated, real-time, and customized STEM workflow that is efficient and intelligent.
Microscopy research was performed at the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory, which is a US Department of Energy (DOE), Office of Science User Facility.

11:30 AM *MT02.01.04

Deep Learning and Generative Networks for Atom-by-Atom Electron Microscopy on Million Atom Scales

Chia-Hao Lee[1,2], Abid Khan[1], Rahim Raja[1], David Ding[1], Kieran Loehr[1], Bryan Clark[1] and Pinshane Y. Huang[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Cornell University, United States

Machine learning (ML) techniques are catalyzing an era of data-driven materials research, enabling new possibilities such as autonomous collection and processing of massive, atomic resolution electron microscopy data sets on the scale of millions or even hundreds of millions of atoms. However, developing ML models that can reliably handle new or changing experimental conditions in such large data sets remains challenging. We address this challenge by developing a cycle generative adversarial network (CycleGAN) for generating realistic simulated Scanning Transmission Electron Microscopy (STEM) images. The CycleGAN includes a novel reciprocal space discriminator, which learns the complicated, low and high spatial frequency information from experimental data and transfers this information to simulated images. We demonstrate that this CycleGAN can convert easily-generated, but unrealistic, simulated data into realistic images that are nearly indistinguishable from experiment. Such images are valuable because they represent a new method to rapidly generate labeled, experimentally realistic training data for ML-based image analysis—thereby addressing a major barrier that has previously limited the accuracy, ease-of-use, and generalizability of ML in materials characterization. These results represent an important step towards autonomous, large-scale data collection and processing of materials characterization data.

SESSION MT02.02: AI for Microscopy and Spectroscopy II

Machine Learning for Understanding Microstructures and Morphologies from Materials for Ionomer-Based Water Electrolysis

Daniela Ushizima[1], Shannon Boettcher[1,2], Ethan Crumlin[1,1], Julie Fornaciari[1], Ahmet Kusoglu[1], David Prendergast[1], Iryna Zenyuk[3] and Adam Weber[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]University of California, Irvine, United States

Integrating experimental data and simulations is critical for advancing data-driven algorithms based on machine learning to create new applications that describe material behaviors. Our research focuses on two main objectives: investigating microstructures from experimental data and enhancing the connection to simulation models for ionomer-based water electrolysis. By examining the intricate morphologies of materials, this work aims to bridge the gap between experimental observations and computational predictions, moving towards a digital twin. Current research at Berkeley Lab includes establishing baselines for interfacial studies in ionomers, examining interfaces in both acidic (e.g., proton-exchange, Nafion) and alkaline environments. Evaluating catalysts is a key consideration, focusing on iridium for the cathode while exploring less costly alternatives. Material formulation involves inspecting catalyst ink, comprising polymer ionomer, nanoparticles, and other components. Imaging and analysis opportunities include monitoring structural changes at material interfaces due to contact with adjacent materials and assessing degradation issues like ionomer decomposition influenced by potential. Our understanding of the length and timescales of experimental data, alongside detailed knowledge of surface

structure, chemistry, and morphology, depends upon using state-of-the-art computer vision (e.g. CNN, vision transformers and hybrids) and natural language processing (e.g. large language models for topic modeling) techniques. Modeling and predicting material properties from microstructures to macroscopic behaviors is essential for designing and/or verifying simulation algorithms that interpret complex data and adapt to various scales, from atomic-level interactions to visible surface patterns. Bringing simulation data to empirical observations in a unity of theory and experiments to interrogate and interpret experiments requires advanced imaging techniques to optimize promising designs. This integration is also vital when using electron and X-ray spectroscopic and imaging data for material characterization. For example, understanding how electrochemical reactions at the electrode-electrolyte interface modify surfaces can significantly influence models. Current investigations about porous transport layer (PTL)-membrane interactions and their deformation monitored in situ using microCT highlight the importance of detailed morphological studies using multimodal information for resolving these soft-hard interfaces for improved function. By focusing on the length and timescales of materials and respective structures, this research seeks to improve the accuracy of models and material predictions. This approach enriches characterization algorithms, enabling them to interpret complex data more effectively and adapt to various scales. This synergy will refine existing computational representations and help pioneer new models capable of predicting the behavior of complex materials. Presenting this work at the Symposium MT02: Machine Learning in Action—Automated and Autonomous Experiments aims to contribute to the dialogue on the potential of machine learning in material science and engineering. This work was supported by the U.S. Department of Energy, Office of Science Energy Earthshot Initiative, as part of the Center for Ionomer-based Water Electrolysis under contract/grant #DE-AC02-05CH11231.

2:00 PM MT02.02.02
Machine Learning Interpretation of Optical Spectroscopy Using Peak-Enhanced Logistic Regression *Ziyang Wang[1], Jeewan Ranasinghe[1], Dennis C. Chan[2], Ashley Gomm[3], Rudolph Tanzi[3], Can Zhang[3], Nanyin Zhang[2], Genevera Allen[1] and Shengxi Huang[1]; [1]Rice University, United States; [2]The Pennsylvania State University, United States; [3]Massachusetts General Hospital, United States*

Optical spectroscopy, a non-invasive molecular sensing technique, offers valuable insights into analyte composition, leading to advancements in material characterization, chemical identification, and disease diagnosis. Despite the informativeness, precision, and versatility inherent in high-dimensional optical spectra, their interpretation remains challenging. Machine learning methods have gained prominence in spectral analyses, efficiently unveiling analyte compositions. While achieving remarkable classification accuracy, these methods still face challenges in interpretability due to a lack of optimization for spectroscopy, large feature noise, and model complexity.

In this context, we introduce a machine learning algorithm—logistic regression with peak-enhanced regularization (PE-LR)—tailored for spectral analysis. PE-LR demonstrates superior performance in both classification and interpretability, achieving an F1-score of 0.95 and a feature sensitivity of 1.0. This outperforms other methods such as elastic net logistic regression (E-LR), support vector machine (SVM), XGBoost, and principal component analysis followed by linear discriminate analysis (PCA-LDA).

Our work highlights PE-LR as a robust tool for advancing the field of spectral analysis, offering enhanced interpretability and classification accuracy essential for studying complex analytes. Applying PE-LR to Raman spectra of Alzheimer's disease (AD) brain slices and healthy controls, we successfully identified AD brains and discerned spectral peaks distinguishing AD samples from healthy ones, suggesting potential disease biomarkers. Our findings underscore PE-LR's potency and promise in spectral analysis, with the capability to detect subtle spectral features and deliver precise, informative interpretations. Moreover, its adaptability extends seamlessly to other spectroscopic methods, including nuclear magnetic resonance (NMR), mass, and electron spin resonance (ESR) spectroscopy.

2:15 PM MT02.02.03

Atomic Lock-On—Quantitative Electron Beam-Matter Interactions at the Single Atom Level Enabled by Picometer Precision Beam Control *Kevin Roccapriore[1], Frances M. Ross[2] and Julian Klein[2]; [1]Oak Ridge National Laboratory, United States; [2]Massachusetts Institute of Technology, United States*

Aberration corrected scanning transmission electron microscopy (STEM) is unmatched for high-resolution imaging and correlative analytical studies down to an individual atom. The sub-Angström focused electron probe is raster scanned, collecting various detector signals in a pixel-by-pixel manner. However, images exhibit unavoidable sample drift and scan distortions due to mechanical and electronic instabilities. While post-processing may correct these distortions, the ability to reliably position the electron probe on a desired atomic site without imparting dose to the surrounding regions has remained out of reach. Moreover, many in situ applications would benefit from undistorted atomic lattice information and dynamic probe placement at specific atomic targets. This ability would enable repeated atomic, site-selective spectroscopic measurements or precise structural modifications such as deterministic defect generation.
In this talk, we describe "atomic lock-on," an in situ electron beam control algorithm for rapid, minimally invasive, and picometer-precise beam placement [1, 2]. Using a sparse annular scan pattern, which reduces scan distortions, we mathematically reconstruct atomic lattice information from the high angular annular dark-field (HAADF) detector data. Optimizing annular scan parameters, we apply this method to a thick sample (13 nm) of CrSBr [3] achieving a consistent targeting precision of sub-20 pm. The approach avoids exposing the area of interest and demonstrates robustness in low-dose environments, as further demonstrated with a monolayer (< 1 nm thin) of MoS_2 and WS_2. The total execution time, including scan and correction, is under 100 ms, significantly faster than typically relevant specimen drift rates. The high targeting precision and speed make the approach suitable for various in situ experiments. We therefore integrate atomic lock-on into custom-designed automated experimental workflows. We repeatedly track and measure the weak core-loss electron energy loss spectroscopic (EELS) signal of a single V dopant in MoS_2. Moreover, we place the electron beam on different atomic sites in WS_2 to study single atom kinetics and observe ejection, recapture and atomic bistability behavior with sub-millisecond time resolution. Atomic lock-on fills a critical gap in the STEM repertoire, enabling unique high-precision experiments and improved studies of beam-matter interactions.

2:30 PM MT02.02.04

Multi-Modal Active Learning for Dye-Surfactant Solutions—Utilizing SANS and UV-vis to Explore Complex Formulation Spaces *Duncan Sutherland[1,2,3], Tyler Martin[1] and Peter Beaucage[1]; [1]National Institute of Standards and Technology, United States; [2]University of Colorado Boulder, United States; [3]Cornell University, United States*

The desire for greener formulations, safer products, and cost efficient re-design is at the heart of many industries, whether it is removing PFAS, breaking down toxic byproducts, or using environmentally friendly substitutes. Often, promising alternatives lack the research backing of an established process, and unforeseen side effects from the large number of components delay or prohibit reformulation. Surfactant-azo dye systems are a relevant example where chemical functionality of the dye dramatically impacts the efficacy of a surfactant to trap and solubilize it. Additionally, efficient surfactants like Triton-X series are known mutagens but still widely used because they have a *low CMC threshold and high dye solubility. Modifying the chemical space, by changing dye functionality, adding a hydrocarbon cargo, and modifying the pH all impact the onset of surfactant micelle formation and shape, and dye solubility. The autonomous formulation lab (AFL) is a uniquely suited solution mixing and testing platform capable of searching the complex spaces. We utilize efficient autonomous experimentation for solution design of both Triton-X 100 and Tergitol surfactants with various azo dyes, hydrocarbon cargos, solution pH, and an additional ionic surfactant. These active learning (AL) campaigns are driven by small angle neutron scattering for solution structure and UV-vis spectroscopy to analyze dye solubilization for both optimization and structure exploration.*

2:45 PM MT02.02.05

Quick Analysis and Adaptive Mapping of Micro-Beam X-Ray Diffraction Through Machine Learning *Kentaro Kutsukake[1,2], Kota Matsui[1], Ichiro Takeuchi[1,2], Takashi Segi[3], Takuo Sasaki[4], Seiji Fujikawa[4] and Masamitu Takahasi[4]; [1]Nagoya University, Japan; [2]RIKEN, Japan; [3]Kobelco Research Institute, Inc., Japan; [4]National Institute for Quantum Science and Technology, Japan*

X-ray diffraction is one of the crucial characterization methods for the materials. The measured data of X-ray diffraction patterns recently have become highly complicated, and the number and size of datasets have increased thanks to the technological developments of optical systems and detectors. The analysis of such complex 'big data' is not always straightforward.

In this study, we first employed unsupervised machine learning to analyze numerous complex X-ray diffraction patterns using feature patterns derived from the data. Our study focused on a crystalline SiGe film on a Si substrate with spatial variations in both composition and crystal orientation, resulting in intricate multipeak diffraction patterns. Non-negative Matrix Factorization (NMF), a method in unsupervised machine learning, was applied to 961 patterns obtained via spatial mapping from micro-beam X-ray diffraction measurements. NMF provided four feature patterns that corresponded to typical SiGe film diffraction patterns, capturing variations in Si composition and crystal orientations. Using the four feature patterns, the relative Si composition and crystal orientation were evaluated in less than 1 s without time-consuming numerical fittings.

In the second step, we implemented Bayesian optimization (BO) and active learning (AL) for level set estimation (LSE) to the spatial mapping of micro-beam X-ray diffraction with NMF analysis. The BO found characteristic points with large crystallographic inclinations, and the AL-LSE revealed the spatial size and shape complexity of the fluctuation. These results demonstrate that the mapping system and algorithms work as designed. The performance of the BO and AL-LSE was evaluated and compared to conventional mesh grid mapping. The results show that both methods are effective in reducing the number of measurement points

The combination of NMF for the feature pattern extraction and BO and AL-LSE for the adaptive mapping showcased in this study promises efficient analysis of numerous X-ray diffraction patterns exhibiting extensive and intricate fluctuations.

Mastering Compositional Complexity in Materials for Energy Applications—Accelerated Materials Discovery by Integration of High-Throughput Experimentation, Simulation and Materials Informatics

Alfred Ludwig; Ruhr-Universität Bochum, Germany

Discovery of new materials is a key challenge in materials science. New materials for sustainable production/storage/conversion of energy carriers are necessary to improve existing and to enable future energy systems. Compositionally complex materials, frequently called high entropy materials, offer a vast multidimensional search space, which provides opportunities for discovering new materials. However, efficient methods for the exploration and exploitation of this search space are necessary. Here, the integration of high-throughput thin-film combinatorial materials science methods with simulation and materials informatics (1) is presented as an effective means to produce large datasets on new materials, which enables mastering of the search space. The approach combines theoretical predictions from high-throughput computations with production of large, consistent and complete experimental datasets, which are used for materials informatics. Thin-film materials libraries are fabricated by combinatorial sputter deposition and optional post-deposition treatments, followed by high-throughput characterization, and finally the organization of the acquired multi-dimensional data in adequate databases as well their effective computational analysis and visualization, e.g., of quinary systems in the form of composition-processing-structure-function diagrams, interlinking compositional data with structural and functional properties. The talk will discuss examples of combinatorial discoveries (2, 3) and the targeted development of new compositionally complex materials for electrocatalysis (4) where compositional complexity offers a new design principle (5). This includes also a new type of microscale thin film materials libraries (6). Furthermore, a new approach (7) to accelerate atomic-scale measurements for complex alloys is presented as well as applications of materials informatics to accelerate and improve the materials discovery process (8, 9).

High Throughput Rheology and Calorimetry of Reactive Resins Using Machine Learning Inference *Ignacio Arretche[1], Qibang Liu[1], Javier Balta[1], Connor Armstrong[1], Tanver Hossain[1], Jacob Lessard[2], Ramdas Tiwari[1], Michael Zakoworotny[1], Mya Berkey[1], Abbie Kim[1], Philippe Geubelle[1], Jeffrey S. Moore[1], Nancy R. Sottos[1], Randy Ewoldt[1] and Sameh Tawfick[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]The University of Utah, United States*

During frontal ring-opening metathesis polymerization (FROMP), a polymerization front propagates spatially, driven by its exothermic heat of reaction. Only a small amount of energy is required for polymerization, thus offering a route to energy-efficient polymer manufacturing. Furthermore, recent studies have shown such highly efficient thermosetting polymers can be deconstructed or even repossessed. The low environmental footprint of these materials both in terms of energy consumption and reusability make FROMP an attractive manufacturing method for casting and direct ink writing of polymeric materials.

The chemistry space of resins which support a frontal curing reaction is extensive given the vast number of monomers, initiators, and inhibitors that can be used to undergo FROMP. Although a few different monomers and formulations have been characterized, these spaces remain rather unexplored. Our work here aims to enable high throughput characterization of new resin formulations through two modules that can be easily integrated into a robotic lab setup. The first module aims to infer the viscosity evolution of the resins due to their background reactivity. This module uses the concept of protorheology, i.e. inference of rheological properties from nonuniform flow fields, to identify the time windows where these resins can be used for casting or direct ink writing. A series of vials filled with resin are flipped every 10 minutes and videos of the flow are recorded with an optical camera. A convolutional neural network trained with videos of fluids of known viscosity infers the viscosity of the samples from the recorded videos. The evolution of the resins' viscosity is then tracked as a function of time to find the workable pot life. Although not as accurate as rheometers, this module can test several samples at once and can be simply integrated with a robotic arm. The second module aims to infer front speeds, thermal properties, and reaction kinetics. The module thermally initiates an array of 8 fronts in parallel. We measure the spatiotemporal temperature field during the reaction using an IR camera and the energy input with heat flux sensors. We use heat flux data, image analysis, and different regression models to calculate front velocities and infer thermal conductivity, specific heat, and heat of reaction of the resins. This is 30 to 100 times faster than differential scanning calorimetry, at a lower accuracy. We hope that the future integration of these modules into a robotic lab accelerates the material discovery to enable higher manufacturing efficiency, better reusability, and longer storage times of these promising polymeric systems.

4:15 PM MT02.03.03

Designing a MAP for Discovery of Solid Polymer Electrolytes *Pablo Quijano Velasco[1], Chang Jie Leong[1], Eleen H. Koay[1], Hazel X. Lau[1], Kedar Hippalgaonkar[2,1] and Jayce J. Cheng[1]; [1]Institute of Materials Research and Engineering, Singapore; [2]Nanyang Technological University, Singapore*

Materials Accelerated Platforms (MAPs) relying on high-throughput automated laboratory equipment can produce the large amounts of high-quality data needed to reap the benefits of data-hungry machine learning algorithms to reduce the time required to discover and optimize the properties of novel materials. To build a MAP, manual workflows are automated by integrating hardware and software that can execute the tasks normally performed by a scientist at each step of the material development process[1]. The challenges of integrating automatic synthesis, fabrication and characterization equipment increase substantially with each additional target property measurement. For this reason, using the right strategies to seamlessly interface different synthesis and characterization equipment is key to create successful workflows. Here, we describe heuristics used in designing Pescador a MAP for the development and discovery of polymer electrolytes for electrochemical energy storage with the goal to optimize mechanical and electrochemical properties for structural battery applications.

In this talk we will cover how we use an object-oriented hardware approach to design automated equipment and labware that ensure seamless conversion from manual to automated lab workflows. Our approach uses multiscale modularity in sample, array, and equipment to ensure agility and flexibility in our workflows. Pescador is built by integrating Qubots, which are spatially and temporally deconflicted Cartesian robots in the workspace capable to perform a specific set of tasks in the materials development process (e.g. formulation, synthesis, characterization). Each of the tasks performed by the Qubots are orchestrated using control-lab-ly, an in-house developed code library that allows seamless integration of hardware and execution of workflows in different platforms with minimal editions. This approach allows us to interface automated stations that perform each step of polymer electrolyte development including accurate and fast viscous liquid handling for the electrolyte formulation, reaction stage for UV photocuring, and testing stages for mechanical and electrochemical characterization.

Accelerating the Development of Semiconductor Thin Films Through Combinatorial Deposition and Advanced Automated Characterization *Sebastian Siol; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland*

The discovery of new functional materials remains a key challenge in the development of next-generation sustainable technologies. Fueled by advances in high-throughput computation, new exciting materials are being predicted at an ever-increasing rate. Combinatorial high-throughput materials science techniques hold the promise to match this rate by facilitating the rapid exploration of complex phase spaces. Today, combinatorial materials science workflows are employed in many laboratories around the world. While gradient deposition of combinatorial thin-film libraries can be implemented in most standard deposition equipment, a comprehensive toolbox for rapid materials characterization, which is just as crucial, is often harder to realize. In this presentation, it will be shown how accelerated thin-film materials development is performed in the Coating Technologies group at Empa. We employ a workflow consisting of reactive combinatorial physical vapor deposition, automated characterization and semi-automated data analysis, which covers most common thin-film characterization techniques as well as functional property mapping. In recent years, we extended this infrastructure to include high-throughput surface analysis, but also optical measurement setups for accelerated aging studies. This extension not only complements the existing workflows, but provides additional insights that were previously much harder to obtain. It will be shown how surface analysis mapping can facilitate the discovery of new semiconductor materials in complex phase spaces, such as wide band gap nitride semiconductors.[1-3] In addition, it will be shown how accelerated optical aging studies combined with machine-learning assisted data analysis can generate insights into the operational stability and degradation kinetics of more volatile materials.[4] The results presented here showcase the potential of integrating advanced characterization techniques into high-throughput materials science workflows for the rapid development of new functional materials.

SESSION MT02.04: AI for Halide Perovskite Discovery and Characterization
Session Chairs: Andi Barbour and Yongtao Liu
Tuesday Morning, December 3, 2024
Hynes, Level 2, Room 209

8:15 AM *MT02.04.01

Merging High-Throughput Autonomous Experiments and Machine Learning Supercharge Discovery of Two-Dimensional Halide Perovskites *Jonghee Yang[1], Yongtao Liu[2], Sheryl L. Sanchez[3], Elham Foadian[3], Addis Fuhr[2], Sergei V. Kalinin[3], Bobby G. Sumpter[2] and Mahshid Ahmadi[3]; [1]Yonsei University, Korea (the Democratic People's Republic of); [2]Oak Ridge National Laboratory, United States; [3]The University of Tennessee, Knoxville, United States*

Two-dimensional halide perovskites (HPs) combine the richness of physical functionalities of inorganic materials and complexity of organic molecules (spacer cations) in a single dynamic material. However, discovery and optimization of these materials require joint optimization of the composition of the inorganic components and selection of the molecular moieties, to harness the phase formation and self-assembly processes on the material level, and extend it to micro- and macroscale functional devices[1].

In this talk, I will discuss the potential of high throughput automated experiments to expedite the discovery of 2D and quasi 2D halide perovskites (HPs), optimize processing pathways, and enhance understanding of formation kinetics[2,3]. This approach requires maximal acceleration of the synthesis-characterization-prediction cycle, enabled by the incorporation of rapid characterization and machine learning (ML) methods in the discovery loop. In many cases, the intrinsic latencies of theoretical modeling for sufficiently complex systems favor the experiment-first discovery approach. I will showcase how high throughput automated synthesis and characterization provides a comprehensive guide for designing optimal precursor stoichiometry to achieve functional quasi-2D perovskite phases in films capable of realizing high-performance optoelectronics[2,3]. With excellent agreement between theoretical and experimental observations, I show that with judicious selection of spacer cations, 2D HP can manifest self-assembly of twisted Moire structure, which has not been observed from conventional 2D HP systems with linear spacers[4]. These studies exemplify how merging high-throughput automated experimental workflow and ML effectively expedites discoveries and processing optimizations in complex materials systems with multiple functionalities, facilitating their realization in scalable optoelectronic manufacturing processes[5].

Smart Manufacturing of Metal Halide Perovskite Nanocrystals Enabled by an Intelligent Multi-Robotic Platform

Jinge Xu, Fazel Bateni, Chrisropher H. Moran and Milad Abolhasani; North Carolina State University, United States

Metal Halide Perovskite (MHP) quantum dots (QDs) have shown great potential for energy and display applications, due to its unique optical characteristics that can be accurately tailored by adjusting their shape, size, and composition(1). The surface ligation, which depends on an acid-base equilibrium reaction, can not only enhance the colloidal stability but also mediate the optical characteristics of MHP QDs(2). Utilizing diverse carboxylic acids as surface capping ligands leads to different growth mechanisms and thus diverse QD morphologies. Besides the surface ligand influence, the optical properties of MHP QDs are also strongly impacted by the processing conditions, including the precursor concentrations during synthesis and anion exchange reactions that facilitate swift and precise control of nanocrystal composition, enabling band gap engineering and extending the emission range across the entire visible spectrum(3). As a result, the optical characteristics of MHP QDs are profoundly influenced by both the ligand structure (a discrete parameter) and the reaction conditions (continuous parameters). The expansive and multidimensional nature of this parameter space presents a substantial challenge for comprehensive and effective exploration of the manufacturing conditions for MHP QDs to achieve optimal optoelectronic properties.

Conventional synthesis strategies for MHP QDs often rely on manual flask-based techniques that are time-intensive, material-intensive, and laborious. Traditional methods may struggle to elucidate the intricate interdependencies of reaction and processing parameters in colloidal QD synthesis—hindering the discovery of optimal formulations, limiting our understanding of underlying mechanisms, and inspiring the creation of more efficient investigative techniques(4).

In this work, we have developed a multi-robot, self-driving lab (SDL) aimed at accelerating synthesis studies of room temperature-synthesized and halide exchange–modified MHP QDs. This SDL facilitates the systematic, automatic, and efficient investigation of how ligand structure and precursor concentrations impact the bandgaps, photon-conversion efficiency, and nanocrystal size uniformity of MHP QDs. Subsequently, we used the multi-robot SDL to autonomously map the Pareto front of the optical properties for various target bandgaps of MHP QDs.

We addressed the challenges of traditional applied and fundamental MHP QD research by exploring the science and engineering of a multi-robot, intelligent experimentation platform. We developed a closed-loop MHP QD manufacturing strategy by combining this intelligent platform with Machine Learning modeling and Bayesian Optimization for experiment planning. The SDL expedited the mapping of the ligand structures and processing conditions to the optical properties of MHP QDs—enhancing our understanding of how ligand structure can impact the shape, morphology, and optical properties of MHP QDs. The knowledge generated by the SDL furthers our ability to conduct the on-demand synthesis of MHP QDs with optimized optical properties, paving the way for the advancement of future energy and display technologies .

Machine Learning Toolkit for Automatic Quantification of Perovskite Microstructural Characteristics *Yalan Zhang and Yuanyuan Alvin Zhou; The Hong Kong University of Science and Technology, Hong Kong*

Metal halide perovskites (MHPs), especially perovskite solar cells (PSCs), have emerged as a focal point of due to their favorable optoelectronic properties and photovoltaic (PV) performance. While the commercialization of PSCs still requires the field to overcome a few key challenges including the relatively low stability and processing reproducibility. Artificial intelligence (AI) and machine learning (ML) methods have been examined as transformative tools in the frontier of material science. And in recent years, many AI-assisted studies including automatic synthesis, automatic characterization, and close-loop experiment optimization have attracted lots of attention in the field of perovskite, for their potential to accelerate the development of MHPs and PSCs. While for the large number of experiment results generated, they still lack efficient methods to analyze and extract useful information. Here, we developed a ML-based toolkit for extracting and quantifying microstructural characteristics of MHP from atomic force microscope, enabling a high-throughput and reliable statistical analysis. A convolutional neural network with U-Net structure was trained for grain region extraction, and multiple kinds of algorithms were designed for quantifying the microstructural characteristics including grain surface area, grain boundary groove angles, groove width, grain surface depression and bulge. Based on this toolkit, we then expanded the study from localized measurement to their statistical distribution over the whole film, and reveal their correlation with the perovskite solar cells performance. This work presents a methodology on automatic analysis of microscope images, especially the information transfer from 2D images to 1D quantified variables. This methodology puts one step closer to fully self-driven laboratory and could be further applied to other kinds of materials.

9:15 AM MT02.04.04
Systematic Engineering of Perovskite Solar Cells Through Algorithm-Guided Experimentation *Donghyun Oh, Sanggyun Kim, Carlo Andrea Riccardo Perini, Juan-Pablo Correa-Baena and Nikolaos Sahinidis; Georgia Institute of Technology, United States*

Perovskite Solar Cells (PSCs) have great potential for clean power generation. However, research that focuses on high-performance PSC optimization remains challenging due to a lack of systematic approaches for optimizing various design parameters. In particular, understanding the discrete impacts of material composition and fabrication processing parameters on device performance is intricate, and their interconnectedness further complicates the discovery of optimal designs in a vast design space. In this work, we present a combined experimental-computational framework to systematically enhance the photovoltaic performance of PSCs. By employing black-box optimization algorithms, our framework guides the sampling of the design space to search for optimal designs. We then fabricate devices based on this algorithm-guided experimental design and test them under illumination to validate and refine the optimization process. The results show notable performance enhancements with power conversion efficiencies exceeding 23%, which demonstrate an effective combination of mathematical optimization and experimental research. Additionally, we utilize advanced characterization techniques in our analysis to enhance the comprehension of the underlying science as well as the key factors that contribute to achieving high performance.

9:30 AM MT02.04.05

Accelerating Bandgap Discovery in Hybrid Perovskites with Advanced Modeling Techniques *Sheryl L. Sanchez[1], Elham Foadian[1], Maxim Ziatdinov[2], Jonghee Yang[1], Sergei V. Kalinin[1], Yongtao Liu[3] and Mahshid Ahmadi[1]; [1]The University of Tennessee, Knoxville, United States; [2]Pacific Northwest National Laboratory, United States; [3]Oak Ridge National Laboratory, United States*

Hybrid perovskites are remarkable for their ability to be tuned to different bandgaps, which is crucial for creating highly efficient tandem solar cells. However, the relationship between the composition and the optical bandgap in these materials can be complex and unpredictable [1]. This makes it challenging to find the right composition that offers the desired bandgap properties. Our research introduces a novel experimental workflow using advanced Gaussian Process (GP) models to tackle this problem [2]. By applying structured and custom GP models, we can simultaneously discover new material behaviors and understand the underlying physical principles more efficiently [3]. This method has been validated with simulated datasets, showing that it significantly speeds up the discovery process. Specifically, our approach uses a few initial data points to guide further experiments, reducing the number of necessary preparations. We demonstrated that this iterative method quickly identifies the bandgap characteristics of $MA_{1-x}GA_xPb(I_{1-x}Br_x)_3$*., revealing important relationships in the bandgap diagram. This innovative approach not only simplifies the discovery process for binary systems but can also be extended to more complex material systems, offering a powerful tool for advancing perovskite research.*

9:45 AM MT02.04.06

Resource-Efficient Autonomous Lab for Multi-Objective Optimization of Mixed Halide Perovskite Nanocrystals *Nikolai Mukhin, Fernando Delgado-Licona, Sina Sadeghi, Jinge Xu and Milad Abolhasani; North Carolina State University, United States*

Metal halide perovskite (MHP) nanocrystals (NCs), conventionally pursued through time- and labor-intensive manual batch experimentation have shown significant potential to innovate in areas such as displays, LEDs, and solar cells. Despite their promising capabilities, the fast formation kinetics of MHP NCs have shown to cause variability in synthesis of MHP NCs in manual batch experiments. Continuous flow chemistry has shown to adapt well to their fast formation kinetics, and can even reduce the time and labor required for numerous experiments. Additionally, continuous experimentation, in-situ characterization, and reaction miniaturization are easily available to flow chemistry producing a superior synthesis platform for analyzing the input parameters of MHP NCs [1]. Although continuous flow chemistry addresses the aforementioned challenges, it suffers from wasting material while the system is waiting for steady-state to be achieved.

Due to the immense experimental space of MHP NCs through their continuous (e.g., reaction temperature, reaction time) and discrete (e.g., different surface ligands and halide sources) parameters, an efficient way to conduct experiments to find the highest performing NCs is needed. Performing closed-loop experimentation integrating machine learning (ML)-guided experimentation with automated platforms known as self-driving labs (SDLs) has gained popularity in chemical and materials science [2]. MHP NCs have competing objectives:

maximizing photoluminescence quantum yield (PLQY) and minimizing full width at half maximum (FWHM) at target emission wavelengths. These competing goals necessitate multi-objective optimization to determine the optimal input conditions for high-performing MHP NCs.
In this work, we present a single-droplet fluidic platform that is able to synthesize mixed halide perovskite NCs using a 5 uL droplet per reaction condition. The single-droplet platform decreases material waste and time due to the decoupled precursor formulation and synthesis sections. After thoroughly characterizing, validating, and benchmarking the physical and digital components of the SDL, we utilize this advanced autonomous approach to perform multi-objective optimization of mixed halide MHP NCs. We then showcase the SDL's capability for autonomously selecting synthetic routes to high-performing MHP NCs, achieving the highest PLQY and lowest FWHM through closed-loop Pareto-front mapping across a broad UV-Vis spectrum range.

***Artificial Intelligence-Driven Prediction for Efficient CNT Growth Simulation** Junyoung Shin, Scott Kovaleski, Matthew Maschmann, Marshall Lindsay, Charlie Veal, Andy Varner, Connor Gunter and Derek Anderson; University of Missouri, United States*

Carbon nanotube (CNT) forests are comprised of vertically oriented CNTs frequently synthesized to hundreds of microns of length. Because of morphological imperfections and continuous CNT delamination during synthesis, the ensemble properties of CNT forests are often orders of magnitude less than what is predicted from the properties of individual CNTs. Concurrently, the parametric space for CNT forest synthesis is inexhaustible. In a conventional chemical vapor deposition synthesis, the parameter space includes combinations of catalyst film composition, catalyst buffer layer composition, growth temperature, carbon feedstock, water vapor concentration, pressure, carrier gas, among others. The conventional synthesis and characterization process is expensive and prone to error. Artificial Intelligence (AI) driven experimental exploration, as demonstrated by the AFRL Autonomous REsearch System (ARES), has demonstrated a drastic acceleration in determining fundamental single-walled CNT synthesis mechanisms. In this work, we explore machine learning predictions versus traditional Finite-Difference Time-Domain (FDTD) based simulations to expedite the numerical exploration process of CNT forests.
Simulating the growth and assembly of dense forest CNTs has been demonstrated using a time resolved finite

element simulation. The simulation considers distributed CNT growth rates, diameters, the interactions between contacting CNTs, and mechanical delamination of CNTs from the growth substrate. After CNT forest growth and assembly, the simulation may be used to simulate the mechanical, electrical, and thermal properties of the forest. The simulation is viewed as increasingly important for applications such as CNT interface materials, composite materials, and electron emitters. Because of the low cost and relative speed of simulations, the numerical approach may be a means to accelerate the search of process-structure-property relationships for custom applications. However, conventional methods become increasingly computationally expensive as CNT forest structures increase in length and complexity and may limit the application of numerical approaches.
To address this limitation, we present a custom recurrent neural network (RNN) pipeline for efficient CNT growth prediction. By leveraging time-varying data from past simulations, the proposed model incorporates growth positional information directly. In the computational synthesis of CNTs, two principal forces are critical - internal elastic forces within each CNT influence the direction and height of growth, and the external van der Waals force determines the attractions and repulsions between different CNTs. These forces inherently lead to the collective deformation of growing CNTs. Unlike traditional RNNs that consider static time evolving signals, the proposed method not only forecasts the growth of the CNTs but also considers changes in the forest structure due to internal CNT-CNT interactions. Compared to iterative physics-based simulations, this framework reduces computational costs, facilitating more efficient search of CNT growth parameters. While applied to CNT growth, the proposed method shows promise for a diverse range of growth phenomenon where underlying structures change during the growth process. This methodology demonstrates replacing computationally expensive iterative simulation with machine learning emulation.

10:45 AM MT02.05.02
Machine-Learning Driven Predictive 3D Ramified Foam Fabrication and Mechanistic Understanding *Yifei Liu and Donglei (Emma) Fan; The University of Texas at Austin, United States*

Hierarchical nanosuperstructures, ubiquitously found in nature, present dually enhanced mass transport and interfacial chemical reactions due to their unique 3D cascading features. Their man-made counterparts have demonstrated meritorious benefits towards electrocatalysis, flexible supercapacitors, and water disinfection. However, fabricating 3D superstructures with accurate structural characteristics remains exhaustive and challenging due to multiple variables in both experimental conditions and structural features. In this work, we explore three machine learning (ML) methods—linear regression, neural network regression, and Gaussian process regression—and, for the first time, realize accurate predictive fabrication of designed 3D microbranched foams using a small training dataset. Our findings demonstrate the advantageous accuracy of Gaussian process regression of over 87% across all benchmarks. We also effectively unravel the weighted roles of various experimental conditions, shedding light into the synthetic mechanisms. Overall, this work represents a new advance in the ML-enabled predictive fabrication of complex structures and materials with mechanistic elucidation.

11:00 AM MT02.05.03
Task Agnostic Model for Material Property Prediction Using Joint Embedding Predictive Architecture
Abhiroop Bhattacharya, Jaime Benavides-Guerrero and Sylvain G. Cloutier; École de Technologie Supérieure, Canada

Task-agnostic models (TAM) are a promising approach to develop machine learning models that are both accurate and computationally efficient. Despite the complexities involved in their development, TAMs have the potential of revolutionizing computational chemistry by implementing generalized representations capable to predict multiple material properties. This paper, introduces a self-supervised graph-based representation for material structures, *designed to be task-agnostic. We demonstrate that our representation, when combined with a linear model, is capable to predict a diverse set of properties. Our model's performance is benchmarked using the publicly available Materials Project dataset. Additionally, our findings reveal that the model learns representations with sufficient expressive power, suitable for both regression and classification tasks. We demonstrate the versatility of our proposed model by predicting the total energy of cubic perovskites and the formation defect energy of impure crystal. Importantly, we demonstrate that our trained model is readily applicable to specialized, curated datasets , even those with a limited number of data points.*

Uncertainty Sampling-Based Efficient Data Generation for Development of Machine Learning Model to Predict Catalyst Degradation *Dongjae Shin[1], Christopher Tassone[2] and Kirsten Winther[2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States*

Assessment of the long-term stability of a laboratory-developed catalyst is an essential step to determine if the catalyst can be commercialized. Currently, long-term stability testing requires long running time on stream studies which are costly and generally not performed in academic settings. Accelerating the ability to assess the long-term stability is a critical step to improve rates of commercialization for novel laboratory-developed catalysts. The reverse water-gas shift (RWGS) reaction is a critical step in the Power-to-liquids (PtL) technology, which uses renewable electricity to provide sustainable liquid fuels, and is a component unit operation in the strategy to decarbonize the production of fuels and chemicals. While many promising catalysts have been reported in the literature, these catalysts require high operating temperatures in order to be thermodynamically favorable to the desired products, raising questions as to the long-term stability of the catalyst materials under operating conditions.
In this contribution, we have developed a machine learning (ML) model to rapidly predict the degradation of oxide-supported metal catalysts, such as Rh/rutile-TiO_2, of which single metal atom morphology has been reported to catalyze RWGS pathway with high selectivity [1]. As the generation of reactivity test data is highly costly, we adopted uncertainty sampling (US) approach, one of active learning (AL) techniques, to efficiently sample the experimental data. Using those experimental data collected by AL, several ML models were trained, and the best model was chosen to use for rapid prediction of catalyst degradation. In addition to the prediction of degradation by a regression model, useful knowledge on the relationship between experimental features and catalyst degradation was extracted by interpretable ML method such as SHAP (Shapley Additive exPlanations). This work is expected to give a guidance for data-efficient exploration of search space to map the relationship between experimental catalytic features and a catalytic property of interest.

11:30 AM MT02.05.05

Achieving High-Accuracy Battery Cycle Life Prediction Through Ultra High Precision Coulometry and Machine Learning *Tyler Sours[1], Omar Allam[1], Shivang Agarwal[1], Jordan Crivelli-Decker[1], Marc Cormier[2], Steffen Ridderbusch[1], Dan Zhao[1], Yunyun Wang[1], Stephen Glazier[2] and Ang Xiao[1]; [1]SandboxAQ, United States; [2]Novonix, Canada*

Predicting battery cycle life with high accuracy (e.g., within 5% of actual capacity) is critical for speeding up the iteration loop during battery materials optimization. Traditional long-term cycling methods, while effective at capturing overall performance across a cell's lifetime, often fail to provide detailed insights from the early cycles due to lower resolution data. Ultra-High Precision Coulometry (UHPC) offers transformative potential for predictive machine learning (ML) models by providing high-resolution early-life cycling data that captures subtle *electrochemical changes not readily observed by conventional long-term cyclers. By leveraging UHPC data and advanced feature engineering, our prediction framework trains machine learning models that predict battery degradation with high fidelity using only a few initial cycles measured on UHPC cycling systems. These engineered features enable our models to generalize well across different cell chemistries, suggesting broader applicability than traditional methods. Our models leveraging UHPC can quickly and reliably estimate the cycle number at which significant capacity loss occurs, drastically reducing the time to accurate predictions compared to traditional long-term cycling tests. This approach not only improves our understanding of degradation mechanisms but also offers a scalable and efficient solution for battery management, thereby accelerating advancements in battery technology.*

11:45 AM MT02.05.06

RadHull1—A rough but More Complete Convex Hull of Stability *Janosh Riebesell*[1,2]*;* [1]*Radical AI, United States;* [2]*Lawrence Berkeley National Laboratory, United States*

By combining machine learning energy models trained on large, chemically diverse datasets with combinatorial enumeration of structure prototypes and all possible charge-balance-allowed assignments of elements to crystal sites, Radical AI built perhaps the most complete convex hull of thermodynamic stability to date. While below density functional theory in accuracy, it spans the entire space of plausible inorganic compounds and can be used as a guide to explore energetically favorable regions of phase space with more accurate methods. We use this hull internally to guide explorative synthesis with Radical AI's self-driving lab and show initial results on the new kinds of materials this may yield in practice. The complete convex hull is made freely available to the community in the hopes that it enables more far-flung exploration of uncharted chemical space in future research.

1:30 PM *MT02.06.01

Adsorption Energies on Electrocatalyst Surfaces Using High-Throughput Experimentation and Machine Learning *Hannah-Noa N. Barad; Bar-Ilan University, Israel*

*One of the most important ways to close the anthropogenic carbon dioxide (CO_2) cycle is by electro-reduction of CO_2 into value-added chemicals and sustainable fuels. One of the main aspects in electrochemical CO_2 reduction reaction (CO_2RR) is the catalyst, which decreases the dissociation energy of CO_2. Various materials have been investigated as catalysts for CO_2RR, yet, generally, high selectivity for desired products of interest, namely C_{2+} carbonates, is low. One approach for increasing product selectivity is to discover new materials, based on metals and metal oxides with more components (e.g., quaternary systems), which may improve activity, as a result of synergistic effects between the composing elements. Yet, the parameter space for these systems is huge and must be focused. One feature that describes the reaction propagation pathway is intermediate adsorption energy, e.g., *H, *CO, which could assist in determination of product selectivity. However, adsorption energies of known and new materials are not always experimentally determined and have not been studied systematically.*
Here, we tackle the problem of determining adsorption energies by experimental measurement and machine learning predictions. We built a machine learning model that aims to predict the adsorption energies of known

materials, which we plan to implement on new materials. The model is based describing the adsorption environment using simple and direct features, and more elaborate descriptors related to material structure and geometry using orbital field matrix.[1] *We also use high-throughput synthesis and characterization methods to gain more relevant data points of adsorption energies on known and new multinary materials. The coupling of machine learning and high-throughput materials science assists in narrowing the large multinary materials parameter space, which will lead to new selective* CO_2RR *catalysts.*

2:00 PM MT02.06.02

Predicting Phase Evolution During Solid-State Synthesis Using Cellular Automata *Max Gallant*[1,2]*, Matthew J. McDermott*[1]*, Bryant Li*[1,2] *and Kristin A. Persson*[1,2]*;* [1]*Lawrence Berkeley National Laboratory, United States;* [2]*University of California, Berkeley, United States*

Computational tools, like the selectivity metrics from [1] for solid-state synthesis recipe design can significantly aid in the experimental realization of novel functional materials proposed by high-throughput materials discovery workflows. With the emergent setting of the autonomous laboratory in mind, we present a new simulation framework and digital twin for predicting solid-state synthesis reaction outcomes. This framework uses the cellular automaton formalism [2] to predict the time-dependent evolution of intermediate and product phases during solid-state reactions as a function of precursor choice and amount, reaction atmosphere, and heating profile. Our framework incorporates high-throughput thermodynamic data, machine-learning estimators for melting points and finite temperature Gibbs formation energies, and empirical heuristics to estimate reaction rates. These rates are then utilized in repeated applications of an evolution rule to produce a trajectory which can be analyzed to uncover reaction pathways and intermediates, thereby enabling the synthesis scientist to test their recipe in silico. We analyze seven experimental case study recipes from the literature detailing the synthesis of $BaTiO_3$ *and* $YMnO_3$ *to illustrate the predictive power of this model in capturing reaction selectivity, reaction onset temperature dependence, the effect of precursor choice, and recovery of the experimental reaction pathway. Finally, we share our vision for the use of this model in the autonomous laboratory [3] and the optimization framework, emphasizing its capacity both to optimize existing recipes and to accelerate the identification of effective recipes for yet unrealized solid materials.*

Quantification of Total Curcuminoids in Powdered Turmeric Using Ridge Regression and a Coarse-Fine Decision Tree Approach on NIR Spectra *Hasika Suresh, Swanti Satsangi, Amruta Behera, Shankar K. Selvaraja, Abhishek K. Singh and Rudra Pratap; Indian Institute of Science, India*

Near-infrared spectroscopy (NIRS), in combination with multivariate statistical analysis, is renowned for its non-invasive, rapid, and environmentally friendly attributes, making it a valuable tool for accessing the quality and quantity of active ingredients in food and agricultural products. This study explores a novel approach for quantifying total curcuminoids in powdered turmeric using NIRS, covering the spectral range of 1550-1950 nm, acquired by a microelectromechanical systems-based handheld spectrometer system assembled in-house, paving the way for point-of-use applications in the field.

It is challenging to have one single model work with reasonable accuracy over a broad range of predictor parameters, which in this case is curcumin content. Although, in some turmeric species curcumin content can be as high as 12% w/w, the prominent range is found to be 1-4%. To ensure uniform prediction accuracy across this range, we propose a coarse-fine decision tree model consisting of two sets of mathematical models- a coarse model for the initial prediction spanning the broad range of 1-4% curcumin, and a second set of five finer models (in the ranges 1-2%, 2-3%, 3-4%, 1.5-2.5%, and 2.5-3.5%) for the final prediction. The decision for the choice of the fine model is reckoned using the error of prediction from the coarse model. We use ridge regression algorithm due to its ability to handle multicollinearity present in NIR spectral data.

The work involves collecting reflectance spectra from 148 turmeric samples, of which 133 were used for training and 15 for blind testing. These samples include both commercially available turmeric powders as well as dry turmeric roots directly from farmers. The roots are procured from different states of India, namely, Andhra Pradesh, Tamil Nadu, Karnataka, Kerala, Maharashtra, and Meghalaya. Initial quantification of curcumin was performed using High-Performance Liquid Chromatography (HPLC), providing a benchmark for the predictive model.

The coarse model demonstrated a coefficient of determination (R2) of 0.91, with Root Mean Square Error of Cross-Validation (RMSECV) and Root Mean Square Error of Prediction (RMSEP) values of 0.06 and 0.22, respectively. For finer models, the error metrics significantly improved, with training and validation errors ranging between 0.01-0.07 and 0.05-0.13, respectively, leading to a 67% improvement in prediction accuracy. The fine models collectively achieved an R2 of 0.98, showcasing the enhanced precision of the proposed method.

The coarse-fine decision tree approach involves an initial coarse prediction, followed by the selection of an appropriate fine model based on the coarse model's error margin. This hierarchical decision-making process ensures the accurate final prediction of curcumin content. The study highlights three distinct scenarios for model selection: ranges fitting within one fine model, ranges spanning two models, and ranges entirely within two models. Each scenario dictates specific strategies for final prediction, thereby optimizing accuracy.

The miniaturized spectrometer, combined with the ridge regression-based coarse-fine decision tree model, provides a robust integrated hardware-software solution for rapid and precise quantification of curcumin in turmeric, holding significant potential for field applications in the food and agricultural industries. It is a reliable alternative to conventional laboratory techniques, which require more time, involve the usage of chemicals and skilled labor. The proposed method simplifies the process, by integrating state-of-the-art hardware with advanced machine-learning techniques for computation, thus, reducing time and resource requirements while maintaining high accuracy.

2:30 PM *MT02.06.04

Inorganic Crystal Structure Generation and Synthetic Predictions Enabled by AI *Yousung Jung; Seoul National*

University, Korea (the Republic of)

Materials informatics utilizes data to establish relationships between the structures and properties of materials, enabling the exploration of the vastness of the materials space through the use of models. Trained on diverse datasets, the generative models can unlock the potential for predicting novel materials with tailored properties. However, while the key advantage of generative models is a potential to produce novel materials, often times they may be "too novel" and cannot be synthesized. In order to minimize the time and resources for experimental synthesis attempts, models that can predict the synthesizability (and, if synthesizable, synthesis recipes as well) would be immensely helpful. Thus, in this talk, I will delve into two important aspects of materials design: generation and synthesis prediction based on data and machine learning. I will also present the results of using large language models as strong baseline for synthesizability predictions and precursor selection problems.

Hypothesis-Driven Autonomous Experimentation for Accelerated Research *Benji Maruyama[1], Robert Waelder[2,1] and Rahul Rao[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States*

The current materials research process is slow and expensive; taking decades from invention to commercialization. The Air Force Research Laboratory pioneered ARES™, the first autonomous experimentation system for materials development. A rapidly growing number of researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of making research progress orders of magnitude faster than today.

We will focus on our recent campaign of hypothesis-drive search, where carbon nanotube growth is optimized based on free energy of reduction of metal catalysts. Our reduction hypothesis enabled us to collapse a huge search space of CVD synthesis, confirming our hypothesis.

We will discuss concepts and advances in autonomous experimentation in general, and associated hardware, software and autonomous methods that are part of the Autonomous Materials Innovation Infrastructure (AMII). We consider the impact of autonomous experimentation on human scientists and the scientific enterprise: Changing roles for humans and robots, expectations. In the future, we expect autonomous experimentation to revolutionize the research process, and propose a "Moore's Law for the Speed of Research," where the rate of advancement increases exponentially, and the cost of research drops exponentially.

4:00 PM MT02.07.02

Digital Laboratory with Modular Measurement System and Standardized Data Format for Thin-Film Materials Exploration *Kazunori Nishio[1], Akira Aiba[1], Yota Suzuki[1], Kei Takihara[1], Shigeru Kobayashi[2], Ryo Nakayama[2], Ryota Shimizu[2] and Taro Hitosugi[2,1]; [1]Tokyo Institute of Technology, Japan; [2]The University of Tokyo, Japan*

To accelerate materials exploration, machine learning, robotics, and data-driven experiments are underway worldwide. [1-5] *In this study, we constructed a digital laboratory to collect experimental data on the synthesis process, measured properties, analytical results, and measurement conditions for studying solid-state thin-film materials. The features of the digital laboratory are summarized as follows:*
1. Each modular experimental device is physically connected, enabling fully automated processes from thin-film material synthesis to surface structure observation, compositional analysis, crystal structure evaluation, electrical conductivity, and optical property measurements.
2. Data output from each measurement device is unified in XML format (MaiML: Measurement, Analysis, Instrument Markup Language [6]*) and collected in a cloud-based database. Additionally, the data is analyzed and utilized by software in the cloud.*
3. Through machine learning and robots can autonomously conduct material discovery.
We have previously reported the digital laboratory on the hardware.[7] *In this presentation, we will explain the overall system configuration related to software, including data format collection in MaiML, a common data format of the Japanese Industrial Standards (JIS).*

4:15 PM MT02.07.03
Continuous Flow Chemistry and AI/ML Autonomous Driven Experiments *Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States*

There is a lot of interest in artificial intelligence and machine learning (AI/ML) in materials. They have appended the ability to rapidly optimize synthetic routes, manufacturing methods, and characterization of properties. Digital twins with simulation (DFT, FEA, Multiphysics) and using neural networks with algorithms enable the application of logic-derived design, including regression analysis, which can go beyond Bayesian and statistical methods. This supersedes an otherwise trial-and-error approach in the synthesis, fabrication, and characterization of soft matter. This talk demonstrates continuous flow reaction chemistry and polymerization to optimize unit operation and the possibility of autonomous design and synthesis with real-time ML. There is a high possibility that a combination of P, V, T, and flow rate control enables new methods of copolymerization and the ability to use kinetics as a handle for optimized macromolecular properties and design for controlled yield and faster optimization. The automation for online monitoring is possible with improved instrumentation and the development of a feedback loop learning for possible deep learning (DL) development. With AI/ML, it is possible to optimize both the formulation and advanced manufacturing methods. The next stop is autonomous systems, but proving that human-on-the-loop is still the norm.

4:30 PM *MT02.07.04
Algorithms for Autonomous Experiments—Optimizing Priors and Maximizing Physics Discovery *Rama K. Vasudevan, Aditya Vatsavai, Yongtao Liu and Sumner B. Harris; Oak Ridge National Laboratory, United States*

Autonomous experiments (AE) offer a potential to dramatically improve the efficiency of the growth and discovery of new materials, as well as improve the efficiency of experiments by enabling focusing of efforts on only those experiments that are statistically likely to yield improved understandings or optimized properties. Traditional AE has relied heavily on the use of Bayesian Optimization (BO) methods, which are extremely useful for optimizing targeted properties when faced with limited experimental data and high uncertainty.

Here, we will explore methods that extend beyond traditional BO, to explore whether the error signal in a data-driven or physics-based model can be a useful target to minimize. This follows principles derived from curiosity-driven reinforcement learning, but are applied within a more classical optimization setting. We explore this concept via creating a data-driven model that takes as input features of image patches, and predicts whole spectra, and then utilize an agent where the goal is to predict the error of this original data-driven model to drive experimental measurements. We discuss the similarities and differences with the traditional deep kernel learning approach. Next, we then explore the use of continuous control via model-based predictive methods. These methods are useful in cases where continuous control must be exerted over a dynamical system, and for which a dynamics model can be postulated. Finally, I will touch on the ability to merge physics-based simulations with experiments with RL based approaches. Together, this suite of algorithms can be used in autonomous laboratories to extend beyond traditional BO, incorproate physics-based knowledge, and attempt to maximize physics discovery, as opposed to any specific materials objective.

Implementation of a Biologically Plausible Neural Network-Based Disturbance Observer for Real-Time Control Systems *Jongmin Yoon and Taesung Kim; Sungkyunkwan University, Korea (the Republic of)*

In most automated applications, a control loop system which consists of a feedback loop and a controller is designed to make the system responses follow given commands. The system is operated in real-time by sensing errors between the commands and actual responses, and calculating control inputs to minimize these errors. Parameters for the controller (e.g. PID controller) are optimized based on a mathematical model which approximates the real system. Therefore, control performance can be degraded if there exist unexpected disturbances or discrepancies between the model and the real system. A Disturbance Observer (DOB) can be employed to address these degradations. It compares actual system responses with model-predicted responses, calculates compensation inputs, and adds these to the existing control inputs. Among various DOBs, Artificial Neural Network-based DOBs (ANN-DOB) [1] have demonstrated superior performances in many control problems. However, conventional ANN-DOBs have suffered from significant computational burdens, because they require repetitive learning and inference operations per each control cycle time (typically 50 μs to 1 ms).

In this study, a Biologically plausible Neural Network-based DOB (BNN-DOB) is proposed to overcome the above computational burden issues. The biological plausibility means mimicking functionalities of neurons in biological *brains, where learning and inference operations occur through spike signal flows and neuron interactions without any computational processes. In the proposed BNN-DOB, the conventional ANN structure is replaced with a Spiking Neural Network (SNN) structure [2], and a Reward-modulated Spike Timing-Dependent Plasticity (R-STDP) rule [3] is adopted to train weights of neurons in the SNN. R-STDP is a modified STDP that additionally adjusts weight updates using reward signals, changing the original STDP from an unsupervised learning rule to a supervised rule. In the BNN-DOB, model – actual system response errors are used as reward signals.*

The performance of the proposed BNN-DOB is verified using simulations under a control scenario where unexpected system nonlinearities, load condition variations, and external disturbances are added to a real system compared to an expected model. The results demonstrate that the proposed BNN-DOB can maintain the system's command tracking performances even with added system nonlinearities and load condition changes, and reduce disturbance-induced system oscillation to 0.1 times the system oscillation when no DOB is used.

MT02.08.02

Deep Learning-Based Optimization of Metasurface Designs for Enhanced Photonic Applications *Willem S. De Veirman[1,2], Loubnan Abou-Hamdan[1], Emil Marinov[1,3], Adelin Patoux[3] and Patrice Genevet[1,3]; [1]Colorado School of Mines, United States; [2]Rose-Hulman Institute of Technlogy, United States; [3]Centre National de la Recherche Scientifique, France*

Metasurfaces have emerged as a groundbreaking technology in the field of photonics, enabling unprecedented control over light propagation at subwavelength scales. This study leverages deep learning techniques to enhance the design and optimization of active metasurfaces, addressing critical challenges in fabrication and functional performance. We present a generalized neural network model specifically trained to recognize and classify defects in metasurfaces, using a comprehensive dataset derived from simulated and experimentally fabricated metasurface images. The model employs a convolutional neural network (CNN) to achieve high accuracy in defect detection, thereby facilitating rapid and precise quality control during the fabrication process. Our results seek to demonstrate significant improvements in the performance and reliability of metasurface-based photonic devices with the proposed methodology not only streamlining the design process, but also providing a robust framework for future advancements in metasurface technology.

MT02.08.03

A Protocol to Establish Trust in Automated Synthesis Methods by Validating the Transfer of Properties Across Scales *Kanokwan Tungkitkancharoen[1], Alexander E. Siemenn[1], Basita Das[1], Fang Sheng[1], Eunice Aissi[1], Hamide Kavak[2] and Tonio Buonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]Cukurova University, Turkey*

To accelerate the discovery and optimization of new materials, rapid synthesis methods are increasingly explored, including drop casting, ink-jet printing, spraying, and microcrystal synthesis. While these methods are undoubtedly faster, they can also produce samples with undesired phases and defects, potentially compromising the quality of information gained through characterization, and hence, the materials-discovery process itself [1, 2].

Up-to-date as of November 14, 2024

To establish trust in materials produced using rapid-synthesis methods, we present a structured protocol to compare different classes of properties with higher-fidelity, lower-throughput, traditional synthesis methods such as spin coating.

In our study, we explore three degrees of synthesis automation and sample sizes: (1) non-automated manual spin coating of sub-micrometer-thick films with centimeter-scale [3], (2) automated OpenTrons synthesis and drop casting of microcrystals [4], and (3) automated Archerfish multi-material printing of millimeter-sized samples [5]. The transferability of said properties across these three levels of automation and size scales is quantified by benchmarking the following properties with manual spin coating: (1) crystallographic phase, (2) elemental composition, (3) surface morphology, (4) bulk transport properties, and (5) optical band gap. We demonstrate strong transferability of optical reflectance (>95% cosine similarity) and band gap (<0.03 eV differential) for hybrid organic-inorganic lead-halide perovskites and strong elemental correspondence (<5 at.% differential) for all-inorganic halide perovskites across the least automated to most automated workflows. While crystallographic phase has shown to transfer better for certain compounds over others, surface morphology has proven challenging to transfer for most compounds and may affect outcomes of contact measurements like four-point-probe.

Trust in automation hinges on proving transferability across these automation scales; thus, in closing, we present preliminary work to "bridge the gap" between automated and traditional synthesis methods.

Multivariate Statistical Analysis of High-Resolution Hyperspectral Image Datasets Using Nanoscale Capacitance-Voltage Measurements for Ferroelectric Thin Film Characterization

Yoshiomi Hiranaga[1], Yuki Noguchi[1], Takanori Mimura[2], Takao Shimizu[2], Hiroshi Funakubo[2] and Yasuo Cho[1]; [1]Tohoku University, Japan; [2]Tokyo Institute of Technology, Japan

The key to understanding various unexplained phenomena related to ferroelectric materials and discovering new ones, as well as improving the properties of these materials, is to comprehend the domain dynamics at the nanoscale. Among various microscopy techniques, piezoresponse force microscopy (PFM) has been widely used for this purpose.[1,2] Another approach is the recently developed local capacitance-voltage (C-V) mapping method, which allows nanoscale analysis of domain dynamics through dielectric rather than piezoelectric measurements.[3,4] This method has advantages over PFM-based methods, such as high-speed and high-

sensitivity observation, enabling quick acquisition of high-resolution hyperspectral image data. Here, we present a methodology to analyze C-V datasets using a machine learning approach to extract and visualize the information necessary for understanding ferroelectric domain dynamics.

Using this methodology, we focus on the effect of grain boundaries on polarization switching in ferroelectric films, an issue that has been debated for a long time and is critically important. We chose doped HfO_2 thin films as the specific target of our measurement. This material has outstanding properties, such as maintaining ferroelectricity even at a thickness of less than 20 nm, and is expected to be used in applications such as nonvolatile memory and neuromorphic devices. However, to realize such devices, it is necessary to solve problems related to the change in properties during cyclic electric field application, called wake-up and fatigue. In this study, we analyzed doped HfO_2 films before wake-up using local C-V mapping. The acquired datasets were then clustered into several regions based on the similarity of their polarization properties using unsupervised learning methods such as k-means and Gaussian mixture models (GMMs). In addition to the typical butterfly-shaped C-V curves that represent normal polarization switching, these clusters contained asymmetric butterfly curves that may be caused by domain pinning or other built-in field-derived effects. Subsequent statistical analysis suggested that, in pristine HfO_2 films before wake-up, although defects at grain boundaries have some effect on the polarization switching properties, they are not the main cause of the variation in properties.

MT02.08.05

Q Factor Optimization of a Photonic Crystal Through Machine Learning *Iago Sánchez[1], Irene Castro Fernández[2], Daniel Ramos[2] and María José Martin Hernandez[1]; [1]Centro Español de Metrología, Spain; [2]Consejo Superior de Investigaciones Científicas, Spain*

In recent years, both machine learning [1] and quantum technologies [2] have seen a massive progress, impacting many areas of physics. Outside science, artificial neural networks have been used for all kinds of functions, from simple things like image classification, to self-driving cars. In physics, for example, they are being used to forecast the properties of materials [3], analyze astronomical images [4], categorize phases of matter [5], model quantum wave functions [6], and manage quantum devices [7]. This, already promising, can only be exponentially improved by applying quantum physics to the acceleration of machine learning. Neural networks are essentially function approximators, for which thousands of examples are needed for a correct training. The basic component of these networks are the neurons, with their corresponding weights wi (coefficients) and biases bi (offsets), each producing values and combinations through the activation functions, to end with a target value: prediction. These multineuron networks are called deep networks [8].

Now, we are mainly interested in applying it into metrology. With the objective being the implementation (design, fabrication and characterization) of a nanophotonic and nanometric primary pattern, we apply machine learning to optimize the Q-factor of a two-dimensional photonic crystal (hole placement, *size, shape, etc). With enough simulations (thousands), a neural network can be trained, and this optimization can be performed, much faster than by hand. The photonic crystal studied is a hexagonal, two-dimensional silicon photonic crystal. Several kinds of crystal were studied, like an L3, L5 (getting rid of 3 and 5 holes in the center, respectively), or a kind of L2 (leaving one center hole, and eliminating the next hole on both sides), but mainly focusing on the L3. All of these crystals have a thickness of d = 220nm, and varying the rest of the parameters (lattice parameter, distances, etc.).*

Auto-SEMEDX—Automated SEM-EDX Analysis of Inorganic, Solid-State Particle Samples in a Self-Driving Lab

Andrea Giunto, Pragnay Nevatia, Nathan Szymanski, Olympia Dartsi and Gerbrand Ceder; Lawrence Berkeley National Laboratory, United States

Self-driving labs hold the promise to substantially accelerate the process of material innovation by reducing the time required to synthesize novel materials [1]. We employ the A-lab, a robotic setup for inorganic solid-state synthesis [2]. Starting from solid powdered precursors, A-lab autonomously doses and mixes the powders, and fires them in a controlled atmosphere. The reaction products are then autonomously characterised via X-Ray Diffraction (XRD) and automated Rietveld refinement [3]. Hence, for each reaction, the A-lab identifies the crystal phases and their relative fractions. However, relying on a single characterization method has limitations. XRD cannot detect amorphous products, and closely overlapping peaks from different phases can make it difficult to identify the obtained reation product with a high confidence. Multiple complementary characterization methods are desirable to accurately determine the reaction products and strengthen the confidence in the characterisation results.

To this end, we have implemented Auto-SEMEDX, a framework for automated Energy-Dispersive X-Ray Spectroscopy (EDX) at a Scanning Electron Microscope (SEM) to measure the composition of the reaction products. EDX provides information about amorphous phases and can be employed to cross-check XRD results by offering a second method to determine phase composition.

Samples are (autonomously) prepared via a setup built in-house, where micron-sized particles are transferred from a crucible containing powder reaction products onto a carbon-taped SEM stub. The stubs are transferred to the SEM, and Auto-SEMEDX is initiated, proceeding as follows:
- *Single particles of few microns are located on the C tape via image processing.*
- *EDX spectra are collected at the particles.*
- *Machine-learning algorithms such as k-means clustering and non-negative matrix factorization are employed to determine the phases observed in the sample.*
- *The measured compositions are cross-checked with the XRD-determined phases, and overall confidences for each phase are calculated using Bayes' theorem.*

The process repeats iteratively until phases can be determined with high confidence.

Auto-SEMEDX rapidly and autonomously collects compositional data with statistical significance, allowing to determine the composition of phases present in the sample with a high confidence. By combining automated SEM EDX analysis and XRD refinement, this work showcases the power of complementary characterization techniques in a robotic synthesis lab, reducing human workload.

MT02.08.07
Deep Learning Assisted Hybrid Metrology of Nanosheet Transistors for Fast Film Characterization *Tao Cai[1], Yifei Li[1], Daniel Schmidt[2] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]IBM Research-Albany, United States*

Gate-all-around (GAA) nanosheet field effect transistors (FETs) are on the cusp of emerging into household products and leading another leap forward in computing. In order to achieve commercial implementation, in-line characterization improvements are essential as critical dimensions get smaller and require higher accuracy. This is especially true for GAA nanosheets where the three-dimensional geometries, multi-step processing, and need for precise control may require real-time monitoring during manufacturing. In particular, the formation of the stacked nanosheet governs many of the device critical dimensions such as the nanosheet dimensions and the pitch. However, there are few techniques that alone can provide multi-stack dimensions and compositions in a fast and non-destructive manner. Here we present a framework for combining multiple metrology techniques, known as hybrid metrology, alongside machine learning methods to improve the accuracy and speed of data analysis for thin film characterization.

We demonstrate this idea by using a deep learning algorithm for combined analysis of both spectroscopic ellipsometry (SE) and Raman spectroscopy data to enable characterization of critical device parameters in multilayer Si and Si(1-x)Ge(x) thin-films for fabrication of GAA nanosheet FETs. We employ a composite neural network that consists of a convolutional neural network to analyze SE spectra and a multilayer perceptron component to analyze the Raman data. Over one million SE spectra and Raman peaks are simulated as a training dataset using optical property databases from literature, and both simulated and experimental test datasets are used to confirm the accuracy of the neural network. This method was first utilized to study a simple two-layer stack of Si and SiGe where we demonstrated that only with the incorporation of Raman data, the neural network correctly predicts the critical dimensions from a single SE spectrum and with a mean absolute error of 1%. We then extended this method to a full eight-layer stack of alternating Si and SiGe with varying thicknesses and compositions of SiGe. The inclusion of Raman data successfully improved the accuracy of the neural network predicted parameters by up to 50% in the full nanosheet stack and was able to accurately predict parameters with a mean absolute error of less than 5% within milliseconds per stack. We believe these improvements are a result of the Raman data constraining the massive parameter space of SE that usually makes its analysis difficult without human input. Here we demonstrate the success of this method for silicon GAA nanosheet FETs, but it is applicable to any multi-stack thin film where the optical properties are known. These results are promising for future automation of rapid and non-destructive in-line characterization in commercial mass production settings.

MT02.08.08
Self-Supervised Vision Transformers for Anomaly Detection in 3D Printing *Bowen Zheng, Xingquan Wang, Zeqing Jin and Grace Gu; University of California, Berkeley, United States*

Fused filament fabrication (FFF), a widely used 3D printing process, faces challenges in printing quality such as under- and over-extrusion. The accumulation of these anomalies can degrade printed parts in mechanical properties and surface quality. Previous research has used computer vision to detect printing defects. However, traditional computer vision techniques are mostly based on supervised learning, and therefore require intensive and costly manual data labeling. In this work, we combine self-supervised learning and transformers to detect *anomalies in FFF 3D printing in an annotation-efficient manner. Self-supervised learning allows the model to learn from random, unlabeled examples, and transformers enable selectively focusing on certain parts of their input. Using tens of thousands of unlabeled frames recorded by a camera near the nozzle area as training data, our model can segment printed area and background and discover printing defects with no supervision or any segmentation-targeted objective. Additionally, the model is intrinsically interpretable, thus contributing to a higher-level of image understanding. Our work presents a data-driven anomaly detection technique less dependent on labeled data, which may be important for domains where annotated images are scarce such as in additive manufacturing and medical imaging.*

MT02.08.09

Deep Learning for Real-Time Tool Wear Prediction in Milling Operations *Rêner P. Tavares; Universidade Estadual de Campinas, Brazil*

This work presents the development of a tool wear monitoring and prediction system using deep neural networks. Tool wear impacts both the quality and efficiency of machining. Traditionally, wear is monitored directly through microscopy or indirectly by capturing physical signals such as vibration, cutting force, and electric current. In this study, an indirect monitoring approach was used to predict tool wear and optimize real-time machining performance. The system leverages a combination of convolutional and recurrent neural networks to analyze sequential data. Experiments were conducted using a five-axis machining center and VP20 TS steel, a material commonly used for molds and dies. The milling process was optimized through a Taguchi experimental design, utilizing an L32 orthogonal matrix to evaluate parameters such as cutting speed, feed, and cut depth. Sensors recorded data throughout the tests, and this data was pre-processed for normalization and feature extraction. Three machine learning models were trained on this data. The results show that these hybrid models can detect anomalies and predict wear more accurately than traditional methods, enabling preventive tool replacement before failure occurs. This system has potential applications in other machining-dependent industries, offering improved efficiency and reduced operational costs.

Designing Experiment Workflows to Inform and Evaluate Computation Models *John M. Gregoire; California Institute of Technology, United States*

In the quest to accelerate materials discovery via experiment automation and artificial intelligence, we recognize the challenges in emulating human capabilities with respect to contextualizing data and rapidly adapting experiments based on real-time data streams. In the development of infrastructure for next-generation workflows, these aspects of traditional research are most tightly connected to instrument control software and the management of experimental data. We will describe the evolution of these capabilities at Caltech, from automated workflows focused on throughput and consistency to workflows that embrace modularity and responsiveness to new knowledge, where techniques for this latter approach are being developed collaboratively with Modelyst, Inc. and Toyota Research Institute. The lessons learned with respect to data management may be *the most generalizable to the materials chemistry community, especially our development of Event-Sourced Architecture for Materials Provenance Management (ESAMP) and the Materials Experiment Knowledge Graph (MekG), which addresses the hierarchical nature of materials data. Regarding representation of materials data, high-level descriptors can be provided by the chemical elements, crystal structure motifs, and types of materials properties, and ultimately a given piece of data must be considered in the context of its acquisition. Detailed descriptors of a piece of experimental data include not only the metadata for the experiment that generated it, but also the prior history of synthesis and metrology experiments. Graph databases offer an opportunity to represent such hierarchical relationships among data, organizing semantic relationships into a knowledge graph. Initial reports of knowledge graphs in materials science highlight the breadth of approaches for their development. We describe a knowledge graph of materials experiments whose construction encodes the complete provenance of each material sample and its associated experimental data and metadata. Additional relationships among materials and experiments further encode knowledge and facilitate data exploration. MekG is sufficiently large and complex to demonstrate a path toward a global materials knowledge graph. We characterize the scalability of this approach, especially with respect to executing queries, illustrating the value that modern graph databases can provide to the enterprise of data-driven materials science.*

8:30 AM MT02.09.02

High Throughput Robotic Experiments for Autonomous Discovery of Multi-Components Electrolyte for Advanced Lithium-Ion Batteries *Shoichi Matsuda; National Institute for Materials Science, Japan*

Data driven approach for materials discovery, has attracted significant recent attention even in the field of rechargeable batteries. Instead of relying on the experience and intuition of researchers for exploring new materials, the approach employs data scientific techniques that can reduce the time and cost of the discovery of new materials with superior battery performance. High throughput automated robotic experimental system was recently developed by our group for accelerating the discovery of multi-component electrolytes for advanced lithium-ion batteries (ref. 1, 2). Although superior searching throughput analyzing more than 1000 samples per day was achieved, adequate experimental design is essential to realize high-throughput exploration of electrolyte composition from large searching space. For example, when considering a combination of selecting 5 types from 20 types of chemicals, the candidates are over 10^7*. Thus, it is not realistic to comprehensively evaluate all the possible combination even through such robotic experiments. Therefore, a specific electrolyte composition that realizes a superior battery performance must be determined with only a limited number of experimental trials.*

In the present study, we demonstrate the effectiveness of the orchestration system to realize a closed loop between AI searching algorithms and robotic experiments for the accelerated discovery of novel electrolyte for lithium-ion batteries. Generally, different searching algorithms are utilized depending on the motivation of a materials exploration task and the procedure for controlling the devices largely depends on the characteristics of the robotic systems. Thus, the control software has far been developed on a case-by-case manner, limiting the widespread use of searching algorithms for robotic experiments. Based on these considerations, we recently developed the NIMO to implement a closed loop of AI and robotic experiments for automated materials exploration (ref. 3). Notably, NIMO treats each AI algorithm and each robotic system as separate modules, resulting in the implementation of a closed loop with any combination of these modules. When modules for new AI algorithms or robotic systems are prepared, new closed-loop systems can be easily controlled via NIMO. In the present study, optimization tools for PHYSics based on Bayesian Optimization (PHYSBO), BoundLess Objective-free eXploration (BLOX), and Random Exploration (RE) methods was utilized as AI techniques in autonomous robotic experiments. PHYSBO supports single- and multi-objective optimizations, and multiple proposals are calculated. BLOX is based on an algorithm designed to select the next experimental conditions, to perform uniform sampling in the space of the objective functions. For materials science, curious materials can be found using BLOX. Specifically, BLOX trains machine learning models to predict objective functions from experimental *conditions. Experimental conditions that realize uniform sampling in the space of objective functions are found based on the Stein discrepancy evaluated using the prediction results. By utilizing these AI techniques, the robotic experiments autonomously discover the novel electrolyte composition that maximizes the battery performance.*

Fully Automated Scanning Probe Microscope Based on Reward Driven Workflows *Richard Liu[1], Utkarsh Pratius[1], Roger Proksch[1,2], Jason Bemis[2] and Sergei V. Kalinin[1,3]; [1]The University of Tennessee, Knoxville, United States; [2]Oxford Instruments Asylum Research, United States; [3]Pacific Northwest National Laboratory, United States*

The rapid development of computation power and machine learning algorithms has paved the way for accelerating scientific discovery with automated scanning probe microscopy (SPM). Here we introduce a fully automated SPM powered by reward-driven machine learning algorithms. We start with the implementation of an interface library enabling Python-based control of the instrument from both local computers and remote clusters. We will also show how to abstract routine SPM operations into automated workflows. Next, we present the reward-driven automation of advanced SPM operations such as tapping mode topography mode, hysteresis loop spectroscopy and Kelvin Probe force microscopy mode. These automations are the foundations of fully automated SPM and rule out the operator biases in the SPM research. At a higher level, we show how to automate material discovery workflows with user-defined rewards and policy. Finally, we present example workflows including automated material discovery based on structural features, automated exploration based on spectral features (Deep Kernel Learning), and high-throughput automated discovery of combinatorial libraries. The fully automated SPM can promote collaboration in the SPM community by offering standardized results and allows providing fast feedbacks to material synthesis and theory by high-throughput material characterization.

9:00 AM MT02.09.04

Autonomous Closed-Loop Plastic Forming Process with Real-Time Optimization *Shun Muroga[1], Takashi Honda[2], Yasuaki Miki[1], Hideaki Nakajima[1], Don N. Futaba[1] and Kenji Hata[1]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]ADMAT, Japan*

The rapid changes in the social environment and the accelerating data society have necessitated a shift in research paradigm in various fields. In this context, there is a need to reconsider how to utilize data generated from materials and processes more effectively. In this area, we have made efforts in different areas, such as exploring multi-faceted analysis methods to extract new insight [1], utilizing multimodal deep learning to predict and optimize material properties by integrating multiple data streams [2], and developing closed-loop autonomous processes to remove human intervention [3].
The forming of plastics into diverse shapes is industrially needed to provide function to a relatively inexpensive material. However, the plastic forming is a complex process which requires the control of viscoelastic fluids melted at high temperatures to produce the desired products. Fluidity, a critical factor in the forming process, is dependent on numerous factors, such as molecular structure, molecular weight distribution, additives, recycled plastic blends, storage and thermal history, and environmental conditions (e.g. atmospheric temperature). Thus, identifying the optimal forming conditions for a given materials is difficult particularly for new materials, which lack significant prior data. To address these issues, we developed a prototype autonomous closed-loop plastic forming

process based on an active learning decision-making algorithm. In the forming component of our system, polycarbonate plastic pellets were fed, melted, transported, and extruded through a die (ie. slit) to form a film, then cooled and collected onto a roll. Equipped with real-time in-situ evaluation, consisting of cameras and laser displacement sensors, the film dimensions (width and thickness) could be accurately captured and used as inputs to the autonomous processor as the measurement-adjustment iteration to realize autonomous control of process conditions governing material input, draw rate, and applied heat. The use of an active learning algorithm afforded our system to proceed optimization in the absence of training data, which is unavailable due to the complex relationships between the control factors (material supply rate, applied force, material viscosity) within the plastic forming process. Application of this system towards nine distinct film width-thickness conditions demonstrated the ability of the system to quickly determine the appropriate and stable process conditions (average 11 characterization-adjustment iterations, 19 minutes) and the ability to avoid traps, such as repetitive over-correction. Furthermore, comparison of the achieved film dimensions to the target values showed a high accuracy (R2 = 0.87, 0.90) for film width and thickness, respectively. The proposed method in this study is general and can be extended to most any types of research and manufacturing processes involving continuous forming of materials from synthesis to slurries, pastes, and melts. In this presentation, we will discuss the details of this autonomous process and our vision for the future transformation of R&D.

Rethinking Machine Learning for Small Data to Enable Automous Experiments *Nila Mandal, Yushuo Niu, Maryam Pardakhti, Graham Roberts, Ethan Chadwick, Anson Ma, Mu-Ping Nieh and Qian Yang; University of Connecticut, United States*

While many powerful tools from machine learning (ML) have found their way to impactful applications in materials science, there remain barriers to applying data-driven methods broadly in experiments. One of these key barriers is posed by small datasets: while powerful modern ML methods rely on massive datasets and compute, the vast majority of experimental and computational datasets are comparatively small. In this talk, we will address the small data challenge by re-thinking commonly held paradigms for how machine learning algorithms are applied. Three examples will be discussed: (1) model selection for active machine learning, (2) data-efficient computer vision for in-situ defect detection, and (3) model selection for multi-class classification as demonstrated on inverse analysis for small angle scattering data.

In the first example, we will discuss the problem of model selection for active learning. Active learning (AL) is of great interest for automated scientific labs, where there is a strong need to minimize the number of costly experiments necessary to train predictive models. However, many AL methods assume fixed model hyperparameters that are chosen a priori. In practice, it is rarely true that good hyperparameters will be known in advance. To resolve this, we have developed a simple and fast method for practical active learning with model selection, based on weighted leave-one-out cross validation (LOOCV) on the biased actively sampled training dataset. We show empirically that our method can find hyperparameters that lead to better performance, and utilize it for process optimization in 3D printing among other applications.

In the second example, we will discuss data-efficient methods for deep learning-based defect detection in materials. One of the persistent challenges for a classification problem such as defect detection is the lack of sufficient labeled samples of the many different types of defects possible. We tackle this challenge by reformulating the problem as a change detection problem, leveraging ideas from one-shot and few-shot learning to significantly decrease the training dataset size required. We show that our lightweight model, which is designed to be easily amenable to transfer learning, achieves better performance than state-of-the-art models based on generative adversarial networks and transformer architectures in the absence of massive datasets.

Finally, in the third example, we tackle the common challenge of inverse analysis of experimental data, such as small angle scattering data, where the goal is to identify material structure from experimental scattering curves. For small angle scattering, identifying morphology from scattering curves is a multi-class classification problem, which can be time-consuming to solve by human experts with the assistance of fitting software. Accordingly, ML-based approaches have been proposed. We show that re-thinking model selection for multi-class classification can achieve highly accurate models using classical methods such as SVC, which is comparatively easy to train and requires much smaller datasets than deep learning approaches.

9:30 AM MT02.09.06

Machine Learning Aided Tools for Novel Workflows in Studying Crystallization Pathways of Complex Crystals

Domagoj Fijan, Brandon Butler, Maria Ward Rashidi and Sharon C. Glotzer; University of Michigan, United States

Nucleation and crystallization processes are critical in diverse materials, such as colloidal, soft, molecular, metallic, and ionic crystals. While there's considerable understanding of nucleation in simple crystals, research on complex crystals' nucleation is limited due to the lack of suitable computational tools. A significant challenge is the lack of a tool that can capture the key property of crystalline materials—symmetry—in a continuous and efficient manner. Another major issue is the absence of system-independent tools for the automatic analysis of molecular simulation trajectories to identify those exhibiting interesting behavior. We address these problems using machine learning-assisted tools that automate the detection of rare events (both post-analysis and online) and introduce an order parameter that describes local structures with continuous point group symmetry.

To enhance the automation of event detection and manage the data-intensive demands of these simulations, we developed dupin, a Python-based tool for detecting rare events in molecular simulation trajectories. While primarily designed for molecular simulations, dupin is also versatile enough to analyze experimental data, such as trajectories from microscopy experiments. This tool automates the detection of rare events, opening new research avenues in the study of rare events, nucleation, and crystallization. It enables the automated analysis of vast amounts of trajectories, facilitating the curation and preparation of datasets for machine learning applications focused on nucleation pathways. Additionally, dupin can operate on-the-fly during simulations or experiments, allowing for real-time adjustments based on detected events. An example of its utility is enabling very high-frequency sampling of molecular dynamics particle positions upon detecting a rare event minimizing data storage needs and enabling detailed studies of nucleation events at very high temporal resolution.

Given our focus on nucleation and crystallization, we have developed an order parameter specifically designed to quantify the structural evolution of local environments in complex crystals to work in tandem with dupin. Complex crystals feature different local environments; understanding nucleation at the most fundamental level necessitates tracking the progression of symmetry elements across these environments. Traditional order parameters, such as Steinhardt's Parameters (SOP) and its variants, often combine multiple symmetries into a single value, without useful and meaningful geometric or structural significance. In contrast, our Point Group Order Parameter (PGOP) provides a per-particle value that enables the continuous quantification of point group symmetries exhibited by particle arrangements. This method effectively quantifies the alignment of local

environments with specific symmetry operations, enabling the distinct differentiation of local environments within complex crystals.
We illustrate dupin's capability to automatically detect diverse events in soft matter simulations, such as complex nucleation processes and polymer collapses. Employing both tools in tandem allows for a deeper understanding of nucleation in complex crystallization pathways, analyzed through molecular dynamics simulations interacting with various potentials. We highlight dupin's ability to perform real-time, on-line detection, which enables the sampling of exceptionally detailed nucleation process trajectories. We showcase PGOP's utility in effectively quantifying different crystalline environments in various crystals during the nucleation process. Collectively, these tools not only advance the study of nucleation and crystallization but also open new avenues for research in large-scale crystallization projects and the application of emerging fields, such as machine learning, to explore nucleation and crystallization pathways.

***Autonomous Closed-Loop Mechanistic Investigation of Molecular Electrochemistry via Automation** Jingwen Sun[1], Hongyuan Sheng[1], Oliver Rodríguez[2], Joaquin Rodriguez-Lopez[2] and Chong Liu[1]; [1]University of California, Los Angeles, United States; [2]University of Illinois at Urbana-Champaign, United States*

Electrochemical research often requires stringent combinations of experimental parameters that are demanding to manually locate. Recent advances in automated instrumentation and machine-learning algorithms unlock the possibility for accelerated studies of electrochemical fundamentals via high-throughput, online decision-making. Here we report an autonomous electrochemical platform that implements an adaptive, closed-loop workflow for mechanistic investigation of molecular electrochemistry. As a proof-of-concept, this platform autonomously identifies and investigates an EC mechanism, an interfacial electron transfer (E step) followed by a solution reaction (C step), for cobalt tetraphenylporphyrin exposed to a library of organohalide electrophiles. The generally applicable workflow accurately discerns the EC mechanism's presence amid negative controls and outliers, adaptively designs desired experimental conditions, and quantitatively extracts kinetic information of the C step spanning over 7 orders of magnitude, from which mechanistic insights into oxidative addition pathways are gained. This work opens opportunities for autonomous mechanistic discoveries in self-driving electrochemistry laboratories without manual intervention.

10:30 AM *MT02.09.08
***Automating Battery Workflows with AiiDA— Towards Autonomous Labs that are FAIR by Design** Giovanni Pizzi[1,2], Peter Kraus[3,4], Edan Bainglass[1], Francisco F. Ramirez[2], Enea Svaluto-Ferro[4], Loris Ercole[2], Benjamin Kunz[4], Sebastiaan P. Huber[2], Nukorn Plainpan[4], Nicola Marzari[2,1] and Corsin Battaglia[4,5,2]; [1]Paul Scherrer Institute, Switzerland; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]Technische Universität Berlin, Germany; [4]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [5]ETH Zürich, Switzerland*

Scientific discovery can be significantly accelerated by the development of autonomous workflows, driving simulations and experiments via artificial intelligence algorithms to discover new materials or optimise materials properties. A preliminary requirement for autonomous labs, though, is the availability of automated workflows both for simulations and experiments. On the simulation side, in the past decades robust workflows have been developed with the aim of performing automated high-throughput simulations carried out by workflow engines. One example of such engine is AiiDA (https://www.aiida.net), that has historically managed advanced simulation workflows, storing the full provenance (i.e., all the simulation steps, their inputs and outputs, and their logical relationships), thus ensuring full reproducibility of complete simulation processes. In this talk, I will discuss how *we successfully interfaced off-the-shelf battery cycling hardware with AiiDA, allowing us to control experiments, in combination with the experimental scheduler tomato [2]. Advanced features of AiiDA have also been exploited to control experimental workflows, such as live monitoring for early detection of failed experiments. This integration serves as a first crucial step toward fully autonomous optimisation of batteries. I will highlight how the use of AiiDA is beneficial in the context of autonomous laboratories, where the amount of generated data can be very large, but with the advantage of being fully automated. It is thus of paramount importance to ensure that such data is properly stored with all its metadata to make results reproducible, and semantically annotated to facilitate searches and reuse. To illustrate this point, I will discuss the complexities of managing open research data (ORD) from mixed experimental/simulation workflows across research data management (RDM) platforms, and I will highlight the efforts of our PREMISE project (https://ord-premise.org), funded by the Swiss ETH Board ORD program. The mail goal of PREMISE is to enable and facilitate ORD interoperability between experiments and simulations, laying the foundation of autonomous laboratories that produce data that is FAIR by design, removing most of the burden from researchers to make their data open. Finally, I will briefly discuss additional use cases of autonomous integration of experiments and simulations. Also in the context of batteries, I will mention the integration of AiiDA with the FINALES brokering software, developed as part of the European BIG-MAP project (https://www.big-map.eu). FINALES has been already successfully demonstrated to scale to experiments distributed at the international level, with fully automated FAIR data storage and with semantic annotations [3,4]. Additional use cases include the control of crystal growth and the characterisation of the Fermi surface of metals.*

11:00 AM MT02.09.09

Retrofitting Physical Vapour Deposition Equipment for Self-Driving Operation with a Modular Machine Learning Workflow *Jonathan Scragg and Sanna Jarl; Uppsala University, Sweden*

The concept of a Self-Driving Lab (SDL) – an experimental platform using automation and AI to autonomously explore and optimize materials – is gaining traction due to reduced barriers for AI application. However, the challenges involved vary with the type of synthesis processes targeted. Moreover, making SDLs a reality in a typical materials science lab may be an expensive prospect.

Our focus is on exploring and optimising new inorganic compound materials produced by physical vapour deposition (PVD), e.g. novel semiconductors like $BaSn_2S_3$ *and* $BaZrS_3$*. This area presents special challenges for SDLs. First, the hardware must access the wide range of conditions under which inorganic materials can be grown and their properties tuned. Second, inorganic materials have multiple degrees of freedom in stoichiometry, defects, and structure, leading to a high-dimensional parameter space for the SDL to probe. Achieving the requisite capabilities with end-to-end automation and high throughput is difficult outside of dedicated (expensive/inflexible) cluster systems. Here, we present our approach for constructing an SDL for inorganic thin film materials based on retrofitting standard PVD hardware; making it potentially transferrable to many labs with relatively modest investments.*

Our SDL hardware utilizes co-sputtering to deposit the metal elements of the subject material. We employ combinatorial deposition with QCM sensors to interpolate chemical composition in real time. The samples are then reacted with H_2S *in a high-vacuum RTP furnace, allowing investigation of a temperature range up to 1000°C at pressures from* 10^{-6} *to* 10^{1} *Torr, with excellent control of the thermal pathway. These stages are automated by* *custom Python codes, while sample transfer is achieved with a 6-axis robot arm. The sample turnover time is approximately 10-20 minutes – rapid for such experiments. To avoid extending cycle time, characterization and analysis rely on non-contact imaging techniques. All process data is continuously dumped to a NOMAD Oasis.*

To explore and optimise materials "from scratch", our self-driving workflow comprises a series of machine learning modules that progressively narrow the search space, starting with sputtering alone and then the full two-step synthesis process. Each module uses active learning to iteratively train on accumulated experiment data and propose the next experiment, until a learning criterion is met. Different input data are used for each learning module, based on the principle of measuring "just enough" data for the task at hand. In the first module, active learning with a multilevel perceptron classifier eliminates sputtering conditions with low deposition rates (due to plasma quenching or flux attenuation). This constrains a second module using Bayesian multi-output Gaussian process regression, which learns deposition rates from each QCM sensor over the remaining parameter space. The outputs of this module, fitted to a flux-distribution model, delineate the space of sputtering processes yielding specific compositions (e.g., 1:2 Ba for $BaSn_2S_3$*). In the third stage, the full process is utilized to produce samples, with input data for continued exploration derived from images processed through an autoencoder. This subdivides the remaining parameter space based on the visual outcome of experiments, leading to phase-diagram-like datasets where "phase regions" are first identified and only later assigned by small number of ex-situ experiments. Future workflow extensions include functional-property measurements (e.g., photoluminescence imaging) to enable optimization of functional properties in a given phase region.*

In this presentation we will detail the equipment and workflow, including results on optimization of individual modules and the overall sequence, and early results on phase diagram derivation. The aim is to help inspire SDL implementation more widely, especially in PVD contexts.

11:15 AM MT02.09.10
Towards Autonomous Physical Vapor Deposition of Inorganic Thin Film Materials *Davi M. Febba, Stephen Schaefer, Brooks Tellekamp, Hilary Egan and Andriy Zakutayev; National Renewable Energy Laboratory, United States*

Growth and characterization of thin film materials require long experimental campaigns to tune the processing conditions until desired material properties and chemical composition are achieved. If devices are under study, the cycle of synthesis, characterization and optimization is stretched even further, since now phenomena occurring at the materials interfaces play a significant role.
In this context, autonomous experimentation is transforming the landscape of synthesis and characterization of materials and devices. The incorporation of automation of repetitive tasks and artificial intelligence techniques to plan experiments based on the available data accelerate the materials discovery chain while minimizing human intervention, freeing researchers to focus on more strategically relevant tasks.
In this presentation, I will present the progress on autonomous experimentation at NREL for synthesis of inorganic thin films by physical vapor deposition, namely sputtering[1] *and molecular beam epitaxy*[2]*, all enabled by automated instruments driven by artificial intelligence algorithms. Equipped with sophisticated capabilities such as multidimensional Bayesian analysis and computer vision techniques, these systems intelligently navigate through large parameter spaces, such as substrate and effusion cell temperature, power, pressure, gas flow and shutter times.*
I will also discuss the many challenges and solutions encountered during the adaptation of existing laboratory infrastructure to accommodate autonomous workflows, such as instrument automation, workflow orchestration, data management, software development, and establishment of sub networks for communication between a remote server and command-and-control computers.

Accelerating Solid-State Material Development Through AI-Driven Autonomous Synthesis Laboratories *Yan Zeng[1,2]; [1]Florida State University, United States; [2]Lawrence Berkeley National Laboratory, United States*

Many technological advancements, including the development of novel electrode and electrolyte materials for energy storage, rely on the creation of new solid-state materials. Identifying promising material design strategies is only the initial step; synthesizing these materials poses a greater and more time-consuming challenge. To streamline the design–make–measure cycle, we have established an autonomous solid-state synthesis laboratory driven by AI and automation. This lab autonomously generates synthesis recipes from a comprehensive archive of historical literature, conducts experiments through robotic systems and automated instruments, and applies machine learning for data interpretation. Active learning algorithms guide the experimental direction to optimize results. This presentation will detail a case study on determining the solubility limit of fluorine in disordered rocksalt materials using the autonomous lab. Employing a Bayesian optimization workflow, we can minimize experimental trials and maximize information gain using an entropy search algorithm. This integrated approach not only refines existing synthesis methods but also advances the exploration and development of a wide array of oxide-based powder materials.

SESSION MT02.10: AI-Driven Autonomous Experimentation III
Session Chairs: Yongtao Liu and Zijie Wu

Harnessing Language Models for Experimental Materials Science *Krishna Rajan; University at Buffalo, The State University of New York, United States*

In this presentation we explore the use of large language models (LLM) and natural language processing (NLP) technique as a guide for experimentation in materials science. A specific focus of our discussion is the exploration of LLM and NLP methods to bridge disparate experimental information across multimodal experiments; especially to establish structure-processing-property relationships. We also discuss the application of LLM and NLP methods as a means to accelerate the discovery in identifying links and/or gaps in knowledge in experimental studies.

2:00 PM MT02.10.02
Closed-Loop Transfer Enables AI to Yield Chemical Knowledge *Seungjoo Yi, David Friday, Changhyun Hwang, Tiara Torres-Flores, Martin Burke, Ying Diao, Nick Jackson and Charles Schroeder; University of Illinois at Urbana-Champaign, United States*

AI-guided closed-loop experimentation has recently emerged as a powerful method to optimize objective functions, yet its potential to generate new scientific insights remains underexplored. In this talk, I will discuss the integration of closed-loop experiments with physics-based feature selection and supervised learning, denoted as Closed-Loop Transfer (CLT), to simultaneously generate chemical insights and optimize objective functions. Our work shows that CLT generated a robust predictive model for the photostability of light-harvesting oligomers, revealing that high-energy regions of the triplet state manifold influence molecular photostability across a diverse library of light-harvesting donor-bridge-acceptor oligomers, which challenges the conventional focus on the lowest energy triplet state. This pivotal insight emerged after automated modular synthesis and experimental characterization of only ~1.5% of the theoretical chemical space. The model's reliability was enhanced by multiple experimental test sets and validated by adjusting triplet state energies to surpass photostability plateaus. After completing the CLT campaign, we designed a new set of molecular building blocks to control photostability by covalently linking the triplet state quencher (TSQ) cyclooctatetraene (COT) to a thiophene block. Our results show that the photostability of light-harvesting oligomers is enhanced when COT is non-specifically added to solution, but enhanced rates of photodegradation were observed for light-harvesting oligomers containing covalently linked COT, which was fully consistent with our predictive models based on density functional theory (DFT) calculations of triplet state energies for these molecules. Importantly, this outcome reinforced our main findings from the CLT campaign that COT's high-energy regions within the triplet state manifold significantly contribute to photodegradation in light-harvesting molecules. Motivated by these insights from the model validation phase, we are now designing new molecular building blocks based on redox-mediated TSQs such as anthraquinone. Current efforts are focused on using DFT to evaluate the thermodynamic viability of quenching reactions between TSQ candidates and light-harvesting molecules, and promising candidates are being synthesized and characterized in terms of solution-state and solid-phase photostability. Overall, these results demonstrate that combining physics-based modeling with closed-loop discovery campaigns and automated synthesis methods holds the potential to accelerate the discovery of new materials with advanced function.

2:15 PM MT02.10.03

DiSCO—A Human Knowledge Embedded Automated [Di]scovery, [S]ynthesis, [C]haracterization, and [O]ptimization Platform for Identifying Synthesizable Inorganic Materials *Basita Das, Alexander E. Siemenn, Teresa Le, Fang Sheng, Kangyu Ji and Tonio Buonassisi; Massachusetts Institute of Technology, United States*

Advent of generative design algorithms have successfully helped create databases with millions of inorganic material candidates. However, identifying synthesizable candidates and successfully synthesizing them remain to be outstanding challenges. In our current body of work, we aim to address the challenge of synthesizability by a two-fold approach of

1. predicting synthesizability of novel materials by embedding human knowledge in the form of "Filters" in material discovery pipeline and,

2. validating the ground truth of novel materials by implementing a medium-fidelity high-throughput automated material synthesis and characterization.

Our two-fold solution aims to tackle the problem of novel material synthesizability in two ways. First, we embed chemical rules, practical constraints (raw material availability, ease of synthesis, etc.), and human intuition drawn from tacit knowledge as post-generation "Filters" into our materials discovery pipeline. Each filter embodies a single chemical rule, constraint, or human intuition which needs to be satisfied for the successful synthesis of a novel material. We use these individual filters in different configurations to develop unique screening pipelines. The "Filter" pipeline in combination to material generation algorithm forms the discovery part of our DiSCO platform. The intention of use of such "Filter" pipelines is to screen generated material libraries and identify materials which have a higher probability of being synthesizable. Such post-generation screening pipeline also *enables the downselection from million or more potential candidates in generated material libraries to a few hundred compounds which are actually chosen for synthesis, and hence helps with better resource allocation. The downselected materials are sent for synthesis in the next step.*

In the second part of our workflow, we synthesize the downselected novel materials, and validate their ground truth. The physical synthesis of the downselected compounds presents several challenges as the formation of the target compound is a function of the expertise of the experimentalist, precursor temperature, precursor molarity, synthesis temperature, substrate temperature, environmental humidity, etc. To address these challenges, we developed the later part of DiSCO featuring islands of automation performing automated synthesis, characterization and optimization. The system combines (a) high-throughput pipetting robots with temperature control for synthesis, thus reducing human introduced variances, (b) automated characterization tools for faster cycles of learning and validating the ground truth, and (c) a graph database system for tracking the meta-data and results. The intention of use of this high-throughput automated platform is to enable very fast synthesis and characterization of the downselected material candidates at different processing conditions, and identify which of the attempted material candidates was successfully created and under what conditions. The purpose of the graph database management system is to seamlessly store the data and meta-data to enable future learning and prediction.

Post high-throughput synthesis and characterization, we used tradition high-fidelity characterization methods to validate the actual composition and structure of the formed compounds to establish further trust in our medium fidelity high-throughput system. As a use case of this material exploration platform, we explore halide “perovskite-inspired” materials system involving 60 phase spaces, to identify materials of bandgaps within the 1 to 2 eV range, by following the process of discovery, synthesis, characterization, and optimization, and creating a database consisting of information on precursor solubility, material processing condition, characterization, and validation data. We identify 2 novel material compositions by following this process.

8:00 AM *MT02.12.01
Autonomous Alignment at Synchrotron Facilities Using Bayesian Optimization *Thomas Morris[1,2]; [1]Yale University, United States; [2]Brookhaven National Laboratory, United States*

Autonomous alignment will be an indispensable component of autonomous experimentation at synchrotron facilities, as beamlines drift over time and must be constantly re-aligned. Bayesian optimization is a machine learning-based algorithm well-suited for high-dimensional, expensive-to-sample, and potentially noisy optimization problems, and it has been successfully implemented to autonomously align beamlines at several facilities. However, there are beamline-specific obstacles that can hinder the robustness and efficiency of these efforts, meaning that most are tailored to a narrow context of optimization problems. In this talk, I outline these obstacles and their solutions, and show that it is possible to construct an adaptable, generalized framework for *autonomous alignment that performs well at many different kinds of beamlines across different facilities. I outline the application of Bayesian optimization to different optimization problems at several light sources (ALS, APS, NSLS-II, LCLS). I discuss the prospect of a unified, collaborative approach to beamline automation.*

8:30 AM MT02.12.02

A Fully Convolutional Approach to Denoising Material Dynamics Data from X-Ray Photon Correlation Spectroscopy *Nisar Nellikunnummel, Lutz Wiegart, Tatiana Konstantinova, Maksim Rakitin, Anthony M. DeGennaro and Andi M. Barbour; Brookhaven National Laboratory, United States*

X-ray photon correlation spectroscopy (XPCS) is a technique used to measure the dynamics of materials through coherent X-ray beams. The nonequilibrium dynamics of the sample are studied using a two-time correlation function (2TCF), which is evaluated from the beam scattered off the sample. The 2TCF is subject to various types of noise, including random and correlated fluctuations, as well as heterogeneities that obscure the average dynamic parameters of the sample. The correlated nature of the noise makes off-the-shelf solutions, such as Gaussian filters, inadequate for denoising such data.

Previously reported deep learning models based on a convolutional neural network encoder-decoder (CNN-ED) architecture have successfully improved the signal-to-noise ratio in the 2TCF. However, these models are limited to specific dynamics (e.g., equilibrium) with a fixed number of time samples (lags). A newly developed fully convolutional model can be applied to denoise a wide range of material dynamics and lags, eliminating the need for multiple customized models. In earlier models, a linear latent space layer played a crucial role in denoising by filtering out unwanted features from the input. The proposed model, which consists solely of convolutional layers without a latent space, can learn the functional form of the signal through supervised training. We demonstrate that fully convolutional encoder-decoder models trained on experimental data can effectively suppress noise in the 2TCF for a variety of material dynamics at NSLS-II. Noise reduction enhances quantitative usage of XPCS data and creates the potential for automating the analytical workflow, which is key to autonomous experiments.

8:45 AM MT02.12.03

Multimodal Co-Orchestration to Uncover Structure-Property Relationships in Combinatorial Libraries *Boris N. Slautin[1], Utkarsh Pratius[2], Ilia N. Ivanov[3], Yongtao Liu[3], Rohit Pant[4], Xiaohang Zhang[4], Ichiro Takeuchi[4], Maxim Ziatdinov[5] and Sergei V. Kalinin[2,5]; [1]Universität Duisburg-Essen, Germany; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States; [4]University of Maryland, United States; [5]Pacific Northwest National Laboratory, United States*

The rapid progress in automated synthesis techniques has enhanced cost-effectiveness and sped up the development of new materials. Combinatorial libraries are among the earliest examples of such high-throughput synthesis. However, a bottleneck remains in the characterization phase, which often requires an extensive analysis of various electric, mechanical, chemical, and structural material properties. Characterizing combinatorial libraries, for instance, involves exploring multiple aspects of their structures and functionalities using a wide range of local investigative methods, such as scanning probe microscopy, electron microscopy, Raman microscopy, and others.

The ongoing revolution in autonomous instrumentation and novel artificial intelligence-based approaches is introducing groundbreaking capabilities for integrating multimodal tools, equipped with several sequential detection methods, or several characterization tools into automated workflows Here we present a co-orchestration workflow designed to facilitate the exploration of combinatorial libraries and similar systems through the simultaneous application of multiple methods (modalities). The central concept of this workflow is the real-time use of knowledge gained from one property to expedite the exploration of other properties measured by different methods. The proposed framework integrates dimensionality reduction through variational autoencoders

(VAEs) with multi-task Gaussian Processes (MTGP) to harness correlations between modalities and use them for the characterization expedition.

In multimodal co-orchestration, a process of characterization of a combinatorial library comprises sequential steps. At each of these steps, the orchestrating agent selects the measurement modality and location for the next exploration step based on the expected knowledge gain and associated measurement cost. The low-dimensional compositional space within a combinatorial library makes the implementation of Bayesian optimization (BO) a highly robust solution for governing the orchestrating agent. At the same time, raw measured data are often represented in high-dimensional datasets, such as spectra and images. In multimodal co-orchestration, the compositional dependencies of the VAE latent variables for the different modalities are employed to train the multi-task GPs (MTGP). The multimodal acquisition function is constructed based on the MTGP outputs. Leveraging VAEs for dimensionality reduction allows us to transfer the interpretation and feature extraction from raw data from humans to AI agents, enabling GPs to be trained on the compositional dependencies of complex features without direct human involvement.

The proposed framework's effectiveness was evaluated by applying it to the co-orchestration of piezoresponse force microscopy hysteresis loops (BEPS) and micro-Raman spectra for exploring the Sm-BiFeO$_3$ (Sm-BFO) combinatorial library. This system exhibits a phase transition from the ferroelectric phase of pure rhombohedral BiFeO$_3$ to a non-ferroelectric orthorhombic phase in BiFeO$_3$ doped with 20% Sm, passing through the morphotropic phase boundary. The workflow demonstrated its effectiveness in optimizing autonomous exploration, particularly when the VAE latent variables showed smooth compositional dependencies. We believe that the multimodal co-orchestration workflow provides a flexible and robust solution for an expedition of the characterization of combinatorial libraries and similar material systems.

Dueling Robots—Concurrent, Robotic, AI-Driven SAXS and SANS for Industrial Coating Optimization *Tyler Martin, Duncan Sutherland and Peter Beaucage; National Institute of Standards and Technology, United States*

Virtually all materials studies involve the fusion of multiple kinds of data and multiple experimental modes, often in an iterative way and nearly universally connected by human scientific reasoning rather than unified models. This is particularly exemplified by x-ray and neutron based measurements, typically conducted at national or international user facilities on a six-month (or longer!) lead time in a highly competitive proposal landscale. For instance, a SAXS study of multicomponent nanoparticle assembly might raise questions around component identity, prompting researchers to perform contrast-matched SANS experiments. These studies would be presented alongside one another in a paper, but would seldom be truly co-refined. The nature of large user facilities means that the experiments might be months and thousands of miles apart, with iteration between the two practically impossible.

This talk will describe a recent first effort toward realtime, multimodal, national-user-facility based materials optimization using two NIST Autonomous Formulation Laboratory (AFL) platforms concurrently refining the same phase map at two beamlines: the I22 synchrotron SAXS and the LARMOR SANS, both at the Rutherford Appleton Laboratory site in Oxfordshire, UK. The AFL is a highly flexible, newly developed platform that can automatically prepare a specified chemical composition using pipetting, transfer it to an instrument, and trigger a measurement. Its custom-developed, open software and hardware stack allows the highly flexible intake and reduction of this measurement data, assignment of data to phase, Gaussian process regression of a phase diagram, and selection of a next measurement point based on user-specified criteria that balance specific exploration of the landscape with scientific questions of interest. This software stack has been upgraded to include classification strategies that understand the physical advantages/disadvantages of individual techniques and next point selection that similarly contemplates expected information gain. The result is that any number of AFL platforms anywhere in the world can *be set up with parallel (or analogous) physical configurations, pointed using a HTTP connection to the same AI server, and collaboratively and concurrently begin refining a common model of the same phase diagram. As a first, demonstrative materials science problem, we studied the binary co-assembly of polymer and ceramic nanoparticles used in coatings (e.g. latex paints). SAXS is sensitive nearly exclusively to the high-x, high-density ceramic component while SANS is conducted in contrast-matched solvent to study only the polymeric component. Early results show a promising acceleration of the number of samples needed to identify a target phase by the use of concurrent measurement over separate grid searches.*

***AI-Assisted Synchrotron X-Ray Scattering Experimentation** Esther Tsai; Brookhaven National Laboratory, United States*

The extraordinarily high flux at synchrotron light sources continue to enable versatile in-situ and autonomous experimentation for the invention and development of functional nanomaterials. Synchrotron beamlines are however constantly oversubscribed, efficient use of beamtime and sustainable beamline operation are thus essential. X-ray scattering beamlines often adopt various customized or in-situ setups, integration to beamline and dexterous control of each component are critical for smooth and efficient experimentation. Advances in artificial intelligence and machine learning, including natural language processing methods, can be utilized for effective and sustainable beamline operation, focused scientific discovery, human-AI integration, as well as user support and education.

***A Modular Framework for AI-Driven, Multimodal Synchrotron Experiments** Daniel Olds[1], Adam Corrao[1], Stuart Campbell[1], Matthew R. Carbone[1], Thomas Caswell[1], Howie Joress[2], Bruce Ravel[1] and Phillip Maffettone[2]; [1]Brookhaven National Laboratory, United States; [2]National Institute of Standards and Technology, United States*

Multimodal characterization, which combines information from different measurement techniques, often greatly benefits material studies. However, these campaigns can be challenging due to the experimental logistics and analysis expertise required to integrate multiple methods. Typically, the multimodal aspects of materials research can only be considered after measurements are complete, during the combined analysis to derive deeper insights. Recently, we demonstrated AI-driven simultaneous multi-beamline experiments using combined synchrotron total scattering and X-ray Absorption Fine Structure (XAFS) measurements. This world-first achievement opens new opportunities for human/AI collaborative operational modes, where AI algorithms work alongside facility users to enhance scientific output.
Using the Bluesky data acquisition platform, we conducted fully and partially autonomous coordinated experiments in real-time across spatially distant beamlines with asynchronous measurements at vastly different collection rates. An ensemble of AI agents is crucial for these autonomous experiments, processing both raw data and results from scientific analysis (e.g., Rietveld refinement, XAFS modeling) from asynchronous multimodal measurements to drive real-time decision-making. This highly extensible framework offers plug-and-play capabilities, allowing AI agents for data reduction, analysis, and decision-making to be easily swapped for optimal solutions. Additionally, we have enabled in silico experiments, providing an environment for offline testing of AI agent performance. We will discuss the design and implementation of this AI-driven experiment framework and demonstrate the enhanced efficiency for sample exploration through several use cases.

A Hybrid Modelling Approach Coupling Physics-Based Simulation and Deep Learning for Battery Electrode Manufacturing Simulations *Utkarsh Vijay[1,2], Diego Galvez-Aranda[1], Franco Zanotto[1,3], Tan Le-Dinh[1], Mohammed Alabdali[1,3], Mark Asch[1] and Alejandro A. Franco[1,2,3]; [1]Université de Picardie Jules Verne, France; [2]ALISTORE-European Research Institute, FR CNRS 3104, Hub de l'Energie, France; [3]Réseau sur le Stockage Electrochimique de l Energie (RS2E), FR CNRS 3459, France*

The future projection concerning Lithium-ion Battery indicates the necessity to find ways to accelerate the optimization of the electrode's manufacturing process. The traditional solvent-based manufacturing process includes the optimization of several steps and their complex relationships to produce an optimized electrode. In state of the art, this optimization is heavily based on trial-and-error approaches, resulting in high resource utilization, high scrap rates, high energy consumption, and high emissions. Previous research efforts have combined empirical and traditional computational methods to understand these complex relationships to further simplify the optimization process. However, these methods themselves are demanding in terms of resources such as materials or computational effort. In this work, we proposed a novel supervised Deep Learning (DL)-based workflow that couples with physics-based cathode manufacturing simulation frameworks previously reported by us [1,2] further reducing computational cost in synthetic electrode microstructure production, and showing generalizability to various electrode chemistries. The trained DL model, integrates well into the physics-based simulation framework and shows good performance in reducing simulation time and forecasting Nickel Manganese Cobalt Oxide (in the ratio of 1:1:1), Lithium Iron Phosphate, and All-Solid-State Battery based cathode slurry microstructures with 3D spatial resolution. The proposed novel hybrid approach, combining DL with physics-based manufacturing simulations, can successfully predict how slurry formulation and solid content influence its microstructure and experimental properties, such as density and viscosity as a function of the shear-rate. The resulting slurry microstructures are in turn used to inform a physics-based simulation pipeline of the drying and the calendering to predict electrode microstructures (defined by the spatial arrangement of the materials particles and pores) and their associated functional properties, such as the porosity and electrical conductivities. Our hybrid electrode manufacturing simulation approach promises to streamline lab-scale electrode manufacturing and reduce errors, waste, and resource consumption[3].

High-Throughput and Low-Cost Precision Fluid Handling for Direct Material Printers in Autonomous Research *Eunice Aissi, Sharil Maredia, Katelyn Lam, Alexander E. Siemenn and Tonio Buonassisi; Massachusetts Institute of Technology, United States*

Autonomous and machine learning driven research presents abundant opportunities to accelerate materials discovery at the rate needed for rapid climate action. Due to the high data demands of machine learning driven research, high-throughput synthesis methods are essential to successful implementation of accelerated materials *research. However, high-throughput synthesis methods are often inaccessible due to their high complexity, commonly employing robotic systems with large space and technical skill demands at a price tag of over $500k. Low-cost, home-built, high-throughput material printing tools offer an accessible platform for high-throughput materials synthesis; these methods, however, can lack both precision and reproducibility.*

We address the need for low-cost, high-precision, and high-throughput fluid handling devices for materials synthesis by designing and validating a home-built system capable of dispensing and mixing gradients of up to 10 fluids in the microliter to milliliter scale at speeds of up to 1000 compositions a minute. The system features a carefully curated wetted material path consisting only of chemically inert PTFE, nylon, and borosilicate glass. Three subsystems are used to ensure the functionality of the device: fluid dispensing, fluid mixing, and droplet generation. Fluid dispensing allows for known and measurable dispensing of fluids at ul to ml scale, fluid mixing allows for uniform mixing of all streamlines in low Reynolds number regimes, and droplet generation allows for dispensing uniform droplets. All components are built in-house and contribute to a total price of about $7000, making it an affordable tool when compared to existing fluid-handling systems. Fluorescent dyes of varying wavelengths are used to test and validate each subsystem of the fluid-handling device. Careful and thorough measurements and characterization of the fluid dispensing system are done to understand its operating conditions and associated errors. Hyperspectral images of the system output are taken to ensure proper fluid mixing and the composition of droplets with varying concentrations of dyes.

Machine Learning for Voluminous Quantum Materials Data *Eun-Ah Kim[1,2]; [1]Cornell University, United States; [2]Ewha Womans University, Korea (the Republic of)*

Decades of efforts by the quantum materials research community drove a "data revolution." Modern experimental modalities produce high-dimensional data in large volumes. Unprecedented control and new facilities imply new dimension and new knobs, such as time-resolved probing or scanning probing. Moreover, massive amounts of high-throughput ab-initio data and curated experimental data are becoming accessible to researchers. Much needed are data-centric approaches that accelerate discoveries from these data through synergetic interaction with expert human researchers' insights. A synergy between data science and quantum materials research is essential for such endeavors to result in scientific progress. I will present cases of fruitful collaborations that led to new insights and started to shape an approach to data sets of the new era. Specifically, I will discuss how to use unsupervised learning to discover new physics from large volumes of evolving data and how to use supervised learning to uncover descriptors of emergent properties from limited volume of expertly curated data.

Robust Adaptive Design of Experiments—An Acquisition Function Based on Graph Theory and Topological Data Analysis *Ankush Kumar Mishra[1], Enrique D. Gomez[2] and Baskar Ganapathysubramanian[1]; [1]Iowa State University of Science and Technology, United States; [2]The Pennsylvania State University, United States*

Bayesian optimization (BO) is an efficient method for searching the input space of expensive black-box functions – synthesis and characterization workflows -- relying on previous experiments to guide the selection of subsequent experiments. BO balances exploration of unknown regions and exploitation of regions likely to yield the maximum value of the quantity of interest (QoI). Common acquisition functions in BO, such as Upper Confidence Bound (UCB), Probability of Improvement (PI), and Expected Improvement (EI), utilize the mean and standard deviation at each point to determine the next experiment. However, these acquisition functions do not account for the QoI robustness, i.e. how sensitive is the quantity of interest (QoI) to perturbations of the input variables? This becomes an important consideration in automated workflows, where the ideal extremal value of the QoI may not be practically usable due to the inherent uncertainty and stochasticity in processing and synthesis conditions.

We introduce a novel acquisition function that searches and identifies robust maxima – i.e. that have a low sensitivity to perturbations in input parameters. We use concepts from topological data analysis, specifically persistence diagrams, and graph theory, specifically connected components, to define a robustness factor into standard acquisition functions. Both concepts are specifically chosen for their ease of use, algorithmic efficiency, and availability of optimized codes (in python) for democratized use.
The new acquisition function is implemented for straightforward use into available BO toolboxes like BoTorch. We illustrate the new acquisition function using both computational as well as experimental workflows.

ParetoUCB—Simple and Fast Multi-Objective Bayesian Optimization for Materials Synthesis Experiments
Mark Lee and Julia W. Hsu; The University of Texas at Dallas, United States

The objective of many new materials synthesis experiments is to simultaneously optimize two or more material properties, for example maximizing infrared/visible transparency while minimizing DC electrical resistivity in transparent conductors [1]. Often the physics and chemistry needed to optimize one property conflict with that needed for other properties, so attaining globally optimal values for all objectives as if they were independent is not possible. In such a case the experiment becomes a classic multi-objective optimization problem with the goal of determining the Pareto frontier: the set of objective values where further improvement in any one objective can only come at the expense of degrading one or more other objectives.

Many machine learning (ML) algorithms exist for finding the Pareto frontier of multi-objective optimization problems involving black-box functions using a Bayesian optimization approach. Most of these are based on general methods which in theory are scalable to the mathematically difficult problem of high dimensional spaces for both input predictors and output objectives and so are computationally intensive and non-intuitive. Such ML methods may be overkill for many if not most real materials synthesis experiments involving predictor space dimensions ≤ 6 and only two or three objectives. This work describes a ML Bayesian optimization approach to determine the Pareto frontier that is computationally simple, intuitive, easily extendible to batch sample acquisition, and converges rapidly for the relatively low dimensional problems typically encountered in materials synthesis experiments. We nicknamed this method “ParetoUCB” because it uses as the acquisition function *upper confidence bound (UCB) values evaluated solely over the Pareto frontier of a Gaussian process regression model generated from sampled data. In several trials using synthetic data generated by common test functions on problems with predictor dimensions ≤ 4 and two or three objectives, ParetoUCB (coded in Matlab running on a desktop Apple M2 CPU) converged onto the Pareto frontier more accurately, with the same or fewer number of data evaluations, and as fast or faster in real computational time benchmarked against the widely used BoTorch Python package using its qEHVI or qNEHVI multi-objective acquisition functions (coded in Python running on either a desktop Apple M2 GPU core or an Nvidia GPU via Colab). Limitations of ParetoUCB when extended to higher dimensional problems and its use with actual experimental data will be discussed.*

This work is supported by NSF CMMI-2109554.

Understanding and Mitigating Bias in Autonomous Materials Characterization and Discovery *Jason R. Hattrick-Simpers; University of Toronto, Canada*

Since the publication of the Mission Innovation Materials Acceleration Platform, AI is increasingly responsible for driving automated experimental and computational tools. There have been multiple case studies for which autonomy was demonstrated to successfully drive materials optimization or discovery problem and the world of scientific robots has moved from science fiction to reality. However, within the broader AI community it is well known that AI's carry with them their creators' biases and this has serious implications on model development and deployment. Using several case studies, I will illustrate how biases can arise in materials science and specific steps that can be taken to remove them. Specifically, I will discuss some of our recent work in (1) reducing human bias in label generation by applying robust statistics to spectroscopic data analysis, (2) identifying and mitigating search space bias through model disagreement, and (3) circumventing the big data bias loop by illustrating how to the presence of information redundancy in large computational datasets and (4) how construct an optimally informative dataset for model training.

Property Directed Generative Design of Inorganic Materials *Kedar Hippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Institute of Materials Research and Engineering, A*STAR, Singapore*

A combination of AI, high-throughput experiments (robotics) and high performance simulations can be used to accelerated materials development. For inorganic crystalline materials, structure determines property. Therefore, property-driven generative design, driven by machine learning, critically requires understanding of the structure of materials. A deep understanding of crystal structures and their symmetries is essential for accurate generative design.

Thus, the development of symmetry-aware generative models becomes critical to ensure property-directed learning branches. Further, generated crystal structures require validation, both computationally and experimentally. First, I will introduce a generative design framework (WyCryst) [1], composed of three pivotal components: 1) a Wyckoff position based inorganic crystal representation, 2) a property-directed VAE model and 3) an automated DFT workflow for structure refinement. We successfully reproduce a variety of existing materials *for both ground state as well as polymorphic structure predictions. We also generate several new ternary materials not found in the inorganic materials databases, which are proved to be stable, retaining their symmetry, and we also check their phonon stability, using our automated DFT workflow highlighting the validity of our approach. We believe our symmetry-aware WyCryst takes a vital step towards AI-driven inorganic materials discovery. Next, we address the challenge of experimental synthesis of these materials paired with data-driven characterization techniques to assess their properties. This is challenging due to the lack of a general method to rapidly synthesize and (optimally) dope bulk materials. We invented a rapid self-sintered solid-state synthesis technique (tested on GeTe, Copper, Silver Antimony Telluride), achieving phase-pure crystalline materials synthesized in the milligram scale in as little as 15 seconds. This accelerates the solid-state reaction process by a factor of >100 relative to the traditional route of mix-and-bake and produce direct experimental validation.*

4:00 PM MT02.13.06

Batch Bayesian Optimization for High-Dimensional Experimental Design— Simulation and Visualization

Imon Mia[1], Armi Tiihonen[2], Mark Lee[1], Roman Garnett[3], Tonio Buonassisi[4], William Vandenberghe[1] and Julia W. Hsu[1]; [1]The University of Texas at Dallas, United States; [2]Aalto University, Finland; [3]Washington University in St. Louis, United States; [4]Massachusetts Institute of Technology, United States

Optimization is a common task in materials science. Bayesian optimization (BO) is increasingly used in experimental work involving varying levels of automation. Before implementing BO in an experimental campaign, many researchers prefer to implement BO in a simulation environment using synthetic data, which provides pedagogical and troubleshooting value. Two large differences between experimental and simulation work are (1) experiments are often performed in batches, i.e., processing multiple samples at once, to save materials cost or time, and (2) experimental data contain aleatoric uncertainties manifesting as noise.

*In this work, we develop a framework to visualize BO step by step, first as an evaluation tool for simulation environments (and later possibly a debugging tool for experiments). We showcase an example of simulated data with increasing noise, evaluating optimization strategies as a function of noise magnitude. In our demonstration, we implement batch BO using the Emukit package to find the optimum to 6-dimensional Ackley and Hartmann functions. 6 dimensions in the predictor inputs (**X**) are chosen to mimic the number of input variables commonly used in experimental work. The Ackley function represents a needle-in-a-haystack experimental manifold, i.e., hard-to-find global maximum in the objective (y), while the Hartmann function represents a more gradual landscape but contains a second local maximum similar in objective value to the global maximum but at a significantly different **X** value. Using synthetic data without noise, the optimization, i.e., learning, progress is first studied for how it is affected by the choices of acquisition function (expected improvement vs upper confidence bound), hyperparameters, and batch-picking method. Latin hypercube sampling (LHS) is used to pick initial **X** values for collecting data, followed by 50 learning cycles with a batch size of 4 at each round. 99 LHSs are implemented to understand statistical variations. The optimization results are evaluated based on instant regret in **X**, which is the Euclidian distance between the final optimal $\mathbf{X}_{opt}$ from the model and the $\mathbf{X}_{max}$ of the ground truth y maximum, averaged over the 99 LHS. While most papers in the literature track the difference between the model and ground truth y values, we argue that **X** is more important to experimenters because the inputs are what can be controlled and varied, and y values from the model deviate from the ground truth because of the details of the Gaussian process regression. The effects of noise on the optimization are evaluated for normally distributed noise levels ranging from 1 to 20 %. We show that adding noise based on the percentage of the ground truth y maximum, as is commonly done in the literature, overestimates the noise when compared to the signal-to-noise ratio in* *experiments. We also develop several visualization methods to show the optimization progression and outcomes as visualization is important for high-dimensional problems because it is difficult for humans to comprehend results for problems higher than three dimensions.*

This work is supported by NSF CMMI-2109554. JWPH and TB acknowledge the support of Simons Foundation Pivot Fellowship.

4:15 PM MT02.13.07

Dynamic Multi-Fidelity Decision-Making Based on Extended Bayesian Optimization *Luca Torresi and Pascal Friederich; Karlsruhe Institute of Technology, Germany*

State-of-the-art Bayesian optimization algorithms have the shortcoming of relying on a rather fixed experimental workflow. The possibility of making on-the-fly decisions about changes in the planned sequence of experiments is usually excluded and the models often do not take advantage of known structure in the problem or of information given by intermediate proxy measurements [1-3]. We hypothesize that an extended Bayesian optimization procedure, with surrogate models and acquisition functions that can flexibly choose to modify the workflow on the fly, will improve the performance of state-of-the-art methods for optimization in SDLs, in terms of time, materials consumption, and quality of discovered optima.

To address these limitations, we developed a surrogate model composed of a sequence of Gaussian processes, that can take advantage of the modular structure of experimental processes and that is capable of handling sparse datasets where only partial information (proxy measurements) is available for certain or even the majority of data points [4]. We implemented an acquisition function, based on a mixture of expectation improvement and upper confidence bound, that allows the optimizer to selectively sample from individual sub-processes. Finally, we devised a synthetic dataset generator to simulate multi-step processes with tunable function complexity at each step, to evaluate the efficiency of our model compared to standard BO under various scenarios.

We conducted experiments to evaluate our model across nine distinct scenarios involving two-step processes, optimizing 20 randomly generated processes in each scenario. In all scenarios our multi-step optimizer outperformed the benchmark methods, demonstrating superior performance in terms of both the quality of the optimum found within the allotted budget and in terms of convergence speed. This advantage is particularly evident in scenarios where the complexity of the first step exceeds that of the second step. We are currently in the process of validating our results on real-world datasets.

4:30 PM MT02.13.08

More Robust Bayesian Optimization of Materials with Humans in the Loop *Armi Tiihonen[1], Louis Filstroff[2], Petrus Mikkola[1], Emma Lehto[1], Samuel Kaski[1,3], Milica Todorović[4] and Patrick Rinke[1]; [1]Aalto University, Finland; [2]Université Lille, France; [3]The University of Manchester, United Kingdom; [4]University of Turku, Finland*

Bayesian Optimization (BO) is a machine learning method that can be used for guiding autonomous materials optimization experiments, such as perovskite composition optimization for more stable solar cells. BO usually optimizes the target property in a sample-efficient manner, which makes it a popular choice especially for costly experiments. However, coupling BO with fully or semi-automated sample preparation introduces the challenge of ensuring a sufficient sample quality during the material optimization loop: Low-quality samples could obscure the optimization process but they can be difficult and sometimes expensive to detect automatically. Such sample quality concerns currently hinder automated materials optimizations. This holds especially in largely unexplored materials domains – where unexpected types of low-quality samples may appear – and in high-dimensional optimizations – that would require a high level of automation to reach the necessary sample sizes.

To make BO-guided materials optimization more robust, we add humans into the BO loop (HITL) as an additional data source to comment on the sample quality. Humans can make sample quality estimations in a flexible way either visually or by prescribing additional characterizations. Humans are in our approach queried only when necessary to minimize the burden to humans. The code implementation is such that the human feedback can also be given asynchronous to the experiment loop to avoid humans from becoming bottlenecks of the optimization.

We implemented three HITL schemes, two based on data fusion via an added cost to the BO acquisition function, and one on multifidelity BO using Bayesian Optimization Structure Search (BOSS) package [1]. We tested these approaches in realistic simulations built on previously obtained perovskite experiments [2], where the low-quality samples consisted predominantly of samples crystallized into non-photoactive phases of material.

We show by simulated BO benchmarks that HITL is a straightforward yet effective way to gain information on the regions with low-quality samples and to avoid the BO search from converging into those regions, with a reasonable added effort from humans: Our data fusion HITL BO method queried on average 7% of the samples from humans when the BO run was repeated 25 times. This lead to on average only 2% of samples drawn from the low-quality region, in contrast to the 25% with the reference method without humans. Thus, HITL makes the BO approach more robust toward sample quality variations, and provides an opportunity to pursue more complex materials domains with semi-autonomous setups.

Accelerating High-Throughput Material Experimentation via Human-AI Collaborations *Ming-Chiang Chang[1], Sebastian Ament[1], Maximilian Amsler[1], Duncan Sutherland[1], Hongrui Zhang[1], Lan Zhou[2,2], John M. Gregoire[2,2], Carla P. Gomes[1], Louisa Smieska[1], Arthur Woll[1], R. B. Van Dover[1] and Michael O. Thompson[1]; [1]Cornell University, United States; [2]California Institute of Technology, United States*

Experiment-based materials discovery has remained a "hard problem" because of the number and complexity of experiments required to efficiently search high-dimensional parameter spaces, along with the prohibitive time and cost constraints. In the past, physical intuition based on an engineer's knowledge and experience has been absolutely critical to narrow the search sufficiently to yield viable workflows. But in other fields such as computer *programming, development of large language model-based artificial intelligence “assistants” over the past few years have enabled software engineers to efficiently generate well-defined boilerplate code. We argue that there need to be, and can be, similar AI assistants for experimental labs to which scientists can delegate specific aspects of a complex experiment protocol. The goal of this task division, which must be clearly delineated and strictly defined, should enable the scientist or engineer to step back to a higher level and only steer the direction of experiments using their understanding of the topic and goals. The main challenge in the design of such AI-assisted experimental workflow lies in the question of where to draw the boundary so both the scientist’s and AI’s strengths can be exploited and maximized.*

In our study, we have designed a Bayesian optimization-based autonomous experimental framework that allows seamless AI-human collaboration for targeted material synthesis and material property optimization. The AI agents incorporates on-the-fly probabilistic analysis of high-throughput characterization data (e.g. X-ray diffraction and spectroscopy), Gaussian processes, and advanced numerically stable acquisition functions for robust experimental decision making. In addition, we designed a family of acquisition function that allow the supervising scientist to tune the workflow dynamically, modifying in real-time the objective of the AI in order to guide the experiment direction. As an example, we demonstrate a seamless flow from exploration of potential metastable phases in complex alloys, to exploitation of an identified phase for specific properties. We show that such workflow can dramatically reduce the number of experiments required to approach the objective, and can be executed at experimental loop times consistent with continuously developing automated high-throughput experimentation.

***PANDA—A Self-Driving Lab for Studying Electrodeposited Polymer Films** Harley Quinn, Gregory Robben, Zhaoyi Zheng, Joerg G. Werner and Keith A. Brown; Boston University, United States*

We introduce the polymer analysis and discovery array (PANDA), an automated system for high-throughput electrodeposition and functional characterization of polymer films. The PANDA is a custom, modular, and low-cost system based on a CNC gantry that we have modified to include a syringe pump, potentiostat, and camera with telecentric lens. This system can perform fluid handling, electrochemistry, and transmission optical measurements on samples in custom 96-well plates that feature transparent and conducting bottoms. We begin by validating this platform through a series of control fluid handling and electrochemistry experiments to quantify the repeatability, lack of contamination, and accuracy of the system. As a proof-of-concept experimental campaign to study the functional properties of a model polymer film, we optimize the electrochromic switching of electrodeposited poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) films. In particular, we explore the monomer concentration, deposition time, and deposition voltage using an array of experiments selected by Latin hypercube sampling. Subsequently, we run an active learning campaign based upon Bayesian optimization to find the processing conditions that lead to the highest electrochromic switching of PEDOT:PSS. This self-driving lab integrates optical and electrochemical characterization to constitue a novel, automated approach for studying functional polymer films.

Automated, Modular Cyclic Voltammetry Experiments *Rebekah A. Duke-Crockett, Siamak Mahmoudi, Aman P. Kaur, David Eaton and Chad Risko; University of Kentucky, United States*

Automation is increasingly crucial in cutting-edge science. Automated experiments can achieve greater accuracy and consistency at a large scale, enhancing both the quantity and quality of generated data. Furthermore, automated experimental systems with modular components enable artificial intelligence (AI)-driven autonomous experiments, a rapidly advancing field with proven results. Electrochemistry plays a crucial role in fields as diverse as materials development, energy generation and storage, drug discovery, and environmental chemistry. The complexity and diversity of electrochemical experiments demand dynamic automation systems capable of adapting to a wide range of experimental protocols and conditions. Here we present an automated system that integrates robotic hardware with our innovative ExpFlow software to streamline various electrochemical experiments. Our software efficiently translates human-developed protocols into a workflow of modular but connected robotic actions, launched and managed with the robust job management software Fireworks. Our hardware includes a robotic arm and modularized stations for actions such as dispensing liquid, measuring solution density, weighing, collecting data, etc. The system's modularity allows researchers and/or AI to customize and expand its capabilities as needed. When validated with well-known electroactive systems, our system yields results that closely align with established literature values. This approach accelerates research, promotes reproducibility, and paves the way for large-scale, data-driven discoveries in electrochemistry.

8:45 AM MT02.14.03

Machine Learning-Driven Optimization of Gas Diffusion Layer Microstructure for PEM Fuel Cells *Rashen Lou Omongos[1,2], Diego Galvez-Aranda[1,2], Franco Zanotto[1,2], Andras Vernes[3,4] and Alejandro A. Franco[1,2,5]; [1]Université de Picardie Jules Verne, France; [2]Reseau sur le Stockage Electrochimique de lEnergie (RS2E), FR CNRS 3459, Hub delEnergie, France; [3]Technische Universität Wien, Austria; [4]AC2T Research GmbH, Austria; [5]Universite de Picardie Jules Verne, France*

Proton exchange membrane fuel cells (PEMFCs) have long been studied as a clean energy technology, known for their high efficiency, low operating temperatures, and zero carbon emissions.[1] As the electric vehicle market grows, PEMFCs are increasingly viewed as a complementary solution to battery electric vehicles (BEVs), particularly for applications like heavy-duty trucks where BEVs face limitations[2].
A key factor in PEMFC performance is the gas diffusion layer (GDL), which plays a critical role in mass and heat transport. Optimizing the GDL's microstructure can significantly improve these transport properties, leading to more efficient and durable fuel cells.
In the present study, we developed a novel machine learning approach to optimize GDL microstructure and its associated functional properties. Our approach starts with a design of virtual experiments (DoVE) to systematically investigate the relationship between GDL microstructure and its functional properties. The DoVE considered five manufacturing parameters that are used to stochastically generate a large amount of GDL microstructures: fiber diameter, fiber volume fraction, binder volume fraction, GDL thickness, and compression ratio. Seven functional properties are then evaluated: through-plane and in-plane thermal conductivity, electrical conductivity, diffusivity, and contact resistance between the GDL and the microporous layer. Latin hypercube sampling was employed to achieve an efficient exploration of the hyperparameter space and generate a comprehensive well distributed set of input parameters. A Random Forest + Adaboost regression model was then employed to learn the complex relationships between the five input and seven output parameters. After training the regressor, a multi-objective optimization was performed for the following 4 cases: : 1. minimum contact resistance, maximum TP, IP diffusivity; 2. minimum contact resistance, maximum TP, IP electrical conductivity; 3. minimum contact resistance,

maximum TP, IP thermal conductivity; and 4. minimum contact resistance, maximum TP, IP electrical and thermal conductivities and diffusivity. This work has taken inspiration from our previous study on machine learning-assisted optimization of electrode manufacturing of lithium-ion batteries.[3]
The implemented optimization framework, the first of its kind as far as we know, exhibited high efficacy in identifying optimal manufacturing parameters for GDL microstructures, and their associated functional properties. The validation of our machine learning approach was carried out by comparing the predicted GDL functional properties to the ones calculated through physics-based simulations using the optimal manufacturing parameters predicted by the optimizer. This optimization strategy holds promise for enhancing gas transport, water management, efficient current collection, and thermal regulation within PEMFCs.[4]

Design of a Robotic Probe Driven by Convolutional Neural Networks Autonomously Characterizes Perovskite Photoconductivity

Alexander E. Siemenn, Basita Das and Tonio Buonassisi; Massachusetts Institute of Technology, United States

High-throughput deposition of functional materials has become a core component of automated experimental systems in recent literature [1, 2]. These high-throughput deposition procedures significantly accelerate the rate at which we can explore the compositions of new materials. However, as our synthesis methods continue to accelerate, relevant methods of characterization lag behind, introducing a bottleneck. Recently, there have been advancements in high-throughput and automated optical characterization methods of functional materials [3, 4], but a gap still exists in the acceleration and automation of contact-based characterization methods, limiting the accelerated characterization of materials to only certain functional properties. Hence, in this contribution, we develop the design of a four-degree-of-freedom (4DOF) robotic four-point probe that is autonomously driven by the output of a convolutional neural network (CNN) to estimate the $\mu\tau$ *product and bulk electrical transport quality of each material from photoconductivity at a high-throughput rate of over 400 unique measurements per hour.*

We build upon existing methods of contact-based electrical characterization of functional materials, such as the work presented by Bash et al. [5]. The proposed 4DOF robotic probe in this study advances current techniques through the utilization of integrated computer vision and CNNs to predict a set of optimal contact points, or poses, to measure for each high-throughput synthesized material that capture the maximum range of measurable variance per material. Furthermore, we implement a controllable shade-minimizing LED mount on the tip of the probe for measuring photoconductivity. The combination of these advancements enables the robot to sense, plan, and act accordingly to the input provided by computer vision, ultimately achieving full autonomy in the photoconductivity characterization procedure.

We design the CNN that controls the motion of the robot such that its loss function is completely spatially differentiable for every input computer vision frame. The importance of this spatially differentiable loss function is that it enables the direct geometric optimization of poses within the neurons of the CNN rather than requiring a slow iterative optimization procedure. This means that by simply minimizing the loss of the CNN, we can rapidly generate sets of optimal poses at a rate of less than one second per material. We demonstrate the performance of this proposed 4DOF robotic probe and spatially differentiable loss function on the rapid measurement of both sheet resistance and photoconductivity across over ten thousand unique contact points in less than 24 hours for Indium Tin Oxide and high-throughput synthesized formamidinium (FA) and methylammonium (MA) mixed-cation perovskite $FA_{1-x}MA_xPbI_3$ materials. Therefore, with this design, contact-based methods of characterizing high-throughput deposited materials can be accelerated and automated while maintaining an accurate representation of variance for reliable implementation into autonomous materials discovery platforms.

Towards Data-Rich Experimental Workflows for Nanomaterial Synthesis Through Modular Automated Reactor and Purification Platforms *Jeff Xu, Conan Huang, Logan Keating, Moonsub Shim and Paul Kenis; University of Illinois at Urbana-Champaign, United States*

Automated workflows increasingly are implemented towards nanomaterial synthesis for optoelectronic and catalytic applications. One application of these automated platforms and workflows is to investigate the effect of synthesis parameters on nanoparticle synthesis outcomes to generate hypotheses for nanoparticle nucleation and growth mechanisms and thus to guide future synthesis. Such automated platform-based investigation requires thorough characterization of reaction product streams to determine size distribution, shape, and phase of synthesized nanoparticles.

Presently, however, most automated nanoparticle synthesis platforms rely on optical characterization due to its availability and ease of integration. This limits the types of materials that can be explored with automated workflows. While interfacing automated platforms with powerful structural characterization tools such as TEM imaging of X-Ray beamline-based methods is theoretically possible, in practice this is difficult due to the complexity of most automated platforms, in terms of portability and set-up. Furthermore, for structural characterization such as TEM imaging requires purification of synthesized nanoparticles. Addressing this issue requires the development of modular, portable synthesis and purification platforms that can be seamlessly interfaced with powerful platforms in specialized materials characterization facilities.

This talk will report on a modular, portable purification platform that enables downstream in-situ TEM imaging for automated nanoparticle synthesis workflows. Using commercial off-the-shelf hardware and silica media, we fabricated a versatile, automated size-exclusion chromatography system for efficient separation of CdSe quantum *dots (QDs) from crude organic-phase reaction mixtures. These purified nanoparticles can then be rapidly characterized using liquid-phase TEM or characterized in batches at a higher resolution using grid TEM. Integrating this automated nanoparticle purification platform with downstream TEM platforms and upstream portable automated synthesis platforms, enables data-rich automated synthesis and structural characterization workflows that facilitate investigation into the mechanisms of nanoparticle formation for different systems.*

Accelerated Materials Discovery, Optimization and Manufacturing with Autonomous Robotic Experimentation in Flow *Milad Abolhasani; North Carolina State University, United States*

Accelerating materials discovery as well as green and sustainable ways to manufacture them will have a profound impact on the worldwide challenges in energy and sustainability. The current human-dependent paradigm of experimental research in chemical and materials sciences fails to identify material solutions for worldwide challenges in a short timeframe. This limitation necessitates the development and implementation of new strategies to accelerate the pace of materials discovery. Recent advances in reaction miniaturization, automated experimentation, and artificial intelligence (AI) provide an exciting opportunity to reshape the discovery, development, and manufacturing of new advanced functional materials related to energy transition and sustainability. In this talk, I will present an Autonomous Fluidic Lab for accelerated discovery, optimization, and manufacturing of emerging advanced functional materials with multi-step chemistries, through the integration of flow chemistry, online characterization, and AI.[1-5] *I will discuss how modularization of different synthesis and processing stages in tandem with constantly evolving AI-assisted modeling and decision-making under uncertainty can enable resource-efficient navigation through high-dimensional experimental design spaces. Example applications of the Autonomous Fluidic Lab for the fast-tracked synthesis of clean energy nanomaterials will be presented to illustrate the potential of autonomous labs in reducing materials discovery timeframe from >10 years to a few months (or even weeks).*

Machine Learning-Driven Prediction of Corrosion Inhibition Performance by Pyrimidine Derivatives *Ishaq A. Raji, Nestor K. Ankah and Nasirudeen Ogunlakin; King Fahd University of Petroleum and Minerals, Saudi Arabia*

Corrosion inhibition is a crucial aspect of material protection in various industries. Pyrimidine derivatives have shown promising results as corrosion inhibitors, but predicting their performance remains challenging. This study leverages advanced machine learning techniques to develop a predictive model for the corrosion inhibition performance of pyrimidine derivatives. Utilizing a comprehensive dataset of molecular descriptors, algorithms including random forest, support vector machines, and neural networks were applied to model the relationship between molecular structure and inhibition efficiency.

The model demonstrated excellent predictive performance, with metrics such as R-squared of 0.95 and MAE of 3.2, significantly outperforming traditional methods. This machine learning-driven approach enables the rapid screening and design of pyrimidine-based corrosion inhibitors, accelerating the discovery of new materials. The findings have significant implications for the development of sustainable and efficient corrosion protection strategies, offering a transformative approach for materials science and industrial chemistry.

Utilizing Machine Learning to Analyze the Effects of PI3K Inhibition on Shear-Mediated Platelet Kinematics and Adhesion *Vincent Lo[1], Aryan Agahtehrani[2], Isabelle Chan[3], Jawaad Sheriff[4], Peineng Wang[4], Xiaotian Wang[4] and Miriam Rafailovich[4]; [1]Evergreen Valley High School, United States; [2]DuPont Manual High School, United States; [3]Michael E. DeBakey High School for Health Professions, United States; [4]Stony Brook University, The State University of New York, United States*

The introduction of medical devices, such as stents and grafts, into the body's circulation is commonly used to restore or enhance physiological function disrupted by cardiovascular diseases. However, their surface chemistry promotes the adsorption of proteins, such as von Willebrand factor (vWF), a glycoprotein found in blood plasma, leading to platelet adhesion and aggregation, making these foreign materials prone to thrombosis. In the initial stages of clot formation, shear stress from blood flow causes platelets to flip on their edge before firmly adhering to vWF-coated surfaces and encouraging coagulation. One promising strategy to prevent flow-induced thrombosis is modulating PI3K, as previous literature suggests that it functions as a hub for mechanotransduction and that its inhibition impedes platelet coagulation. Therefore, it is crucial to analyze platelet behavior in the context of PI3K. Previously, platelet adhesion has been analyzed via flow cytometry, surface density, etc. Peak platelet flipping velocity during initial adhesion may help describe and predict trends in subsequent morphology change, stable adhesion, multi-platelet aggregation, and clot formation. Recent machine learning methods such as unsupervised image classification and segmentation have provided a standardized and reliable method for analysis[1]. This study aims to design a test bed for assessing the effects of drugs on platelet activity and integrate a novel machine-learning model to analyze platelet flipping under different flow conditions.
Custom microchannels constructed of polypropylene, a hydrophobic polymer, simulated foreign insertions. These rectangular flow channels measured 1 mm in width and 100 μm in height, and were pre-coated with vWF. Blood samples were collected from healthy adult humans (IRB2024-00008), centrifuged, and filtered to obtain purified gel-filtered platelets (GFP). GFP were then separated into control and treatment groups, with the latter receiving TGX-221, a PI3K inhibitor. The flow channels were connected to a syringe pump, allowing GFP to flow under a constant shear of 15 dynes/cm2. Platelets were imaged with an inverted DIC microscope, recording 6-second videos of flipping incidents at 1000 frames per second. Video frames were segmented and binarized to format the

data for automated analysis. A semi-unsupervised learning system, consisting of a series of convolutional neural networks that process image data to identify and characterize platelet morphology, was used. Using a policy and reward network to train the model allowed for increased accuracy in platelet image segmentation. These images were then used to measure other geometric parameters such as platelet surface area, major axis length, minor axis length, and thickness. Using these parameters, a graph illustrating the relationship between the time and the platelet's rotational angle was obtained for each flip. After removing outliers and utilizing a wavelet denoising technique, a polyfit regression was applied to each graph to determine peak flipping velocity.
Results revealed that PI3K inhibition in platelets caused faster flipping, with the average peak velocity increasing by 49.28% compared to untreated samples (n = 11), indicating reduced platelet adhesion and clotting. This suggests that PI3K inhibition potentially mitigates life-threatening thrombosis promoted by blood-contacting foreign materials. This study also highlights the efficacy of the experimental design as a platform for testing drug delivery on vascular surfaces, allowing for the application of artificial intelligence for standardized characterization of thrombotic events. These results are promising for future platelet and coagulation research, necessitating further sampling and investigation.
We would like to acknowledge the Louis Morin Charitable Trust for their support in our research.

Data-Driven Optimization Strategies for Accelerating Materials Discovery *Andre K. Low[1,2], Flore Mekki-Berrada[3], Pablo Quijano Velasco[2], Jin Da Tan[3,2], Mihir R. Athavale[4,2], Yao Jing[1,1,1], Pritish Mishra[1,1] and Kedar Hippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Agency for Science, Technology and Research, Singapore; [3]National University of Singapore, Singapore; [4]The University of Manchester, United Kingdom*

In recent years, the integration of high-throughput experimentation with machine learning has revolutionized materials discovery. Here, we present a multitude of case studies in using optimization algorithms for data-driven experiment planning.

We showcase our proposed algorithm Evolution-Guided Bayesian Optimization (EGBO) which integrates a one-step evolution process to mediate exploration and exploitation (J Mat Int, 2023). EGBO shows superior performance in Pareto Front coverage as well as constraint handling, demonstrated for an automated nanoparticle synthesis platform (Npj Comp Mat, 2024).

We also present on challenges and approaches for domain-specific problems. Firstly, preferencing objectives in a multi-objective problem to achieve accurate viscous liquid transfer with minimal transfer times (Digit Discov, 2023). Secondly, efficiently dealing with input constraints in a terpolymer synthesis problem. Lastly, batch-constrained high-throughput sampling for optimization of microring laser fabrication.

Finally, we will also share about successes in implementing both traditional Bayesian optimization as well as multi-task transfer learning for different perovskite synthesis projects (Adv Mat, 2024).

11:15 AM MT02.15.04
Artificial Intelligence-Driven Autonomous Agent for Smart Hybrid Energy Storage Systems with Integrated Renewable Sources *Vinav Shah[1,2], Nathan Qiu[3,2], Qingyi Jiang[4,2], Jenny Jia[5,2], Indus Boddu[6], Eliana Matsil[2], Chaofan Lin[2], Peng Zhang[2] and Miriam Rafailovich[2]; [1]The Pingry School, United States; [2]Stony Brook University, The State University of New York, United States; [3]Canyon Crest Academy, United States; [4]Shenzhen College of International Education, China; [5]The Experimental High School Attached to Beijing Normal University, China; [6]High Technology High School, United States*

Hybrid energy storage systems (ESS) utilizing both green hydrogen and lithium batteries provide sustainable energy storage for microgrid applications. Rapid-deployment microgrids are crucial for energy infrastructure in disaster response, military applications, and off-grid communities. Working with the Shinnecock Indian Nation as a case study, we worked to design an reinforcement learning (RL) based artificial intelligence agent which can optimally allocate generated energy to either hydrogen storage or lithium batteries for the community's rapidly-built emergency housing units.

The Shinnecock Nation generates power through a 96-panel solar array, with peak wattage providing around 22 kW. Over a three week period in July, we found an average daily generation of 136 kWh per day. During the same time period, we identified that the average consumption was 41 kWh per day. We assumed a battery with nominal energy of 15.5 kWh, nominal power of 4.5 kW, and a hydrogen fuel cell with nominal energy of 223 kWh, nominal power 20 kW. Formulating the microgrid's objectives and constraints mathematically, our model aimed to minimize load and energy curtail. Before implementation of an energy storage system (ESS), our computational model provides crucial data on whether solar energy generation is sufficient for off-grid capabilities — the assessment showed that an appropriate ESS can entirely meet the energy demands of the homes.

We then implemented a Q-learning RL algorithm to teach an AI agent optimal energy management. The agent's action space includes storing, discharging, or selling energy to the grid, modeled as a Markov Decision Process. After each action, the solar generation and energy demand were randomly updated, simulating non-stationary energy dynamics. Using an epsilon-greedy strategy, the agent initially explores random actions, then exploits the best actions for long term reward based on a learned Q-table, updated via the Bellman equation. This off-policy approach emphasizes robust policy learning with a goal of better reflecting real-world energy uncertainties.

While the more efficient batteries are better for short-duration energy storage, we found that higher energy density hydrogen fuel cells are more effective in the long-term. A machine-learning trained agent can optimize the power flow between an energy-generation solar cell, lithium-ion phosphate battery, and hydrogen fuel cell, solving a crucial challenge of hybrid energy storage systems. Predictive ability enables an agent to dynamically make intelligent storage decisions — using lithium battery storage to offset the short-term loss in generation on a cloudy day, for example. Therefore, an autonomous system provides the ability for improved efficiency in the combined use of a hydrogen fuel-cell and lithium-ion battery.

Our research supports the goal of continuous operation for the Shinnecock Nation with zero load curtailment and grid import. An AI agent can identify optimal solutions to hybrid energy storage automation decisions, enabling efficient microgrid management through the use of hybrid lithium-ion and hydrogen fuel cell storage with a predictive system for optimal energy balancing. Such an agent makes hybrid energy storage more viable for widespread usage, with the ability to dynamically adjust to complex trends, aligning with global efforts for clean energy storage.

Reaction Graph Networks for Inorganic Synthesis Condition Prediction *Thorben Prein[1,2,3], Fuzhan*

Rahmanian[1,2], Yifei Duan[4], Elton Pan[4], Elsa Olivetti[4] and Jennifer L. Rupp[1,2,5]; [1]Technische Universität München, Germany; [2]TUMint Energy Research GmbH, Germany; [3]Munich Data Science Institute, Germany; [4]Massachusetts Institute of Technology, Germany; [5]Fritz Haber Institute of the Max Planck Society, Germany

The integration of advanced machine learning (ML) techniques with density functional theory (DFT) has significantly enhanced the prediction of stable material structures. However, translating these computational predictions into successful laboratory syntheses—whether by autonomous labs or human scientists—remains a challenge due to the complex optimization of solid-state reaction parameters. In this work, we model inorganic solid-state reactions through a graph neural network to incorporate precursor interactions into the prediction of synthesis conditions. We evaluated our methodology on literature-reported syntheses of clean energy materials, demonstrating enhanced performance over prior synthesis condition predictions. Our approach has the potential to streamline the transition from computational predictions to actual material synthesis, potentially acclerating the discovery of new materials.

Accelerated First-Principles Exploration of Structure and Reactivity in Graphene Oxide *Zakariya El-Machachi[1], Damyan Frantzov[1], A. Nijamudheen[1], Tigany Zarrouk[2], Miguel A. Caro[2] and Volker L. Deringer[1]; [1]University of Oxford, United Kingdom; [2]Aalto University, Finland*

Graphene oxide (GO) materials are widely studied, and yet their atomic-scale structures remain to be fully

understood. Here we show that the chemical and configurational space of GO can be rapidly explored by advanced machine-learning methods, combining on-the-fly acceleration for first-principles molecular dynamics with message-passing neural-network potentials. The first step allows for the rapid sampling of chemical structures with very little prior knowledge required; the second step affords state-of-the-art accuracy and predictive power. We apply the method to the thermal reduction of GO, which we describe in a realistic (ten-nanometre scale) structural model. Our simulations are consistent with recent experimental findings and help to rationalise them in atomistic and mechanistic detail. More generally, our work provides a platform for routine, accurate, and predictive simulations of diverse carbonaceous materials.

10:45 AM MT03.01.02

Fast and Accurate Machine Learning Potential of hBN to Simulate Synthesis and Predict Thermal Conductivity *Kad D. Kook, Mayur P. Singh and Satish Kumar; Georgia Institute of Technology, United States*

Hexagonal Boron Nitride (hBN) is a 2D material with high in-plane thermal conductivity and low out-of-plane thermal conductivity. Due to its anisotropic and dielectric properties, hBN films have a high potential for the thermal management of heterogeneous-integrated (HI) electronics. The construction of Process-Structure-Property (PSP) relations of hBN film can help in accelerating the synthesis of hBN films with desired thermal properties. Multi-scale numerical simulations are an essential component for the successful construction of PSP relations. The biggest difference between hBN compared to 3D crystals is that the interatomic interactions in cross-plane are very weak compared to the in-plane. Covalent bonds connect atoms in a layer while Van der Waals forces are dominant for the interactions of atoms on different layers. In-plane force fields are well developed but the out-of-plane force fields considering Van der Waals forces lead to the prediction of in-accurate thermal properties. There are mainly two interlayer potentials for hBN: one is Lennard-Jones (LJ) potential [1] and the other is Interlayer Potential (ILP) [2]. LJ potential is fast but inaccurate, and ILP potential is accurate but slow. For efficient data generation of hBN deposition and property prediction, an accurate and fast interlayer force field is needed.

To achieve high accuracy and speed in predicting interlayer forces for hBN, a machine learning potential (MLP) will be developed. Data sets will be generated using density functional theory from various geometries of hBN considering different types of defects, which will be used to train and develop efficient MLP. This potential will be verified by calculating thermal conductivity and comparing it with other accurate force fields or measured values. After determining the potential is valid, the deposition of hBN will be simulated based on various process conditions used in Pulsed Layer Deposition such as temperature, pressure, etc. Various structures will be simulated, and the corresponding thermal conductivity will be calculated. Using this fast and high-fidelity MLP, PSP relations for hBN will be constructed, which will guide the experimentalists to accelerate the optimization of hBN synthesis to achieve high thermal conductivity values.

Knowledge Discovery from Magnetic Domain Structure Image Using Feature Extended Landau Free Energy Model *Ryunosuke Nagaoka and Masato Kotsugi; Tokyo University of Science, Japan*

Microscopic image data is key information to developing next-generation low-power, high-speed electronic devices. The increasing complexity of nanoscale magnetic domain structures has necessitated advanced analytical techniques to optimize the design of such electronic devices. Traditional visual analysis methods are not only labor-intensive but also highly subjective, often leading to inconsistent and qualitative interpretations. To address these challenges, we have developed an "Extended Landau Free Energy Model" that integrates topology, *machine learning, and free energy principles to automate the interpretation of magnetic domain structure data [1-6]. This model enhances our understanding of the mechanisms underlying magnetic interactions and proposes more efficient device structures, contributing significantly to the field of materials science.*

Experiment

Our approach combines topology and data science with the Landau Free Energy Model to analyze real materials with complex nanostructures. The traditional Landau Free Energy Model, which explains magnetization reversal based on magnetization and magnetic fields, is limited in its applicability to real materials. To overcome this limitation, we utilized persistent homology, a concept from topology, to extract features from complex magnetic domain structures. Interpretable machine learning techniques were then employed to map these features onto a new energy landscape within the information space, resulting in the creation of the "Extended Landau Free Energy Model."

This model allows for the analysis of magnetization reversal processes by correlating changes in magnetic domain structures with energy barriers. Through simple variable transformations and differentiation, the model establishes a bidirectional connection across the hierarchy between micro-scale magnetic domain structures and macro-scale magnetization reversal phenomena. This quantitative analysis enables the identification of physical interactions that govern these processes.

Results&Discussion

Applying our model to the analysis of information recording processes in nanomagnetic bodies revealed the dominant role of the demagnetizing field effect. The model successfully visualized the spatial concentration of energy barriers that impede changes in magnetic domain structures, transforming previously undecipherable microscopic data into valuable insights. This result suggests that microscopic data, once considered unusable, can now serve as a rich source of information for device optimization.

Moreover, the model facilitated the proposal of a nanostructure that consumes less energy, highlighting its potential for device design. The model's versatility extends to various materials with complex mechanisms, making it applicable to a wide range of manufacturing fields, including electric vehicle motors and autonomous distributed systems.

The methodology of knowledge discovery along with rule mining, in our model could pave the way for broader impacts in materials research. By automating the interpretation of complex magnetic domain structures, our approach could democratize AI in materials science, enabling more efficient and effective research and development processes.

Elucidating Atomistic Mechanisms in Thermal Processing of Graphene Through Deep Learning Molecular Dynamics

Haoran Cui and Yan Wang; University of Nevada, Reno, United States

Two-dimensional materials, such as graphene, have garnered significant interest owing to their distinct electronic, optical, thermal, and mechanical properties. However, realizing the practical application of graphene often necessitates tailored manipulation of its nano- or micro-structures, including deliberate introduction of defects such as nanoholes or oxidations to its basal plane or edges. Despite efforts to apply lasers or microwaves for processing graphene or graphene oxide flakes dispersed in water to fabricate various larger-scale structures, the underlying thermal and chemical processes during manufacturing remain poorly understood. In this talk, we will present our recent investigations utilizing deep-neural-network-based molecular dynamics to study laser-irradiated graphene and graphene oxide flakes in water. Specifically, we will delve into the unique heat transfer mechanisms between graphene, graphene oxide, and water under laser irradiation or microwave heating. Furthermore, we will explore potential chemical reaction processes observed in the simulations, including reduction, dehydration, or nanohole creation in graphene oxides, as well as the oxidization of graphene. Our research holds promise in offering valuable insights for the design and optimization of laser or microwave-based manufacturing of two-dimensional materials in wet environments.

Location Preference of Boron and Nitrogen Dopants at Graphene/Copper Interface *Boan Zhong and Yue Liu; Shanghai Jiao Tong University, China*

Controlling the placement of dopants can significantly tailor graphene's properties, but this process is influenced by copper substrates during vapor deposition. Understanding the influence of interfacial atomic structures on the preference for dopant locations is crucial. In this work, we conducted a systematic first-principles study of boron and nitrogen-doped graphene on copper {111}, considering both sublattice and superlattice configurations. Our calculations revealed that the formation energy is minimized at top-fcc^b site (-0.60 eV) for boron and hcp-fcc^a site (1.94 eV) for nitrogen, suggesting a possible selective distribution of dopants in both sublattice and superlattice arrangements at the graphene/copper interface. Furthermore, a lower formation energy indicates a higher release of energy during doping, resulting in a stronger interfacial binding. Since formation energy is closely associated with out-of-plane interactions, while in-plane interactions remain relatively stable, these differences offer potential avenues for modifying dopant distribution at graphene/copper interfaces.

Honeycomb Layered Ruthenium(III) Trihalide Polymorphs Stabilized by High-Pressure Synthesis *Danrui Ni[1], Xianghan Xu[1], Xin Gui[2], Kelly M. Powderly[3] and Robert J. Cava[1]; [1]Princeton University, United States; [2]University of Pittsburgh, United States; [3]Washington University in St. Louis, United States*

Magnetic latices with strong bond-dependent competing spin anisotropy, yielding frustrated spin configurations on a single site, described by the Kitaev model, can give birth to interesting magnetic behavior and uncommon state of quantum materials. The layered honeycomb lattice material α-$RuCl_3$ has emerged as a prime candidate for displaying the Kitaev quantum spin liquid state and as such has attracted much research interest. Here we

describe the iodine- and bromine-based version of $RuCl_3$, whose layered honeycomb structured polymorphs are synthesized at moderately high pressures and are stable under ambient conditions. Preliminary characterization reveals that layered α-RuI_3 is a metallic conductor, with the absence of long-range magnetic order down to 0.35 K and an unusually large T-linear contribution to the heat capacity. However, α-$RuBr_3$ is an insulator with a broad antiferromagnetic ordering transition at around 35 K. The layered honeycomb α-$Ru(Br_{1-x}I_x)_3$ solid solution with varying x was then prepared. The variation with changing I to Br ratio was thus revealed, including an insulator-to-metal transition between $RuBr_{0.75}I_{2.25}$ and $RuBr_{0.5}I_{2.5}$, and a dramatic change in their magnetic properties. By introducing the disorder of halogen atoms, the frustration and randomness increased, triggering short-range magnetic correlations and what may be spin-glass-like behavior in the materials.
We propose that this system, with a high-pressure-stabilized layered honeycomb lattice and strong spin-orbit coupling, provides a new route to fabricate and study quantum materials. The solid solution may further provide a new venue for studying quantum spin phenomena with disorder and strong spin-orbit coupling for both magnetic frustrated insulators and metallic systems, and thus may open a door to further understanding and modifying the interaction of spin and orbital degrees of freedom of Kitaev systems.

Interpreting Computer Vision Models for Inverse Design of Chalcogenides *Isaiah A. Moses and Wesley Reinhart; The Pennsylvania State University, United States*

The use of data-driven approaches for the design and characterization of materials is growing. An important source of data for such design is the experimentally obtained scanning probe microscopy images, which are inadvertently available in limited volume. The characterization of the images provides information on the quality of the grown materials, their properties, and potential applications. Great advances have been made in the deployment of computer vision models for image detection and analysis. Transfer learning, where the knowledge gained in training a model on larger (usually natural) data is used in materials science target data, has been indispensable in mitigating the effect of limited data and improving the generalization of computer vision models in materials science. However, to maximize the potential of the computer vision models for materials design, it is important to go beyond obtaining the predictions provided to explore the basis and the hows of the model's decisions. For instance, images go through different layers of representation in convolutional neural network (CNN) models. Some features of a few dimensions could be obtained from the later layers, usually with fully connected nodes. A major utility is derivable if such features, known as the latent features, could be interrelated with the physical feature of the image. We present CNN transfer learning models trained on five different classes of transition metal dichalcogenides (TMDs) and differently on the materials based on their growth conditions. The materials include MoS_2, WS_2, WSe_2, $MoSe_2$, and Mo-WSe_2, which were grown by metal-organic chemical vapor deposition (MOCVD) at the 2D Crystal Consortium (2DCC) of the Pennsylvania State University. The trained models, which present excellent accuracy, enable a systematic approach to analyzing the interrelationship among the latent features, TMD classes, their chemical composition, the materials properties, and the growth conditions. This demonstrates the use of computer vision for the inverse and high-throughput design of materials for technological application.

Unfolding the Electronic Structure of Two-Dimensional Heterostructures *Georgios Kopidakis and Georgios Vailakis; University of Crete, Greece*

Intense research activity on two-dimensional (2D) heterostructures in recent years is due to their unique properties and potential for applications. Detailed theoretical understanding of these properties is of fundamental interest and facilitates novel materials design. We present results based on density functional theory (DFT) for the atomic and electronic structure of 2D nanostructures with defects and twisted van der Waals heterostructures (vdWHs) *consisting of combinations of transition metal dichalcogenide (TMD) monolayers (MLs) and graphene (Gr). Due to the large simulation cells required and strong deviations from periodicity, DFT calculations are challenging and results need careful interpretation. We present methods we develop for the construction of optimized simulation cells and for unfolding the corresponding electronic band structure. The effective band structure (EBS) produced allows for a clear and direct comparison between electronic properties of defected 2D nanostructures and heterostructures with their pristine and constituent ML counterparts. Applying our methodology to Gr/TMD and TMD/TMD vdWHs, several experimental observations are explained and predictions are made [1]. Our methodology also proves very useful in investigating defects and adsorption on 2D MLs. In conjunction with experiments, DFT calculations show how n-doped* WSe_2 *ML becomes a p-doped semiconductor via photochlorination [2]. Energetics and EBSs show that chlorine fills chalcogen vacancies, neutralizing defect states close to the conduction band minimum and creating defect states close to valence band maximum. Current efforts in combining DFT, atomistic simulations, and experimental results with machine learning models for predicting 2D heterostructure properties will be discussed.*

First-Principles Calculations to Deciphering Sodium-Ion Storage—2D-Sulfide vs. Oxide *Shilpi Sengupta[1], Atin Pramanik[2], Caique C. de Oliveira[3], Shreyasi Chattopadhyay[2], Tymofii Pieshkov[2], Pedro A. Autreto[3], Pulickel Ajayan[2] and Manab Kundu[1,4]; [1]SRM Institute of Science and Technology, India; [2]Rice University, United States; [3]Universidade Federal do ABC, Brazil; [4]International Iberian Nanotechnology, Portugal*

Energy storage technologies are essential for maximizing the utilization of clean and renewable energy sources. While lithium-based systems are widely used in rechargeable batteries, their high cost due to lithium scarcity drives the search for alternatives based on more abundant elements [1]. Sodium-ion batteries (NIBs) are a promising alternative due to the low cost, natural abundance, and environmental friendliness of sodium [2]. Despite these advantages, further advancements in NIBs require the development of materials with superior electrochemical performance and energy density. Transition metal-based materials are particularly promising for NIBs due to their high theoretical capacity. Among these, sulfides are considered superior to oxides because of their enhanced conductivity and charge transfer properties [3]. In this study, we studied the tungsten sulfide (WS2) microflowers that were synthesized via thermal sulfurization of tungsten trioxide (WO3) [4]. The synthesized resulting WS2 nanostructures exhibited a higher specific capacity and more stable performance compared to their oxide counterparts [4]. To understand the underlying mechanisms, first-principles calculations based on Density Functional Theory (DFT) were conducted to investigate the electronic structure and interactions of both nanostructures with sodium ions. Our results indicate that conductivity decreases from the bulk to the 2D counterparts in both materials. Additionally, the oxide nanostructure demonstrated higher energy diffusion barriers (0.50 eV) compared to the 2D WS2 (energy barriers as low as 0.05 eV). These findings are explained by the binding energy of sodium ions. For 2D WO3, sodium binds strongly (-1.00 eV for the weakest adsorption site), whereas the interaction with 2D WS2 is much weaker (+0.47 eV for the adsorption site), resulting in reduced mobility on the oxide. This study is the first to investigate the storage performance of WO3 and WS2 using experimental and theoretical perspectives, contributing to the development of novel electrode materials for *sodium-ion batteries.*

Reinforcement Learning Informed Growth Dynamics in 2D Materials *Aditya Koneru[1,2], Adil Muhammed[1,2], Henry Chan[2], Mathew J. Cherukara[2] and Subramanian Sankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States*

The utilization of two-dimensional materials despite their extraordinary physical and chemical properties have been limited in applications like foldable electronics, memristors, water treatment owing to poor understanding of their synthesis protocols. This can be attributed to the limited understanding or absence of data on aspects like substrate selection, possible metastable and defective configurations. While Molecular Dynamics (MD) can provide such atomistic details for various time dependent synthesis protocols, it remains limited in the timescales that it can access. Additionally, it is cumbersome or rather impossible to probe all the possible synthesis protocols. To address this issue, we developed a Deep-Q-Networks (DQN) based reinforcement learning (RL) approach combined with an efficient and accurate force-field model to grow Phosphorene (alpha and beta) polymorphs on different orientations of copper substrate. Our RL agent is assigned to vary growth parameters such as temperature, cooling rate, deposition rate, and substrate crystal orientation. In each iteration, the final configuration is evaluated against the desired phase using SOAP fingerprinting and/or graph isomorphism. With this feedback, the RL agent then conducts a series of exploratory or exploitative iterations to determine the optimal growth parameters for achieving the desired conditions. Also, it has an added advantage of retrieving possible metastable configurations obtained while performing the search for a desired phase. Furthermore, this technique holds promise for integration with self-autonomous experimentation tools, accelerating the development and application of present and future 2D materials.

Ion Beam Synthesis of Layer-Tunable and Transfer Free Graphene for Device Applications *Yongqiang Wang[1], Gang Wang[2] and Caichao Ye[3]; [1]Los Alamos National Laboratory, United States; [2]Ningbo University, China; [3]Southern University of Science and Technology, China*

Direct synthesis of layer-tunable and transfer-free graphene on technologically important substrates is highly valued for various electronics and device applications. State of the art in the field is currently a two-step process: a high-quality graphene layer synthesis on metal substrate through chemical vapor deposition (CVD) followed by delicate layer-transfer onto device-relevant substrates. Here, we report a novel synthesis approach combining ion implantation for a precise graphene layer control and dual-metal smart Janus substrate for a diffusion-limiting graphene formation, to directly synthesize large area, high quality, and layer-tunable graphene films on arbitrary substrates without the post-synthesis layer transfer process [1].

Carbon (C) ion implantation was performed on Cu-Ni film deposited on a variety of device-relevant substrates. A

well-controlled number of layers of graphene, primarily monolayer and bilayer, is precisely controlled by the equivalent fluence of the implanted C-atoms (1 monolayer ~ 4E15 C-atoms/cm2). Upon thermal annealing to promote Cu-Ni alloying, the pre-implanted C-atoms in the Ni layer are pushed towards the Ni/substrate interface by the top Cu layer due to the poor C-solubility in Cu. As a result, the expelled C-atoms precipitate into graphene structure at the interface facilitated by the Cu-like alloy catalysis. After removing the alloyed Cu-like surface layer, the layer-tunable graphene on the desired substrate is directly realized.
This presentation will focus on graphene layer formation mechanism, detailed characterizations, and performance characteristics of select devices fabricated through this ion beam approach including near-IR photodetectors.

Strain Effect on Adatom Diffusion, Island Nucleation and Monolayer Growth on Metal and Oxide Surfaces

Ahmad Ahmad and Anter El-Azab; Purdue University, United States

Multiphase thin films grown via pulsed laser deposition (PLD) have gained much interest owing to their unique anisotropic and strain-coupled properties in both vertical and horizontal directions. Due to lattice and elastic moduli mismatch, elastic strains arise in the multiphase material which impacts the growth processes of the film such as surface diffusion. For instance, it was hypothesized that tensile strain regions result in high energy activation barrier and favorable binding sites [1]. The impact of tensile strain fields due to array of misfit dislocations in the substrate yields to higher probability of nucleating islands [2,3]. Moreover, it is worth mentioning that diffusion and binding of adatoms depends on both the type of adatom and the atomic structure of the surface, with adatoms attracted or repelled from strained regions depending on the strain state [4]. Motivated by the growth of Au-CeO_2 multiphase system on $SrTiO_3$ [5], we use density functional theory (DFT) to understand the impact of strain on surface diffusion of Au adatom and CeO_2 admolecule on both the metal and oxide surfaces. We show that applying compressive or uniaxial can either favor or disfavor the binding of adatoms depending on the type of surface materials. In addition to that, applying strain induces distortion to the crystal lattice that favors the diffusion of one direction over another leading to anisotropic effect. On the larger scale, we utilize the DFT calculations to parameterize kinetic Monte Carlo (kMC) simulations where we demonstrate the impact of elastic strains on island nucleation and self-organization on different surfaces. The kMC model is approximated up to first order using tensorial notation. The results reveal that not only does strain impact the self-assembly process, but also the significance that utilizing elastic strains in multiphase systems can drive the phase-separation and patterning.

Fabrication of Single-Crystalline Barium Titanate Thin Films for Electro-Optic Applications *Prachi Thureja, Andrew W. Nyholm, Martin Thomaschewski, Phillip R. Jahelka, Julie Belleville, Samuel K. Seah and Harry A. Atwater; California Institute of Technology, United States*

We demonstrate the fabrication of single-crystalline barium titanate (BTO) thin films using spalling, a mechanical exfoliation process for producing large-scale thin films from bulk substrates. Recently, electro-optic thin films have emerged as an attractive platform for various technologies, including free-space optics, photonic integrated circuits, and quantum computing hardware. Thin-film lithium niobate (LN) has seen significant technical advancement; however, its electro-optic coefficient is not sufficiently high for versatile applications requiring low power consumption. Alternative materials, such as BTO, offer a promising alternative with Pockels coefficients exceeding those of LN by over 30 times. Traditionally, thin-film BTO is grown using bottom-up methods, such as molecular beam epitaxy, pulsed laser deposition, or sputtering. However, these methods often result in extrinsic defects, variable grain sizes, porosity, and deviation from stoichiometric BTO, leading to reduced Pockels coefficients [1]. Moreover, many bottom-up growth methods are slow and expensive.

In contrast to conventional growth techniques, we propose spalling of commercially available single crystal BTO substrates as a low-cost approach to obtain large-scale single crystalline thin films. Spalling is a commonly used technique for separating III-V semiconductor layers from their host substrates [2]. The process involves mechanically fracturing the substrate by depositing a metal stressor layer, electroplated nickel (Ni) in our case, on top. The Ni layer introduces compressive stress within the substrate. When the residual stress in the substrate reaches the critical stress, a crack is initiated upon application of an external pull force, such as exfoliation with tape. We demonstrate that by controlling the thickness of the electroplated Ni – and thus the compressive stress induced in the substrate – we can obtain single-crystal thin films of BTO with thicknesses ranging from 100 nm to several microns and areas upwards of 100 x 100 μm^2. We confirm our results using both (100) and (001) oriented single crystal substrates and report roughness values around 20 nm for 200 nm thick films. We observe a scaling of roughness with film thickness due to domain switching introduced through compressive stress in ferroelectric materials. Spalled thin films are transferred from tape onto desired substrates using a PPC/PDMS method, similar to what is used for transfer of 2D van der Waals materials. For spalled film thicknesses below 1 µm, optical microscope images reveal different colors in areas with varying film thicknesses due to thin film interference effects. We use transfer matrix calculations to create a large-scale spatial thickness map and identify areas with the target thin film thickness. Finally, transparent gate electrodes are deposited onto desired areas, and the electro-optic coefficients of the spalled films are measured as function of frequency using a Teng-Man setup [3]. The method outlined in this work presents a novel approach for producing high-quality, single crystal thin films. Based on the achieved film quality, we envision the integration of spalled electro-optic BTO thin films in various nanophotonic and quantum technologies including metasurfaces and integrated photonic circuits.

Two-Dimensional Cobalt Telluride ($CoTe_2$) for Sensor Detection—A Combined Experimental and Theoretical Studies *Anyesha Chakraborty[1], Surbhi Slathia[1], Bruno Ipaves[2], Caique C. de Oliveira[2], Solomon D. Negedu[3], Juan R. Gomez Quispe[2], Suman Sarkar[4], Chandra Sekhar Tiwary[1] and Pedro A. Autreto[2]; [1]Indian Institute of Technology Kharagpur, India; [2]Universidade Federal do ABC, Brazil; [3]Jimma University, Ethiopia; [4]Indian Institute of Technology*

Jammu, India

In recent years, the sensing field has experienced significant advancements due to the ongoing exploration of innovative materials such as 2D transition metal dichalcogenides (TMDs). These materials exhibit enhanced properties, including a large surface area, adjustable band gaps, stability in aqueous environments, low toxicity, and unique optical functionalities. Among these, 2D transition metal tellurides (TMTs) have emerged as a promising class for sensing applications [1, 2]. In this study, to address the challenges associated with ultrasensitive dopamine sensing for regular health monitoring, a flexible paper-based sensor utilizing 2D-CoTe2 was successfully fabricated and used for real-time detection of dopamine in artificial sweat. Furthermore, since pesticides pose risks to human health and the environment, 2D-CoTe2 was employed as a template material to detect some compounds as mancozeb and gamma aminobutyric acid (GABA) using spectroscopic and electrochemical techniques. To corroborate and elucidate some points in the experimental results, we confirmed the adsorption of dopamine and mancozeb on 2D-CoTe2 by calculating the binding energy, differential charge densities, and projected density of states (pDOS) using density functional theory (DFT). This work combines experimental and theoretical approaches to understand the interaction between the $CoTe_2$ *surface and various compounds, opening a frontier for the development of new and more precise sensors.*

Unveiling The Evolution of Charge Density Wave Order in Twisted Bilayers of NbSe2—A Machine Learning Approach *Norma Rivano, Zachary Goodwin, Francesco Libbi, Chuin Wei Tan and Boris Kozinsky; Harvard University, United States*

Niobium diselenide has attracted significant attention over the past decade due to the coexistence of superconductivity and a charge density wave (CDW), which have been experimentally observed down to the monolayer limit. Their coexistence, and evolution with varying numbers of layers and different twist angles are central topics in twistronics, and would benefit from accurate atomistic simulations. A fundamental question that remains largely unexplored in the literature is whether CDWs persist within moiré structures and how they are altered compared to the pristine monolayer. Traditional first-principles methods encounter limitations in addressing such questions due to the computational resources required to model the long-wavelength moiré pattern. For instance, investigating a 1-degree twist angle would necessitate approximately 10,000 atoms, rendering such simulations impractical. This study adopts a practical approach by leveraging ab-initio data to develop accurate machine learning interatomic potentials thanks to the ALLEGRO architecture, an open-source code for building highly scalable and accurate equivariant deep learning interatomic potentials. We explore the formation and evolution of CDW order in monolayers and twisted bilayers. Our results are validated against density functional theory calculations, encompassing structural relaxation and phonon dispersions, with minimal errors observed in energy and forces. We find that the CDWs persist in a mosaic-like pattern in the moiré lattice. Expanding our approach to multilayers and considering variables like doping, strain, substrates, and proximity *effects promises to refine CDW behaviors. These advancements could lead to new technological applications and scientific insights in this field.*

Simulation and Synthesis of Ultrathin Transition Metal Carbides and Transition Metal Dichalcogenides Heterostructures *Jiayang Wang, Alexander J. Sredenschek, David Sanchez, Mauricio Terrones and Susan B. Sinnott; The Pennsylvania State University, United States*

Non-layered transition metal carbides (TMCs) and layered transition metal dichalcogenides (TMDs) are two extensively studied material families that have garnered significant attention over the past century. Recently, the focus on two-dimensional (2D) materials and heterostructures has given rise to a new field centered on TMC/TMD heterostructures. These heterostructures, formed through chemical conversion, display various configurations featuring coupled 2D–3D interfaces, which result in unique and exotic properties. Xu et al. [1] developed a liquid-metal-assisted chemical vapor deposition (LMCVD) technique to grow large-area ultrathin Mo_2C and investigated their robust superconducting properties down to a few nanometers in thickness. Through chemical conversion, Jeon et al. [2] synthesized the β-Mo_2C/MoS_2 lateral heterostructures exhibiting low contact resistance and a low Schottky barrier height, highlighting their potential as critical hybrid building blocks for future device applications. By combining computational methods, controlled synthesis, and advanced characterization, our collaborative team developed a comprehensive workflow to synthesize and analyze W_xC/WS_2 heterostructures in a series of consecutive steps.

The initial step involves synthesizing ultrathin tungsten carbide. Due to the material's 2D geometry, the surface effect alters the phase stability, which traditional phase diagrams cannot accurately describe. By utilizing density functional theory (DFT) calculations and thermodynamic analyses, we constructed a chemical potential diagram for W_xC in thin-film structures, revealing a different phase stability order compared to its bulk counterpart. Using LMCVD, we identified two phases of tungsten carbide: WC on copper substrates and metastable W_2C on gallium substrates. In the next step, we observed that high-temperature (800–900°C) heat treatment in hydrogen sulfide (H_2S) partially converted the tungsten carbide (WC and W_2C) nanoplates into crystalline WS_2. Characterization revealed that WS_2 formed on both the edge and basal surfaces of the tungsten carbide platelets. On the basal surface, distinct Moiré patterns indicated the presence of epitaxial and twisted WS_2. Using DFT calculations, we explored how W or C termination influences the adhesion work of the resulting heterostructure. The conversion of tungsten carbide to WS_2 was found to be more efficient at slightly lower temperatures and shorter durations for W_2C than for WC, with facets completely transforming into multilayer WS_2. This enhanced conversion for W_2C is attributed to a lower diffusion barrier for sulfur atoms into the tungsten carbide crystal, as quantified by nudged elastic band (NEB) calculations. In the final steps, we applied DFT calculations onto atomic models to study the electronic and transport properties across the WC/WS_2 and WC/WSe_2 interface [3].

The Moiré pattern heterostructure exhibited a greater energetic favorability when compared to the coherent epitaxial strain heterostructure. Our calculations revealed the formation of Schottky barriers within these systems, *with the type (n-type or p-type) and height of the Schottky barriers being determined by the termination atoms of WC. We concluded that WC-c/WSe_2 has the smallest p-type Schottky barrier height (0.08 eV) among all other heterostructures. Transport properties were further assessed using the Simmons tunneling injection model [4]. These findings yielded valuable insights that can be leveraged in the design of high-performance nano-electronic devices built upon 2D materials.*

Adsorption Characteristics of Boron and Nitrogen on 3x3 Reconstructed Surface of 6H-SiC *Larry Blank[1], Jay Lee[1], Luke Bissell[1], Michael Newburger[1], Robert Bedford[1], Shamsul Arafin[2] and Ajit Roy[1]; [1]Air Force Research Laboratory, United States; [2]The Ohio State University, United States*

Regarding the subject of hexagonal boron nitride (h-BN) film growth on dielectric substrate, elemental adsorptions of boron and nitrogen on silicon carbide(SiC) are studied using density functional theory. Among various SiC surface reconstructions stable at temperature lower than that of thermal decomposition and spontaneous graphitization, the choice of substrate is made to be the 3X3 reconstructed 6H-SiC (0001), which is the least reactive with a twisted layer of Si ad-atoms featuring a single dangling bond. The analysis on trajectory ensemble of 1152 adsorptions, spanning the whole surface, reveals all adsorption sites available for B and N on 6H-SiC (0001) 3X3 surface. We found that those multitudes of adsorption sites can be grouped into three regions surrounding three non-twisted silicon ad-atoms on the surface. Adsorption sites with the highest adsorption energies are found to be identical for B and N, however, with distinguishable configurations. The capture ratio relating to the initial population of each adsorption site is found to be governed by the surface configuration, being the highest near the extruded Si ad-atom, but weakly correlated to the adsorption energy of the corresponding site.
Study of elemental adsorption on substrate can be directly associated with MBE process using elemental flux toward substrate. Even in MOCVD or ALD process, elemental adsorption characteristics indirectly contribute to the overall understanding of the growth process, as surface reactions involving precursor compounds often result in elements adsorbed on the surface.

9:15 AM MT03.03.03

Super Flat Graphene Growth on Candidate Substrate Selected by Molecular Dynamics—Theoretical and Experimental *Satoru Kaneko[1,2], Takashi Tokumasu[1], Manabu Yasui[1], Masahito Kurauchi[1], Daishi Shiojiri[1], Chihiro Kato[1], Satomi Tanaka[1], Masahiro Yoshimura[1], Shigeo Yasuhara[3], Musa Can[4], Ruei Yu[5], Sumanta Sahoo[6], Kripasindhu Sardar[7], Mariana Inonita[8] and Akifumi Matsuda[2]; [1]KISTEC, Japan; [2]Tokyo Institute of Technology, Japan; [3]Japan Advanced Chemicals Ltd., Japan; [4]Istanbul University, Turkey; [5]Asia University, Taiwan; [6]Radhakrishna Institute of Technology and Engineering, India; [7]Tohoku University, Japan; [8]Politehnica University of Bucharest, Romania*

Stability of functioning materials on a target surface is one of important factor for thin film growth. For thermodynamic stability, Schlom et. al. comprehensively investigate oxide materials face to silicon (Si) surface[1].

The paper is the reference on growth of oxide on Si surface, however, their study does not include any crystallographic consideration, such as lattice constants and orientation of crystal growth. By introducing an adsorption energy, the orientation of epitaxial film was predicted on candidate materials[2]. In this study, the absorption energy was again used to select candidate substrates for flat graphene growth, and graphene films were experimentally deposited on the candidate substrates by using a pulsed laser deposition (PLD), and showed flat surface of Ra ~ 63 pm close to super flat surface reported by molecular beam epitaxy [3].

A candidate substrate was selected by molecular dynamics (MD) simulation. A supercell was consisted of carbon clusters placed on variety of substrates with vacuum slab. As carbon clusters, (1) C atom, (2) six-membered ring (6-ring) and (3) seven six-membered rings (nanographene) were placed on SrTiO, silicon and sapphire substrates. Each carbon clusters and substrate surface were optimized before consisting supercells. On the sapphire surface, for an example, carbon cluster was placed on (1) aluminum or oxygen atoms, and the adsorption energy was estimated using the density functional theory (DFT) with a semi-core pseudopotential. The generalized gradient approximation (GGA) method was used to obtain the electron density. Materials Studio and DMol3 were used for preparing and optimizing supercells, respectively.
The adsorption energy showed not much different on the candidate surfaces, however, carbon cluster vertically stood up on some candidate substrates, which prevents films to flatly grow on the surfaces. Carbon cluster of both six-ring and nanographene flatly covered the surface on only SrTiO substrate.

Carbon film was experimentally deposited on the candidate substrates by a PLD with 248 nm at the repetition rate of 2 Hz reduced by the slower Q-switched method [4]. On SrTiO substrate, an atomic force microscopy (AFM) showed a flat graphene grew with Ra ~ 63 nm. Interestingly, MD simulation showed 6-ring vertically stood up on Si substrate, and nano balls experimentally scattered on Si substrates.

Suitable substrate was selected by using a MD simulation on candidate substrates, and carbon film experimentally deposited on the candidate substrates. The simulation showed carbon cluster flatly cover on only SrTiO substrate, and flat graphene experimentally grew on SrTiO with Ra ~ 63 nm[5]. The same method was also applied onto oxide film, and crystal orientation of epitaxial film was predicted on Si (001) substrate. Magnesium oxide, for an example, was experimentally deposited on Si(001) substrate, and x-ray diffraction showed the simulation results agreed with the epitaxial film deposited on Si(001).

Low Scaling Quantum Chemistry Methods for Predicting Electronic Properties of 2D Materials

Idan Haritan[1], Xiao Wang[2] and Tamar Goldzak[1]; [1]Bar-Ilan University, Israel; [2]University of California, Santa Cruz, United States

The electronic structure of periodic systems, such as 2D materials, presents significant computational challenges *due to the infinite nature of these systems. While density functional theory (DFT) has been the cornerstone for such calculations, it can sometimes fall short in accurately predicting properties like band gaps and Van der Waals interactions. Ab initio quantum chemistry methods, traditionally developed for molecular systems, offer a systematically improvable alternative. In particular, spin-component scaled (SCS) and scaled opposite-spin (SOS) modifications of second-order Møller-Plesset perturbation theory (MP2) have shown improved accuracy over conventional MP2 for molecular properties and hold potential for application to periodic systems.*

This work aims to extend and apply SCS and SOS MP2 methods to simulate and predict the electronic properties of complex 2D materials. These methods, known for their balance between computational cost and accuracy, have proven effective for molecular systems in predicting ground state properties. They have relatively low scaling and mostly give an accuracy that is better than MP2, and for some properties even can be comparable to CCSD. Their application to periodic systems, however, remains limited. Our research focuses on developing efficient algorithms for periodic SCS and SOS MP2 calculations using Gaussian type orbitals, Brillouin zone sampling, and density fitting techniques.

We present a novel periodic SOS-MP2 algorithm based on density fitting and Laplace transformation, which reduces the computational scaling with respect to the number of basis functions and k-points. This approach leads to an attractive low-scaling approach for periodic systems with complex unit cells. Preliminary results show that periodic SCS/SOS-MP2 calculations provide accurate ground state properties. These methods outperform leading density functionals and offer a reliable approach to reaching the thermodynamic limit in extended systems.

Our preliminary promising results demonstrate the potential of these methods for Van der Waals 2D materials. Since both Van der Waals 2D materials and point defects present significant challenges for density functional theory (DFT) methods, the application of a novel periodic SOS-MP2 algorithm can aid in the development of novel exchange-correlation functionals and force fields for molecular dynamics applications.

Furthermore, accurately predicting and understanding electronic properties and transfer mechanisms in these systems could lead to the discovery of novel materials and phenomena. Significant implications are expected for device design and quantum information applications, since point defects in 2D materials, in particular, are promising candidates for quantum information technologies.

In summary, this work introduces and applies advanced quantum chemistry methods to periodic systems, demonstrating their effectiveness and potential for broader application in material science and condensed matter physics. By extending the capabilities of SCS and SOS MP2 methods to complex 2D materials, we pave the way for more accurate and efficient computational techniques in the study of extended systems.

Theory Insights into the Synthesis of 2D Materials—2D Metals, Single-Crystal TMD Monolayers, Frustrated Salts and Disclinated Graphene *Vincent Crespi[1], Yuanxi Wang[2], Nadir Nayir[3], Amir Nourhani[4], Adri van Duin[1], Boyang Zheng[1], Ben Katz[1], Lev Krainov[1] and Maxwell Meyers[1]; [1]The Pennsylvania State University, United States; [2]University of North Texas, United States; [3]Istanbul Technical University, Turkey; [4]The University of Akron, United*

States

Most air-stable 2D monolayers are semiconductors or insulators wherein the bandgap protects the material against oxidation. Air-stable wafer-scale 2D metals are thus rare. Growth of metal monolayers or bilayers underneath an epitaxial graphene cap provides a route towards a broad family of air-stable wafer-scale 2D metals whose synthesis can be understood with first-principles insights. Wafer-scale single-crystal semiconducting monolayers are similarly rare, since epitaxy of 2D materials is weak and nucleation typically occurs at multiple sites across a substrate. "Step-epitaxy" on sapphire suibstrates improves the consistency of domain alignment in wafer-scale growth and insights into the mechanism thereof can be gained by a combination of first-principles calculation and empirical molecular dynamics. Graphene remains an archetypal 2D material and continues to hold surprises, such as (1) the possiblity to host geometrically frustrated salt crystals with anions and cations on opposite sides of the sheet and (2) the potential role of 2-fold coordination defects in disrupting growth and (3) general rules for how networks of disclinations yield semiconduting or metallic behavior, wth a striking rescaling of the density of states between systems within a given class.

Exotic Honeycomb NaCl Structures on a Lead Halide Perovskite Substrate—New Insights from Ab Initio Calculations *Adriana Pecoraro[1], Ana B. Muñoz-Garcia[1], Gennaro V. Sannino[1,2], Paola Delli Veneri[2] and Michele Pavone[1]; [1]University of Naples Federico II, Italy; [2]ENEA, Italy*

Sodium chloride (NaCl) is an ionic compound that plays a crucial role in the fine-tuning of electronic properties at heterogeneous junctions. NaCl is effectively employed in perovskite solar cells as an interlayer between the photoactive material and the charge transport layers. Despite its apparent simplicity, NaCl can exhibit unexpectedly complex interfacial structures, particularly under high pressure or at reduced dimensions.[1] The most stable surface facet of cubic NaCl is the (100) plane. However, recent experiments have revealed different surface terminations depending on the chemical nature and structure of the substrate. For instance, a hexagonal surface of NaCl has been observed on the diamond (110) surface.[2] In this context, this contribution delves into the interface between NaCl and the prototypical lead halide perovskite methylammonium lead iodide (MAPI) using first-principles calculations at the density functional theory (DFT) level.[3] Our results indicate various possible NaCl surface reconstructions depending on the MAPI terminations and the nature of the interactions involved. The impact on the electronic structure of MAPI, including work function and band edge potentials, is also examined. These insights are pivotal for the development of new and more efficient perovskite solar cells. We also investigate the role of the salt in mitigating interface defects and improve charge transport between layers. Our findings highlight the importance of considering interface engineering in the design of perovskite solar cells. The ability to fine-tune the electronic properties of the interface through the choice of interlayer materials like NaCl opens new avenues for enhancing device performance.

11:00 AM MT03.04.03

Uncertainty Quantification of Total Energy Tight Binding Models for van der Waals Materials *Daniel Palmer and Harley Johnson; University of Illinois at Urbana-Champaign, United States*

Interatomic potentials can range greatly in complexity, accuracy, and transferability. Understanding the uncertainty of an interatomic potential is crucial for any application area. Thus, uncertainty quantification (UQ) for interatomic potentials has become an important area of research. Total Energy Tight Binding (TETB) models, which are semi-empirical potential energy descriptions constructed with information about the electronic degrees of freedom in a material, are often more computationally scalable than fully ab initio methods. However, little has been done to quantify uncertainty in TETB models. In this work, we develop Markov-chain Monte Carlo methods for uncertainty quantification in TETB models. We apply our methods to twisted bilayer graphene systems because of their strong dependence on electronic degrees of freedom in lattice reconstruction, and the use of models in these systems that span multiple energy scales. We use our UQ methods to determine uncertainties in particular quantities of interest such as corrugation of twisted bilayer graphene, bandwidths of relaxed structures, and magic angle Fermi velocities. Comparisons to UQ in classical interatomic potentials are made throughout.

11:15 AM MT03.04.04

Establishing Structure-Function Relationships of MXenes Using Machine Learning *Tej Choksi, Lavie Rekhi, Pranav Roy, See Wee Koh and Hong Li; Nanyang Technological University, Singapore*

Two-dimensional materials like MXenes have exquisitely tunable electronic properties leading to promising applications in energy storage/conversion and electromagnetic shielding. One such electronic property that underpins structure-function relationships is the work function. Experiments indicate that the work function can be altered across a wide range through changes to the MXene composition or altering the surface termination of MXenes. Recent advances have expanded the range of possible surface terminations to several p-block elements like O, N*, F*, Cl* S* etc. MXenes also function as supports in low-dimensional heterostructures consisting of metal layers adsorbed on the MXene. Such heterostructures have distinctive electronic properties due to charge transfer between the metal and the MXene. The stability of these heterostructures is governed by the adhesion energy between the metal and the MXene. This metric of stability determines whether a metal sheet exists in a low-dimensional heterostructure or as 3D nanoparticles. The ever-expanding space of MXenes presents a new challenge for efficiently predicting properties like the work function and the adhesion energy.*

We construct machine learning models that predict functional properties of MXenes like the work function and the adhesion energy of metal overlayers on MXenes. A feature space consisting of physico-chemical properties of the constituting elements is used. The feature space includes properties like the electronegativity, ionization potential, orbital radii, etc that are available in databases. Several regression models like ordinary linear regression, neural networks, and random forests are used. To lend physical interpretability to our non-linear models, we also employ symbolic transformers. We employ two independent techniques to identify the most important features that govern these structure-property relationships. First, we perform a sensitivity analysis using permutation feature importance. Next, we compute the occurrence probability of different features in the most accurate models.

A 15-feature neural network model emerges as the best performing model and can predict the work function of MXenes from the properties of constituting atoms with a training and testing error of 0.13 eV and 0.25 eV respectively. The sensitivity analyses illustrates that the work function is governed by properties of the surface termination of the MXene. Leveraging insights from our sensitivity analyses, we construct a simpler 5-feature neural network that predicts the work function of MXenes with errors of 0.28 eV, which is comparable to the best performing model. We implement a transfer learning approach that efficiently re-trains the neural network to compositions beyond the training set. Experimental measurements of the work function of Ti_3C_2 *terminated with various p-block elements confirm the trends in the work function established through our model.*

While non-linear models are necessary to predict the work function of MXenes, the adhesion energies of metal films on MXenes is robustly estimated using simple linear models. Key features that govern these adhesion energies include the electronegativity of the termination, the strain on the metal film, and the work function of the support. Model predicted adhesion energies are estimated with errors of 0.01-0.03 eV/A^2. These adhesion energies are used to assess the thermal and electrochemical stability of the MXene based heterostructures. We leverage this framework to identify thermally and electrochemically stable heterostructures from a space of 5000+ structures. Key trends are validated against experimental reports taken from the literature. Taken together, this work showcases the power of machine learning methods in predicting functional properties of MXenes using readily available physico-chemical properties as inputs.

11:30 AM *MT03.04.05
Precursor, Substrate and Other Parties—In The Quest for Quality 2D-Commodity *Boris I. Yakobson; Rice University, United States*

2D materials synthesis has reached maturity stage when the challenge shifts from just "making something new" up to making it fast, at scale, and of defect-free highest quality, so to meet the needs and stringent standards of electronics manufacturing industry.
● We will discuss how the theoretical insight and computational modeling help to reveal the molecular mechanisms of the reactions (mostly of CVD type), determine the gas phase precursor, optimal substrates in achieving the wafers-size monocrystal graphene, hexagonal boron nitrogen, free borophene phases, and the novel, better TMDs.
● If time permits, we may also touch an intriguing topic of how to define the crystal shapes—so vividly seen for many 2D materials—when their edge energies are fundamentally undefinable, due to the lattice low symmetry.
Supported by the DOE BES grant DE-SC0012547 and in part (case of BN) by the ARO grant W911NF1920269.

SESSION MT03.05: Energy and Environmental Applications of 2D Materials

1:30 PM *MT03.05.01
Prediction of 2D Materials for Energy Applications Using Computational Methods *Yatong Wang[1], Murat Sorkun[1], Ceren Tayran[1], Geert Brocks[2] and Suleyman Er[1]; [1]DIFFER, Netherlands; [2]Technische Universiteit Eindhoven, Netherlands*

The recent application of data-driven methods for molecule and material discovery has shown significant promise. In this context, we have developed an artificial intelligence (AI)-aided virtual screening recipe for two-dimensional (2D) materials discovery, enhancing the search for new materials with specific physical and chemical properties. As part of this effort, we have established the Virtual 2D Materials Database (V2DB), a publicly available resource that includes potentially stable 2D materials along with their AI-predicted key physicochemical properties [1].

Our subsequent focus is on pinpointing the functional 2D materials constituted by abundant chemical elements for energy applications, particularly those suitable for solar-driven photocatalytic water splitting to produce hydrogen (H2). The challenge lies in efficiently navigating the vast chemical space to identify promising 2D *materials. To tackle this, we utilize a data-centric approach, screening the V2DB to find stable candidates with appropriate band gaps and optimal photocatalytic properties. This robust virtual screening process incorporates machine learning (ML), high-throughput density functional theory (HT-DFT), hybrid-DFT, and GW calculations.*

Through this approach, we have identified 27 new 2D materials that show good potential for photocatalytic water splitting [2,3]. We then performed a detailed analysis of their solar water splitting properties, including electronic and optical features, solar-to-hydrogen conversion efficiency, and carrier mobility. These studies not only introduce new 2D photocatalysts but also highlight the efficiency of a data-driven strategy in systematically exploring materials in an extensive chemical space.

Our approach is versatile in identifying materials with specific properties for various renewable energy applications, including photovoltaic systems and electro/photo-catalytic conversion of feedstock molecules like H_2O, CO_2, *and* N_2 *into valuable fuels and products, thereby exploring previously uncharted chemical spaces of 2D materials.*

Tuning Rashba Spin Splitting Strength and Photocatalytic Activity Through Van der Waals Heterostructures

Dhirendra Kumar and Sudip Chakraborty; Harish-Chandra Research Institute, India

Recently, Janus two-dimensional (2D) materials have attracted much interest due to possessing unique properties caused by the lack of inversion symmetry. In this work, we study the structural, vibrational, Rashba spin splitting, and photocatalytic properties of Janus SbXBr (X = S, Se) monolayer and their van der Waals heterostructures with different stacking. The inclusion of spin-orbit coupling (SOC) lifts spin degeneracy which exhibits Rashba splitting at the high symmetry Γ point in the conduction band and the valence band, respectively. The strength of Rashba splitting is obtained more in vdW heterostructures. All structures are found in indirect bandgap semiconductor nature with significant bandgaps. The Rashba splitting and semiconductor nature of these materials leads them to applications in spintronics, photovoltaic solar cells, and photocatalytic water splitting. The highest value of Rashba splitting is obtained to be 1.17 eVÅ. All heterostructures form Type-II band alignment which can be exploited to enhance the life of interlayer excitons. For the photocatalytic water splitting, we study the band edge position of the conduction band minimum (CBM) and the valence band maximum (VBM) with respect to vacuum level, all heterostructures fulfill the criteria of redox potential of the H_2 *and* O_2 *reactions. Additionally, we study the charge transfer between atomic layers to understand the carrier mobility across band alignment and Rashba splitting. All properties are carried out using first-principle density functional theory (DFT) as implimented in VASP with the inclusion of SOC. For more accurate bandgaps, HSE06 hybrid functional is used with and without SOC.*

Layer-Dependent Binding of NH_3 ***on*** MoS_2

Tina Mihm, Zifan Wang, Xi Ling and Sahar Sharifzadeh; Boston University, United States

Two-dimensional transition metal nitrides (TMNs) are a new class of material that have shown great promise for use in electronic and optoelectronic devices due to their high conductivity and stability. However, the synthesis of these large-area thin films of TMNs is still not fully understood. Current studies have shown that exposing layered

MoS_2 crystals to NH_3 causes the MoS_2 to rapidly convert to Mo_5N_6, but the mechanism by which this convergence happens is still unknown. Here, we apply first-principles computational density functional theory (DFT) to investigate the nature of binding of NH_3 on layered MoS_2, considering the role of defects and number of layers. Our calculations show that the molecule binds selectively to defects, with a layer-dependence of the binding energy that is consistent with measured reactivity only in the presence of defect complexes containing multiple sulfur vacancies. Overall, this study indicates that defects are necessary for the atomic substitution synthesis of TMNs.

Fully Ab Initio Mechanism of the Organometallic Chemical Vapor Deposition of MoS_2—Molecular Precursors to Transition Metal Dichcalcogenide Monolayers *Sagar Ghorai and Ananth Govind Rajan; Indian Institute of Science, India*

The development of a fully ab initio theory for the chemical vapor deposition (CVD) synthesis of two-dimensional (2D) materials is a prominent challenge in computational chemistry and materials science. In this talk, I will discuss the use of quantum-mechanical density functional theory calculations to discover the mechanisms underlying the nucleation and growth of monolayer 2H molybdenum disulfide (MoS_2) during organometallic CVD. Starting with molybdenum hexacarbonyl ($Mo(CO)_6$) and hydrogen sulfide (H_2S) as molecular precursors, we elucidate processes such as the decomposition of $Mo(CO)_6$ to $Mo(CO)_3$, sulfidation of $Mo(CO)_3$, formation of metallic trigonal-phase (1T) Mo-S clusters, transition to semiconducting hexagonal-phase 2H MoS_2, and the competition between the growth of Mo- and S-zigzag edges that leads to triangular and hexagonal flakes. We demonstrate thermodynamic and kinetic control, respectively, over the formation of Mo- and S-zigzag edges. Additionally, we find the removal of hydrogen (H_2) to be the rate-determining step in the growth process. We further compute the free energy of formation of the investigated Mo-S clusters on amorphous SiO_2, demonstrating the important role played by the SiO_2 substrate in the initial stages of nucleation and growth. We also show the feasibility of forming Mo-S clusters with more than two Mo atoms on the SiO_2 surface. Our work lays the foundation for developing fully ab initio models of 2D material synthesis.

Moire Structures of Transition Metal Dichalcogenides (TMDCs) and Oxide Perovskite Barium Titanate (BaTiO3) *Priya Vashishta, Anikeya Aditya, Nitish Baradwaj, Ken-ichi Nomura, Aiichiro Nakano and Rajiv Kalia; University of Southern California, United States*

Two-dimensional van Der Waal structures, such as Transition Metal Dichalcogenides (TMDCs) and recent fabrication of BTO twisted nanometer thick layers structures have brought about exciting research opportunities. These materials possess unique physical, electrical, and optical attributes that can be fine-tuned through twisting,

rotations and mechanical deformations.
In this talk, I will discuss the following three topics:
1. *Wrinkle-Ridge formation in 2-D $MoSe_2$ under uniaxial and biaxial strain [1]*
2. *Ferroelectric domains in MoS_2 Moire structures under a variety of twist conditions*
3. *Oxide Moire structures – Twisted 15-20nm thick layers of BaTiO3 (BTO) - that show vortex and antivortex structures [2]*

We have investigated the effects of lateral compression on out-of-plane deformation of 2-D $MoSe_2$ layers. A $MoSe_2$ monolayer develops periodic wrinkles under uniaxial compression and Miura-Ori patterns under biaxial compression. When a flat $MoSe_2$ monolayer is placed on top of a wrinkled $MoSe_2$ layer, the van der Waals (vdW) interaction transforms wrinkles into ridges and generates mixed 2H and 1T phases and chain-like defects. Biaxial strain induces regions of Miura-Ori patterns in bilayers. Strained systems analyzed using a convolutional neural network show that the compressed system consists of semiconducting 2H and metallic 1T phases. The energetics, mechanical response, defect structure, and dynamics are analyzed as bilayers undergo wrinkle–ridge transformations under uniaxial compression and moiré transformations under biaxial compression.

Moire supercells, formed by the stacking of 2D TMDC materials with small twists, have been shown to exhibit novel electronic and optical properties. The stacking order of these 2D materials plays a crucial role in determining their electronic and optical characteristics. These Moire supercells have also been observed to give rise to a superlattice of out-of-plane ferroelectric domains. Specifically, we examine how the initial twist angle of the stacked 2D materials affects the formation of polarized domains. Additionally, we explore how the initial twist angle can be utilized to control the size of the ferroelectric domains.

Exciting experiments involved stacking freestanding perovskite layers of BTO of thickness of 15- 20nm, at different twists of 3°, 6°, 10.4°, and 50° degrees. The system shows the emergence of electric polarization vortices and antivortices. The couplings across the interface between the twisted layers drive large strain gradients in the ferroelectric layers, resulting in vortex-like modulations of the homogeneous polarization state due to the flexoelectric effect. It is noted that the periodicity of the 2D vortex pattern can be largely tuned by controlling the twisting angle.

3:45 PM MT03.06.02

Anomalous Dynamical Dewetting of Silicene Flakes with Dendritic Pyramids *Jean-Noel Aqua[1], Kejian Wang[1], Mathieu Abel[2], Isabelle Berbezier[2] and Antoine Ronda[2]; [1]Sorbonne Université, France; [2]Aix-Marseille Université, France*

The production by exfoliation of two-dimensional (2D) materials has opened up a fertile field of study, enabling their integration into a variety of structures for different materials. However, their production by epitaxy, which is a priori more controlled, remains largely to be developed and mastered. This is the case in general, and in particular

for systems such as silicene, which cannot be produced by exfoliation. Group IV elements such as Si (silicene) and Ge (germanene) are indeed promising alternatives, that are predicted to be Dirac materials in which electrons behave as relativistic massless particles. In addition, their buckling, as well as their larger spin-orbit coupling, make it easier to create a non-negligible bandgap. Numerous attempts to grow silicene have been made on different metallic or van-der-Waals substrates, with varying degrees of success in terms of the reality, quality and size of the 2D Si layer thus produced. In addition, fabrication of functional electronic devices requires non-metallic supports. A natural option is therefore to introduce a buffer layer for decoupling the 2D adlayer from its substrate. Recent experiments reported the possibility to grow silicene on a high quality graphene grown by CVD on a 6H-SiC(0001) substrate. They demonstrated the possibility to grow large silicene flakes over 100nm in size, surrounded by a ring and coexisting with three-dimensional dendritic islands, 3 to 4 monolayers thick. This anomalous growth mode is not described by conventional epitaxial growth models.
We have developed a modelling of van der Waals epitaxy by considering a lattice model that takes into account the surface thermodynamics specific to these systems. In addition to the classic processes of deposition, diffusion and attachment, we have incorporated atomic processes at step edges and between different layers. We have revisited the classical modeling of dewetting thermodynamics, incorporating adsorption energies on the different layers that prove to be a crucial process dictating atomic fluxes between layers. We solved the far-from-equilibrium many-body dynamics thanks to kinetic Monte Carlo simulations. Several energy barriers are a priori unknowns in the problem, which we have managed to determine thanks to meticulous analysis of the experimental microscopy images. We have been able to reproduce the flakes morphological characteristics, their density, but also the long-time evolution resulting in non-coalescent dendritic pyramids for large deposits. The ringed 2D flakes revealed by the experiments appear to be a metastable state resulting from the dewetting dynamics of a system evolving towards the more energetically stable dendritic pyramids. This modelization enables us to rationalize both qualitatively and quantitatively the anomalous growth of silicene flakes, and allows to target the mechanisms at work in these systems. It paves the way to a new understanding and better experimental control of silicene growth.

$Cr_xMn_{1-x}SbSe_3$—A Quasi-One-Dimensional van der Waals Magnet *Alyssa Horne, Matthew D. Sisson, Yongmei Jin and Ranjit Pati; Michigan Technological University, United States*

A van der Waals (vdW) material is characterized by the presence of low-dimensional charge neutral units that exhibit strong covalent bonding within the units and weak van der Waals interaction between the units. The recent discovery of magnetic ordering in low-dimensional vdW materials has garnered considerable interest. Both two-dimensional and quasi-one-dimensional vdW magnets have been reported.

In this study, we employed first-principles density functional theory (DFT) to investigate the composition-dependent structure-property relationship of $Cr_xMn_{1-x}SbSe_3$, a quasi-one-dimensional vdW magnet. The concentration of Mn is found to have strong effects on the electronic structure and magnetic properties of the system. Using the exchange coupling parameters between magnetic atoms obtained from DFT, in conjunction with Monte Carlo method for spin dynamics, we estimated the Curie temperature of this material to understand its thermodynamic stability. For $CrSbSe_3$, our calculated Curie temperature is shown to be in good agreement with the experimental value of ~70 K. Our results further reveal a stable phonon dispersion and a narrow band gap with distinct energy bands for the majority and minority spins, confirming $CrSbSe_3$ as a ferromagnetic semiconductor at low temperatures.

Symmetry and Chemical Stability of M_3X_8 (M = Nb, X= Cl. Br, I) and Other Ionic Kagome Materials *Varsha*

Kumari[1], Julia Bauer[2] and Alexandru B. Georgescu[1]; [1]Indiana University Bloomington, United States; [2]Yale University, United States

The 2D van der Waals transition metal Kagome halides M_3X_8 are a class of correlated materials showing potential multiferroic properties, spin liquid behavior, and have recently been used in field-free Josephson diodes for quantum computing applications.[1] However, relatively few such materials have been synthesized successfully compared to the 2D dihalides and trihalides (MX_2 and MX_3) –only the M=Nb and (X=Cl, Br, I) compounds can be found in the literature.[2] Key to these materials' properties is a breathing distortion of the Kagome lattice, associated with a triangular M_3 cluster formation coupled to a trimer orbital formation – extended along the three transition metals in the cluster. Using density functional theory simulations, symmetry analysis, and Crystal Orbital Hamiltonian Populations (COHP), we show that the unique chemical stability of the Nb compounds is intrinsically tied to the metal cluster formation in these materials, and the specific bonding and antibonding symmetry of the trimer molecular orbitals associated with it. Using this theoretical method, we propose new possible materials for synthesis in this materials family and extend our theory to understand dynamic electrochemical doping in the Kagome Oxide $Li_xScMo_3O_8$.[3]

Advanced Intercalation Strategies for Enhanced Thermoelectric Performance in TaS_2 and $TaSe_2$ *Francesco Siddi, Antonio Cappai, Luciano Colombo and Claudio Melis; Università degli Studi di Cagliari, Italy*

Transition metal dichalcogenides (TMDCs) have recently gained significant attention in various research fields due to their versatile electronic properties, coupled with mechanical flexibility and optical sensitivity. These characteristics make TMDCs suitable for applications in semiconductor systems, lightweight wearables, and flexible technologies. Recently, TMDCs have also been proposed as potential thermoelectric materials because of their relatively high carrier mobility and tunable thermal conductivity. In this context, atomic-scale engineering represents a promising approach to further enhance their intrinsic thermoelectric performances, allowing a fine tuning of the three key quantities involved in determining the figure of merit ZT, i.e., thermal conductivity κ , electrical conductivity σ , and Seebeck coefficient S; thereby opening new opportunities for their practical implementation in thermoelectric devices.

In this work, we explore two different strategies to enhance the thermoelectric figure of merit of two specific TMDCs, namely TaS_2 and $TaSe_2$. First, we demonstrate through first-principles DFT calculations that the intercalation of specific functional groups, such as tert-butyl isocyanate, can dramatically decrease the lattice thermal conductivity of TaS_2 without affecting the corresponding thermoelectric power factor ($S^2\sigma$) [1,2]. This effect can be attributed to two key mechanisms: i) the increase in inter-layer separation and ii) the presence of low-frequency molecular optical modes. The first mechanism inhibits specific Van der Waals quasi-acoustic inter-layer vibrational modes, which contribute approximately 55% of the lattice thermal conductivity. The second mechanism involves a significant decrease in phonon group velocities due to phonon-crossing phenomena between low-frequency molecular modes and acoustic modes, leading to a substantial reduction in all phonon lifetimes. These combined effects result in a strong reduction in thermal conductivity, thereby enhancing the thermoelectric performance of TaS2 by a factor ~40.

In the second strategy, a significant increase in the power factor was achieved using a similar intercalation approach, but with metallic cations as spacers between TaSe2 layers. We demonstrated that the inclusion of metallic cations, similar to organic functionalization, impacts the low-frequency region of the phonon spectrum by reducing phonon group velocities. Additionally, the metallic cations induce non-negligible modifications in the electronic band structure, thereby affecting the power factor. The result of this second intercalation strategy is a substantial overall increase i the figure of merit, achieving an improvement by a factor of up to 10.

CO Adsorption in Bare MXenes Ti_xC_{x-1} (X=2,3), MAX Slabs and Their Surfaces Passivated with Oxygen

Maria G. Moreno-Armenta; Universidad Nacional Autónoma de México, United States

This work is focused on the carbon monoxide molecule (CO) adsorption on the MXenes Ti_2C, Ti_3C_2 in its MAX slabs phases Ti_2AlC, Ti_3AlC_2 and Ti_2CO_2, $Ti_3C_2O_2$, Ti_2AlCO_2, $Ti_3AlC_2O_2$.The calculation was performed using the density functional theory (DFT) as is implemented in the Vienna Ab initio Simulation Package (VASP). Since the structures are arranged in layers, Van der Waals dispersive force interactions were considered. A 3 x 3 x1 supercell was used to study the different structures. The consecutive slabs were separated by a vacuum of ~15 Å to reduce self-interactions due to periodic conditions.
The structure of the MXenes were built from the corresponding MAX phase, by removing the Aluminium atom. The slabs were obtained by cuts of the MAX phase with different surface terminations like Titanium, Aluminium or Carbon. The stable one was finished in Titanium, and we used it to construct slabs with stoichiometries: Ti_2AlC, $Ti_2Al_{0.5}C$, $Ti_6Al_2C_3$, Ti_3AlC_2, $Ti_3Al_{0.5}C_2$ $Ti_9Al_2C_6$, where every surface were passivated with oxygen atoms. In all of them we adsorbed the CO molecule on the high symmetry sites. Furthermore, the CO was placed in 3 different positions with respect to the surface: horizontal, vertical with the C pointing to the surface and vertical with the O pointing to the surface. Vibrational frequencies for the adsorbed CO were determined by freezing all MAX and Mxenes atoms from the support, that is, the normal vibrational modes of the CO have been uncoupled from the surface phonons and every atom displaced independently to its equilibrium position. The CO-surface interaction was neglected and only the adsorbate was calculated.
We optimized the MAXs phases, their corresponding MXenes and different configurations for the MAXs phases, where we varied the proportion of Al:Ti:C. We organized them into 2 groups named: (I) MAX Ti_2AlC, Ti_2AlCO_2 and its derivatives and (II) MAX Ti_3AlC_2,$Ti_3AlC_2O_2$ and its derivatives. All optimizations were carried out under the same calculation conditions. CO adsorbed perpendicular to the titanium surface is placed on both the C and O atom sides. The adsorption energy was calculated as:
Where is the system energy with the adsorbate, adsorbate energy (CO) in vacuum, clean surface energy. The configurations with lower adsorption energy were selected to calculate the vibrational frequencies, where only the CO displacements perpendicular to the surface were active.
In group (I) the value of the calculated frequency is slightly increased as the proportion of aluminum increases, the variation in intensity is negligible. The frequency and intensity values are very similar for group (II), except for MXene which has a lower value, indicating that Aluminum is not present inside the cell. Due to the differences in adsorption energy, as well as in frequencies and intensities, between these MXenes and slabs of their MAX phases, that are very close to each other, we considered that any of these stoichiometries can be used for the CO adsorption.

Acknowledgments

Identifying Crystal Structure of Boron Nitride from DFT Obtained XAS Spectra Using Machine Learning

Reika Hasegawa[1], Arpita Varadwaj[1], Alexandre Lira Foggiatto[1], Masahito Niibe[2], Iwao Matsuda[2] and Masato Kotsugi[1];
[1]Tokyo University of Science, Japan; [2]The University of Tokyo, Japan

The recent advancement of IoT devices has driven the rapid growth of high-capacity, high-speed, and wide-area information communications. 2D materials have attracted enormous attention due to their potentials for use in low-cost, stable communication devices[1]. Among these materials, hexagonal boron nitride (h-BN) and crystalline boron nitride (BN) have attracted huge attention on its semiconducting nature. However, it is challenging to understand how structural changes influence physical properties. In particular, point defects and stacking have a significant influence on the electronic structure[2]. Furthermore, interpreting spectral data requires expert's domain knowledge, and manually analyzing large datasets is labor-intensive.

In this study, we demonstrate a structure-to-property linkage using machine learning approach. We performed first-principles calculations of electronic structures and X-ray absorption spectroscopy (XAS) spectra of hexagonal (h-BN), cubic (c-BN), and wurtzite (w-BN), which are different phases of BN crystal phases. We applied interpretable machine learning to connect the information between lattice structure, electronic structure and XAS spectra.

All computations were performed using PBE functional and the PAW exchange-correlation potential within the GGA by VASP. XAS spectra (B K-edge) were obtained by SCH[3] (super-cell core-hole) method implemented in VASP. We considered different phases of BN, such as h-BN ($P6_3/mmc$) both in monolayer and bulk form, c-BN ($F\text{-}43m$), and w-BN ($P6_3/mc$) with their single B and N vacancy analogues for our study. All structures were energy minimized, before obtaining their corresponding XAS spectra. Principal Component Analysis (PCA), Multidimensional Scaling (MDS), and Uniform Manifold Approximation and Projection (UMAP) machine learning models were applied to embed the XAS spectral data into lower dimensions.

The structural properties and XAS spectra of different phases of BN obtained using DFT are in reasonable agreement with experimental data[4-6]. By applying various dimension reduction methods, we confirmed that UMAP effectively arranged the spectral data points according to their crystal structure. This is because UMAP can capture the overall shape of the spectrum and slight peak shifts, not just the points with large dispersion. It is also confirmed that UMAP could identify differences in the atomic point defects and the number of layers. In the reverse analysis of the UMAP results, we were able to identify the π^* and σ^* peaks for h-BN, and σ^* peaks for c-BN and w-BN structures. Hence, the dimension reduction approach using UMAP can distinguish the XAS spectra of BN by nature of crystal structures.

"Easy Peel" 1T-$CrTe_2$—Studying the Chemistry Change from $KCrTe_2$ to 1T-$CrTe_2$ *Karishma K. Prasad and Jian Wang; Wichita State University, United States*

Among a few ferromagnetic materials that have ferromagnetic transition above room temperature, 1T-$CrTe_2$ has attracted growing interest due to the combination of ferromagnetic properties and two-dimensional (2D) crystal structure. 1T-$CrTe_2$ is cataloged as 2D ferromagnets. 2D ferromagnets became ideal platforms for studying magnetism in low-dimensional systems. The conventional way to prepare 1T-$CrTe_2$ would be an indirect synthesis method of extracting K from $KCrTe_2$. Due to the presence of residual K, 1T-$CrTe_2$ crystals are hard to exfoliate. In this work, we are curious about the chemistry change from pristine $KCrTe_2$ to 1T-$CrTe_2$ such as the oxidation state of Cr. We report the crystal structure and physical properties of $KCrTe_2$. The chemistry change such as the oxidation states of Cr from $KCrTe_2$ to $CrTe_2$ was studied via X-ray photoelectron spectroscopy (XPS). In addition, residual K was removed from 1T-$CrTe_2$ via a simple method. The 1T-$CrTe_2$ became "easy peel".

Language Model-Based Generative Model for Catalyst Discovery *Dong Hyeon Mok and Seoin Back; Sogang University, Korea (the Republic of)*

Recent advancements have shown that autoregressive language models can effectively generate inorganic crystal structures. Motivated by these advancements, we explored the potential of using a language model as a generative *model for inorganic catalyst structures that include surface and adsorbate atoms, as well as a discovery tool for novel and promising electrocatalysts. We trained a language model based on the GPT architecture with 2M catalyst structures sourced from OC database of Meta, enabling the generation of string representations of catalyst structures. Since the validity metrics used in crystal structure generative models are not fully applicable to catalysts, we developed new validity metrics specialized for catalyst structures. The trained model struggles to prevent the generation of invalid structures containing overlapping atoms, while validly generated structures have high-quality. We addressed this issue by introducing a simple method to bypass overlapping atoms, which effectively prevented structurally invalid generations without compromising generation quality. Furthermore, we fine-tuned the model with our own data for the discovery of two-electron oxygen reduction reaction (2e-ORR) catalysts. Despite the relatively small size of the dataset (about 1,500 data points), the fine-tuned model successfully learned the intrinsic rules of the dataset and maintained high-quality catalyst generation. From the fine-tuned model, we discovered five novel and promising 2e-ORR catalyst candidates. In conclusion, our work not only highlights the autoregressive language model's robust catalyst generative performance but also its practical application in electrocatalyst design.*

Large Language Models Design Sequence-Defined Macromolecules via Evolutionary Optimization *Wesley Reinhart[1] and Antonia Statt[2]; [1]The Pennsylvania State University, United States; [2]University of Illinois at Urbana-Champaign, United States*

Self-assembly of macromolecules is a critical phenomenon in both technology and biology, with sequence-defined molecules offering significant tunability. However, the vast number of possible sequences poses a challenge for evaluation. In previous work, we have explored the self-assembly of model copolymers using unsupervised representation learning and Recurrent Neural Networks (RNNs). While successful in solving the design problem through high-throughput screening, this approach requires a large corpus of training data to be effective.

Recent advancements in Large Language Models (LLMs) have shown promise in optimization tasks. Here, we demonstrate the ability of a LLM to perform evolutionary optimization for materials discovery. Anthropic's Claude 3 Opus model significantly outperforms both an active learning scheme with handcrafted surrogate models and an evolutionary algorithm in selecting monomer sequences to produce targeted morphologies in macromolecular self-assembly. The model can perform this task effectively with or without context about the task itself, but domain-specific context improves performance when there are no other hints about the solution. Furthermore, when this context is withheld, the model can infer an approximate notion of the task (e.g., calling it a protein folding problem). This work provides evidence of Claude 3's ability to act as an evolutionary optimizer, a recently discovered emergent behavior of LLMs, and demonstrates a practical use case in the study and design of soft materials.

11:00 AM MT04.01.03

Autonomous in Silico Materials Discovery with Large Language Models *Victor Fung, Shuyi Jia and Chao Zhang; Georgia Institute of Technology, United States*

Discovering new materials can have significant scientific and technological implications but remains a challenging problem today due to the enormity of the chemical space. Recent advances in machine learning have enabled data-driven methods to rapidly screen or generate promising materials, but these methods still depend heavily on very large quantities of training data and often lack the flexibility and chemical understanding often desired in materials discovery. We introduce LLMatDesign, a novel language-based framework for interpretable materials *design powered by large language models (LLMs). LLMatDesign utilizes LLM agents to translate human instructions, apply modifications to materials, and evaluate outcomes using provided tools. By incorporating self-reflection on its previous decisions, LLMatDesign adapts rapidly to new tasks and conditions in a zero-shot manner. A systematic evaluation of LLMatDesign on several materials design tasks, in silico, validates LLMatDesign's effectiveness in developing new materials with user-defined target properties in the small data regime. Our framework demonstrates the remarkable potential of autonomous LLM-guided materials discovery in the computational setting and towards self-driving laboratories in the future.*

11:15 AM MT04.01.04

LLaMP—Large Language Model Made Powerful for High-Fidelity Materials Knowledge Retrieval and Distillation *Yuan Chiang[1,2], Elvis Hsieh[1], Chia-Hong Chou[3] and Janosh Riebesell[4,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Foothill College, United States; [4]University of Cambridge, United Kingdom*

Reducing hallucinations in Large Language Models (LLMs) is imperative for use in the sciences, where reliability and reproducibility are crucial. However, LLMs inherently lack long-term memory, making it a nontrivial, ad hoc, and inevitably biased task to fine-tune them on domain-specific literature and data. Here, we introduce LLaMP, a multimodal retrieval-augmented generation (RAG) framework of hierarchical reasoning-and-acting (ReAct) agents that can dynamically and recursively interact with computational and experimental data on Materials Project (MP) and run atomistic simulations via a high-throughput workflow interface. Without fine-tuning, LLaMP demonstrates a strong ability to use tools to comprehend and integrate various modalities of materials science concepts, fetch relevant data stores on the fly, process higher-order data (such as crystal structure and elastic tensor), and streamline complex tasks in computational materials and chemistry. We propose a simple metric combining uncertainty and confidence estimates to evaluate the self-consistency of responses by LLaMP and vanilla LLMs. Our benchmark shows that LLaMP effectively mitigates the intrinsic bias in LLMs, counteracting the errors in bulk moduli, electronic bandgaps, and formation energies that seem to derive from mixed data sources. We also demonstrate LLaMP's capability to edit crystal structures and run annealing molecular dynamics simulations using pre-trained machine-learning force fields. The framework offers an intuitive and nearly hallucination-free approach to exploring and scaling materials informatics and establishes a pathway for knowledge distillation and fine-tuning other language models.

11:30 AM MT04.01.05

ForceGen—End-to-End De Novo Protein Generation Based on Nonlinear Mechanical Unfolding Responses Using a Language Diffusion Model *Bo Ni[1,2], David L. Kaplan[3] and Markus J. Buehler[2]; [1]Carnegie Mellon University, United States; [2]Massachusetts Institute of Technology, United States; [3]Tufts University, United States*

Through evolution, nature has presented a set of remarkable protein materials, including elastins, silks, keratins and collagens with superior mechanical performances that play crucial roles in mechanobiology. However, going beyond natural designs to discover proteins that meet specified mechanical properties remains challenging. Here we report a generative model that predicts protein designs to meet complex nonlinear mechanical property-design objectives. Our model leverages deep knowledge on protein sequences from a pre-trained protein language model and maps mechanical unfolding responses to create proteins. Via full-atom molecular simulations for direct validation, we demonstrate that the designed proteins are de novo, and fulfill the targeted mechanical properties, including unfolding energy and mechanical strength, as well as the detailed unfolding force-separation curves. Our model offers rapid pathways to explore the enormous mechanobiological protein sequence space unconstrained by biological synthesis, using mechanical features as target to enable the discovery of protein materials with superior mechanical properties.

11:45 AM MT04.01.06

Text-Mined Dataset of Solid-State Syntheses with Impurity Phases Using LLM *Sanghoon Lee[1,2], Kevin Cruse[1,2], Viktoriia Baibakova[1,2], Gerbrand Ceder[1,2] and Anubhav Jain[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States*

Solid-state synthesis is widely used to obtain various inorganic materials, such as battery materials and thermoelectrics. Despite its prevalence, the process remains a "black box" due to the lack of a general theory and well-understood underlying reaction mechanisms[1,2], thereby posing inherent challenges to controlling the outcome.

Recent advances in machine learning have motivated data-driven approaches in materials synthesis and control, which require comprehensive synthesis datasets. While prior works have successfully extracted structured datasets from literature, they often neglect or overlook product phase purity or yield[3]. Traditionally, the formation of impurity phases has been viewed as undesirable or indicative of failed synthesis[4]. This can lead to two issues: a lack of negative data points if phase-impure syntheses are filtered out, and inaccurate results if phase-impure syntheses are incorrectly classified as phase-pure.

In this work, we construct a structured solid-state synthesis dataset that includes impurity phases via information extraction with LLM. We investigate the formation of these impurity phases and their interpretability using Materials Project phase diagrams. Our findings provide valuable insights into the conditions leading to impurity phase formation, contributing to a more comprehensive understanding of solid-state synthesis processes and paving the way for improved synthesis control.

Rapid Exploration of Crystal Chemical Space *Aron Walsh; Imperial College London, United Kingdom*

Traditional materials modelling workflows, even in the form of high-throughput approaches, are limited to small numbers of compositions and structures. I will present progress in materials informatics solutions for navigating a *larger crystal chemical space. This includes techniques for compositional screening based on elemental features and mapping from chemical formulae to three-dimensional crystal structures [1,2]. A focus will be placed on hand-built chemical filters to reduce the magnitude of the search space and filters that are learned from data in the form of deep learning models based on crystal graphs. The performance of data-driven and domain knowledge-inspired approaches will be compared. Outstanding challenges in the field including robust synthesisability metrics [4] and generative artificial intelligence models for sampling new materials will also be discussed.*

Accelerating Thermodynamic Simulations of Electrochemical Interfaces at the Atomic Scale *Xiaochen Du, Jiayu Peng and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States*

Surfaces and interfaces play a critical role in diverse applications, including catalysis, energy storage, and electronics. Traditional thermodynamic studies of material surfaces relied on a limited set of guess structures validated by costly first-principles calculations. This approach is insufficient for exploring the vast compositional and configurational spaces required by complex materials in use today. Recent advancements, such as the Virtual Surface Site Relaxation-Monte Carlo (VSSR-MC) algorithm developed in our group [1], leverage machine learning force fields (MLFF) and various sampling strategies to accelerate surface reconstruction studies under vacuum and gas conditions. In this work, we extend the VSSR-MC algorithm to investigate aqueous electrochemical interfaces by developing a framework to describe thermodynamic equilibria under the Pourbaix grand potential. We demonstrate that a fine-tuned foundational MLFF can reveal surface reconstructions of perovskite materials relevant to electrocatalysis. Finally, we construct surface Pourbaix diagrams that enhance our understanding of electrochemical interfaces compared to previous studies.

High-Throughput Machine-Learned Force-Fields Employing Workflow for Heterocatalyst Screening *Ondrej Krejci[1], Prajwal D. Pisal[1] and Patrick Rinke[1,2]; [1]Aalto University, Finland; [2]Technical University of Munich, Germany*

Heterogeneous catalysis consumes significant energy resources and would thus benefit from the discovery of new catalytically active materials that would lower the energy consumption and therefore reduce the cost of the produced chemicals. The adsorption energies (AEs) of reactants and intermediates of a given chemical reaction are a good descriptor for a catalyst's activity [1] and could be used for as proxies for catalyst discovery. Modern *computing infrastructure and density functional theory (DFT) facilitate the calculation of AEs for many materials with satisfying speed and accuracy. Still, DFT calculations are too expensive for high-throughput scans of thousands of materials when multiple binding sites and different materials facets should be considered for a more sophisticated description of materials activity. Machine learned force-fields (MLFFs) providing offer a solution to this accuracy-efficiency dilemma, since they provide close to DFT accuracy for a fraction of the computational cost.*

*In this work, we will present our current workflow for obtaining the relevant AEs for CO_2 thermoreduction to methanol. For a list of candidate metals and their alloys, we start with bulk geometries from the Materials Project database [2] with the python API. We then use a trained MLFF from the Open Catalyst Project [3] to calculate the surface stability for all facets with Miller indices {-2, -1, 0, 1, 2}. We pick the most stable cuts for each facet. Subsequently, we identify all possible high symmetry binding sites on those facets and predict AEs for the reaction key intermediates: *H, *OH, *OCHO and $*OCH_3$ [4]. To validate the MLFF, we compare the AEs for more than 100 materials to results from selected single-point DFT calculations, to estimate the mean absolute error for each material and adsorbate. The last step is important for checking the accuracy of used MLFFs. We find that for more than 80% of materials, the MLFF is accurate to within 0.25 eV for the AEs. Materials with distinctly worser accuracy (above 0.5 eV), e.g. MnCo, MnGa, FeCo, In_3Ru, are flagged and removed from our discovery pipeline. We believe that our workflow can easily be used to speed-up the search for new catalysts, when good accuracy, complexity of materials structure and its surfaces is crucial for a good activity estimation.*

A FAIR Approach to Constructing a Computational Perovskite Database

Rushik Desai, Alejandro Strachan and Arun Kumar Mannodi-Kanakkithodi; Purdue University, United States

In the last decade, ABX3 perovskites have revolutionized the fields of photovoltaics and photocatalysis due to their exceptional electronic, optical, and defect properties. Halide perovskites have shown immense potential in applications such as LEDs, lasers, and sensors for both UV and IR spectra. Given the massive compositional space spanned by ABX3 perovskites in terms of cation/anion choices and alloying, high-throughput density functional theory (DFT) computations have become a pivotal tool for exploring the perovskite chemical space, helping generate extensive property datasets that feed into advanced machine learning (ML) models for predictive analysis [1-3]. Despite the wealth of studies and data, there remains a significant gap in how these datasets are stored, shared, and utilized in perpetuity for research and education. Ensuring data is Findable, Accessible, Interoperable, and Reusable (FAIR) [4] is critical for advancing research and facilitating collaboration within the scientific community.

Our work introduces a comprehensive workflow that addresses this challenge by utilizing nanoHUB's Sim2Ls framework [5,6] to systematically parse DFT calculations for perovskites and store them in a universally indexed database. This database is designed to be easily queried via a Python-based API, simplifying data access and manipulation for researchers. Moreover, by integrating compositional and crystal graph-based machine learning models, our workflow enables rapid and accurate predictions of fundamental material properties. This capability accelerates the discovery and development of new materials and guides exploration into uncharted chemical spaces. Our comprehensive online tool walks users through visualization and understanding of the ever-growing *dataset and enables on-demand prediction and design of novel perovskites with multiple desired properties. The approach presented here is a significant step in organizing high-throughput computational data. By ensuring that this data is systematically stored and readily available, we promote a more collaborative research environment and support ongoing advancements in studying perovskite materials.*

***Using Experimental Data in Computationally-Guided Rational Design with Machine Learning** Heather J. Kulik; Massachusetts Institute of Technology, United States*

I will discuss our efforts to use machine learning (ML) to accelerate the computational tailoring and design of complex materials by leveraging experimental datasets. The breadth of transition metal chemical space covered by databases such as the Cambridge Structural Database is not conducive to application-specific modeling and the development of structure–property relationships. I will discuss how we have employed both supervised and unsupervised natural language processing (NLP) techniques to link experimentally synthesized compounds in the CSD to their respective applications - for catalysis, photophysical activity, biological relevance, and magnetism. I will describe how we have analyzed the chemical substructures within each dataset to reveal common chemical motifs in each of the designated applications. Next, I will describe how we have used large subsets of materials from the CSD to train machine learning models, leading to the design mechanically active components polymers from the ground up that lead to novel network scale toughness. I will describe how we have leveraged the large amount of experimental data available for metal-organic framework (MOF) materials. I will describe how we have trained machine learning models to predict their stability in terms of heat, activation, water, and in acidic/basic mixtures. I will show how we use these models in combination with computed properties for the multi-objective optimization of MOFs with unprecedented properties. Finally, I will conclude with a perspective on some of the challenges of working with and extracting experimental data for machine learning accelerated materials discovery.

New Opportunities Through an Efficient Combination of Machine Learning and High-Throughput Computing
Janine George[1,2]; [1]Bundesanstalt für Materialforschung und –prüfung, Germany; [2]Friedrich-Schiller-Universität Jena, Germany

The underlying data is crucial for machine learning (ML) tasks.[1] Ab initio data is often used as a target *(occasionally as features[2]). High-throughput calculations and automation make it possible to generate such data as efficiently as possible and with uniform standards.[3,4] The high-throughput data of the Materials Project has recently been used to train new foundation interatomic potentials[5].*

The presentation aims to show further possibilities and challenges that arise when combining high-throughput computation and machine learning. The focus will be on training ML interatomic potentials sufficient to predict harmonic phononic properties of materials. Typical foundation models in this area now achieve acceptable results but are still far from routinely replacing DFT.[5,6] Building on the promising results from the ref [7], we will present new fully automated workflows for training and benchmarking ML interatomic potentials with force predictions that are accurate enough to compute harmonic phonons in very good agreement with DFT for different structures of the same composition. This is a first step towards foundation models accurate enough for phononic properties as well.

In particular, the arrival of foundation models in the field of machine learning also makes it possible to think much further about the combination of automated ab initio computations and machine learning. Workflows now also need to be designed for fine-tuning tasks. The latter has the potential to significantly accelerate the combination of ML and high throughput for use in material design or material searches.

Pyiron—Simulation Workflows for the Design of Sustainable Materials *Jan Janssen and Joerg Neugebauer; Max Planck Institute for Sustainable Materials, Germany*

One aspect of designing sustainable materials is to reduce the reliance on rare earth elements. A critical step in achieving this is to have efficient and accurate tools to screen the entire periodic table for potential candidates. We have therefore developed automated simulation workflows that predict thermodynamic properties with ab-initio accuracy and allow quantitative comparison with experiments. These workflows combine a wide range of *different tools and utilities, with a recent focus on machine-learned interatomic potentials. This typically starts with the generation of atomistic structures, continues with the evaluation of these structures with an ab-initio reference method such as Density Functional Theory (DFT), the fitting of the interatomic potential and finally the validation of the resulting potential.*

To maintain the provenance of the individual steps in these workflows and guarantee the reproducibility of the development process of interatomic potentials, we developed pyiron an integrated development environment (IDE)[1, 2] for the development and assessment of interatomic potentials. Rather than implementing its own DFT simulation code or interatomic potential fitting code, the pyiron IDE combines existing codes developed in the community and provides one unified high-level interface to access these codes in an generic way. To highlight the features of pyiron, we present a specific workflow that combines the VASP DFT simulation code, the FitSNAP interatomic potential fitting code, and the LAMMPS molecular dynamics to develop and validate an interatomic potential.

4:30 PM MT04.02.09
Trillion-Atom Exascale Performance Portability of FLARE for Catalysis *Anders Johansson[1,2] and Boris Kozinsky[1]; [1]Harvard University, United States; [2]Sandia National Laboratories, United States*

Machine learning interatomic potentials (MLIPs) have become a prevalent approach to bridging the gap between slow-but-accurate ab initio calculations and fast-but-inaccurate empirical potentials for molecular dynamics. Among MLIPs, there is a Pareto front of models with different tradeoffs between accuracy and speed. The FLARE interatomic potential has previously pushed the boundary of scalability and performance on NVIDIA GPUs, reaching 500 billion atoms at record speed on 27336 GPUs [1], while maintaining sufficient accuracy to study complex, reactive systems.

In this work, we demonstrate recent performance results with FLARE and its Kokkos implementation in LAMMPS on OLCF Frontier, the current fastest supercomputer in the world [2]. Using the tens of thousands of AMD MI250X GPUs available on Frontier, we breach the trillion-atom barrier for molecular dynamics simulations on GPUs and achieve performance parity with NVIDIA A100 GPUs with no AMD-specific changes to the code. We also discuss recent optimizations of FLARE that more than double its performance across different platforms, as well as its new functionality for performing Bayesian active learning directly in LAMMPS. Finally, we highlight how the extreme performance of FLARE enables a detailed study of heterogeneous catalytic processes through large-scale simulations.

SESSION MT04.03: Algorithms and Methodologies for Autonomous Materials Development Systems
Session Chairs: Jian Lin and Dmitry Zubarev
Tuesday Morning, December 3, 2024
Hynes, Level 2, Room 210

8:00 AM *MT04.03.01
Design of Functional and Sustainable Polymers Assisted by Artificial Intelligence *Rampi Ramprasad and Akhlak Mahmood; Georgia Institute of Technology, United States*

Artificial intelligence (AI)-based methods continue to make inroads into accelerated materials design and development. Here, I will review AI-enabled advances made in the subfield of polymer informatics, with a particular focus on the design of application-specific practical polymeric materials. I will describe exemplar design attempts within a few critical and emerging application spaces, including materials designs for storing, producing, and conserving energy, and those that can prepare us for a sustainable economy powered by recyclable and/or biodegradable polymers. AI-powered workflows help efficiently search the staggeringly large chemical and configurational space of materials, using modern machine-learning (ML) algorithms to solve "forward" and "inverse" materials design problems. A theme explored throughout will be a practical informatics-based design protocol that involves creating a set of application-specific target property criteria, building ML model predictors for those relevant target properties, enumerating or generating a tangible population of viable polymers, and selecting candidates that meet design recommendations. The protocol will be demonstrated for several energy and sustainability-related applications. Finally, I will offer an outlook on the lingering obstacles that must be overcome to achieve widespread adoption of informatics-driven protocols in industrial-scale materials development.

8:30 AM MT04.03.02
Navigating the Microscopic World—Synergy of Human Expertise, ML Efficiency and API Enabled Automation *Yongtao Liu[1], Rama K. Vasudevan[1], Sergei V. Kalinin[2] and Maxim Ziatdinov[3]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States; [3]Pacific Northwest National Laboratory, United States*

Microscopy has become a standard tool in characterization laboratories and greatly enhanced our understanding of nanoscale structure-function relationships. However, traditional microscopy operations often rely on manual, human-centric approaches. To overcome these limitations, we present the integration of application program interface (API) with machine learning. We developed AEcroscoPy, a cross-platform Python API designed to automate microscopy experiments. The integration of API-driven automation, human expertise, and machine learning (ML) efficiency showcases the power for accelerating scientific discovery. Our development of ML driven automated and autonomous experiment (AE) in scanning probe microscopy (SPM) facilitates the exploration of material functionalities and mechanisms. Using AE-SPM, we discovered coexistence and interplay of two ferroelectric subsystems in wurtzite ferroelectric thin films. By employing ML-driven approaches, we have investigated phenomena such as domain wall dynamics and switching mechanisms in ferroelectric materials, as well as the interactions between domain structures and local properties. By incorporating physical hypotheses in active learning model, our approach has enabled the microscope to autonomously discover the physical laws influencing domain switching. This approach not only enriches our understanding of material properties at the nanoscale but also opens new avenues for the application of ML in experimentation. Although these methodologies were applied to specific materials, they possess broad potential to revolutionize various characterization techniques.

8:45 AM MT04.03.03
An Extreme-Scale Computational Multiscale Paradigm Towards Autonomous Synthesis of Thin-Film 2D Materials *Soumendu Bagchi, Ankita Biswas, Ayana Ghosh, Ryan Morelock, Matthew G. Boebinger and*

Panchapakesan Ganesh; Oak Ridge National Laboratory, United States

Traditional approaches to bridge atomistic dynamics with experimental observations at the microstructural level often rely on phenomenological models of the underlying physics, whose free parameters are in turn fitted to a small number of intuition-driven atomic scale simulations under limited number of thermodynamical drivers (e.g., temperature, pressure, chemical potential etc). This tedious and time-consuming approach becomes particularly cumbersome to study synthesis of materials with complex dependencies on local environment, temperature and lattice-strains e.g., heterostructure interfaces of nanomaterials. In this talk, I will present workflows that couple automated exascale high-throughput large-scale molecular dynamics simulations with a wide range of uncertainty quantification-driven active learning paradigms for on-the-fly learning of material synthesis. By implementing such a workflow to study recrystallization of amorphous transition-metal dichalcogenide (TMDC) phases under various growth parameters, I will show that such automated scale-bridging frameworks can be promising towards achieving controlled epitaxy of targeted multilayer moiré devices paving the way towards a robust autonoumous discovery pipeline to enable unprecedented functionalities.

9:00 AM MT04.03.04

Accelerating Materials Recipe Acquisition via LLM-Mediated Reinforcement Learning *Andrew J. Lew; Independent, United States*

Artificial intelligence tools have empowered advancements in materials research, from accelerating the forward prediction of properties to enabling inverse design of materials with desired properties. The impacts of such prediction methods are broad, for example predicting beam buckling under compression has been demonstrated on both simple homogeneous plastics and more esoteric biopolymer composites - such as bread. Successes in generating material structures possessing desired mechanical properties has also been previously demonstrated with machine learning workflows, for instance hierarchical lattices with specified stiffness or graphene sheets with bespoke fracture paths. However, the broader question of defining the "recipe" to acquire a desired material remains. While the "recipe" for certain material structures may be trivial, for example a macroscopic lattice design can simply be 3D printed, others such as bespoke graphene sheets are considerably more difficult to synthesize. Materials generated as a result of chemical reactions require a precise set of instructions with numerous differing parameters including reactant ratios, mixing procedures, temperatures, and reaction times. Here, we employ recent advances in large language models to organize how differences in materials synthesis "recipes" manifest as differences in property. Then, we use a reinforcement learning approach to learn how to rapidly navigate the space of potential recipes relevant for obtaining a desired resultant property. In doing so, we aim to accelerate the scientific workflow for materials discovery not only in the theoretical identification of a material but also in the practical implementation of how to acquire it. Specifically, we will demonstrate the approach for a class of materials recipes that the public is well acquainted with, yet still has direct parallels to a laboratory setting - recipes for baked goods.

9:15 AM MT04.03.05

Representation Learning of Porous Materials for Zeolite Synthesis *Mingrou Xie[1], Nga Vu[2] and Rafael Gomez-Bombarelli[1]; [1]Massachusetts Institute of Technology, United States; [2]Bucknell University, United States*

Representation of periodic, porous materials for machine learning remains a challenge due to specificity of prediction tasks and open questions about the type and use of information embedded in the representation. Having a good representation produces better predictions, insight into the underlying application, and better generalizability to new chemical space, but it is not always possible a priori to determine the appropriate representation. Zeolites are a class of such nanoporous materials used heavily in the chemicals industry for *catalysis and separations. They are synthesized using molecules (termed organic structure directing agents or OSDAs), which stabilize the crystallization of the zeolite from solution during hydrothermal synthesis.*

Previous work has looked at how high throughput docking and computation combined with machine learning can aid screening of a large library of molecules to find suitable OSDAs for targeted zeolites, but the models fail to extend to unseen zeolites. In this work, we investigate the use of Voronoi nodes to characterize the void space within zeolites. We utilize message passing on both the crystal atoms and Voronoi nodes to learn zeolite embeddings, and showcase the models' ability to generalize to unseen zeolites. We also show preliminary work on active learning for intelligently acquiring new samples to update our models in the vast, unseen chemical space of hypothetical zeolite - hypothetical OSDA pairs. These tools hold promise for unlocking otherwise inaccessible synthesis routes to a large pool of hypothetical zeolites and therefore novel chemistry.

9:30 AM BREAK

10:00 AM *MT04.03.06
Automus—AI-Powered Platform for the Chemical Industry *Semion Saikin; Kebotix, Inc, United States*

The chemical industry, fundamental to material production, significantly influences our lives at many levels. The global chemical industry is worth over $4 trillion, and the US sector represents around $800 billion, approximately 25% of GDP. The industry primarily focuses on optimizing the cost and performance of chemical production, but this often leads to detrimental environmental consequences and risky production methods. The push towards introducing sustainable chemicals in the market faces hurdles, including high discovery costs, the requirement for new production facilities, and challenges in market adoption.

Automus helps to address these challenges by providing data acquisition, properties and reactions prediction, process optimization, and lab operation control capabilities. This allows us to efficiently discover, prototype, and test new chemicals while optimizing technical performance and price competitiveness. We develop a holistic approach to designing organic molecules, where human experts cooperate with an AI-controlled platform in generating new hypotheses, testing them, and making decisions about the next iterations. The platform is modular, combining multiple tools, and can be integrated with external lab and computational capabilities. This platform has been used to invent over 200 distinct compounds for dozens of industrial clients. I will illustrate our developments using examples of process optimization and finding lead candidates, and also discuss some challenges with the adoption of AI tools.

10:30 AM *MT04.03.07
Accelerating Process Development for Semiconductor Device Fabrication *Richard A. Gottscho, Keren J. Kanarik, Wojciech T. Osowiecki, Yu Lu, Talukder Dipongkar, Niklas Roschewsky, Sae Na Park, Mattan Kamon and David M. Fried; LAM Research Corporation, United States*

Although chips have been designed by computers for decades, the processes used to manufacture those chips have eluded design based on physics or data. Virtually all processes used to manufacture chips have been developed, not designed, by trial and error – a costly endeavor using highly trained and experienced process engineers searching for a combination of tool parameters that produce an acceptable result on the device. Because the solution space dimensionality is so large ($\sim 10^{20}$) and because process development is time-consuming and costly, machine learning approaches have been hampered by too little data. Physics based approaches suffer from large numbers of unknown parameters and complex equations that require excessive computational time to solve.

This talk will review results from a study, which showed a "human first, computer last" approach could reach process engineering targets dramatically faster and at substantially lower cost compared to today's empirical approach. A virtual plasma etching environment was created to enable comparison of humans to machines and algorithms to algorithms. The use of synthetic data from a virtual environment, even though it is not precisely predictive, provided a path to leverage the strengths of human experts and their domain knowledge as well as the strengths of machine learning to deal with "little data" and accelerate the pace of innovation in semiconductor process engineering [Kanarik, et al. Nature 616, 707–711 (2023)]. The virtual environment enabled determination of not only the best methodology and algorithm, but also a value assessment of experience relative to education. It also provides a means to quantitatively assess the effectiveness of work force development efforts in semiconductor process engineering.

11:00 AM MT04.03.08
Inverse Design of Organic Mixtures Using First-Principles Calculations Mediated Bayesian Optimization *Eun Ho Kim, Jun Hyeong Gu, Kyung-Yeon Doh and Donghwa Lee; Pohang University of Science and Technology, Korea (the Republic of)*

Various properties of organic mixtures used for electronic materials in smart device, memory module and IC packaging generally come from their constituents. There are several factors that affect the target properties of organic mixtures, among which the molecular combinations and their compositions are the most important. Traditionally, to find the optimal input for desired properties, a trial-and-error experiment method has been used, but it is costly because many samples need to be prepared and tested. Machine learning based optimizations can be employed to optimize compositions, but they are limited to handling fewer than 20 variables. In this study, we optimize molecular combinations and compositions of over 750 organic materials through first-principles calculations mediated Bayesian optimization. Because optimization directly from targets to vast number of compositions are difficult, we first encoded composition space of experimental dataset to physical property space using first-principles calculations. Then, these encoded data are used as inputs for optimize from targets with Bayesian optimization. We obtain optimal molecular combinations and their compositions from optimized physical property. Through this approach, we achieve average optimized errors (%) of less than 3%. This study holds considerable significance for effectively optimizing combinations of a wide range of organic materials to achieve desired products.

11:15 AM MT04.03.09
Accelerated Optimization and Manufacturing of Lead-Free Perovskite Nanocrystals with a Self-Driving Fluidic Lab *Sina Sadeghi and Milad Abolhasani; North Carolina State University, United States*

Metal halide perovskite (MHP) nanocrystals (NCs) are cutting-edge colloidal materials widely used in photonic and energy devices due to their superior characteristics, such as high photoluminescence quantum yield (PLQY) and adjustable optical properties. Their integration into printed technologies, however, is profoundly restricted by the lead toxicity and their instability against light, moisture, and heat.[1] Recently, cesium copper halide perovskite NCs have been of great interest as a promising lead-free analogue, offering intriguing composition-tunable emissions.[1–3] A specific class of copper-based MHP NCs is cesium copper iodide ($Cs_3Cu_2I_5$) with an orthorhombic crystal structure that exhibits a high stability in ambient environment.[1] In addition, incorporating various metal halide additives into the halide source precursor has been shown to enhance the $Cs_3Cu_2I_5$ NCs PLQY.[4–6] Despite the successful synthesis of cation-doped $Cs_3Cu_2I_5$ NCs, significant challenges remain for their fundamental studies due to the batch-to-batch variations caused by these NCs fast formation kinetics. Herein, a machine learning (ML)-guided microfluidic platform was developed to enable autonomous manufacturing of metal cation-doped $Cs_3Cu_2I_5$

NCs in flow, achieving enhanced optoelectronic properties. Utilizing the developed self-driving fluidic lab (SDFL), we first autonomously studied the effect of various experimental parameters (e.g., dopant/copper ratio, precursors injection ratio, reaction time, and temperature) on the optical properties of the in-flow synthesized doped $Cs_3Cu_2I_5$ *NCs. We then employed the closed-loop autonomous experimentation platform to accelerate mapping the parameter space and optimize the synthetic route to achieve the highest-performing cation-doped* $Cs_3Cu_2I_5$ *NCs at minimal experimental cost.*

Hynes, Level 2, Room 210

1:30 PM *MT04.04.01

Explainable AI Enables Molecular Design *Jonas Teufel[1], Rebecca Davis[2] and Pascal Friederich[1]; [1]Karlsruhe Institute of Technology, Germany; [2]University of Manitoba, Canada*

Most current explainable AI methods are post-hoc methods that analyze trained models and only generate importance annotations, which often leads to an accuracy-explainability tradeoff and limits interpretability. Here, we propose a self-explaining multi-explanation graph attention network (MEGAN) [1]. Unlike existing graph explainability methods, our network can produce node and edge attributional explanations along multiple channels, the number of which is independent of task specifications. This proves crucial to improve the interpretability of graph regression predictions, as explanations are intrinsically connected to their effect on the predictions. This makes MEGAN a successful attempt to escape the accuracy-explainability dilemma of post-hoc explanation models.

We first validate our model on a synthetic graph regression dataset with known ground-truth explanations. Our network outperforms existing baseline explainability methods such as GNNExplainer [2] for the single- as well as the multi-explanation case, achieving near-perfect explanation accuracy during explanation supervision. We demonstrate our model's capabilities on multiple real-world datasets, e.g. molecular solubility prediction. We find that our model produces sparse high-fidelity explanations consistent with human intuition about those tasks. Finally, we demonstrate in a real-world task in the area of molecular discovery that the MEGAN model can be combined with counterfactual approaches for predictive in-silico molecular design, which we validated experimentally [3]. To our knowledge, this is the first example of rational molecular design with explainable machine learning models. We currently extend our model toward explaining 3D crystalline materials.

2:00 PM MT04.04.02
A Physics-Aware Materials Discovery Platform for Stable High Entropy Alloys *Miguel Tenorio and James Chapman; Boston University, United States*

High entropy alloys (HEA) have become a topic of significant interest due to their combinatorial nature and their potentially superior properties in application spaces such as catalysts and high temperature aerospace and manufacturing. However, materials discovery pipelines for HEA still lag behind other materials classes such as polymers and molecules. To address this, we take the approach of combining both discovery and design into a single process, where our discovery pipeline also learns the underlying physics behind structure-property mappings. This combination creates an informative feedback loop where new materials can be down-selected from the search space based on physis-awareness and not purely statistical similarity. We showcase this pipeline for the HEA system $Co_xMo_{70-x}Fe_{10}Ni_{10}Cu_{10}$*, which has been studied extensively due to its reported superiority as a catalyst for ammonia decomposition. We show that by combining density functional theory (DFT) with physics-aware graph neural networks (GNN), we can learn properties such as mixing free energy, providing a basis for solid solution stability of the HEA. We also show that by learning the mixing free energy with our GNN framework we can autonomously rank geometric and chemical HEA descriptors based on their importance towards the mixing free energy, a natural output of our GNN architecture. This framework provides a set of design rules and property predictions, creating an informative search criterion for new HEA systems.*

Interpretability of Machine Learning for Predicting Band Gap Energies from Chemical Compositions *Taichi Masuda and Katsuaki Tanabe; Kyoto University, Japan*

The band gap is a thesaurus parameter directly associated with the usefulness of materials in optical, electronic, and energy applications. However, for many years, accurately calculating band gaps through theoretical computations at a reduced computational cost has been a significant challenge. To address this issue in theoretical band gap calculations, research has been conducted on predicting band gaps using data-driven machine learning approaches, leveraging the theoretical calculation datasets and experimental datasets. However, there is a trade-off between model prediction accuracy and interpretability. Complex models, often referred to as black-box models, possess high predictive accuracy but are difficult to interpret. This study analyzed *machine learning models for predicting band gaps from chemical compositions using explainable artificial intelligence techniques. Specifically, we employed explainable artificial intelligence methods such as the permutation feature importance (PFI), partial dependence plot (PDP), individual conditional expectation plot, accumulated local effects plot, and shapley additive explanations. Using these methods, we analyzed the support vector regression (SVR), gradient boosting regression, and random forest regression models for reproducing band gaps measured experimentally and calculated using the density functional theory (DFT). These methods elucidated the relationship between the band gaps and the characteristics of the constituent elements of compounds used as features. Our findings indicate that, according to PFI, the average metallic valence and average mass density of the elements within compounds are particularly important features for the band gap prediction models. PFI also demonstrated its capability in identifying the important features that significantly influence the predictive performance of the models. Furthermore, PDP enabled the visualization of the dependency between the band gaps and the characteristics of the constituent elements. Specifically, we elucidated the dependency that an increase in the average mass density of the elements within compounds leads to a decrease in the band gap. These results could be theoretically interpreted from the perspective of the electronic structure of materials. Additionally, among the three models, SVR's PDP was found to be most suitable for capturing the relationship between the characteristics of the constituent elements and the band gap. By comparing PDP of the experimental band gaps with those of DFT band gaps, we identified the issues related to DFT calculations of band gaps. These findings provide important guidelines for selecting promising descriptors in the development of highly accurate and interpretable models for predicting band gaps, thereby facilitating the development of novel semiconductor materials. Furthermore, they demonstrate the utility of explainable artificial intelligence for discovering new scientific insights that are crucial for semiconductor material research.*

Multimodal Machine Learning for Materials Science—Composition-Structure Bimodal Learning for Experimentally Measured Properties *Sheng Gong; Massachusetts Institute of Technology, United States*

The widespread application of multimodal machine learning models like GPT-4 has revolutionized various research fields including computer vision and natural language processing. However, its implementation in materials informatics remains underexplored, despite the presence of materials data across diverse modalities, such as composition and structure. The effectiveness of machine learning models trained on large calculated datasets depends on the accuracy of calculations, while experimental datasets often have limited data availability and incomplete information. This paper introduces a novel approach to multimodal machine learning in materials science via composition-structure bimodal learning. The proposed COmposition-Structure Bimodal Network (COSNet) is designed to enhance learning and predictions of experimentally measured materials properties that have incomplete structure information. Bimodal learning significantly reduces prediction errors across distinct materials properties including Li conductivity in solid electrolyte, band gap, refractive index, dielectric constant, energy, and magnetic moment, surpassing composition-only learning methods. Furthermore, we identified that data augmentation based on modal availability plays a pivotal role in the success of bimodal learning.

Harnessing Physics-Inspired Machine Learning to Design Nanocluster Catalysts for Dehydrogenating Liquid Organic Hydrogen Carriers *Tej Choksi, Chuhong Lin, Bryan C. Lee, Uzma Anjum, Asmee Prabhu and Rong Xu; Nanyang Technological University, Singapore*

Using liquid organic hydrogen carriers for the trans-oceanic shipment of hydrogen requires selective and low-cost dehydrogenation catalysts. Pt-based bimetallic nanoparticles have emerged as a promising class of materials that catalyse these reactions. Yet, these catalysts are limited by their high cost and poor selectivity. Machine learning *methods can accelerate the discovery of catalysts meeting cost and selectivity benchmarks. The state-of-the-art machine learning methods however cannot perform this task because of challenges associated with building predictive models for large cyclic intermediates containing 20+ atoms that adsorb and react on low-symmetry active sites of bimetallic nanoparticles. Using deep learning methods is unfeasible because of the computational cost of building training datasets for such complex molecules. Hence, specific kinds of machine learning methods that are tailored for small datasets are required. Moreover, incorporating physics-based features is also essential to improve the transferability of such models to catalyst compositions outside the training set.*

Focusing on methyl cyclohexane dehydrogenation to toluene, an industrially relevant hydrogen carrier, we introduce a machine learning approach to accelerate the design of selective and cost-effective catalysts. Using inputs to a gaussian process regression model that are inspired by physical theories, we predict the adsorption energies of large hydrocarbon intermediates and transition states that are encountered during methyl cyclohexane dehydrogenation. An active learning process is employed to minimize the size of the training set. This active learning process leverages the inherent uncertainty quantification capabilities of gaussian process regression. Across active sites of bimetallic nanoclusters having varied shapes and compositions, our model yields mean absolute errors of 0.11 – 0.25 eV for adsorption and reaction energies on test sets. Moreover, fewer than 50 datapoints per reaction intermediate are required. This performance for large hydrocarbon intermediates is superior to more data heavy deep-learning models that are built to predict the catalytic properties of less complex systems. This model is integrated with a novel lumped microkinetic model to determine the rate and selectivity of catalysts towards methyl cyclohexane dehydrogenation. The microkinetic model reveals that modifying Pt nanoclusters with IB, IIB, and post-transition elements increases dehydrogenation rates, reduces unselective reactions, and lowers Pt utilization, and in turn, the catalyst cost. These observations are consistent with experimental reports from the literature. The scalable and efficient active learning approach introduced in this work marks a significant advancement in designing catalysts for reactions involving large cyclic hydrocarbons that occur on low-symmetry active sites. The framework introduced in this work can be translated to design tailored catalysts for dehydrogenating other types of liquid organic hydrogen carriers, thus accelerating the deployment of such technologies that are vital enablers of the trans-oceanic shipment of low-carbon hydrogen.

Learning Physically Constrained Microscopic Interaction Models of Functional Materials Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Bosch, United States

Discovery and understanding of next-generation materials requires a challenging combination of the high accuracy of first-principles calculations with the ability to reach large size and time scales. We pursue a multi-tier method development strategy in which machine learning (ML) algorithms are combined with exact physical symmetries and constraints to significantly accelerate computations of electronic structure and atomistic dynamics. First, density functional theory (DFT) is the cornerstone of modern computational materials science, but its current approximations fall short of the required accuracy and efficiency for predictive calculations of defect properties, band gaps, stability and electrochemical potentials of materials for energy storage and conversion. To advance the capability of DFT we introduce non-local charge density descriptors that satisfy exact scaling constraints and learn exchange functionals called CIDER [1]. These models are orders of magnitude faster in self-consistent calculations for solids than hybrid functionals but similar in accuracy. On a different level, we accelerate molecular dynamics (MD) simulations by using machine learning to construct generalized potential and free energy functions with arbitrary nonlinear dependence on external fields and temperature. This framework enables learning and prediction of dielectric and vibrational response properties [2] and coarse-grained free energies [3].

We demonstrate these methods via first principles ML MD simulations of dynamics of phase transformations, heterogeneous reactions, ferroelectric transitions, nuclear quantum effects, and soft materials.

Domain-Specific Knowledge Integration Through Curriculum Learning Method in Machine Learning for Spectral Analysis

Hajime Shinohara, Akihiro Kishimoto, Indra Priyadarsini S, Lisa Hamada and Seiji Takeda; IBM Research-Tokyo, Japan

We present a novel approach to enhance machine learning models for predicting UV spectra from SMILES string. By incorporating domain-specific knowledge through a curriculum learning method, we improve the predictive performance of these models. Our research demonstrates the potential of implementing domain-specific knowledge for machine learning to advance spectral analysis and its applications across various fields such as organic solar cells and photocatalysts.

UV spectroscopy provides crucial insights into the electronic structures and properties of molecules. However, effective application of machine learning to spectral prediction faces challenges due to the complexities of UV spectra, such as peak overlap and instrumental variability. Our approach leverages the unique characteristics of UV spectra from organic molecules, which typically have relatively broad and smooth peaks compared to other spectroscopic techniques.

We implement this domain-specific knowledge through a curriculum learning process which makes the model to progressively learn from simpler to more complex spectral patterns. Our method utilizes neural network architectures optimized for spectral prediction tasks, with input layers accepting molecular representations and output layers corresponding to spectral data points.

The curriculum learning method employs a unique interpolation technique between selected data points at each resolution stage. The training process is divided into multiple stages of increasing spectral resolution, allowing the model to gradually adapt to more detailed spectral features.

We evaluated our approach using a diverse dataset of experimental spectra and corresponding molecular structures. The dataset was appropriately split to ensure robust training, validation, and testing of the model.

Our results demonstrate the effectiveness of the curriculum learning approach. We evaluated different curriculum learning strategies, comparing them to a baseline model trained directly on full-resolution spectra. The multi-stage curriculum learning approach consistently achieved lower test loss, indicating improved predictive accuracy.

Our method highlights the transformative potential of integrating domain-specific knowledge into machine learning models for UV spectral prediction. The implementation of curriculum learning methods consistently enhanced model accuracy and physical realism, which represents significant advancements in spectral prediction capabilities.

Future research should explore the extension of these domain-specific knowledge enhancements to other spectroscopic techniques and expand the scope of datasets to further validate the robustness and transferability of the proposed methods. Investigating the interpretability of the enhanced models could provide valuable insights into the underlying mechanisms of the structure-spectrum relationship.

In conclusion, we showcase the potential of implementing domain-specific knowledge enhancement into

machine learning for advancing spectral analysis and its applications. By integrating curriculum learning methods, we have developed more accurate and physically realistic models for UV spectral prediction. These advancements open to new avenues for scientific discovery and innovation, contributing to challenging problems in various fields such as organic solar cells and photocatalysts, and beyond. Structural Design Strategies of Organic Cathodes for Sustainable Li-Ion Batteries Using Graph-Based Explainable AI *Jun Hyeong Gu, Eun Ho Kim, Hyo G. Shin and Donghwa Lee; Pohang University of Science and Technology, Korea (the Republic of)*

As the impact of carbon emissions on global warming continues to increase, there is growing interest in sustainable cathode materials for Li-ion batteries consisting of organic materials [1]. Additionally, organic materials have the advantage of flexible structural design, allowing easy modulation of cathodic properties [2]. Due to these advantages, extensive research has been conducted on exploring new materials and analyzing structure-property relationships in a wide structural space. Recently, several machine learning (ML) techniques have been employed to accelerate property prediction and propose new materials [3,4]. These studies have successfully explored new candidate materials in a wide structural space, but the black-box nature of ML models has limited the analysis of the impact of structure on properties. Beyond material exploration, structural design strategies for modulation electrochemical performance are crucial for providing insights into novel cathode designs. In this study, we present structural design strategies for property modulation of organic cathodes using explainable AI (XAI) and statistical techniques. We develop GNN models to predict various cathodic properties (voltage, capacity, specific energy, and voltage descent) and analyze them using graph-based XAI. Through statistical analysis of the results, we identify positive effect motifs (P-motif) and negative effect motifs (N-motif) for each property, proposing structural design strategies to optimize cathodic properties in organic cathodes. Our findings demonstrate the utility of graph-based XAI analysis in understanding complex structure-property relationships and applying them in structural design strategies. Furthermore, this methodology can be easily extended to other material fields, such as catalysis and redox flow batteries, to uncover the unknown structure-property relationships.

From Text to Graphs—Visualizing Materials Space with ForceAtlas2 and MEGnet *Tomasz J. Galica, Matilda M. Sipilä and Milica Todorović; University of Turku, Finland*

Visualizing and mapping the relationships between materials is a challenging task due to both the large volume and complexity of material data. Extracting materials information from text using large language models (LLMs) is additionally complex, because text must be converted into numerical form. Conversion enables data comparison with similarity measures such as Euclidean distance but does not result in intuitively understandable high-dimensional vectors. Unsupervised learning techniques such as PCA and t-SNE can address dimensionality issues but often lead to less interpretable data distributions: data points may overlap or scatter too widely. To resolve these data visualization issues, alternative methods based on artificial forces and pseudo-physical simulations can be employed. Data point overlaps can be minimized using pseudo-electrostatic or pseudo-spring forces, and *large empty spaces can be reduced with pseudo-gravity. In our study, we aim to map the material-property space of data extracted from scientific literature using LLMs to enable guided decision-making and a new approach to materials design [1].*

We explored the ForceAtlas2 (FA2) algorithm [2] to represent chemical formulas of materials as graphs. We evaluated three attribute descriptors for vector representation and determined that MEGnet [3] maintains the most chemical information: on a small scale by clustering similar compounds together, and on a large scale by forming distinct groups of different compound classes. We studied FA2 parameters such as gravity strength, scale factor and number of iterations to obtain the most interpretable graphs. Our results indicate that force-based graphs can enhance the placement of data points compared with t-SNE, preventing data overlap, and minimizing empty spaces. This research demonstrates how alternative force-based methods can address challenges of visualizing materials and textual data. Our approach offers better interpretability of complex materials relationships, improving big data analysis and helping to guide decision-making and materials design.

Extracting Materials Information from Scientific Articles with Vision Transformer Models *Defne Çirci, Miles Bradley, Bhuwan Dhingra and Catherine Brinson; Duke University, United States*

The rapidly developing predictive power of modern machine-learning algorithms necessitates parallel advancements in the size and quality of domain-specific datasets for effective training. Unfortunately, many academic domains, such as materials science, lack such datasets due to the unstructured nature of real-world information. Despite the wealth of domain knowledge generated in modern materials science research, much of it remains underutilized because the underlying experimental data is often buried in tables and figures. Vision transformer models present a new opportunity to rapidly and accurately extract data and insights from published literature and transform them into structured data formats. However, current end-to-end image-to-text transformer models for chart-to-table translation fail to capture the diverse and complex nature of materials science figures, making the extraction of underlying data tables a critical yet challenging step. This leads to issues such as inconsistent extraction of axis labels, irregular presentation of row and column data, and neglecting the extraction of line labels from a chart's legend. We propose an approach that decomposes the task of extracting composition and property information from charts into two steps: (1) converting charts to structured formats such as tables, and (2) inputting these tables into language models to obtain sample information with their associated properties and compositions. To address the challenges in step one, we aim to fine-tune a pretrained image-to-text model on materials science figures with complete and consistent annotations. Additionally, we introduce evaluation techniques tailored to the specifics of materials science. Focusing on the subdomain of polymer composites, we demonstrate both the successes and challenges of using multimodal models to extract tabular and chart data. Successfully extracting chart-to-table and experimental sample information can further enable downstream tasks such as question answering, summarization, and property prediction, enhancing the utilization of materials science research data.

An Algorithmic Approach for Optimizing PEGDA Scaffold Formulations with Additives in Bone Tissue Engineering *Samaher Shaheen[1], Ozlem Yasar[2] and Ozgul Yasar-Inceoglu[1]; [1]California State University, Chico, United States; [2]The City University of New York, United States*

Developing biocompatible scaffolds to support cell regeneration and proliferation is an active field of study in tissue engineering. Poly (ethylene glycol) diacrylate (PEGDA) has been established as an ideal candidate for bone tissue engineering due to its highly tunable mechanical properties, biodegradation rate, and high biocompatibility. While PEGDA is an ideal candidate material for fabricating scaffolds, it also allows integration of additives such as nanoparticles to further enhance the mechanical properties of the engineered scaffold. The transition from material analysis to clinical applications can be cumbersome due to the extensive testing necessary to determine the effects of various additives on the mechanical properties of PEGDA scaffolds. Limited access to testing equipment along with the high cost of materials and labor can further complicate this process.
Addressing these challenges, this study introduces a novel algorithm that provides predictive mechanical and structural analysis of PEGDA scaffolds and potential additives using machine learning techniques and computational modeling. The algorithm presented in this work requires the desired concentration of PEGDA and water for the hydrogel and various additive parameters such as size, shape, and chemical composition. After processing these parameters, a comprehensive prediction of the additive's mechanical, structural, and chemical effects is provided, such as the tensile strength, elasticity, diffraction angle, average distance between polymer chains, hardness, and chemical bonds. This tool provides an effective method of investigating suitable additives and expediting the design of PEGDA-based tissue scaffolds to meet desired criteria, making it an invaluable tool for the field of tissue engineering research. The algorithm integrates the predictive capabilities of machine learning models to enable extensive investigation and optimization of diverse material formulations. The efficacy of this algorithm is demonstrated through the comparative analysis of varying concentrations of 700mn PEGDA (20, 40, 60, 80, and 100%), both with and without the embedment of 20 nm spherical silicon dioxide (SiO2) nanoparticles. The results of this study are validated against simulated and experimental results for each concentration with and without the inclusion of SiO2.

Kolmogorov-Arnold Networks for High-Entropy Alloys Design *Yagnik Bandyopadhyay[1], Harshil Avlani[1,2] and Houlong Zhuang[1]; [1]Arizona State University, United States; [2]Basis Chandler High School, United States*

Deep learning-based machine learning techniques have been extensively applied to the design of high-entropy alloys (HEAs), yielding numerous valuable insights. However, challenges remain in accurately predicting outcomes with sparse and complex datasets and ensuring the interpretability of the models. Kolmogorov-Arnold Networks (KANs) are a recently developed architecture that aims to improve both the accuracy and interpretability of input features. In this work, we explored three different datasets for HEA design and demonstrated the application of KANs for both classification and regression models. In the first example, we used a KAN classifier model to predict the probability of single-phase formation in High Entropy Carbide Ceramics (HECCs) based on various physical *properties. In the second example, we employed a KAN regressor model to predict the yield strength and ultimate tensile strength of HEAs based on their chemical composition and mechanical properties. The third example involved a classifier model to determine whether a certain elemental composition is an HEA or non-HEA, followed by a KAN regressor model to predict the bulk modulus of the identified HEA, aiming to identify HEAs with high bulk modulus. In all three examples, KANs either outperformed or matched the performance of existing machine learning models, particularly the Multilayer Perceptron (MLP), which served as our point of comparison. Our work opens new opportunities for adopting novel AI algorithms in the design and development of HEAs. By demonstrating the efficacy of KANs in handling both classification and regression tasks, we provide a promising direction for future research to explore advanced machine learning techniques, which lead to more accurate predictions and better interpretability of complex materials, ultimately accelerating the discovery and optimization of HEAs with desirable properties.*

MT04.05.03

Predicting Inelastic Neutron Scattering Spectra from the Crystal Structures *Bowen Han and Yongqiang Cheng; Oak Ridge National Laboratory, United States*

Inelastic neutron scattering (INS) spectroscopy is an ideal tool to measure lattice dynamics, such as phonon dispersion, density of states, and anharmonicity. Physical insight is often obtained by comparing the measured INS spectra with simulations on various structural models. Although it is possible to compute the phonon properties with modern electronic structure methods, such as density functional theory, the high computational expense is a significant bottleneck for its application. Over the past decade, machine learning has become a favored alternative to quantum mechanical calculations due to its high efficiency and versatility. In this study, we developed a quantum-based INS database and employed a symmetry-aware graph neural network to predict the force constants of any given materials and, subsequently, the phonon dispersion, density of states, and the corresponding INS spectra. This work offers a convenient and efficient approach for INS experiment planning and data analysis. It will also shed light on fast and accurate calculations of other properties related to lattice dynamics, such as heat capacity. Finally, we will illustrate how these new capabilities can be implemented in a graphical user interface to benefit the INS user community.

Atomic-Scale Insights into Polarization Mechanism in HfO_2 Ferroelectrics Using Multi-Phase Machine Learning Potential *Hyo G. Shin, Jun Hyeong Gu, Eun Ho Kim, Hyeon Kim and Donghwa Lee; Pohang University of Science and Technology, Korea (the Republic of)*

Recently, HfO_2 ferroelectrics have emerged as key materials for future semiconductor technologies. However, they face practical challenges due to high coercive fields and slow domain wall mobility, which impact their operational performance. To address these issues, it is essential to understand the phenomena associated with the polarization of HfO_2 ferroelectrics at the atomic level. Additionally, since HfO_2 has various metastable and stable phases, developing an accurate machine learning potential (MLP) that can simulate the energy stability between these multiple phases is important to reveal the polarization mechanisms at the atomic level. Therefore, in this study, we develop a multi-phase machine learning potential (MP-MLP) that accurately predicts the energy and force of various metastable and stable phases of HfO_2 with quantum mechanical precision, using a graph neural network-based model. The energy order of different phases predicted by the MP-MLP matches exactly with density functional theory (DFT) calculations. We also observe polarization rotation and switching in HfO_2 ferroelectricity using MP-MLP based molecular dynamics simulations under external electric field conditions and identify intermediate phases during polarization switching and rotation. These results provide atomic-level insights related to the wake-up and fatigue of HfO_2 ferroelectric devices. We expect these insights to facilitate the development of *more efficient semiconductor devices, enhancing the performance and reliability of future technologies.*

Machine-Learning Structural Reconstructions for Accelerated Point Defect Calculations *Irea Mosquera-Lois[1], Seán R. Kavanagh[2], Alex M. Ganose[1] and Aron Walsh[1]; [1]Imperial College London, United Kingdom; [2]Harvard University, United States*

Defects dictate the properties of many functional materials. To understand the behaviour of defects and their impact on physical properties, it is necessary to identify the most stable defect geometries[1,2,3]. However, global structure searching is computationally challenging for high-throughput defect studies or materials with complex defect landscapes, like alloys or disordered solids. Here, we tackle this limitation by harnessing a machine-learning surrogate model to qualitatively explore the structural landscape of neutral point defects. By learning defect motifs in a family of related metal chalcogenide and mixed anion crystals, the model successfully predicts favourable reconstructions for unseen defects in unseen compositions for 90% of cases, thereby reducing the number of first-principles calculations by 73%. Using $CdSe_xTe_{1-x}$ *alloys as an exemplar, we train a model on the end member compositions and apply it to find the stable geometries of all inequivalent vacancies for a range of mixing concentrations, thus enabling more accurate and faster defect studies for configurationally complex systems.*

Discovery of Lead-Free Halide Double Perovskites for Solar Cells via Interpretable Machine Learning *Seung Hwan Jung, ChiHun Kim and Yong-Chae Chung; Hanyang University, Korea (the Republic of)*

Developing novel lead-free perovskite materials with suitable band gaps and high stability is essential for advancing the use of perovskite materials in solar cells application. This research paper aims to identify lead-free halide double perovskites for solar cells using machine learning with the SISSO (sure independence screening and sparsifying operator) method. The study uses a dataset of 540 double halide perovskite compounds to apply the SISSO method for feature selection and identify key descriptors that can accurately predict the performance of these materials as solar cell materials. The SISSO method screens and selects the most important features from the dataset, and machine learning algorithms are then employed to identify patterns and relationships among the selected features. The use of machine learning and SISSO in conjunction with a large dataset of halide double perovskites allows for a more efficient and effective identification of promising solar cell materials compared to traditional methods. The results of this study may provide valuable insights into the design and optimization of lead-free halide double perovskites as solar cell materials.

MT04.05.08

Bibliographic Data-Driven Keyword Network Analysis in ReRAM Research *Hyeon Kim, Seong Hun Kim, Jaesun Kim, Eun Ho Kim, Jun Hyeong Gu and Donghwa Lee; Pohang University of Science and Technology, Korea (the Republic of)*

Recently, data informatics has revolutionized the paradigm of scientific research, traditionally based on experiments, formulations, and simulations. Because this type of research is based on the quality and quantity of *data, humans have accumulated experimental, formal, and simulation data in various storage formats. Among these, materials databases have become essential repositories of material properties from experiments and simulations, crucial for data-driven research. Despite their growth, much scientific research data remains stored in journal articles written in natural language. Scientific research using journal articles is increasing, and research trend analysis using bibliographic information is no exception. In this study, we propose a method for trend analysis that automatically analyzes the research field by using bibliographic information. Our method involves sequential steps: searching bibliographic information, extracting keywords from text data, and constructing a keyword network. We validated our method in the field of resistive switching memory (ReRAM) and identified different keyword clusters that can categorize the research trend of ReRAM field. Consequently, our method successfully curated the uptrend in neuromorphic computing, demonstrating its potential for insightful analysis in other scientific research fields.*

Unsupervised Characterization of Interfacial Reaction and Diffusion Mechanisms in ML-Driven Molecular Simulations

Laura Zichi[1], Matteo Carli[1], Jingxuan Ding[1], Menghang (David) Wang[1], Yu Xie[1] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch Research and Technology Center, United States

Recent advances in machine learning interatomic potentials have allowed access to large-scale molecular dynamics (MD) simulations, necessitating automatic and flexible analysis of their dynamics. Conventional techniques, like common neighbor analysis or polyhedral template matching, constrain analysis to crystalline structures or rely entirely on prior knowledge of the system dynamics. Therefore, we employ an unsupervised clustering algorithm to characterize phase transitions and product formation of large-scale interfacial reaction simulations. Representations of local atomic environments of MD trajectories are clustered based on their geometric descriptors. We demonstrate this technique by examining high-temperature and pressure phase transitions of silicon carbide and interfacial reactions leading to the formation of the solid-electrolyte interphase (SEI) in solid-state lithium batteries. We identify the time evolution of possible phases, including complex molecules and crystalline, amorphous, or solid state compounds, to characterize the SEI formation in solid-state batteries. Broadly, this framework provides automated data-driven insights into the dynamics of solid state reactions and phase nucleation using large-scale MD simulations.

Developing Transferrable Machine Learning Force Fields for Metal-Organic Frameworks

Hyunsoo Park and Aron Walsh; Imperial College London, United Kingdom

Metal-Organic Frameworks (MOFs) have garnered significant attention as promising materials for CO_2 capture. However, the development of accurate force fields to describe their potential interactions is challenging due to their large number of atoms and inherent complexity. Classical force fields using the point charge approach struggle to accurately model interactions involving CO_2 and H_2O. In this study, we introduce a transferable machine learning force field that enables simulating potentials across a diverse set of MOFs, rather than focusing on just a few types. Using this new force field, we screen an existing MOF database to identify candidates for CO_2 capture and evaluate CO_2/H_2O selectivity with ab initio levels of accuracy. Additionally, we chemically analyze the critical factors and characteristics necessary for a MOF to be a promising candidate for CO_2 capture, providing a comprehensive understanding of what makes certain MOFs more effective at capturing CO_2. This approach sets a new standard for the rapid and accurate screening and development of MOFs, accelerating progress towards effective solutions for carbon capture technologies.

The Surface Configurations and Their Impact on Pd-Based Alloy Membranes for Hydrogen Separation—An Application of a Universal Neural Network Potential *Taku Watanabe and Akihiro Nagoya; Preferred Computational Chemistry, Inc., Japan*

Pd-based alloy membranes for hydrogen separation are highly efficient and have several important practical advantages over traditional methods like pressure swing adsorption or cryogenic distillation. However, the use of Pd, a rare and expensive metal, and its reactivity with certain gas mixture components pose challenges. To address these issues, Pd alloys have been widely explored in the literature.
In this work, we report our computational study on the alloy configurations and their impact on the adsorption and diffusion of hydrogen at the surface. Our unique universal neural network potential, called Preferred Potential (PFP), was applied to perform necessary atomistic simulations. One of the advantages of using PFP is the capability of simulating chemical reactions at near-DFT accuracy on a much larger system with a much higher speed.
We examined the surface segregation behavior of the fcc Pd-based alloys as a function of temperature and composition using Monte Carlo simulations. Pronounced segregation of the additive species was found in Pd_3Ag and Pd_3Au, but Pd segregation was found in Pd_3Cu, Pd_3Ni, and Pd_3Pt at the fcc(111) surface. These findings are consistent with the previously known facts in the literature.
Beyond the binary phases, selected ternary phases were also explored. The investigation of the combinations of Au-Ag, Au-Cu, and Cu-Ag in host Pd revealed the segregation of Ag and Au at the surfaces in these alloys, similar to the case of the binary alloys. However, interesting subsurface structures were observed and characterized for each composition. The surface segregation of the additional elements significantly affects the surface binding of the hydrogen. The binding energies of the hydrogen atoms on a pure Pd surface are well-defined and distinct: 2.47 and 2.97 eV at top and fcc hollow sites, respectively, in reference to a hydrogen atom. However, the binding energies on the ternary surfaces exhibit very different behavior. There is much more variety in the geometric configurations of the surface adsorption sites. The observed hydrogen binding energies are much higher in general and distributed over a wide range of energy depending on the surface composition. This difference in the surface binding energies has a significant impact on the surface migration as well as the out-of-plane migration energy barriers.
This work will provide the basis for understanding the behavior of the Pd-based alloy membranes and their interaction with hydrogen. The insights and techniques developed in this study can be useful in the design beyond the commonly used Pd-based membranes.

MT04.05.12

A Neural Network Model for Determining Unknown Interfacial Thermal Resistances in VLSI *Haiying Yang, Nitin Tiwari, Surya Vanka and Sanjiv Sinha; University of Illinois at Urbana-Champaign, United States*

In large circuit blocks, the thermal resistances between numerous material interfaces are often known only within an order of magnitude [1]. Experimentally, such interfaces are measured using ultrafast optical techniques on thin-film geometries in simplified stacks [2-3] that may yield values different from the interfaces realized in a foundry process. Given their importance of interfaces in affecting the temperature rise and reliability of VLSI [3-4], there is a clear need to predict/verify ITRs in an operating VLSI circuit. Here, we explore a neural network approach [5] to solve an inverse transient heat diffusion problem where temperature data is provided at discrete points in the circuit, along with material geometries, thermophysical properties, and a heat source distribution. The goal is to realize a net that solves the inverse problem and yields unknown ITRs. We first train a surrogate network using GPU-accelerated forward solution [6] of the heat diffusion equation in a detailed VLSI geometry. Since the outputs in the training process of the inverse problem are not unique, we first need to use the trained surrogate model of the heat diffusion equation to convert them to unique quantities for the definition of the training error of the inverse *network. Our work suggests that neural network models would be a useful way for predicting the unknown thermal interface resistances in VLSI.*

Construction of Machine Learning Potentials Toward the Exploration of High Entropy Alloy Cluster Catalysts

Kentaro Miyamoto[1], Koji Shimizu[2], Anh Khoa Augustin Lu[1] and Satoshi Watanabe[1]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

In recent years, high entropy alloys (HEAs), which contain at least five elements, have received considerable attention due to their unique properties that make them promising candidates for a variety of applications [1]. However, searching for the best HEA to serve a purpose within the huge compositional space by first-principles calculations based on density functional theory (DFT) is computationally expensive. Therefore, we constructed machine learning potentials (MLPs) to efficiently search for HEA catalysts.
In this study, we aim to identify HEA catalysts for the carbon dioxide reduction reaction. As the activity and selectivity of this reaction are highly correlated with the adsorption energies of carbon monoxide (CO) molecules and hydrogen (H) atoms [2], MLPs were trained to predict these values. The training data were obtained from DFT calculations of models with different atomic configurations in bulk crystals (8 atoms per supercell) containing up to 5 of the 9 elements (Co, Ni, Cu, Rh, Pd, Ag, Ir, Pt, and Au), and in octahedral clusters (19 atoms) containing up to 4 of the 9 aforementioned elements. Here, the results for clusters were included to investigate the catalytic performance not only on flat planar surfaces but also on uneven surfaces.
Our MLPs were constructed using a graph neural network-based architecture with the Allegro package [3] and trained with the DFT data. Our results show that the MLP accurately predicts the total energies of the quaternary and quinary alloy models from the training data of the binary and ternary alloy models with a mean absolute error (MAE) of approximately 12 meV/atom. We also confirmed the diversity of our dataset across the entire chemical component space by examining the distribution of high-dimensional features representing the local atomic environment via dimensionality reduction methods (i.e. t-SNE and PCA). In addition, the adsorption energies of H atoms on the octahedral clusters (19 atoms) of binary and ternary alloys were predicted with a MAE of approximately 0.1 eV. In conclusion, it is promising to adapt our machine learning potential in designing high-performance HEA catalysts for carbon dioxide decomposition.
This study was supported by JST e-ASIA Joint Research Program.

Design of N2O Decomposition Catalysts with SO2 Poisoning Resistance Through Data Assimilation Using Machine Learning Potentials

Tatsuya Takakuwa, Iori Imaizumi, Shuya Masuda and Yohei Noda; Sumitomo Electric Industries, Ltd., Japan

Nitrous oxide (N2O), present in exhaust gases and sewage, is a potent greenhouse gas, and its decomposition or suppression is crucial. Current research focuses on the catalytic thermal decomposition of N2O using heterogeneous catalysts. Transition metal oxides such as Ni (Nickel) and Co (Cobalt) have shown high conversion rates in this process. However, sulfur dioxide (SO2), which often accompanies N2O, can poison these catalysts, leading to their degradation during operation. Common practice involves using ammonia (NH3) as a reaction gas to extend catalyst life, but this can lead to the formation of nitrogen oxides (NOx) through side reactions and necessitates additional NH3 supply infrastructure. This not only reduces catalyst efficiency but also increases raw material costs and auxiliary equipment expenses. The development of catalyst designs that improve resistance to SO2 without using NH3 remains an unexplored area. In this report, we introduce a high-speed automated computational method using machine learning potentials to automatically generate possible surface states of heterogeneous catalysts and comprehensively calculate the adsorption patterns of N2O and SO2. This method integrates computational results to create equivalent alternative metrics that can be directly compared with experimental Diffuse Reflectance Infrared Fourier Transform (DRIFT) analysis spectra. These metrics enable the identification of heterogeneous catalyst surfaces with only a few data points, significantly aiding in the elucidation of poisoning mechanisms. We have successfully identified specific adsorption peaks of N2O and SO2 on oxide catalysts at room and reaction temperatures using DRIFT analysis, calculated the similarity between these surrogate values and actual analytical data, and pinpointed the catalyst surface. Furthermore, we discovered a unique adsorption pattern where SO2 specifically desorbs near reaction temperatures—a critical finding for addressing catalyst poisoning. We propose a catalyst composition optimized to maximize the occurrence of this adsorption pattern. Experimental validation confirmed the expected desorption of SO2, demonstrating a successful catalyst design that is resistant to poisoning

MT04.05.15

Combined Materials Map and Supervised Machine Learning Towards Efficient and Accelerated Anion Exchange Membrane Polymer Exploration

Yin Kan Phua[1], Tsuyohiko Fujigaya[1,2,3] and Koichiro Kato[1,2,4]; [1]Kyushu University, Japan; [2]Center for Molecular Systems (CMS), Kyushu University, Japan; [3]The World Premier International Research Center Initiative, International Institute of Carbon Neutral Energy Research (WPI-I2CNER), Kyushu University, Japan; [4]Research Institute for Information Technology (RIIT), Kyushu University, Japan

Decarbonization requires next generation energy generating devices and fuel sources to replace fossil fuel-powered infrastructures. Fuel cells and water electrolyzer are one such candidate to realize decarbonized society, and anion exchange membrane (AEM) is seen as the hopeful to aid their widespread adoption because of its potential to suppress usage of expensive catalyst. However, commercialization of AEM requires improvement in anion conductivity and durability. Many researches have been done to date, with progress being made for the past 20 years. Regardless, AEM that fulfill both high anion conductivity and high durability is yet to be found, and exploration for such material needs to be accelerated for early decarbonization. This is where materials informatics comes into play, with the advent of prevailing machine learning (ML) empowering a transformative opportunity to accelerate AEM material development. ML algorithms can be broadly classified into supervised and unsupervised learning. Supervised ML models seeks for a correlation between target variables (e.g., anion conductivity) and explanatory variables (e.g., polymer structure information) based on labeled data. In contrast, unsupervised ML models explore the relationships among explanatory variables without relying on target variables, enabling the identification of latent patterns and features. Building upon our previous work on supervised explainable ML model [1] and unsupervised ML-based material mapping [2], we present an integrated approach that utilizes unsupervised ML-derived 2-dimensional (2D) map as material design guidelines for identifying promising new AEMs. Through this method, novel AEMs can be designed easily through reflecting knowledge obtained from the guideline. These AEMs are then subjected to supervised ML-based conductivity prediction. Since an opensource AEM database is currently unavailable, we constructed our own database from 78 research *papers. The Mordred library [3] was employed for descriptor transformation of AEM polymer structures. The 2D maps were generated by combining principal component analysis (PCA) and uniform manifold approximation and projection (UMAP). CatBoost was employed for supervised ML. Two types of descriptors were used to train CatBoost: AEM polymers represented using Mordred descriptors and dimensionally reduced descriptors using PCA (PCA descriptor, 32 dimensions). The predictive accuracy of CatBoost was evaluated using the coefficient of determination (R^2). Both descriptor sets yielded high cross-validation accuracy, marking R^2 values of 0.961 and 0.957, respectively. To assess the practicality of our integrated approach, we employed poly(2,6-dimethyl-1,4-phenylene oxide) (PPO)-based AEMs [4] with known ionic conductivity as pseudo new AEM polymer. Assuming the case that this new AEM has not been reported yet, we could have thought of designing it through utilizing piperidinium, a side chain that provided high average anion conductivity to poly(arylene alkylene), with PPO as main chain structure due to its ease of synthesis, all thought of through utilizing the map as guideline. Next, the anion conductivity for the AEM measured at different temperatures was accurately predicted by CatBoost for the test AEM structure, even when represented using either sets of descriptors (Mordred descriptor and PCA descriptor), with R^2 values of 0.906 and 0.888, respectively. Our work demonstrates the remarkable potential of integrating data-driven material mapping and ML for accelerating AEM development. This synergistic approach has the potential to revolutionize AEM research, enabling the rapid identification and design of high-performance AEMs for next-generation AEM fuel cells.*

Revolutionizing Battery Development with AI *Jie Liu[1,2] and Xiao Shen[3]; [1]The University of Hong Kong, China; [2]Hong Kong Quantum AI Lab, Hong Kong; [3]The Australian National University, Australia*

The global lithium-ion battery market achieved a shipment volume of 1,203 GWh in 2023, with a compound annual growth rate (CAGR) of 27.4% and a price learning rate (LR) of 27.3% over the past 20 years. However, rapid battery industry growth and substantial resource consumption have made increasing energy density crucial for sustainable development. Despite significant research progress, energy densities of mainstream LFP and NCM batteries remain around 160-250 Wh/kg, with an energy density learning rate (EDLR) of 5-7%, indicating a 5-7% improvement in energy density each time production doubles. This is in stark contrast to the 17.9% EDLR for best practice batteries, which achieve energy densities exceeding 700 Wh/kg. This substantial gap necessitates a shift from traditional R&D paradigms to an AI -driven approach for battery development, with their full potential impact yet to be completely realized.

In this study, we provide a comprehensive framework for AI driving battery design by integrating quantum chemistry, domain knowledge, databases, knowledge graphs, expert systems, large language models, and automated experiments, which could help bridge the EDLR gap between academic research and practical application. We assess its potential contributions to the future development of lithium batteries, with a focus on material efficiency and cost savings. A scenario analysis under different EDLR conditions for mainstream batteries reveals that even slight improvements in EDLR can lead to substantial material savings. Specifically, if the EDLR of mainstream batteries matches the 17.9% rate of best practice batteries by 2030, the industry could save approximately 16.1 Mt of battery materials and 151 billion USD in material costs.

The findings underscore the significant advantages, both economically and in terms of resource conservation, of accelerating lithium battery R&D. There is a compelling case for seizing the opportunity to integrate AI and Quantum Chemistry in lithium battery R&D. This integration not only promises enhanced energy densities but also marks a significant stride towards more sustainable and cost-effective battery production, potentially yielding returns far greater than the current investments in these cutting-edge technologies.

MT04.05.17

Evaluation of a Universal Neural Network Potential for Predicting Finite Temperature Properties Using Quasi-Harmonic Approximation *Akihiro Nagoya and Taku Watanabe; Preferred Computational Chemistry, Inc., Japan*

Computational materials design has been extensively studied with the development of DFT calculations and related optimization methods. However, material properties are usually evaluated at zero temperature due to the huge computational cost involved in DFT.
As a result, the proposed material may not be experimentally synthesizable. For practical applications, it is also crucial to optimize the synthesis conditions to improve the material properties at an affordable cost. Therefore, it is necessary to establish a reliable computational procedure for evaluating the properties at a finite temperature.
Predicting material properties at finite temperature requires accurate evaluation of thermodynamic quantities such as Gibbs free energy. There are two contributions to this accuracy: the accuracy of the potential energy calculated by DFT and the accuracy of the physical modeling of the phenomena. On the other hand, the calculation throughput, which is a compromise of the accuracy, is important for practical applications. Therefore, an appropriate method should be used to balance its accuracy and throughput.
The Preferred Potential (PFP) implemented on Matlantis™ is a recently developed graph neural network potential with the unique feature of universality[1]. PFP is trained on large DFT data sets, including not only stable crystals and molecules, but also surfaces and disordered structures. As a result, it is applicable to predict finite temperature properties of materials without compromising accuracy. In physical modeling of solids, the temperature dependence of thermodynamic properties can be well described by the Debye model under the quasi-harmonic approximation (QHA) of phonons, which takes into account the thermal expansion of the volume. QHA is suitable for predicting thermodynamic properties with moderate computational costs at the temperature range from room temperature to about two-thirds of the Debye temperature. By combining PFP and QHA, it is possible to efficiently predict material properties at finite temperatures with high accuracy.
In this study, we have systematically validated the accuracy of PFP combined with QHA for predicting the thermodynamic properties at finite temperature. In particular, the calculated temperature dependence of the isobaric specific heats around room temperature, derived from the temperature derivative of the Gibbs free energy, is in good agreement with experiments. The temperature range in which the QHA is applicable has also been investigated with respect to the results obtained from molecular dynamics simulations. These results demonstrate that GNN potentials trained on large dataset well reproduce the potential energy curve around the local minimum, and are applicable to predict material properties at finite temperature.

Deep Learning-Based Superfast Metasurface Design Platform *Ki Won Jeong and Yun Seon Do; Kyungpook National University, Korea (the Republic of)*

The metasurface represents a revolutionary development in electromagnetic wave control that enables manipulation of wavelengths, phases, amplitudes, and polarizations. This study focuses on metasurface color filters (MCFs) that utilize nanoscale structures to generate colors. This approach provides a powerful alternative to conventional dye-based filters for ultra-small pixels for next-generation displays.[1] We aim to optimize the new MCFs design featuring a hole array layer stacked on a disk array layer while solving the general problem of color changing as the incident light angle changes.[2] By optimize design parameters of new MCFs, we strive for angle-independent color properties that are important for dynamic applications such as wearable displays and flexible electronics. Conventional metasurface design methods involve many trials and errors for simulation and experimental validation. There are many studies using deep learning to overcome these problems, but this also *requires a lot of prior data to train the model.[3] This study efficiently optimizes the design parameters by introducing a deep learning-based design platform that integrates forward deep neural networks (FDNNs) and genetic algorithms (GAs). Moreover, FDNNs reduce the time of iterative simulations, and GAs derive a combination of design parameters with desired characteristics.*

GA goes through 15 generations to optimize one color independent of incident light angle and verifies the 500 design parameter combination for each generation. Therefore, a total of 7500 simulations are required to optimize one color. In this work, a total of 7500 simulations are performed in seconds due to the fast computational speed of FDNNs that replaced simulations. For color, CIELAB was adopted, and CIEDE2000 (ΔE) was used for color difference according to angle. As a result, for the optimized three colors, the new MCFs showed much lower color change (average ΔE: 1.6) compared to the conventional MCFs (average ΔE: 46.2). Especially for yellow color, ΔE reached 0. Analyzing the color transmission spectrum, in the case of the conventional MCFs, when the angle of the incident light increases, the peaks are divided and a number of peaks are found. On the other hand, in the case of the new MCFs designed optimally, even if the angle of the incident light increases, the phenomenon of dividing the peaks disappeared.

In this study, we developed a design platform that can quickly derive a combination of design parameters of a metasurface with complex characteristics. This made it easy to obtain the desired characteristics without the need for deep knowledge or vast amounts of data about the metasurface. This design platform can be applied to various metasurface research and promotes innovation in metasurface research using artificial intelligence. It will contribute significantly to accelerating the practical application of metasurface in many fields such as next-generation displays, wearable devices, and flexible electronics.

High-Throughput Computational Search for Stable Compositions and Configurations in High-Entropy Perovskite SrTiO3

Hiroki Kotaka[1], Yosuke Harashima[2,2], Hiroki Iriguchi[1], Tomoaki Takayama[2,2], Shogo Takasuka[2] and Mikiya Fujii[2,2,2]; [1]ENEOS Corporation, Japan; [2]Nara Institute of Science and Technology, Japan

Perovskite oxides exhibit remarkable versatility across various applications due to their structural and chemical adaptability.

SrTiO3 (STO) stands out as a potential water-splitting photocatalyst with a band gap of 3.4 eV, while for efficient solar energy conversion of the photocatalyst, the band gap should be narrowed to less than 2.0 eV. To address this, we have investigated multi-doped STO candidates, aiming to narrow the band gap and enhance photocatalytic performance. For efficient solar energy conversion, there is still room for performance improvement such as band gap control by changing the composition of the constituent metals. Controlling the *valence band structure through combinatorial doping of multiple atomic species with different ionic radii and valences is expected to play a critical role in improving catalytic performance. On the other hand, doping with a different atomic size or valence leads to several difficulties in synthesis. Our approach involves the design of water-splitting photocatalytic materials through heterogeneous composite doping, which introduces high configurational entropy into STO. This strategy relies on the "elemental cocktail effect" arising from substitution with multiple elements.*

Adopting the "PreFerred Potential" (PFP), which is a neural network potential [1], we have created a substantial dataset of metastable optimized structures for hetero-metallic substitution at Sr-sites within STO. The PFP is based on over 42 millions of density functional theory (DFT) datasets and achieves high accuracy and generality for nearly all elements of the periodic table, excluding radioactive ones. Its speed and precision surpass traditional DFT solvers, expediting the optimization process.

Using PFP, we have calculated over 10,000 multi-stable optimized structures. Our extensive computational dataset has enabled predictions of the relationship between metal-site composition ratios and the formation free energy of substitutional solid solution phases, taking into account configurational entropy. Our detailed mapping of performance over composition and stability not only identifies optimal metal combinations for synthesis but also enables the prediction of the limit to solid solution formation. Indeed, our calculations for multi-element doping in STOs have successfully replicated experimental results.

In our presentation, we will showcase how our simulations provide novel insights for material design within the relevant material families. Our calculation results, which consist of substitution composition simulation models created by PFP, are invaluable for guiding material design and advancing data science applications, such as supervised machine learning. These large amounts of stable structure data, categorized by composition, structural stability (formation free energy), configurations, and unit cell geometry (including space group), do not contain electronic structure information (since PFPs are quasi-atomic potentials).

To further our research, we have begun collecting accurate band gap data using DFT on "Fugaku," Japan's preeminent supercomputer. Our presentation will discuss these band gap simulation results and structural insights, contributing to the progression of photocatalytic material design. We strongly believe that these results help to predict feasible metal composition rates for future perovskite synthesis.

Fine-Tuning Foundation Models to Unveil Inhibitory Dynamics of Organic Cosolutes on TiO_2 Photocatalysts

Omar Allam[1,2,2], Mostafa Maghsoodi[3], Samuel Snow[3] and Seung Soon Jang[2]; [1]SandboxAQ, United States; [2]Georgia Institute of Technology, United States; [3]Louisiana State University, United States

The efficient utilization of solar energy for water treatment through photocatalytic processes has been limited by the challenge of understanding and optimizing interactions at the photocatalyst surface, particularly in the presence of non-target cosolutes. This study employs first-principles methods to predict the inhibitory effects of a series of small organic molecules during TiO_2 photocatalytic degradation of para-chlorobenzoic acid (pCBA). Tryptophan, coniferyl alcohol, succinic acid, gallic acid, and trimesic acid were chosen as interfering agents against pCBA to examine the resulting competitive reaction kinetics through bulk and surface phase reactions, following Langmuir-Hinshelwood adsorption dynamics. Fine-tuning models pretrained on millions of configurations with a relatively small dataset yielded machine learning interatomic potentials (MLIPs) achieving chemical accuracy. These models enabled extended timescale simulations that offered deeper insights into adsorption behaviors and inhibitory effects. Our simulations indicated that trimesic and gallic acids exhibited the highest inhibition, confirmed by experimental results. Further, a strong correlation between solute-surface

interaction energies and experimental observations indicates that adsorption site interactions overshadow the role of general reactivity with OH radicals. ML-accelerated explicit solvation simulations showed that water molecules saturate the anatase active sites, leading to primary competitive adsorption between inhibitory cosolutes and water. These findings demonstrate the potential of ML-driven approaches to optimize photocatalytic systems for more effective water treatment applications by enhancing our understanding of surface inhibitory dynamics.

Thermodynamically Informed Multimodal Learning of High-Dimensional Free Energy Models in Molecular Coarse Graining *Blake Duschatko[1], Xiang Fu[2], Cameron J. Owen[1], Yu Xie[1], Albert Musaelian[1], Tommi Jaakkola[2] and Boris Kozinsky[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States*

We present a differentiable formalism for learning free energies that is capable of capturing arbitrarily complex model dependencies on coarse-grained coordinates and finite-temperature response to variation of general system parameters. This is done by endowing models with explicit dependence on temperature and parameters and by exploiting exact differential thermodynamic relationships between the free energy, ensemble averages, and response properties. Formally, we derive an approach for learning high-dimensional cumulant generating functions using statistical estimates of their derivatives, which are observable cumulants of the underlying random variable. The proposed formalism opens ways to resolve several outstanding challenges in bottom-up molecular coarse graining dealing with multiple minima and state dependence. This is realized by using additional differential relationships in the loss function to significantly improve the learning of free energies, while exactly preserving the Boltzmann distribution governing the corresponding fine-grain all-atom system. As an example, we go beyond the standard force-matching procedure to demonstrate how leveraging the thermodynamic relationship between free energy and values of ensemble averaged all-atom potential energy improves the learning efficiency and accuracy of the free energy model. The result is significantly better sampling statistics of structural distribution functions. The theoretical framework presented here is demonstrated via implementations in both kernel-based and neural network machine learning regression methods and opens new ways to train accurate machine learning models for studying thermodynamic and response properties of complex molecular systems.

Unsupervised Learning Discovery of Catalyst Materials for Carbon Dioxide to Methanol Synthesis *Prajwal D. Pisal[1], Ondrej Krejci[1] and Patrick Rinke[2]; [1]Aalto University, Finland; [2]Technische Universität München, Germany*

Novel and highly efficient heterogeneous catalysts are urgently needed to combat greenhouse gas emissions by converting CO_2 into useful products such as methanol. Despite advances in high-throughput computational and experimental materials screening, discovering effective catalysts remains challenging due to the demanding nature of quantum mechanical calculations, the slow, expensive nature of catalyst testing, and the vast materials space. Machine learning offers a powerful tool to predict materials activity [1], speeding up the theoretical predictions; however, the complexity of modern industrial catalysts with many active sites and facets needs to be addressed by a good descriptor.

Adsorption energies of reactants or intermediates have presented themselves as good proxies for the activity of basic metal catalysts [2]. However, a single adsorption energy can fail to describe the activity of more complex materials. Therefore, in this study, we introduce the adsorption energy distribution (AED) descriptor, extending the original concept by incorporating data on various facets and binding sites. We have compiled AEDs of relevant reaction intermediates, specifically for CO_2 to methanol thermal conversion reaction for approximately 200 materials utilizing a machine-learned interatomic potential from the Open Catalyst Project [3]. We have computed pairwise Wasserstein distances between the AEDs and performed hierarchical clustering to find groups of catalysts with comparable catalytic activities. The results show clustering and similar statistical markers for materials exhibiting high methanol yield in the experiment as well as suggesting new potential candidate materials. Notably, our approach identifies similarities between the well-known Cu-Zn-based thermal catalyst [4] and materials such as Ni-Zn and Ga-Cu, which exhibits good catalytic activity for the CO_2 to methanol conversion reaction [5, 6], validating our approach. Furthermore, we have discovered new potential materials, including Cu-Pt, which we intend to evaluate further in collaboration with our experimental team. This approach can be readily modified for the screening of potential heterocatalyst candidates when crucial reaction intermediates are known.

Beyond the Black-Box—New Advances in Bayesian Materials Discovery *Raymundo Arroyave; Texas A&M University, United States*

Over the past decade, Bayesian methods have quickly emerged as some of the best approaches for accelerated materials discovery. These approaches generally frame the process of materials discovery as a 'black box' optimization problem in which the 'black box' function is sequentially and optimally queried. The typical ingredients of Bayesian Optimization (BO) are: (1) a stochastic model of the world that predicts the outcomes of experiments yet to be run as well as the variance in such outcomes; (2) a prescriptive policy that recommends the next best experiment to run given these outcomes. While general purpose BO methods have proven quite useful in solving complex and expensive optimization problems, significant improvements can be achieved if one looks beyond the 'black box' setting. In this talk, I will review different approaches to improving BO applied to materials discovery. Such improvements include taking advantage of multiple information sources, exploiting correlations among materials observables that have different acquisition costs, embedding physics into the BO process itself, embracing knowledge about intermediate materials states, as well as strategies to bringing human expertise into the discovery loop. Several examples will be provided and a perspective for future improvements will be presented.

9:00 AM MT04.06.04
Active Learning Guided Optimization of Perovskites Under Extreme Conditions *Minkyung Han[1,1], Sean Gasiorowski[2], Ruyi Song[2], Daniel F. Ratner[2], Wendy Mao[1,2], Chunjing Jia[3] and Yu Lin[2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]University of Florida, United States*

Halide perovskites have emerged as promising materials for solar cells, demonstrating a dramatic increase in power conversion efficiencies over the past decade. However, organic-inorganic halide perovskites face chemical instability under heat and moisture conditions due to their volatile organic A-site cations. In contrast, inorganic halide perovskites exhibit better chemical stability but suffer from phase instability at ambient conditions due to the small size of the cesium ion at the A-site. The perovskite phase, characterized by corner-sharing octahedra, spontaneously transitions to a thermodynamically more stable but non-functional phase with edge- or face-sharing octahedra under ambient conditions. This phase instability has hindered the commercialization of these materials. One effective strategy to maintain the functional perovskite phase is to achieve a metastable phase by applying pressure or strain. The functional perovskite phase can be metastably preserved when quenched to ambient conditions. This underscores the importance of understanding the relationship between material structure and property changes under extreme conditions. Due to the experimental challenges in accessing metastable halide perovskites, first-principles calculations and machine learning (ML) techniques have been used to simulate extreme conditions and corresponding material properties. Our prior work demonstrated that various ML models achieved highly accurate predictions of the properties of halide perovskites based on their tuned structures under pressure or strain conditions [1]. Motivated by these findings, in this study, we applied an active learning approach to ab initio calculations to accelerate the prediction of the optimal synthetic conditions for achieving metastable halide perovskites with high stability and desirable properties. We then used these prediction results to design experimental validation. Our research provides valuable insights into the development of an efficient workflow for data-driven materials discovery under extreme conditions.

9:15 AM MT04.06.06
Tailoring Semiconductor Defect Properties Using Graph Neural Networks and Active Learning *Md Habibur Rahman and Arun Kumar Mannodi-Kanakkithodi; Purdue University, United States*

Defects and impurities in semiconductors significantly impact their performance in solar cells, photocatalysis, electronic devices, and related applications [1,2]. To address the challenge of quick defect property prediction in semiconductors and subsequent design of novel materials with tailored defect behavior, we developed a comprehensive workflow that integrates active learning (AL) and crystal graph-based neural network (GNNs) models trained on high-throughput density functional theory (DFT) data [2,3]. We generated a large DFT dataset of the crystal structures of technologically-important semiconductors, including well-known binary compounds such as CdTe, ZnS, and SiC, a variety of anion-site or cation-site alloys, and many types of vacancies, self-interstitials, anti-site substitutions, extrinsic interstitial and substitutional defects, and defect complexes simulated in them. Using an innovative approach of sampling optimized, partially optimized, and unoptimized configurations from DFT calculations, we rigorously trained GNN models on > 20,000 crystal structures to yield accurate prediction of the crystal formation energy (CFE) corresponding to any bulk or defective structure in multiple charge states [3].

Using the Atomistic Line Graph Neural Network (ALIGNN) framework [4], we obtain test root mean square errors (RMSE) of < 5 meV/atom for the CFE, which significantly outperforms the current state-of-the-art and is a remarkable accuracy considering its generalizability to supercell sizes, type of alloying, and missing or additional atoms. We also combine ALIGNN predictions with a systematic distortion-based geometry optimization approach which provides an effective surrogate for DFT computations to obtain low energy defective crystal structures for any semiconductor-defect combination [3]. Using AL, model predictions are iteratively improved by launching new DFT calculations based on prediction uncertainties and retraining the models until errors converge. The CFE predictions are extended to obtain defect formation energy plots as a function of Fermi level, chemical potential *conditions, and defect charge, and used to screen through thousands of possible defects and dopants (e.g., group V dopants, Cu, and unintentional impurities like Cl, O, and associated complexes) and generate libraries of low energy defect configurations in the (Cd,Zn)-(Te,Se,S) compositional space, relevant for CdTe-related solar cells [5,6]. These defect configurations are utilized to interpret experimental spectroscopy measurements [7,8] and devise ways to improve optoelectronic performance by tuning semiconductor composition, eliminating certain impurities, and tailoring chemical growth conditions.*

Implicit Differentiation of Energy Landscapes for One-Shot UQ and Fine-Tuning *Ivan Maliyov and Thomas D. Swinburne; Centre National de la Recherche Scientifique, France*

Interatomic potentials are essential to escape ab initio size limitations, but energies and structures depend sensitively on potential parameters. Gauging the effect of parameter variation typically requires expensive resampling, complicating uncertainty quantification and emerging inverse design schemes which use parameters as a proxy for composition. Here, we Taylor expand the structure and energy of relaxed minima through implicit differentiation, using automatic differentiation, dense linear algebra or a novel sparse operator approach. The memory requirement of automatic differentiation is prohibitive for more than a thousand atoms, but our sparse approach is a linear scaling solution applicable to large systems. Our expansion is able to predict large changes in the formation energy and volume of point defects using classical and machine-learning potentials. We also use the implicit derivative for potential fine-tuning in a targeted structure search, finding solute interactions which induce dislocation core reconstruction and thus solid solution strengthening in bcc tungsten.

Machine Learning the Periodic Table *Michele Ceriotti; École Polytechnique Fédérale de Lausanne, Switzerland*

Machine learning models - from those predicting the interatomic potential to those estimating electronic and functional properties - have become an integral part of the atomistic modeling toolbox. The most established

architectures treat individual elements as separate entities, learning their interactions independently, and leading to a steep scaling of the data requirements with the degree of chemical complexity. Several recent models, instead, incorporate the chemical nature of the atoms into fixed-length tokens, that are combined with structural information in a way that avoids a dramatic increase in complexity with growing numberd of species.
I will discuss models that apply explicitly a reduction of dimensionality of chemical space, showing how this makes traditional ML potential capable of achieving accurate, transferable predictions for high-entropy alloys containing up to 25 d-block metals. The highly interpretable architecture provides insights into the functioning of more complicated deep-learning models, and makes it possible to tackle important applicative questions including the onset of short-range order in HEAs, and the preferential segregation of elements at surfaces, which is of great relevance for applications to catalysis.

Reinforcement Learning Accelerated Atomistic Surface Reconstruction in Semi-Grand Canonical Ensemble
Hoje Chun and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Identifying the structure of surfaces and interfaces is crucial for understanding active sites in target reactions and determining defect concentrations as a function of thermodynamic variables for applications in catalysis and electronics. Recent advancements in integrating machine learning with first-principles calculations have demonstrated successful cases of surface reconstruction. Building on these efforts, we present a deep reinforcement learning approach to facilitate atomistic simulations of surface reconstruction. Using $SrTiO_3$ as a model system, we formulate a new reward function that accounts for both thermodynamic and kinetic factors pathways of atomistic growth on surfaces within a semi-grand canonical ensemble. We employ double Q-learning for the deep Q-network (DQN). Efficient data sampling strategies were used for the development of neural network interatomic potentials (NN-IP) for $SrTiO_3$. The trained DQN enables faster acquisition of stable surfaces under given thermodynamic conditions compared to Markov chain Monte Carlo (MCMC) simulations.

Multi-Objective Bayesian Optimization for Materials Discovery with Neural Network Potential—An Application to Li-Ion Battery Cathode Material
Shuhei Watanabe[1], Hideaki Imamura[1], Chikashi Shinagawa[1], Kohei Shinohara[1], So Takamoto[1] and Ju Li[2]; [1]Preferred Networks, Inc., Japan; [2]Massachusetts Institute of Technology, United States

Cathode materials are the key factors of Li-ion batteries and many properties must be considered. Traditionally, it was necessary to narrow down material candidates in advance using domain-specific knowledge as represented by the filtering approach due to the prohibitively expensive density functional theory (DFT) calculations. On the other hand, a fast approximation for DFT calculations such as a neural network potential (NNP) has enabled a large-scale joint optimization of multiple properties for materials discovery rather than the filtering approach.
Our primary aim is to demonstrate that it is possible to successfully draw material candidates with better trade-offs over existing materials in terms of a user-provided set of properties to optimize when we combine multi-objective Bayesian optimization (BO) with an NNP. Furthermore, we investigate search space design that enables more efficient materials discovery. To illustrate an example, some properties of Li-ion battery cathode materials will be optimized.
Our materials search was conducted using our developed universal NNP called PFP, and Optuna, a flexible BO library mainly developed by us that easily realizes multi-objective optimization equipped with rich features such as a web dashboard and a large-scale distributed optimization. At each iteration, Optuna wisely learns to replace the transition metal of existing cathode material, e.g., LiFePO4 and LiCoO2, with other transition metals such as Mn and Ni based on obtained properties, i.e., voltage, capacity per mass, and cost, during an optimization.

Additionally, we tried various different decision (or search) spaces for the metal substitution to study the search efficiency depending on search space designs.
The numerical experiments using PFP and Optuna with 50 GPUs allowed us to find 200+ Pareto solutions out of 10,000 structure evaluations in less than 10 hours. Furthermore, we confirmed that the search space design is a key factor in determining the efficiency of the search. Although the set of properties used in our work is very limited, our results exhibited a possibility that a well-crafted property design enables us to find better material candidates in combination with multi-objective optimization and our search space design.

11:15 AM MT04.06.11
Applications of Multi-Agent AI Systems for Bio-Inspired Materials Discovery *Rachel K. Luu and Markus J. Buehler; Massachusetts Institute of Technology, United States*

A frontier in materials discovery and design is the use of science-focused generative AI tools equipped with interdisciplinary knowledge, analysis, and synthesis capabilities. The field of biological material mechanics stands at the nexus of materials science, biology, and mechanical engineering, boasting a rich legacy of bio-inspired materials studies and discoveries. This interdisciplinary field poses as a unique candidate for exemplifying the potential of integrating AI tools for accelerated materials discovery.

As a first step, we present BioinspiredLLM, an open-source conversational large language model (LLM) finetuned using a corpus of biological materials literature. By harnessing the baseline abilities of a foundational model, we establish a robust method for text/data mining, data distillation, and finetuning using academic literature to develop a specialized model that surpasses the performance and efficiency of existing systems. The finetuned model exhibits strong knowledge recall, reasoning, and hypothesis generation abilities and exists in various form factors of model sizes and efficiency.

Next, we demonstrate the integration of our finetuned model into workflows that interface with various advanced AI systems. In one application, we exhibit how our finetuned language model can interact with image-based diffusion models to generate not only new textual descriptions of bio-inspired materials but also realize them in graphic form. In another application, we show how our finetuned language model can interact with multi-modal agents to extract bio-inspired design motifs from literature and characterize them the through generation of 3D modeling and finite element methods code. The collaboration of multiple agents enriches these workflows, enabling the generation of entirely new designs and insights that are informed by diverse, specialized agents. Multi-agent systems excel because they leverage the collective intelligence and specialized capabilities of individual agents, leading to dynamic coordination in completing complex tasks. These multi-agent frameworks are not only transformative for the next generation of scientific workflows but also highlight the critical need for continued research and development to fully realize their potential.

The impact of this work lies in its potential to reshape materials discovery by facilitating rapid and interdisciplinary creation of novel bio-inspired materials, which could contribute to advancements in diverse fields such as biomedical engineering, sustainable materials, and more.

11:30 AM MT04.06.12
Machine Learning for Predictive Synthesis of Solid-State Materials *Aravind Krishnamoorthy; Texas A&M University, United States*

The main bottleneck in realizing new materials is the discovery of new multi-stage synthesis routes that can be used to fabricate promising materials. Retrosynthesis is widely used in organic chemistry and self-driving *microfluidic laboratories have been demonstrated for high-throughput screening of schedules for liquid-phase molecular and nanoparticle synthesis. There is no comparable scheme for exploring synthesis of condensed phases. As a result, synthesis strategies for promising materials are currently identified by time-consuming trial and error and there are no known predictive schemes for condensed phases and architectures.*

In this talk, I will describe using diffusion models and offline reinforcement learning to predict optimal synthesis strategies for manufacturing functional materials using chemical vapor deposition. These models, trained on molecular dynamics and kinetic Monte Carlo based computational synthesis, learn fabrication parameters including threshold temperatures and chemical potentials for onset of chemical reactions and predicts previously unknown synthesis schedules for heterostructures. The machine-learning driven computational scheme can be extended to predict long-time behavior of reacting systems, far beyond the domain of molecular dynamics simulations, making these predictions directly relevant to experimental synthesis of solid-state materials.

SESSION MT04.07: Generative Models for Inverse Materials Design I

1:30 PM *MT04.07.01
MatterGen—A Generative Model for Inorganic Materials Design *Tian Xie; Microsoft Research, United Kingdom*

The design of functional materials with desired properties is essential in driving technological advances in areas like energy storage, catalysis, and carbon capture. Traditionally, materials design is achieved by screening a large database of known materials and filtering down candidates based on the application. Generative models provide a new paradigm for materials design by directly generating entirely novel materials given desired property constraints. In this talk, we present MatterGen, a generative model that generates stable, diverse inorganic materials across the periodic table and can further be fine-tuned to steer the generation towards a broad range of property constraints. To enable this, we introduce a new diffusion-based generative process that produces crystalline structures by gradually refining atom types, coordinates, and the periodic lattice. We further introduce adapter modules to enable fine-tuning towards any given property constraints with a labeled dataset. Compared to prior generative models, structures produced by MatterGen are more than twice as likely to be novel and stable, and more than 15 times closer to the local energy minimum. After fine-tuning, MatterGen successfully generates stable, novel materials with desired chemistry, symmetry, as well as mechanical, electronic and magnetic properties. Finally, we demonstrate multi-property materials design capabilities by proposing structures that have both high magnetic density and a chemical composition with low supply-chain risk. We believe that the quality of generated materials and the breadth of MatterGen's capabilities represent a major advancement towards creating a universal generative model for materials design.

2:00 PM MT04.07.02
Achieving Desired Crystal Structures and Properties by Gradient-Based Inverse Problem Solving *Akihiro Fujii[1], Anh Khoa Augustin Lu[1], Yoshitaka Ushiku[2] and Satoshi Watanabe[1]; [1]The University of Tokyo, Japan; [2]OMRON SINIC X Corporation, Japan*

In the last decade, machine learning has made significant contributions to material design. Recently, several studies have successfully adapted conditional generative models[1], known for their success in computer vision, to material design by using desired physical properties as conditions. However, conditional generative models may fail to generate materials with the desired properties and cannot measure the properties of the materials they generate. Moreover, there is no guarantee that the generated materials maintain charge neutrality. Furthermore, it is not possible to generate crystal structures that have not been included in the data set.

In this study, we propose a method for optimizing crystal structures towards desired properties using a gradient-based inverse problem-solving approach[2][3] that optimizes inputs (crystal structures) directly through backpropagation. Specifically, we employ a deep learning model to predict the material properties and evaluate the discrepancy between target and predicted properties. We then optimize the crystal vectors, atomic coordinates, and atomic types based on the value of the gradient to achieve the desired physical properties. Optimization is conducted based on the predictions from the model, thereby guaranteeing the properties of candidate materials within the model's accuracy. Furthermore, since atomic types are not directly differentiable, we utilize a method that transforms them into a differentiable atomic distribution for optimization.

This method offers the advantage of adaptively applying various conditions during optimization. For example, when optimizing typical perovskite crystal structures to achieve a specific band gap, it is essential to maintain the charges at sites A, B, and X in a 1:2:-1 ratio, while the angles between crystal vectors should remain at 90 degrees. In this scenario, random perovskite structures are used as the initial configuration. The crystal vectors' lengths, atomic coordinates, and atomic distribution are optimized while the angles between the crystal axes are fixed at 90 degrees. The atomic distribution at each site is composed exclusively of atoms with permissible charges, such as only monovalent cations at site A. Unlike conditional generative models, this method not only readily meets electrical neutrality conditions but also enables the optimization of the crystal structure for desired properties while maintaining the perovskite structure. It is noteworthy that the perovskite structure is preserved without the need for retraining on a dataset composed exclusively of perovskite materials.

We applied our methodology to the perovskite structure to achieve target band gap values of 1.00±0.02 eV and 3.00±0.02 eV. The pre-trained Crystalformer[4] model was used to predict the band gap. This model was trained on the Materials Project dataset, which includes various types of crystal structures in the training set. Our methodology reveals two candidate materials, $¥mathrm{BaCeOS_2}$ and $¥mathrm{CsYbF_2Cl}$, for which the Crystalformer model predicts band gap values of 1.02 eV and 3.02 eV, respectively. Both materials possess perovskite structures and charge neutrality is maintained, showcasing the capabilities of our methodology.

Our method paves the way for practical material design by incorporating specific crystal structures and properties. For instance, our approach allows the design of lead-free perovskite structures with specific band gaps without requiring extensive retraining or fine-tuning of the model. It ensures that the final materials not only meet the desired physical characteristics but also retain structural integrity and charge neutrality.

Discovering Highly Anisotropic Dielectric Crystals Alex M. Ganose; Imperial College London, United Kingdom

Anisotropy in crystals plays a pivotal role in many technological applications. For example, anisotropic electronic and thermal transport are thought to be beneficial for thermoelectric applications, while anisotropic mechanical properties are of interest for emerging metamaterials, and anisotropic dielectric materials have been suggested as a novel platform for dark matter detection. Understanding and tailoring anisotropy in crystals is therefore essential for the design of next-generation functional materials. To date, however, most data-driven approaches have focused on the prediction of scalar crystal properties, such as the spherically averaged dielectric tensor or the bulk and shear elastic moduli. Here, we adopt the latest approaches in equivariant graph neural networks to develop a model that can predict the full dielectric tensor of crystals. Our model, trained on the Materials Project *dataset of c.a.~6,700 dielectric tensors, achieves state-of-the-art accuracy in scalar dielectric prediction in addition to capturing the directional response. We showcase the performance of the model by discovering crystals with almost isotropic connectivity but highly anisotropic dielectric tensors, thereby broadening our knowledge of the structure-property relationships in dielectric crystals.*

Metal-Organic Framework Stability in Water and Harsh Environments from Data-Driven Models Trained on the Diverse WS24 Data Set *Gianmarco Terrones, Shih-Peng Huang, Matthew P. Rivera, Shuwen Yue, Alondra Hernandez and Heather J. Kulik; Massachusetts Institute of Technology, United States*

Metal-organic frameworks (MOFs) are porous materials with applications in gas separations and catalysis, but a lack of water stability often limits their practical use given the ubiquity of water in air and the environment. Consequently, it is useful to predict whether a MOF is water-stable before investing time and resources into synthesis. Existing heuristics for designing water-stable MOFs lack generality and artificially limit the diversity of explored chemistry due to narrowly defined criteria. Machine learning (ML) models offer the promise to improve generality of predictions but require diverse experimental MOF stability data to be trained. In an improvement on previous efforts, we enlarge the available training data for MOF water stability prediction by over 400%, adding 911 MOFs with water stability labels assigned through semi-automated manuscript analysis to curate the new data set WS24. The additional data is shown to improve ML model performance (test ROC-AUC > 0.8) over diverse chemistry for the prediction of both water stability and stability in harsher acidic conditions. We illustrate how the expanded data set and models can be used with previously developed activation stability models to carry out genetic algorithms to quickly screen ~10,000 MOFs from a space of hundreds of thousands for candidates with multivariate stability (i.e., for activation, in water, and in acid). Model analysis and genetic algorithm results uncover metal- and geometry-specific design rules for robust MOFs. The data set and ML models developed in this work, which we disseminate through an easy-to-use web interface, are expected to contribute toward the accelerated discovery of novel, water-stable MOFs for applications such as direct air gas capture and water treatment.

MT04.09.02

Data-driven Early Cycle Prediction Using Large Language Model and Graph Mining for Lithium Metal Battery
Jun Hee Woo, Jaewoong Lee, Steve Park and Jihan Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Lithium metal batteries (LMBs) represent a promising next-generation energy storage technology, characterized by their high capacity, low density lithium metal anodes, and low electric potential. Despite these advantages, *challenges such as low Coulombic efficiency (CE) and limited lifespan due to undesirable side reactions on the solid-electrolyte interphase (SEI) and uneven lithium stripping/plating persist. Addressing these issues necessitates the development of novel materials for battery components.*

Battery performance is heavily influenced by the structure and composition of materials, such as high nickel cathodes, high stability electrolytes, and high entropy separators. While understanding individual material characteristics is important, comprehensively understanding their interactions is essential for optimizing battery performance, lifespan, and stability. To fully harness these innovative battery technologies, a data-driven approach to developing materials based on a holistic understanding of the entire battery cell is necessary.

This like development tackles two critical challenges: (1) how to efficiently collect high-quality data on battery materials and performance, and (2) how to effectively gather information on various material combinations. In this study, we present a data-driven approach to accelerate the discovery and optimization of materials for LMBs. We developed a comprehensive dataset by integrating extensive battery material information with performance metrics, utilizing a large language model (LLM) and the Material Graph Digitizer (MatGD) tool. The LLM, an advanced artificial intelligence (AI) system trained in natural language processing, extracted high-accuracy data on material structure and composition from scientific literature, experimentally validated, through prompt engineering and few-shot learning. Concurrently, MatGD, a graph mining tool, extracted quantitative data from cycle performance and electrochemical impedance spectroscopy (EIS) graphs, consolidating this information into a unified dataset.

This dataset enable the training of supervised machine learning models to predict and design materials with high capacity and long-term lifespan for LMBs. Our models identify material combinations that significantly enhance battery cycle life and stability. The promising LMB compositions discovered through this approach are subsequently validated through experimental testing.

Our research proposes a novel data-driven methodology that not only enhances the understanding of material interactions within battery cells but also expedites the development of high-performance LMBs, potentially revolutionizing the landscape of energy storage technologies.

MT04.09.03

Accelerating the Search for New Solid Electrolytes—Exploring Vast Chemical Space with Machine Learning-Enabled Computational Calculations *Dong Hyeon Mok, Jongseung Kim and Seoin Back; Sogang University, Korea (the Republic of)*

Advancements in all-solid-state lithium batteries, crucial for enhancing safety and energy density, depend heavily on the discovery of new solid electrolytes (SEs). The practical application of SEs is often limited by their low ionic conductivities and chemical instabilities. In response, we report a machine learning (ML) assisted high-throughput virtual screening (HTVS) methodology to identify new SE materials. This method broadens the chemical space for potential SE materials by substituting elements in known structures, generating a vast number of candidate materials. These candidates were initially screened using ML models trained on existing materials databases to predict properties such as formation energy, electrochemical stability window, and Li-ion conductivity. By choosing ML models that utilize composition or modified X-ray diffraction patterns, which do not require structure optimization, we efficiently narrowed down the list of potential SE materials from the vast chemical space. A select number of candidate materials derived from this screening process were subsequently validated through density functional theory (DFT) calculations and Ab-initio molecular dynamics (AIMD) simulations to confirm their stability and conductive properties. The results of the validation identified several promising oxysulfide SE materials that *exhibit both high Li-ion conductivity and enhanced stability, which are required for effective SEs. In summary, we leveraged an ML-assisted HTVS strategy to narrow down the vast chemical space and highlighted the capability of this strategy to identify novel and promising SE materials with reduced computational costs.*

MT04.09.04

Solid State Li-Ion Conductor Discovery Enabled by Graph Based Machine Learning *Mingze Yao, Changwen Xu and Venkat Viswanathan; University of Michigan-Ann Arbor, United States*

Finding a solid state Li-ion conductor with high ionic conductivity is critical for the development of all-solid-state batteries. Graph based machine learning with structrual information as input has been applied to predict many materials properties with high accuracy. However, Li ionic conductivity prediction with graph based machine learning is less seen in the literature. The dataset for Li ionic conductivity usually contains no structural information, thus graph based machine learning algorithms which requires structrual information cannot be applied.

Finding a solid state lithium(Li)-ion conductor with high ionic conductivity is critical for the development of all-solid-state batteries. A promising route to accelerate the materials discovery process is to build machine learning models that predict the Li ionic conductivity. However, graph based machine learning models, which reach high accuracy predictions for many materials properties, are less used for Li ionic conductivity prediction due to the lack of structural information in the Li ionic conductivity dataset.
We propose to overcome the lack of structural information by constructing representative structures from input stoichiometry of the solid state Li-ion conductors. The stoichiometry of the ionic conductor is first matched with the most similar structure in the materials project database according to the Element mover distance and Pettifor scale. Element swapping, atom insertion and deletion are performed subsequently to match the stoichiometry of the representative structure to that of the ionic conductor. With the above structure generation method, we reconstructed an open-sourced Li ionic-conductivity dataset, resulting in 916 data points with representative structures. We used the dataset to train a Crystal Graph Convolutional Neural Network and achieved mean absolute error of 0.8 in $\log_{10}$*(mS/cm) scale on test set. Using the trained machine learning model, we accurately predicted the ionic conductivity of amorphous Li-ion conductors that are reported in recent literatures and are outside the training set.*

MT04.09.05

Towards Guided Predictions of Synthesis—Representations, Modeling and Disorder *Steven B. Torrisi; Toyota Research Institute, United States*

Computational materials discovery campaigns are now at a scale where it is commonplace to produce many more candidates than could be experimentally verified, even with the advantage of automated laboratories. This motivates the development of tools which let us leverage computational predictions to improve the synthesis success rate by promoting or ruling out particular candidates. I will share motivating case studies from ongoing work that has occurred both internal to Toyota Research Institute and its consortium, including exploring the role of disorder, the study of phase transformations within solid-state synthesis, and finding synthesizability measures. Relevant methodologies will include DFT, the interface of DFT and experiment, and high-throughput processing of data.

MT04.09.06

Using Dynasor 2.0 for Connecting Simulation to Experiment Through Correlation Functions *Erik Fransson, Esmée Berger, Fredrik Eriksson, Eric Lindgren and Paul Erhart; Chalmers University of Technology, Sweden*

The dynamic properties of materials are fundamental to their thermodynamic, kinetic, optical, and transport behaviors. The dynamics are commonly probed by neutron or X-ray scattering experiments, which provide quantitative information in the form of dynamic and static structure factors. Structure factors can also be calculated from atomic-scale modeling via molecular dynamics (MD) simulations, offering a quantitative bridge between experiment and atomic-scale modeling.

We present the latest iteration of the dynasor package, a flexible and efficient tool for calculating correlation functions, such as static and dynamic structure factors, as well as related correlation functions from MD simulations. The package is user-friendly written in python and can thus easily be integrated into workflows for analyzing dynamics, simulating experimental spectra, and understanding phonon dynamics. Analyzing correlation functions provides detailed insights into the dynamics of a system without the need for perturbative methods. Additionally, this allows for the direct prediction of experimental spectra by weighting the functions with cross sections (or form factors) of neutrons, X-rays, or electrons. We demonstrate how dynasor can be used to analyze dynamics in various systems from MD simulations based on machine-learned potentials. For example, in the Ni-Al system, we analyze how the dynamics change between the ordered and disordered phases. Additionally, we investigate the quasi-elastic neutron scattering (QENS) spectra of the inorganic halide perovskite CsPbI3, explaining low-frequency intensity features that arise due to soft, over-damped phonon modes. These case studies highlight dynasor's capability to provide detailed insights into the dynamic behavior of materials, and how it can be used to help interpret experimental observations.

MT04.09.07

First-Principles Calculations and Machine Learning Accelerated Superionic Conductivity Predictions for Novel Anti-Fluorite Solid Electrolytes *Meiqi Zhang, Masao Arai, YenJu Wu, Yukinori Koyama and Yibin Xu; National Institute for Materials Science, Japan*

The development of solid-state electrolytes (SSEs) with high ionic conductivity is pivotal for the advancement of next-generation energy storage technologies, particularly solid-state batteries. In a previous study, we leveraged machine learning (ML) techniques to predict the ionic conductivities of nearly 8,000 known lithium-containing compounds, identifying approximately 30 promising candidates for lithium superionic conduction. Notably, these candidates encompass not only well-established crystal structure types for SSEs (e.g., LISICON, garnet, NASICON, perovskite) but also several anti-fluorite structures, a class of materials not traditionally associated with high ionic conductivity.

The primary objective of the present research is to rigorously assess the ionic conductivity of these candidate materials through first-principles calculations. While ab initio molecular dynamics (AIMD) simulations have become the gold standard for calculating ionic conductivity, their computational intensity and time demands pose significant challenges when evaluating extensive candidate lists generated by data-driven material discovery approaches.

To overcome this bottleneck, we have adopted machine learning force fields (MLFFs) to accelerate the prediction of ionic conductivity. MLFFs offer the potential to achieve reliable result comparable to AIMD while substantially reducing computational overhead. By utilizing the on-the-fly AIMD training method within the Vienna Ab initio Simulation Package (VASP), we have efficiently generated MLFFs tailored for predicting the ionic conductivity of our candidate materials.

The results of our investigation indicate that the novel anti-fluorite structures identified in our candidate shortlist *exhibit superionic conductivity behavior around 600-700 K. This contrasts with conventional anti-fluorite compounds such as Li_2S and Li_2Se, which exhibit superionic conductivity at temperatures above 1000 K. This observation, derived from our MLFF-based theoretical calculations, not only validates the efficacy of our data-driven material prediction methodology but also opens up new avenues for the design and development of SSEs. By demonstrating the potential of anti-fluorite structures for achieving high ionic conductivity at or near room temperature, our research contributes to the ongoing quest for materials that can enable safe, high-performance solid-state batteries.*

Furthermore, the successful integration of MLFFs into our computational workflow highlights the synergistic potential of combining machine learning and first-principles calculations for accelerated material discovery. This approach holds promise for expediting the identification and optimization of materials with tailored properties across a wide range of technological applications. Future work will focus on refining our workflow, exploring the broader chemical space of those compounds we validated, and experimentally validating the predicted ionic conductivities of our most promising candidates. This work was supported by JST Grant Number JPMJPF2016.

Accelerating Advanced Material Design Through Versatile Atomistic Scale AI Simulator MATLANTIS

Yuji Hakozaki, Tasuku Onodera and Takashi Kojima; ENEOS Corporation, Japan

In recent years, materials informatics (MI) has attracted significant attention for an efficient material design. Atomistic simulations, such as the density functional theory (DFT) and molecular dynamics (MD) methods, have been recognized as powerful tools in MI to explore innovative materials. For organic materials, e.g., rubbery materials and lubricant, microscopic properties at an interface between organic additives and inorganic materials significantly contribute to macroscopic material properties. However, there are several challenges when applying the DFT and the MD to organic-inorganic complex interfaces. Generally, the computationally expensive DFT calculation is not suitable for rapid materials exploration. On the other hand, the MD calculation runs much faster than the DFT, making it suitable for large-scale systems. However, the MD calculation usually requires empirical force fields, which are well-validated for a specific interfacial system. Empirical force fields require elaborate and rigid validation specifically for materials systems of our interest, resulting in the lack of versatility towards other systems. One of the solutions for these issues is to use a neural network potential. Recently, we have developed "MATLANTIS®" software, which implements a versatile neural network potential called PreFerred Potential (PFP). The PFP is well-trained using large DFT datasets including not only energetically stable crystals and molecules, but also surfaces, disordered structures, and those energetically unstable. Thus, the variety of the training data realizes the versality of PFP. Because of its high-speed calculation and the versatility, MATLANITS offers a powerful tool to achieve the materials discovery of complex systems that requires massive iterative calculations, as represented by organic-inorganic interfaces. In our presentation, two case studies of MATLANTIS are presented.
The first case is an exploration of adsorption structures of coupling agents in a silica filled rubber. Silica is often compounded into a polymeric material in order to improve their mechanical properties such as an elastic modulus and a toughness compared to those of a pure rubber material. In the silica-filled rubber, a tough interface is formed between the silica phase and the polymer phase by the silane coupling agents, which have reaction sites in both the silica and the polymer chain. To measure the properties of the interface, deformation simulations of the coupling agent connected to the silica surface were performed by MATLANTIS for a system consisting of the silica slab, the coupling agent, and the polymers.
The second is to elucidate an adsorption mechanism of oiliness additives in lubricant. Lubricant basically consists of base oil and additives. The composition and the structure of the reaction film, formed by the chemical reaction of additives used in lubricant on metal surfaces, contribute significantly to the lubricant performance. MATLANTIS can elucidate that the adsorption of additives on metal surfaces is influenced by coarseness and density of the oil

film, which results from differences in the structure of the base oil. Furthermore, PFP-based MD simulations on MATLANTIS extracts some important features from liquid structures in the oil film at the metal interface under the high pressure. The extracted features were then used for the additive search in our materials discovery processes. Finally, our recent challenges will be raised to develop MATLANTIS into a more versatile platform for materials scientists. One is to develop a new machine-learning potential called LightPFP which is computationally less expensive than original PFP and enables larger-scale calculations including 10^5-10^6 atoms. Another topic is mesoscale dissipative particle dynamics simulations based on PFP.

Prediction of Thermal Conductivity and Fluid Permeability of Porous Materials by Image-Based Simulations Using Deep Generative Model-Created Three-Dimensional Images *Itsuki Kato, Asuka Suzuki, Naoki Takata and Makoto Kobashi; Nagoya University, Japan*

Open-cell porous materials are used as filters, catalysts, and heat exchangers because of their high specific surface area and excellent fluid permeability. Various properties of open-pore porous materials depend on the three-dimensional pore structure. Therefore, it is essential to obtain three-dimensional images to understand the structures dominating the properties. X-ray computed tomography (CT) and serial sectioning are common methods to acquire three-dimensional images. X-ray CT can obtain three-dimensional images in less than 1 hour, but the resolution is limited in general industrial CT apparatuses. In the serial sectioning, the sample is ground and observed repeatedly with an optical microscope or scanning electron microscope. While relatively high resolution can be achieved, the time required to obtain a three-dimensional image is long.

A generative adversarial network (GAN) is one of the deep generative models that create images similar to real images. Recently, it has been shown that three-dimensional images can be efficiently constructed by using a deep generative model called SliceGAN. This model enables the rapid creation of three-dimensional images by inputting one cross-sectional image of isotropic material or three cross-sectional images of anisotropic materials as training data. This model also contributes to creating high-resolution three-dimensional images if the cross-sectional images are acquired in a high resolution. However, it remains unclear whether the SliceGAN can reproduce the morphology (pore and solid parts) and related properties (thermal conductivity, fluid permeability, elastic modulus, and so on) of porous materials.

In this study, we fabricated open-cell porous aluminum (Al) with porosities of 65–80% and an average pore size of approximately 400 μm by the space holder method using sodium chloride (NaCl) particles. The three-dimensional image of porous Al was taken by X-ray CT. In addition, the three-dimensional image was also constructed by SliceGAN using one cross-sectional X-ray CT image of porous Al. The image-based simulations to calculate the thermal conductivity and fluid permeability of porous Al were performed using the obtained three-dimensional images. Consistency of the porosity, pore size, and tortuosity between X-ray CT and SliceGAN images was also compared. The usefulness of SliceGAN for generating three-dimensional images of porous materials and predicting their properties was clarified by comparing the simulation results using X-ray CT images with those using SliceGAN images.

When SliceGAN was trained, the input image was divided into small segments with 64 x 64 pixels. When the input image had a large pixel number, the representative structure of the porous Al was not included in the segments. In contrast, when the input image had a small pixel number, the input image did not reflect the structure of porous Al because of low resolution. Therefore, the pixel number of the input image was adjusted to a reasonable number. In this study, the number of pixels in a cross-sectional image was adjusted to include one or more cells in the segment. Under these conditions, SliceGAN could construct three-dimensional images similar to X-ray CT images. The thermal conductivity calculated using SliceGAN images was almost consistent with the thermal conductivity calculated using X-ray CT images and followed empirical power law in which the thermal conductivity is proportional to a power of the relative density. The fluid permeability calculated using SliceGAN images was also in *good agreement with the permeability calculated using X-ray CT images. These consistencies were attributed to the consistency of related pore structures (porosity, pore size, and tortuosity) between SliceGAN and X-ray CT images. Thus, SliceGAN could generate three-dimensional images reflecting the characteristics of real open-cell materials by adequately adjusting the input images.*

Wet Hydrofluoric Acid Etching Reaction Mechanism Analysis of Silicon Oxide Using GRRM with Universal Neural Network Potential *Kota Matsumoto, Marina Takahashi, Makoto Sato and Yusuke Asano; Preferred Computational Chemistry, Inc., Japan*

In semiconductor manufacturing technology that is advancing towards miniaturization, the improvement of wet etching process reactions at the atomic level, which utilizes dilute hydrofluoric (HF) acid solution to remove oxides from substrate surfaces, has become increasingly important. Although there has been active research aimed at understanding at the atomic level, it has been difficult to handle the formation and cleavage of bonds in molecular dynamics simulations, and due to the high computational cost, first-principle calculations have struggled with the analysis of extensive phenomena. Despite these difficulties, several studies have been conducted on the formation process of SiF4.

In the case of MD simulation, studies have been conducted on slab models using ReaxFF[1]. In the case of DFT simulations, cluster models[2] and slab models[3][4] have been investigated. However, these studies have been conducted under anhydrous conditions or in the presence of NH4, and the elementary reactions in the presence of surrounding H2O molecules, which are closer to the wet etching environment, have not yet been reported.

Recently, the development of neural network potentials(NNP) has been actively pursued, enabling high-speed examination of reaction pathways for systems with hundreds of atoms at the DFT level. The Preferred Potential (PFP)[5] is a one of the NNP with the unique feature of universality[1]. PFP is trained on large DFT data sets, including not only stable crystals and molecules, but also surfaces, adsorption and disordered structures. As a result, it is applicable to predict reaction mechanisms such as surface reactions in multi-component systems.

While PFP allows for a rapid examination of reaction pathways, manual examination is difficult due to the need to consider processes important to the reaction but not fluorination, such as molecule movement and proton relay. Therefore, we have conducted a comprehensive study of reactions using the SC-AFIR method[6][7], which enables the automatic search for changes in the relative position of molecules and intermolecular reaction pathways.

In this study, we report the results of our attempt at a comprehensive reaction analysis of wet etching, using PFP implemented in Matlantis^{TM} *and the SC-AFIR method implemented in GRRM20. As an example, we report the comparison results of reaction pathways considering the stabilization of intermediates by surrounding HF and* H_2O *in the four-step fluorination reaction of Si.*

MT04.09.11

Investigation of Bayesian Optimization and Generative Model for Crystal Structure Prediction of Molecular Crystals *Takuya Taniguchi; Waseda University, Japan*

Crystal structure prediction (CSP) of molecular crystals remains a significant challenge in materials science and

pharmaceutical research. The ability to accurately forecast how molecules arrange themselves in the solid state is crucial for understanding and manipulating the properties of crystalline materials. This ability is important and has many practical applications. It can help us create new medicines and improve how they are made. It also allows us to design new materials with special properties for various uses.
CSP consists of two parts: structure generation and local structure optimization. Structure generation requires exploring a vast configuration space, and efforts to improve efficiency have been made through evolutionary algorithms and Bayesian optimization. In local structure optimization, DFT calculations are computationally expensive, so neural network potentials are being utilized as a method to maintain computational accuracy while reducing computational cost. Furthermore, in recent years, machine learning architectures have been developed to generate relaxed structures from unrelaxed ones, offering the potential to shorten iterative steps of structure optimization. However, in many cases, these have been verified for inorganic crystals, and their effectiveness in CSP for molecular crystals remains unclear.
This study verified the effectiveness of machine learning techniques in CSP for molecular crystals. The neural network potential provided by Matlantis accurately predicted the potential energy of molecular crystals and yielded the most stable structures that matched experimentally determined structures for several crystals. However, when using a model to generate relaxed structures from unrelaxed ones, the number of steps required for structure optimization increased. This is likely because, even if the coordinates and lattice constants become closer to the relaxed structure on average, they are not structures along the original trajectory, leading to entrapment in different local minima. In the conference presentation, we plan to include results that examine the effects of Bayesian optimization in structure exploration.

Investigation of Machine Learning Force Fields for Biomolecular Systems Using Fragment Molecular Orbital Method Data

Hiromu Matsumoto[1], Ryosuke Kita[1], Chiduru Watanabe[2], Masateru Ohta[2], Naoki Tanimura[3], Koji Okuwaki[4], Yu-Shi Tian[5], Daisuke Takaya[5], Mitsunori Ikeguchi[2,6], Kaori Fukuzawa[5], Teruki Honma[2], Tsuyohiko Fujigaya[1] and Koichiro Kato[1]; [1]Kyushu University, Japan; [2]RIKEN, Japan; [3]Mizuho Research & Technologies, Japan; [4]JSOL Corporation, Japan; [5]Osaka University, Japan; [6]Yokohama City University, Japan

Introduction

In molecular simulations for drug discovery, achieving both high accuracy and low computational cost is crucial. Unlike traditional molecular force fields and quantum mechanical (QM) calculations, machine learning force fields (MLFFs) are expected to meet these demands effectively. Previous approaches to developing MLFFs have relied on QM-based datasets derived from conventional density functional theory (DFT) or ab initio molecular orbital methods. However, the significant computational costs associated with these methods, particularly for large systems such as biomolecules, have considerably restricted the scope of MLFF research in drug discovery. We considered that the Fragment Molecular Orbital (FMO) method1), which offers efficient QM calculations for entire biomolecular systems, could address this issue. In this study, we investigate whether FMO data can be effectively used to construct MLFFs. Furthermore, we explore the use of the FMO Database (FMODB) to enhance MLFF accuracy through transfer learning.

Methods

To evaluate the utility of FMO data in constructing MLFFs, TrpCage, a small protein consisting of 20 residues, was selected as the model system. Additionally, the effectiveness of transfer learning to improve the accuracy of MLFFs was investigated by utilizing the FMODB, a comprehensive public database of FMO calculation results.
For the MLFF training dataset, diverse configurations of TrpCage were sampled through molecular dynamics (MD) simulations. The potential energies and forces acting on each atom for each structure were computed using the FMO method. MD simulations of the TrpCage NMR structure (PDBID: 1L2Y) in water were conducted using

GROMACS software with the Amber ff14SB force field and the TIP3P water model. A total of 5,000 structures were obtained from these simulations, sampled every 1 ns over 50 runs of 100 ns each. Subsequent FMO calculations (FMO2-MP2/6-31G with energy gradient) were performed to evaluate the energy and forces on each structure using the ABINIT-MP program on the Fugaku supercomputer (hp230131). The dataset was divided into training, validation, and test sets in a ratio of 8:1:1 ratio. The MLFF was constructed based on the High Dimensional Neural Network Potential (HDNNP) framework proposed by Behler and Parrinello*$^{2)}$.
Additionally, a pre-trained model for transfer learning was developed using 15,454 energy records from FMODB, including atomic species C, H, N, O, S, F, and Cl.

Results
Without Transfer Learning
The initial correlation coefficient (R) values for the prediction of TrpCage's energy and forces without transfer learning were 0.58 and 0.70, respectively. These results indicated that the constructed MLFF could learn the relationship between structure and force/energy from FMO data, but the prediction accuracy remained moderate.
With Transfer Learning
The prediction results for TrpCage using transfer learning from FMODB data showed improvements. The R values for energy and force predictions increased to 0.61 and 0.73, respectively. These improvements demonstrated the effectiveness of using large scale pre-training datasets to improve the accuracy of MLFFs.

Combinational Data-Driven Innovation of Ecofriendly Transparent Solar Heat Control Coating for Green Buildings

Weibin Zhang; The Hong Kong University of Science and Technology, China

Transparent solar heat control (TSHC) coating is an attractive option for efficient green building to minimize energy consumption and improve indoor living comfort owing to their optical properties of modulating sunlight. However, the complete blocking of the entire NIR spectrum has not yet been realized by the coating technology, and the coating development process remains time-consuming and labor-intensive.
Artificial intelligence technologies open a perspective for efficient TSHC coating development at low cost by accomplishing several basic tasks: predicting the transmittance spectrum of unknown materials based on previous observations, predicting the solar heat control performance, and implementing a feedback from performance to coating preparation. To effectively improve the performance of solar heat control coating for green building, we propose a data-driven combinatory strategy to develop the coating composed of multiple nanoparticles for broadband NIR blocking while maintaining high visible transmittance.
Three types of nanoparticles, namely cesium tungsten oxide (CWO), antinomy tin oxide (ATO), and indium tin oxide (ITO), are chosen to prepare a TSHC coating aiming for an ideal performance of 70% visible transmittance and 100% NIR blocking. The neural network model, trained by 108 real experimental datasets, is capable of precisely predicting the transmittance spectrum of the coating based on the concentrations of multiple nanoparticles and

inversely designing nanoparticle concentrations based on the desired transmittance spectrum in a sample space of 726 samples, thus significantly reducing the development cost and time. The results demonstrate that the optimized TSHC coating has a visible light transmittance of 70% and a near-infrared blocking rate of 96%. Its light-to-solar gain reaches as high as 1.4, indicating strong spectral selectivity, which is the highest value reported for TSHC coatings to date.

Exploring High Entropy Alloys as Nanoparticle Catalysts by Combining Monte Carlo Sampling with Machine Learning

Koki Otsuka[1], Koji Shimizu[2], Anh Khoa Augustin Lu[1] and Satoshi Watanabe[1]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

High-entropy alloys (HEAs), primarily considered for use as structural materials, are now emerging as promising catalytic materials due to synergistic effects among different elements leading to high catalytic activity [1].

Materials with high functionality are expected to exist in the vast compositional space of multi-element systems, thus efficient composition optimization methods are needed. Previous studies have tackled this challenge using methodologies combining first-principles calculation, machine learning, and optimization algorithms. However, optimization using the reaction activity as the objective function led to the discovery of binary systems rather than HEAs. Moreover, the assumption of complete mixing led to discrepancies between experimental value and predicted value in the compositions that actually cause phase separation [2].

To address these shortcomings, we have worked on the development of a more practical composition optimization method for HEAs. In this work, thermodynamic stability and activity for hydrogen evolution reaction (HER) were used as the objective functions for optimization.

First, the total energies and the hydrogen adsorption energies of octahedral cluster models were computed by density functional theory (DFT) calculations. Since actual catalysts are often used as nanoparticles, octahedrons containing edges and terraces were used as the structural models instead of slabs. Nine transition metals were used as candidate elements for composition optimization. Then, based on the DFT data, a machine learning (ML) model was constructed to predict the total energies of clusters with arbitrary atomic arrangements. Using this model, a program which performs Monte Carlo sampling was created to search for stable atomic configurations and predict the physical properties, taking into account elemental segregation. Composition optimization was then performed using free energy calculated by thermodynamic integration as the objective function. Another ML model was then constructed to predict the hydrogen adsorption energy on the nanoclusters. Multiple explanatory variables and regression methods were compared. Finally, composition optimization was conducted for HER activity calculated by the ML model.

For the cluster energy prediction, it was found that the bond centric model, proposed for alloy nanoparticles [3], had higher flexibility than the neural network potential. For the free energy optimization using this model, the covariance matrix adaptation evolution strategy (CMA-ES) was found to be efficient, and an optimal composition containing seven elements was identified. Unlike previous studies, by using the distributions of adsorption energies for evaluation, four-element systems were found to have a higher HER activity than two-element ones. Furthermore, multi-objective Bayesian optimization for stability and reaction activity was performed to narrow down promising compositions.

Our newly developed methodology is robust and enables exploration of high-entropy alloys towards high-performance nanoparticle catalysts.

This research was supported by JST e-ASIA Joint Research Program JPMJSC21E2.

Methods for Developing Specialized Generative AI Tools for Scientific Research in Materials Science and Engineering *Rachel K. Luu and Markus J. Buehler; Massachusetts Institute of Technology, United States*

Generative AI tools, such as large language models (LLMs), have demonstrated transformative abilities in generating content across diverse contexts, while exhibiting broad expertise and analytical rigor. By leveraging the extensive knowledge embedded in research literature, we explore the feasibility of finetuning foundational LLMs for application in scientific workflows. This work details the method behind developing scientific datasets and scientifically finetuned AI models, through our example model, BioinspiredLLM, a conversational LLM finetuned on a literature corpus of biological and bio-inspired materials.

In the initial step of our process, we employ text/data mining techniques to obtain a comprehensive collection of full-text articles in the field of structural biological materials, yielding over a thousand articles. These articles, initially in PDF format, undergo pre-processing using optical character recognition techniques to extract textual content. We then develop a data distillation technique to further process and clean the text, removing extraneous information while preserving the core knowledge and concepts. With this pre-processing step, we observe enhanced conversational performance in the final finetuned models.

We then finetune a variety of open-source foundational large language models using a low-rank adaptation strategy, introducing our specialized dataset while retaining the pre-trained knowledge of the models. We evaluate the finetuned models using custom benchmarks, demonstrating improved performance in tasks such as knowledge recall, hypothesis generation, and synthesis within the specialized domain. Notably, integration with Retrieval-Augmented Generation (RAG) techniques further enhance these capabilities. Additionally, we show that model efficiency and usability can be improved through quantization methods, enabling faster training and inference.

Finally, we discuss the implications of scientifically finetuned AI models and their integration into robust workflows for materials discovery, including multi-agent systems. The impact of this work is the demonstration of consistent performance improvements across various model types, suggesting that this finetuning method can be feasibly applied to a wide range of specialized scientific fields.

MT04.09.16
ChIMES Machine-Learned Interatomic Potential for Hydrogen Phase Diagram Prediction *Safa AlZaim and Rebecca K. Lindsey; University of Michigan–Ann Arbor, United States*

Classical force fields, while computationally inexpensive, are often inadequate for materials discovery because their functional forms do not suitably describe conditions beyond equilibrium. Complex classical models are also difficult to fit, due to their non-linear form. Quantum methods, such as density functional theory (DFT), can provide an accurate model towards design and discovery, but in the case of large phase space or noncrystalline materials, can be prohibitively computationally expensive . Machine learning can bridge this gap; our machine-learned interatomic potential (MLIAP), ChIMES[1] can achieve quantum level accuracy, with significantly improved computational efficiency.

ChIMES is a physics-informed MLIAP, which describes system energy through an explicitly many-body expansion of fully-connected cluster graphs. It uses Chebyshev polynomials as the basis, yielding a parametrically linear *model that can be rapidly generated and has the unique feature of being explicitly chemically extensible Here we highlight that ChIMES can model hydrogen in the region between 0 and 100 GPa, for 300-10,000 K. Understanding this region is crucial for designing and discovering materials that undergo shock, and are subject to extreme conditions. Yet we know very little about the corresponding hydrogen phase diagram due to both experimental and computational limitations. Experimentally, techniques used to drive materials to the relevant conditions preclude measuring temperature and characterizing structural and chemical transformations.*[2] *In this case study, regularization was through the Lasso algorithm, and penalty functions were used to tune the distance of interatomic interactions. The polynomial order was also tuned. Moreover, ChIMES has the capacity for active learning* [3]*, so that the model improves iteratively. Active learning makes materials discovery a more targeted approach: ChIMES can learn how to improve the training database. The broader goal is to transfer this honed model to any C,H,O,N system using ChIMES.*

The ability of ChIMES to simulate overtimes beyond the DFT simulation time is key to understanding phase changes, especially those mediated by chemistry. The ChIMES algorithm maintains force, energy and stress permutational, translational and rotational invariance, enabling facile thermodynamic analysis. For hydrogen, simulating trajectories for the unknown region of this phase diagram is useful for material discovery. Under high enough temperature and pressure, hydrogen can dissociate. This chemistry dictates whether spin polarization should be included in calculations. However, the loci for this transition was not known a priori. Hence, ChIMES enabled the exploration and discovery of this transition.

Ultimately, ChIMES can serve as a key enabling tool for increasing materials discovery workflow efficiency and accuracy. In this case, rather than modeling hydrogen in conventional quantum methods by assembling a collection of DFT trajectories that likely will not cover the region's phase diagram, the ChIMES MLIAP allows exploration of states beyond the training set.

Discovery of Surface Reconstructions via Universal Machine Learning Interatomic Potentials *Ardavan Mehdizadeh and Peter Schindler; Northeastern University, United States*

The atomistic structures of material surfaces play a critical role in heterogeneous catalysis, corrosion, and energy storage [1]. Atoms near the surface of bulk crystalline materials exhibit dangling bonds and a different coordination environment compared to their bulk counterparts. The surface orientation and the atomistic relaxation of the surface atoms determine the final structure of the stable surface and its chemical, mechanical, and electronic properties. In some cases, significant rearrangements of surface atoms, referred to as surface reconstructions, lead to even more stable surfaces than the relaxed, idealized Miller index surface [2]. Surface reconstruction plays an essential role in the identification of the most stable surface and is therefore affects various applications where surfaces and their interfaces play a critical role, such as batteries, fuel cells, and semiconductor devices [3]. It also impacts medical technologies by enhancing the corrosion and wear resistance properties of coated implants [4]. Density Functional Theory (DFT) is commonly utilized for the investigation of surface reconstructions. However, the vast space of possible surface atom arrangements that need to be considered for surface reconstruction discovery makes DFT too computationally expensive. The objective of this study is to overcome these limitations by utilizing universal machine learning interatomic potentials (UIP) in a Monte Carlo framework to facilitate the *discovery of stable surface reconstructions. Recent advancements in UIPs have demonstrated exceptional performance in various computational materials science problems, including issues closely related to surface reconstruction such as catalysis, materials adsorption, and adhesion [5]. However, while UIPs trained on bulk structures, like MACE [6] and M3GNet [7], have shown to accurately predict bulk properties, they often struggle with surface properties such as the surface energy [8]. In our proposed framework, we employ a Monte Carlo algorithm to sample surface reconstructions efficiently [9] and evaluate the atomistically relaxed surface structure at each sampling step using the graph-based EquiformerV2 model that was trained on the OC20 dataset [10]. We show that the pre-trained EquiformerV2 potential performs better on surface energy predictions compared to MACE and M3GNet. Further, we benchmark our workflow's ability to discover known surface reconstructions such as GaN (0001), Si(111) and SrTiO3 (001). By leveraging this advanced computational workflow, we aim to enhance the predictive accuracy and efficiency of surface reconstruction discovery, ultimately contributing to the development of materials with optimized surface properties.*

Integration of Coarse-Grained Simulation and Topological Data Analysis to Advance Mesostructure Analysis of CO_2 Separation Membrane Materials

Kohei Yamane, Tsuyohiko Fujigaya and Koichiro Kato; Kyushu University, Japan

In recent years, the use of data science in materials research and development has been actively promoted. However, its application to polymeric materials has been limited to predicting properties influenced by low hierarchical chemical structures, such as monomer structure. The physical properties of many polymeric materials depend on their mesostructures, which presents a significant challenge in accurate prediction. Predicting mesostructural properties requires machine-readable quantification of mesostructural features. The experimental generation of mesostructure data is time-consuming and costly. Therefore, simulation plays a crucial role in generating mesostructured data. Advanced simulation methods capable of generating plausible mesostructures are necessary. Coarse-graining (CG) methods are effective for large space-time scale objects, such as polymeric material mesostructures. Among CG methods, dissipative particle dynamics (DPD) is advantageous in terms of computational cost. In DPD, interactions between coarse-grained particles are represented by the Flory-Huggins χ parameter. The method for calculating the χ parameter by quantum mechanical (QM) calculations has only recently been developed, with few examples considering QM effects in DPD simulations. It is noteworthy that there are no examples of analysis comparing different ionization states of polymers with ionic functional groups.

In this study, to validate the effect of ionization of the CG structure in DPD, DPD of CO_2 separation membrane materials was performed. We chose the CO_2 separation membrane because pH during the polymerization are *known to affect the mesostructure of the membrane due to the effect of ionization of the ionic groups, thereby the performance of CO_2 separation. Here, ionic functional groups with different ionization states were defined as distinct CG particles. In DPD, pH variations during polymerization were expressed as differences in the ionization state of ionic functional groups. Persistent homology (PH), a topological data analysis method, was applied to analyze the mesostructures obtained by DPD to elucidate ionic state-dependent differences in the distribution of ionic functional groups. The distribution of ionic functional groups is difficult to verify experimentally and serves as a first step in understanding and predicting CO_2 separation performance.*

First, CG particles of CO_2 separation polymers composed of N-[3-(Dimethylamino)propyl]methacrylamide (DMAPM), N-tert-butylacrylamide (TBAm), and N-Isopropylacrylamide (NIPAm) were prepared, and χ parameters were calculated using QM calculations. The ionic functional group of these polymers is the amino group. DPD with these χ parameters yielded a mesostructure of CO_2-separating polymers aggregated into particles, consistent with the experimental results. The coordinates of amino groups were then extracted from the obtained mesostructures, and detailed analyses were performed using PH. Based on the PH results, a logistic regression model was constructed to classify whether a given mesostructure was a neutral or ionized amine. The coordinates of amino groups corresponding to the criteria of the classification model were visualized using PH inverse analysis, showing that neutral amino groups were mostly present in the interior of the particle, while ionized amino groups were mostly present on the particle surface. This may be due to the stronger interaction between the amine groups and the surrounding water due to ionization. This result indicates that DPD with χ parameters including the QM effect can generate mesostructures of polymers with ionic functional groups. Furthermore, it suggests that by combining with PH, we have succeeded in finding that amino groups show different distributions depending on their ionization state. This is a major advance in simulation that generates data and knowledge that would be difficult to obtain through experiment.

Accelerated Material Design in Large Continuous Action Manifolds Propelled by Policy-Driven Search Trees

Suvo Banik[1,2], Troy Loeffler[2], Henry Chan[2], Sukriti Manna[1] and Subramanian Sankaranarayanan[2,1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Modeling materials at various scales is of utmost importance in a diverse array of practical applications, allowing us to predict and gain insights into the favorable properties tailored to our needs. The understanding of material properties is intricately linked to the underlying configurational variabilities and intricate interactions between nanoscale constituents of matter. To tackle the fundamental challenges associated, one must employ techniques that (a) model material behavior (e.g., stability, properties) with precision, and (b) can navigate the complex search manifolds of high dimensionality and locate optimal candidates from innumerable possibilities. To that end, ab-initio approaches at the nanoscale have demonstrated prowess for accurate property predictions, yet scalability remains a significant challenge. Traditional potential energy models offer an efficient alternative, but their parameterization remains challenging due to the associated high dimensionality. Additionally, the complexity of the objective landscape in these models makes it difficult for search algorithms to navigate and avoid sub-optimal minima (metastable phases) while locating the target global solution. A classic example of similar challenges can be found in board games like Chess, Shogi, and Go. Inspired by the remarkable success of tree search algorithms in policy-driven reinforcement learning for games, we have developed a continuous search space adaptation of Monte Carlo Tree Search (MCTS) to tackle material design problems. By tailoring the existing discrete search scheme for the games, we have adapted the algorithm for search spaces of materials. We have benchmarked our approach using standardized high-dimensional artificial landscapes against popular metaheuristics-based global optimization techniques and state-of-the-art policy gradient methods. We have showcased the efficacy of our method in classic defects optimization applications such as 2D transition metal dichalcogenides (MoS2), classic *crystal structure prediction (CSP) for exploring stable and metastable phases of materials spanning different dimensionalities (clusters, bulk, and 2D), and inverse design of superhard materials, as well as the exploration of dopant-induced metastability and resistive states in perovskites as potential neuromorphic materials. Additional applications include the development of high-dimensional potential energy models of representative systems, such as nanoclusters of elements like Al, C, and Cu. Furthermore, we've extended our approach to address representative continuum-scale optimization problems, including mechanical joints and machine components. In general, our approach is agnostic to material classes and adaptable to systems across a multitude of applications.*

BAMBOO—A Predictive and Transferable Machine Learning Force Field Framework for Liquid Electrolyte Development *Sheng Gong; ByteDance, United States*

*Despite the widespread applications of machine learning force field (MLFF) on solids and small molecules, there is a notable gap in applying MLFF to complex liquid electrolytes. In this work, we introduce BAMBOO (**B**yteDance **A**I **M**olecular Simulation **Boo**ster), a novel framework for molecular dynamics (MD) simulations, with a demonstration of its capabilities in the context of liquid electrolytes for lithium batteries. We design a physics-inspired graph equivariant transformer architecture as the backbone of BAMBOO to learn from quantum mechanical simulations. Additionally, we pioneer an ensemble knowledge distillation approach and apply it on MLFFs to improve the stability of MD simulations. Finally, we propose the density alignment algorithm to align BAMBOO with experimental measurements. BAMBOO demonstrates state-of-the-art accuracy in predicting key electrolyte properties such as density, viscosity, and ionic conductivity across various solvents and salt combinations. Our current model, trained on more than 15 chemical species, achieves the average density error of 0.01 g/cm^3 on various compositions compared with experimental data. Moreover, our model demonstrates transferability to molecules not included in the quantum mechanical dataset. We envision this work as paving the way to a ` ` universal MLFF'' capable of simulating properties of common organic liquids.*

MT04.09.21

A Wyckoff-Aware Crystal Generative Flow Network for Materials Discovery *Rees Chang[1], Alex Guerra[2], Nick Richardson[2], Ni Zhan[2], Sulin Liu[3], Angela Pak[1], Alex M. Ganose[4], Ryan Adams[2] and Elif Ertekin[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Princeton University, United States; [3]Massachusetts Institute of Technology, United States; [4]Imperial College London, United Kingdom*

In this presentation, we will discuss an interpretable and controllable generative flow network to accelerate targeted design of inorganic crystals. Prior crystal generative models parametrize probability distributions over unit cells. In contrast, our model learns distributions over Wyckoff positions in the asymmetric unit, which generates the crystal upon applying the space group symmetry operations. This approach equips the model with probability densities that are invariant under space group actions without architectural restrictions. To accelerate discovery of materials with desired properties and convex hull construction for guided synthesis, our generation process optionally enables hard-constrained sampling from user-specified space groups or composition spaces at inference time. We will discuss the generative flow network's potential to accelerate materials design through online and offline learning tasks with reward- and likelihood-based training objectives.

MT04.09.22

An AI-Enhanced Approach for De Novo Discovery of Novel eIF4E Inhibitors Targeting Drug-Resistant ER+ Breast Cancer *Audrey Huang[1,2], Karin Hasegawa[2] and Yuefan Deng[2]; [1]Woodbridge High School, United States; [2]Stony Brook University, The State University of New York, United States*

Eukaryotic translation initiation factor 4E (eIF4E) plays a critical role in regulating protein synthesis, with its overexpression particularly implicated in drug-resistant estrogen receptor-positive (ER+) breast cancer, a form of cancer known to develop resistance through a high number of different aberrations. Instead of focusing solely on the identification of therapeutic agents, to which the cancer has yet to develop resistance, a more viable strategy may involve targeting fundamental processes that support tumor survival and progression, making eIF4E a promising target for drug development [1]. However, despite significant advances in understanding of eIF4E's structure and function, developing effective inhibitors remains challenging. To address this issue, we aim to identify novel inhibitors through AI-driven de novo drug discovery, building on previous frameworks [2].

Two comprehensive datasets from the ChEMBL database were prepared and preprocessed: a general dataset of 2,409,270 molecules and a targeted dataset of 288 reported eIF4E inhibitors. Data augmentation was performed to increase the size of the targeted dataset. An autoencoder was then used to convert the discrete SELFIES representations of molecules into latent vectors, creating the continuous representations necessary for the generative AI algorithms. Using the latent vectors, Neural Networks and Random Forests were trained as QSAR models to predict the pIC50, MW, LogP, SAS, eIF4E1 binding affinity, eIF4E2 binding affinity, and eIF4E3 binding affinity of compounds. The binding affinity training data was created by performing molecular docking using Autodock Vina of known eIF4E inhibitors on the structures of eIF4E1, eIF4E2, and eIF4E3 retrieved from the Protein Data Bank. The Neural Networks outperformed the Random Forests across all metrics in terms of RMSE and were used in the rest of the AI framework.

Transfer learning was performed to train a Wasserstein GAN with Gradient Penalty (WGAN-GP), a WGAN-GP paired with a Genetic Algorithm (GA), and a WGAN-GP paired with a Pareto-based Genetic Algorithm (PGA). The Genetic Algorithms, which performed selection operations to enhance the training data's fitness, improved the properties of the generated molecules. In addition, dominance resistant solutions were periodically removed in the case of the PGA, ensuring solutions far away from the Pareto Front yet hard to dominate were not left in the training set. After the WGAN-GP models were trained, they were used to generate compounds, which were evaluated for validity, uniqueness, novelty, diversity, and their molecular properties. Finally, the generated compounds underwent molecular docking simulations to assess their binding stability and interactions with eIF4E.

The findings of this study not only advance understanding of eIF4E's role in cancer but also pave the way for the development of targeted therapies for drug-resistant ER+ breast cancer. Future studies should focus on the experimental validation of the generated compounds and explore their therapeutic efficacy in later steps of the drug discovery pipeline.

This project is supported by the Louis Morin Charitable Trust. Furthermore, the authors would like to thank Stony Brook Research Computing and Cyberinfrastructure and the Institute for Advanced Computational Science at Stony Brook University for access to the high-performance SeaWulf computing system.

Machine Learning-Driven Prediction of SARS-CoV-2 Spike Protein Properties Under Varying Temperature and pH Conditions

Marissa Huang[1], Ziyuan Niu[2], Georgios Kementzidis[2] and Yuefan Deng[2]; [1]Woodbridge High School, United States; [2]Stony Brook University, The State University of New York, United States

Up-to-date as of November 14, 2024

The spike glycoprotein (S-protein) of SARS-CoV-2 plays a critical role in viral infection, facilitating the virus's entry into host cells. As such, understanding the structural stability and denaturation mechanisms of the S-protein under different environmental conditions is crucial for developing strategies to inhibit viral infectivity. Molecular dynamics (MD) simulations are frequently used to model nanoscale interactions, such as those of the S-protein [1]. However, these simulations are computationally intensive and require significant time and processing power, underscoring the need for more efficient methods [2].

To address this, we aim to use machine learning (ML) models trained on MD simulation data to predict properties, such as stability, of the S-protein under varying temperatures and pH levels by examining three measurements: the backbone root-mean-square deviation (RMSD), solvent-accessible surface area (SASA), and protein-water hydrogen-bonds (HBPW). RMSD measures the deviation between the protein's backbone atoms and the initial structure. SASA is a measure of the surface area of the protein accessible to the solvent. HBPW quantifies the number of hydrogen bonds between the protein and water molecules.

MD simulations were performed using GROMACS with the CHARMM36 force field. The initial S-protein structure (PDB: 6VXX) was retrieved from the Protein Data Bank, with missing loops in its structure reconstructed using Robetta. The S-protein, which consisted of 1273 residues per chain, was placed in an explicit solvent. The cubic simulation box used for the SPC/E water models had dimensions 21×21×21 nm^3, and periodic boundary conditions were applied in all three Cartesian dimensions.

A Conditional Variational Autoencoder with a Wasserstein Generative Adversarial Network with Gradient Penalty was developed for each of the three properties and trained on 200 ns of MD simulation data. The model's performance was evaluated using probability density functions showing the predicted and actual distributions, Jensen-Shannon (JS) divergence values bounded between 0 and 1, and plots of the loss values over the epochs.

The model was able to generate predictions for data it had not previously seen, achieving JS divergence values of less than 0.02 for the SASA data and less than 0.1 for the HBPW and RMSD data. These predictions were plotted as probability density functions and found to resemble the distributions of the actual data. This demonstrates a good start that we plan to refine through further strategies such as revising our architecture.

Our results can enhance viral protein dynamic studies by reducing the need for extensive MD simulations, potentially speeding up simulation efforts many times over and minimizing the amount of computational power needed in such large-scale, long-term modeling. This can aid the development of antiviral drugs targeting the S-protein and its stability, leading to more effective COVID-19 treatments. Furthermore, our approach can also be adapted to other viral protein studies to enhance drug discovery processes.

This project is supported by the Louis Morin Charitable Trust. The authors would also like to thank Stony Brook Research Computing and Cyberinfrastructure and the Institute for Advanced Computational Science at Stony Brook University for access to the high-performance SeaWulf computing system.

Molecular Dynamics and Conditional Generative Adversarial Network Prediction of the Spike Protein in SARS-CoV-2 at Various Temperatures and pH Levels *Ashley Jisue Hong[1,2], Ziyuan Niu[2], Georgios Kementzidis[2] and Yuefan Deng[2]; [1]Punahou School, United States; [2]Stony Brook University, The State University of New York, United States*

As the COVID-19 pandemic remains globally without known definitive treatment, studies in SARS-CoV-2 continue to hold importance. A component of SARS-CoV-2 that plays a pivotal role in viral infection is the Spike Glycoprotein (S-protein), facilitating membrane fusion and host cell machinery replication via viral RNA injection[1]. Understanding the S-protein's structural mechanisms in diverse environmental conditions is critical for inhibiting infection and developing treatment[2]. Therefore, this study aims to use Molecular Dynamics (MD) and Machine Learning (ML) to predict the S-protein's properties better in varying pH and temperatures.

MD models movements of molecules and atoms through computer simulations. Though MD was used to analyze the S-protein, complications arose as MD required significant time and processing power. To increase modeling efficiency, we trained ML models on MD simulation data to predict the S-protein's stability under varying pH and temperatures using three measurements: root-mean-square deviation (RMSD), solvent-accessible surface area (SASA), and protein-water hydrogen-bonds (HBPW). RMSD assesses stability through deviations between the protein backbone and reference structures. SASA assesses stability through folding dynamics shown by the protein's surface area accessible to the solvent. HBPW assesses stability by the number of hydrogen bonds between protein and water molecules.

MD simulation was conducted using the open-source software GROMACS with the CHARMM36 force field. The initial structure of the S-protein was obtained from the protein data bank (6VXX.pdb), any missing loops in the 6VXX structure completed using Robetta. The S-protein, comprising 1273 residues per chain, was placed in an explicit solvent. The simulation box for the SPC/E water models measured 21×21×21 nm^3 with periodic boundary conditions applied in all three Cartesian dimensions. Data was recorded for 30 environmental combinations from 5 temperature and 6 pH values.

A Conditional Generative Adversarial Network (CGAN) for each RMSD, SASA, and HBPW was developed as this study's generative model. Model was programmed in Python and trained on 200 ns of MD simulation data. Model accuracy was summarized through Kernel Density Estimation (KDE) distribution comparison histograms of actual and generated data, generator and discriminator loss as a function of epochs, Mean Squared Error (MSE) loss over epoch, and Jensen–Shannon (JS) divergence of actual and generated data over epoch. JS divergence between two distributions is bounded by 1 and calculated using base 2 logarithms. Model training involved several trials of eliminating extreme environmental conditions and parameter experimentation.

Results showed significance as generated data distributions showed great similarities to actual data distributions. The model was also able to generate data in given conditions with great similarity to the actual data without training. Thus, our results can be applied to further SARS-CoV-2 studies, especially COVID-19 treatment and antiviral drug discovery targeting to disrupt the S-protein's structural integrity. Our model showed lower JS divergence and faster learning compared to previous Conditional Variational Autoencoders (CVAE) models. Such accelerated running efficiency with the combination of CGAN and MD simulations can reduce the need for extensive MD simulations for other viral protein studies, and broader applications can help drug discoveries beyond SARS-CoV-2.

Unified Differentiable Learning of Electric Response *Stefano Falletta, Andrea Cepellotti, Anders Johansson, Chuin Wei Tan, Albert Musaelian, Cameron J. Owen and Boris Kozinsky; Harvard University, United States*

Predicting response of materials to external stimuli is a primary objective of computational materials science. However, current methods are limited to small-scale simulations due to the unfavorable scaling of computational costs. Here, we implement an equivariant machine-learning framework where response properties stem from exact differential relationships between a generalized potential function and applied external fields. Focusing on responses to electric fields, the method predicts electric enthalpy, forces, polarization, Born charges, and polarizability within a unified model enforcing the full set of exact physical constraints, symmetries and conservation laws. Through application to α-SiO_2, we demonstrate that our approach can be used for predicting vibrational and dielectric properties of materials, and for conducting large-scale dynamics under arbitrary electric fields at unprecedented accuracy and scale. We apply our method to ferroelectric $BaTiO_3$ and capture the temperature-dependence and time evolution of hysteresis, revealing the underlying intrinsic mechanisms of nucleation and growth that govern ferroelectric domain switching.

MT04.09.26

Supervised Variational Autoencoders for the Inverse Design of Molten Salt Mixtures *Julián Barra[1], Rajni Chahal[2], Massimiliano Lupo Pasini[2], Stephan Irle[2] and Stephen Lam[1]; [1]University of Massachusetts Lowell, United States; [2]Oak Ridge National Laboratory, United States*

In materials science, the approach of inverse design refers to a new paradigm in which one begins with desired material properties as an input and obtains a material that possesses these properties as an output. This contrasts with the traditional approach taken in materials science that begins with a material and performs experiments and computer simulations to explore its material properties. Several methods have been proposed to perform inverse design in materials, but recent years have seen several important advances through the application of artificial intelligence (AI)/machine learning (ML) methods, more specifically the generative models.

Generative models, such as variational autoencoders (VAEs), are trained on datasets of materials represented in an invertible way: the way the materials are represented in the algorithm allows for their output to be turned back into a new material. After training, these models are used to generate new data points, which themselves can be turned into new materials, similar to the ones present in the dataset. These models are generally coupled with property prediction models to generate a continuous lower-dimensional space, often called latent space, that the algorithms order according to the values of the predicted property. This approach allows for the material generation to be performed according to target values for the property.

There are several examples of different generative modeling methods applied towards the design of molecular and solid inorganic materials, but so far there have been no examples of these methods being applied towards the inverse design of molten salts. This is despite numerous applications of molten salts in energy production and energy storage, where such algorithms are expect to be effective to explore the enormous chemical design space of molten salts, and thereby reduce the computational expense of performing simulations such as molecular dynamics. The many properties that make experimentation on molten salts difficult, like their toxicity, high corrosivity, and the need to experiment on them at high temperatures, makes this approach particularly useful. The current lack of such a workflow might be due to the difficulty of developing suitable, invertible methods for the representation of molten salts in generative models.

For this reason, we have developed a workflow for the inverse design of molten salts through the compilation of an *molten salt properties dataset using an invertible representation and associated information on macroscopic density and viscosity. We gathered the data from the Molten Salts Thermal Properties Database – Thermophysical (MSTDB-TP) and the NIST Properties of Molten Salts Database (NIST-Janz), with additional information given in the form of material property descriptors obtained from the Joint Automated Repository for Various Integrated Simulations – Classical Force-field Inspired Descriptors (JARVIS-CFID). We then implemented a generative model based on a VAE that is coupled with a property prediction neural network. The coupled generative model was trained on our compiled property dataset and used to generate new molten salts according to target values of material properties. We employed ab initio molecular dynamics (AIMD) simulations to compare against the predicted properties from our generative model.*

Our results indicate that the inverse design workflow is successful, with the coupled predictive neural network predicting properties with reasonable accuracy. We find that the coupled model is able to generate a continuous lower-dimensional vector space with the values of the target properties ordered across the principal components, where the molten salts that were generated indeed possess physical property values that are in agreement with the results of AIMD simulations.

Known Unknowns—Out-of-Distribution Property Prediction in Materials *Nofit Segal, Aviv Netanyahu, Pulkit Agrawal and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States*

Designing high-performance materials often requires identifying materials with property values that fall outside the known distribution, specifically, out-of-support (OOS) values. One strategy for finding materials with desired properties is inverse design through conditional generation of materials. A complementary approach is screening candidate materials through property prediction. However, both approaches typically struggle when the desired property is outside of the training target support.

In this work, we aim to learn a predictor that performs zero-shot extrapolation to higher ranges of property values given chemical compositions. Our method utilizes common descriptor-based representations derived from elemental properties, which encapsulate fundamental chemical information that directly influences material characteristics. We employ a transductive approach to predict various properties of inorganic bulk materials and explore its extrapolation abilities. Rather than predicting property values directly from an input composition x', our method learns to make predictions as a function of a training composition x and the difference between their representations d(x',x). We provide an analysis of our approach, showing it detects and leverages trends in the periodic table to make predictions. Our method produces OOS predictions closer to the ground truth distribution, whereas strong baselines fail to make predictions that exceed the training distribution range.

MT04.09.28

The Evolving Role of Computation and AI in Catalyst Discovery *James Hedrick, Nathan Park and Tim Erdmann; IBM Research, United States*

The discovery, development, and deployment of new materials not only provide significant business opportunities but also drive advances in high-value applications, from microelectronics to medicine. As computational chemistry evolves and AI systems gain prominence, their influence on materials discovery—particularly in catalyst design and polymer-forming reactions—is becoming transformative. We have developed a broad class of highly active organic catalysts that operate across a wide range of monomers suitable for ring-opening polymerization as well as polymer recycling. By combining fundamental mechanistic studies with AI-assisted modeling, we have uncovered new pathways to creating well-defined macromolecular architectures.

To address the challenges of time-to-market, the integration of automated synthesis, high-throughput characterization, and AI-driven predictive models into a unified pipeline holds the potential to radically accelerate the discovery and optimization of catalysts. This approach allows for the rapid exploration of vast chemical spaces and the identification of optimal catalysts at a fraction of the time and cost required by traditional methods, positioning AI as a central tool in the next generation of materials development.

MT04.09.29

Ultra-Fast Oxygen Conduction in Sillén Oxychlorides *Jun Meng[1], Md Sariful Sheikh[1], Lane E. Schultz[1], William O. Nachlas[1], Jian Liu[2], Maciej Polak[1], Ryan Jacobs[1] and Dane Morgan[1]; [1]University of Wisconsin-Madison, United States; [2]U.S. Department of Energy National Energy Technology Laboratory, United States*

Ionic conductors play an essential role in diverse energy technologies, enabling the conversion of chemical energy into electricity and vice versa. Recent efforts have been devoted to improving the conductivity of oxygen-active materials, which play a crucial role in enhancing the efficiency of fuel cells, solid-oxide air batteries, electrolyzers, membranes, sensors, and more. In this work, we performed a structure-similarity analysis of >60k oxygen-containing compounds, and identified the MBi_2O_4X (M=rare-earth element, X=halogen element) as a novel family of fast oxygen vacancy conductors. MBi_2O_4X adopts a triple fluorite layered structure, where oxygen ions may diffuse via interstitial- or vacancy-mediated mechanisms. Ab initiostudies of the representative material $LaBi_2O_4Cl$ (LBC) reveal migration barriers of 0.1 eV for oxygen vacancies and 0.6-0.8 eV for oxygen interstitials. With 2.8% oxygen vacancies, single crystal LBC is predicted by ab initio molecular dynamic simulations to exhibit an ionic conductivity of 0.3 S/cm at 25 °C. Furthermore, intrinsic LBC displays substantial ionic conductivity above 700°C, attributed to the spontaneously formed Frenkel pairs at elevated temperatures, which are the dominant defect type in LBC. The ultra-low barrier for oxygen vacancy diffusion indicates the potential of oxygen-deficient LBC to facilitate fast oxygen ion conduction even at room temperature, achievable through aliovalent doping to create vacancies. To experimentally verify the oxygen conductivity in intrinsic and oxygen-deficient LBC, we have synthesized LBC and Sr-doped LBC by a flux synthesis method. Experimental results demonstrate that both LBC and Sr-doped LBC achieve comparable or higher oxygen conductivity than yttria-stabilized zirconia (YSZ) and $(La,Sr)(Ga,Mg)O_3$ (LSGM) below 400 °C, with lower activation energies. However, a large discrepancy between the experimentally observed and computationally predicted conductivities is observed, where experiments show higher activation energy and significantly lower conductivity than predicted for oxygen-deficient LBC. We believe the key to realizing the exceptional predicted room temperature oxygen conductivity of LBC resides in creation of extrinsic oxygen vacancies in LBC (e.g., through aliovalent doping) and potentially through microstructural refinement to reduce grain boundary effects. Realizing the full potential of the ultra-fast oxygen conduction in LBC presents an opportunity to expand the use of oxygen-based energy conversion technologies to lower temperatures.

A Machine Learning Approach for 2D NMR Cross Peak Prediction Via Unsupervised Learning *Yunrui Li[1], Hao Xu[2] and Pengyu Hong[1]; [1]Brandeis University, United States; [2]Harvard University, United States*

Nuclear magnetic resonance (NMR) spectroscopy is crucial in advancing materials science, as it reveals detailed structural information, electronic properties, and molecular dynamic insights. Accurate prediction of NMR peaks from molecular structures enables materials scientists to effectively evaluate and verify candidate structures by comparing predictions with observed shifts in experimental NMR spectra. While substantial progress has been achieved in predicting one-dimensional (1D) NMR using Machine Learning (ML) approaches, 2D NMR prediction remains a challenge due to the scarcity of annotated training data. In this work, we present a modular, AI-driven approach designed for automated cross peak prediction and annotation of experimental 2D NMR data.

Specifically, we developed an unsupervised transfer learning framework, to train a deep learning model and achieved promising results on both prediction and annotation accuracy. We deployed our pipeline on 19,000 unlabeled HSQC spectra for training, and 400 HSQC spectra with expert annotations for testing. The Mean Absolute Errors (MAEs) achieved by the model demonstrate the model outperforms the conventional tools (ChemDraw and Mestrenova) for predicting 2D NMR atomic chemical shifts. The effectiveness of our approach highlights the potential for unsupervised learning and transfer learning in the absence of labeled experimental data, showcasing the broader implications of integrating AI into next-generation structural verification and discovery workflows.

MT04.09.31

Evaluating the Generalizability of Inorganic Pretrained General-Purpose Graph Neural Network Potential in Simulations of Liquid Electrolytes

Suyeon Ju[1], Jinmu You[1], Gijin Kim[1] and Seungwu Han[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute for Advanced Study, Korea (the Republic of)

Lithium-ion batteries (LIBs) are crucial to modern technology, powering a wide range of devices from mobile electronics to electric vehicles. Despite their widespread use, challenges such as safety, charging speed, and temperature resilience continue to limit their broader application. Electrolyte engineering, which directly impacts charge transport and the overall stability of the battery system through the formation of the solid electrolyte interphase (SEI), is key to overcoming these challenges. Theoretical approaches are illuminating in their predictive ability prior to trial-and-error experimental methods. However, recent theoretical studies based on density functional theory (DFT), classical potentials, and machine learning potentials have encountered challenges with the complexity of electrolytes due to the vast combinations of solvents, salts, and additives. The DFT method faces scalability limitations and requires high computational costs to investigate diverse chemical systems. Classical force fields lack transferability and overall accuracy. Machine learning interatomic potentials (MLIPs) offer a promising alternative, extending the length and time scales of simulations while maintaining DFT-level accuracy. Nonetheless, bespoke descriptor-based MLIPs require extensive training sets to capture interactions among numerous species and are limited by the number of elements they can handle.

In this presentation, we address computational challenges in electrolyte simulations by employing a pretrained general-purpose graph neural network interatomic potential (GNN-IP) to explore its applicability in liquid electrolyte systems. Specifically, we assess the generalizability and limitations of the SevenNet-0 model (version 11July2024), which was trained on inorganic crystals from the Materials Project database. We conduct molecular dynamics (MD) simulations on 20 solvents and two salts across various compositional combinations. Our results demonstrate that SevenNet-0 accurately describes the first Li-ion solvation shell, including bond lengths and angles in carbonate solvents, and effectively extends to Na and K ions with accurate cation-oxygen distances. Although the model exhibits systematic shifts in density predictions, leading to an underestimation of diffusivity, scaling densities to experimental values yields diffusivity predictions comparable to experimental results. Through Uniform Manifold Approximation and Projection (UMAP) analysis, we suggest that SevenNet-0 infers organic solvent chemical moieties and Li-ion solvation shells from similar inorganic local structures and other cation-oxygen/fluorine interactions. However, SevenNet-0 shows limitations in accurately predicting energy barriers between cis-cis and cis-trans conformers in linear solvents, as well as in atomic forces for specific chemical moieties with 5-atom rings and fluorine doping. Fine-tuning with a small set of organic structures led to improvements in these areas. This study provides valuable insights into the use of inorganic pretrained models for out-of-distribution systems, emphasizing the importance of carefully assessing relevant properties for target applications. Our findings offer a promising pathway for advancing electrolyte engineering in complex battery systems, potentially accelerating the development of next-generation high-performance batteries.

Bayesian Co-Navigation—Active Learning for Design of Material Digital Twins *Boris N. Slautin[1], Yongtao Liu[2], Hiroshi Funakubo[3], Rama K. Vasudevan[2], Maxim Ziatdinov[4] and Sergei V. Kalinin[5,4]; [1]Universität Duisburg-Essen, Germany; [2]Oak Ridge National Laboratory, United States; [3]Tokyo Institute of Technology, Japan; [4]Pacific Northwest National Laboratory, United States; [5]The University of Tennessee, Knoxville, United States*

Throughout history, science has aimed to uncover fundamental mechanisms and describe them through theoretical models to explain physical phenomena. Progress in this field depends on the dynamic interaction between theoretical insights, modeling, and experimental discoveries. However, integrating theoretical descriptions with experimental data is often a slow process, traditionally driven by community collaboration or additional efforts to incorporate data into models. The ability to dynamically design and refine theoretical models based on real-time experimental insights not only accelerates the integration of theory and experimentation but also lays the foundation for developing "digital twins" for material systems – a cutting-edge focus in the materials science community. A digital twin is a high-fidelity digital representation closely mirroring the current form and the functional responses of a specified physical object based on real-time experimental feedback. Digital twins should not only model material's macroscopic behavior but also uncover the microscopic physical phenomena impacting them. This capability enables addressing the inverse problem and optimizing theoretical model parameters to yield desired macroscopic responses.

We present a Bayesian co-navigation framework that guides the exploration and optimization of a material system's target functionality, using a theoretical model as a digital twin of the material system. The proposed workflow operates through two parallel iterative active learning loops: one theoretical and one experimental. Supposing significant computational cost of direct calculations by the theoretical model, Deep Kernel Learning (DKL) is employed as a surrogate model to explore the theoretical model's object space. At each exploration step, the theoretical DKL model is trained using the data available at that specific iteration. The next object to be investigated is selected using the classical Bayesian Optimization paradigm. The experimental loop is built on the same principles, predicting the experimental functionality and its uncertainty for the respective object space. The core idea of the Bayesian co-navigation lies in the utilization of the third outer theory update loop to align the theory and experiment. In this loop, we apply the theoretical DKL model to predict the target property of the experimentally investigated objects. Important, theoretical exploration and experimental measurements must be performed in identical or reflecting to each other object spaces, and their outputs must be comparable. The error function between the theoretical prediction and experimental observation is employed to tune the theoretical model to minimize the epistemic uncertainty. In other words, the outer theory update loop leverages real-time experimental feedback to transform the theoretical model into a digital twin of the material being explored.

The effectiveness of the framework was validated through the investigation of the local ferroelectric properties of a $PbTiO_3$ *thin film. The FerroSim lattice spin model, which predicts polarization hysteresis based on local domain arrangements, was utilized as the theoretical model. For the experimental study, local ferroelectric hysteresis loops were measured using a scanning probe microscope. Our experimentations showed a consistent reduction in the mismatch between experimental data and theoretical predictions, confirming the reliability of the approach. The co-navigational approach can be used for a diverse array of systems and theoretical models without any limitation on the nature of describing phenomena or model complexity. The implementation of the co-navigational approach is expected to significantly simplify the creation of digital twins for the materials.*

MT04.09.33

An Active Learning Approach to Predict Intermolecular Non-Covalent Interactions in Organic Crystals *Moses Ogbaje[1], Vijaykumar Karthikeyan[1], Kyle Eldridge[1], Vinayak Bhat[2], Baskar Ganapathysubramanian[3] and Chad Risko[1]; [1]University of Kentucky, United States; [2]Columbia College, United States; [3]Iowa State University of Science and Technology, United States*

Intermolecular noncovalent interactions play a crucial role in the assembly of organic semiconductors (OSC). While various quantum-chemical techniques, such as symmetry-adapted perturbation theory (SAPT), are available to evaluate these interactions, they can be computationally expensive, especially for the large building blocks typical in OSC. This computational burden hinders the use of machine-driven searches across the OSC chemical and materials landscape. Machine learning (ML) models have emerged as efficient approaches to provide rapid predictions of molecular and material properties at significantly lower computational costs than quantum-chemical methods. These models, however, often rely on large, labeled datasets that can be difficult to obtain. To address this challenge, we develop an active learning ML approach that is designed to reduce the need for extensive labeled data. The active learning approach identifies areas in the chemical space where the model uncertainty is highest and enables more targeted data generation. This active learning approach is demonstrated to facilitate fast and accurate prediction of intermolecular noncovalent interactions in OSC, opening new avenues for rapid materials discovery.

MT04.09.34

High Throughput Characterization of Combinatorial Library Based on SPM Based with LLMs, Self-Tuning and Reward-Driven Automation *Richard Liu[1], Utkarsh Pratius[1], Roger Proksch[1,2], Ichiro Takeuchi[3], Jon-Paul Maria[4] and Sergei V. Kalinin[1,5]; [1]The University of Tennessee, Knoxville, United States; [2]Oxford Instruments Asylum Research, United States; [3]University of Maryland, United States; [4]The Pennsylvania State University, United States; [5]Pacific Northwest National Laboratory, United States*

Combinatorial libraries offer a high-throughput way to explore different compositions and growing conditions on a single substrate. However, materials discovery based on combinatorial libraries is bottlenecked by the speed of material characterization. Here we present a fully automated SPM system for high throughput characterization of combinatorial libraries. This SPM system can re-tune itself in both imaging mode and spectroscopy mode at different locations of the library to make sure the measurement conditions are the same across the library. We also implemented an image filter system with the help of Large Language Models (LLMs). This system can filter out good areas in the scan so that all the measurements are performed in sample regions with comparable qualities. We will also show implementation of automated workflows with measured physical properties as rewards on real SPM instrument. Finally, we will present the automated discovery of real binary ferroelectric combinatorial libraries of SmBFO and MZO, and ternary library of AlBN.

MT04.09.35

Design of Ligands for Selective Separation of Ga in the Presence of Fe —An ML-DFT Approach *Shubhojit Banerjee[1,2], Debmalya Roy[2] and Vyacheslav Bryantsev[2]; [1]University of Massachusetts Lowell, United States; [2]Oak Ridge National Laboratory, United States*

Gallium (Ga) is a critical strategic element indispensable in advanced technologies, including semiconductors, optoelectronics, and photovoltaic systems. Due to its limited natural occurrence and escalating demand, Ga has been designated as a critical material, underscoring its significance and supply chain vulnerabilities. Ga is predominantly recovered as a byproduct from bauxite and sphalerite ores, though its co-occurrence with iron (Fe) in these sources complicates efficient extraction due to Fe's higher abundance. Developing ligands with high selectivity for Ga over Fe is essential to optimizing separation/recovery processes, minimizing operational costs, and ensuring a stable supply of this element for critical technological applications. However, exploring a wide range of possible ligand space with stand-alone experiments is expensive and time-consuming. As a way out, we have developed a joint machine learning and density functional-based workflow to predict the metal-ligand stability constants (K) for the Ga and Fe. In doing so, we have developed a Gaussian process regression (GPR) model trained on the NIST database for predicting log K. This ML model is then used to predict M-L stability *constants of unknown ligands taken from the PubChem database. Alongside this, DFT-based exploration of stability constants is also performed to validate these ML-based results. Overall, this forward model workflow accelerates the screening of existing ligands for selective Ga binding, for which the experimental stability constant values are unknown. While the forward model is used to screen the existing ligands, a supervised variational autoencoder (SVAE) is employed for the inverse design of new Ligand metal complexes. Incorporating stability constant (log K) values during the training of the VAE created a biased latent space, which is further used to sample new metal-ligand complexes and predict their stability constant. This developed generative inverse design approach allows us to automate the generation of novel ligands. As such, these developed workflows accelerated the ligand screening and the new ligand design.*

MT04.09.37

Accelerating Advanced Data Visualization with RAG-Based In-Context Learning—A Novel Assistant for Scientific Workflows *Holt Bui, Brandi Ransom, Stefan Zecevic and Tim Erdmann; IBM Research, United States*

In the era of big data, the ability to quickly interpret and visualize complex datasets is paramount for advancing scientific discovery, particularly in materials science. While widely used, traditional tools like Excel and Origin often struggle to quickly and efficiently create sophisticated visualizations on-demand from new datasets. To address this limitation, we have developed a visualization assistant that leverages large language models (LLMs) and the Vega-Lite grammar to produce a diverse array of data visualizations on-demand within seconds. This assistant not only accelerates the visualization process but also enables the creation of complex and interactive visualizations that are challenging to construct with conventional tools – or by Matplotlib as frequently used in data science. Initially, we explored fine-tuning LLMs to specialize them for our visualization tasks. However, this approach proved to be difficult and ineffective due to several drawbacks: high computational costs, lengthy training times, required skill levels, and the extreme overhead in adapting to new visualization types over time.
In our talk, we will present how we overcame these challenges by employing Retrieval-Augmented Generation (RAG)-based in-context learning. We will delve into dataset creation, the architecture and workflow of our visualization assistant, and its current capabilities—including creating various chart types, incorporating aggregations, and adding interactive elements. Thereby, all visualizations can be crafted from simple natural language queries, and since the actual data is never sent directly to the LLMs, confidentiality is ensured. Furthermore, we will present recent advancements in transitioning to agentic workflows.
This methodology streamlines the visualization process and addresses data security concerns, making it highly suitable for sensitive research environments. Additionally, we believe that our approach democratizes access to advanced on-demand visualizations and serves as a template for developing RAG-based in-context learning systems for applications in material science, aiming to inspire interdisciplinary collaboration and drive innovation in AI-catalyzed scientific workflows.

MT04.09.38

Data-Driven Acceleration of Battery Reactivity Models from Molecules to Discovery *Lily Robertson, Ilya A. Shkrob, Logan Ward, Ryan Lewis, Casey Stone, Magali Ferrandon, Benjamin T. Diroll and Zhengcheng Zhang; Argonne National Laboratory, United States*

The wealth of data generated in battery research is a wellspring for advancing fundamental discovery, performance prediction, and management via modeling methods. Yet the wide variety of modeling methods coupled with the wide variety of battery types and chemistries require refining the problem to a manageable task. Our approach focuses on a data-generating workflow using the self-driving lab concept. Here, we define a specific challenge in battery science that will benefit from automation, robotics, data handling, and engineering for ultimate autonomous materials discovery.

Redox flow batteries are an energy storage technology still nascent when compared to the ubiquitous lithium-ion batteries in everyday life. Compared to the traditional batteries, flow batteries possess a starkly different configuration based on liquid electrolytes that flow through electrode stacks. There is ripe opportunity for the advanced discovery of the electrolyte via predictive methods. Indeed, many redox-active materials, the charge-storing species of the battery, have been studied, both in the laboratory and in silico. Further, many of these actives have been engineered to dissolve in nonaqueous solvents, attractive due to their wide electrochemical windows for improved energy density. Yet, compared to the actives, new solvent reagents have seen minimal development. To understand which solvents could be good candidates for a flow battery, their reactivity must be mapped with the active species, which led to our goal of building a reactivity model for active-reagent pairs using data-driven modeling methods. We identified over 500 possible battery-relevant solvent reagents for testing with a charged redox-active molecule. Liquid combinations of the reagents and active were prepared using a liquid handling robot in a nitrogen-filled glovebox. As the charged active is highly colored, its decay kinetics can be monitored by UV-vis spectroscopy. Decay kinetics of the active species were measured based on changes in optical density and fed to adaptive sampling methods. Overall, 20% of the reagent space was sampled, under 300 conditions, for a total of > 2500 experiments. From these predictive methods, several new reagent molecules were picked as stable materials and validated by experiment testing.

This research success includes (i) the general metamodels for predicting reactivity and (ii) the use of these metamodels to identify slower reacting reagents that can be potential new electrolyte solvents, with further funneling of these candidates. This research program is driven by Argonne's Autonomous Discovery Laboratory – molecules to materials discovery platform. It also brings together an interdisciplinary team of chemists, materials scientists, robotics experts, and computer scientists for complete execution.

This material is based upon work supported by Laboratory Directed Research and Development (LDRD) funding from Argonne National Laboratory, provided by the Director, Office of Science, of the U.S. Department of Energy under Contract No. DE-AC02-06CH11357. MT04.09.39

Learning Many-Body Potential Energy Landscape Using Neutron Scattering Data

Gaurav Vishwakarma, Yongqiang Cheng and Christina Hoffmann; Oak Ridge National Laboratory, United States

For the discovery of new materials in the field of energy storage, catalysis, and biological processes, molecular dynamics (MD) simulations are an indispensable computational tool. We can achieve highly accurate representations of the potential energy landscape of diverse molecular systems with ab-initio molecular dynamics (AIMD) simulations, but at the cost of high computational time which limits typical applications to 100s of atoms and time scales of ~100ps. This is where machine learning potentials can be used to capture the underlying physics from first principles, where electrons are treated quantum mechanically, while still reaching long simulation times relatively cheaply.

We introduce a workflow for the analysis of neutron scattering data that trains several deep-learning based many-body potentials and interatomic forces from ab-initio reference calculations. Further, to gauge the accuracy of such potentials with classical MD programs, we use the inelastic neutron scattering (INS) spectra as the performance metric. An INS spectra serves as one of the most stringent tests of theory (such as density functional theory), since the model has to predict not only the correct structure but also the correct vibrational dynamics. We *use a genetic algorithm to optimize several hyperparameters used in this workflow. For different molecular samples, we successfully demonstrate that our workflow can replicate the experimental INS spectra.*

MT04.09.40

Geometric Approaches to Crystal Packing and Property Prediction *Zach T. Gardner[1], Chad Risko[1] and Qianxiang Ai[2]; [1]University of Kentucky, United States; [2]Massachusetts Institute of Technology, United States*

The lack of a robust model for large scale labelling of crystal packings has led to difficulty in the analysis of large crystal databases for the purpose of property prediction through machine learning (ML)-based algorithms. Here we seek to more accurately and systematically describe the topology of a crystal with a crystal matching algorithm to enable the comparison of molecular packings in a given structure with those in a large database of crystals. The method facilitates the identification of structurally similar packings, which can guide ML models in property prediction as polymorphs are identified. We also investigate the crystallization of hard particle systems through Monte Carlo simulations to determine the impact of particle shape on crystal formation. This approach offers a cost-effective method to observe and understand crystallization dynamics, potentially providing a powerful tool for accelerating CSP and aid in ML-assisted material discovery.

SESSION MT04.10: Generative Models for Inverse Materials Design II
Session Chairs: Kjell Jorner and Dmitry Zubarev
Thursday Morning, December 5, 2024
Hynes, Level 2, Room 210

8:00 AM MT04.10.01

Flow for Generating Reaction Pathways and Validation of the Trained Neural Network *Akihide Hayashi[1], So Takamoto[1], Ju Li[2], Hirotaka Akita[1] and Daisuka Okanohara[1]; [1]Preferred Networks, Inc., Japan; [2]Massachusetts Institute of Technology, United States*

The reaction pathway and the corresponding activation barrier are closely related to the reaction rate of a chemical reaction. The activation barrier is considered in various scenarios of material discovery, such as studying the synthesis methods of materials and examining changes over time. Activation barriers obtained by computational chemistry using density functional theory or machine learning potentials are also expected to be useful. However, it is challenging to calculate many appropriate reaction pathways that are useful for material exploration. Due to its inherent complexity and non-linearity, estimating these pathways algorithmically and comprehensively has been difficult. In addition, since chemical reactions are intrinsically rare events, exploration based on statistical mechanics, such as molecular dynamics, has not been efficient.
To solve this problem, we proposed a method using neural networks to generate an initial estimate of these reaction pathways [1]. The proposed method starts by inputting the coordinates of the initial state and gradually changing its structure. This iterative process generates an approximate representation of the reaction pathway and the coordinates of the final state. Using this method, it is possible to generate complex reaction pathways such as those seen in organic reactions.
A neural network that learned a dataset including organic chemical reaction pathways was created. It was demonstrated that our neural network has the ability to generate reactions similar to the corresponding test data. Furthermore, it can generate reactions either randomly or according to predetermined conditions. Using the model trained with Transition1x, typical chemical reactions such as the Diels-Alder reaction and the rotation reaction

between the NN in azobenzene could be generated in about 10-30 seconds.
We have verified our proposed model works with the Transition1x dataset. To expand its applicability, we are now focusing on dataset expansion. We are now constructing an automated reaction data correction framework using an improved reaction pathway analysis algorithm and universal neural network potential PFP [2].

Benchmarking Study of Deep Generative Models for Inverse Polymer Design *Ying Li; University of Wisconsin–Madison, United States*

Molecular generative models based on deep learning have increasingly gained attention for their ability in de novo polymer design. However, there remains a knowledge gap in the thorough evaluation of these models. This benchmark study explores de novo polymer design using six popular deep generative models: Variational Autoencoder (VAE), Adversarial Autoencoder (AAE), Objective-Reinforced Generative Adversarial Networks (ORGAN), Character-level Recurrent Neural Network (CharRNN), REINVENT, and GraphINVENT. Various metrics highlighted the excellent performance of CharRNN, REINVENT, and GraphINVENT, particularly when applied to the real polymer dataset, while VAE and AAE show more advantages in generating hypothetical polymers. The CharRNN, REINVENT, and GraphINVENT models were further trained on real polymers utilizing reinforcement learning methods, targeting the generation of hypothetical polymers with high glass transition temperatures. The findings of this study provide critical insights into the capabilities and limitations of each generative model, offering valuable guidance for future endeavors in polymer design and discovery.

8:45 AM MT04.10.04
MatFold—Cross-validation Protocols to Systematically Evaluate Generalization Errors in Materials Discovery Models *Peter Schindler[1] and Matthew Witman[2]; [1]Northeastern University, United States; [2]Sandia National Laboratories, United States*

Machine learning models in materials science validated by a single train/validation/test split or non-nested K-fold splits using a single splitting criterion can yield biased and overly optimistic performance estimates for downstream modeling or materials screening tasks. This can be particularly counterproductive for applications where the time and cost of failed validation efforts (experimental synthesis, characterization, and testing) are consequential. We propose a set of standardized and increasingly difficult splitting protocols for chemically and structurally motivated, nested K-fold cross-validation that can be followed to validate any machine learning model for materials discovery. Among several benefits, this enables systematic insights into model generalizability, improvability, and uncertainty, provides benchmarks for fair comparison between competing models with access to differing quantities of data, and systematically reduces possible data leakage through increasingly strict splitting protocols. A general-purpose toolkit, MatFold, is provided to automate the construction of these chemically motivated train/test splits and facilitate further community use. We employ MatFold to analyze the generalization error of two datasets with distinct model architectures. One dataset contains relaxed vacancy formation energies that are predicted using a graph-convolutional neural network.[1] The other dataset consists of work functions of surfaces predicted utilizing an elemental random forest model.[2] The observed trends in generalization errors and their variances for various MatFold splitting protocols reveal unique scaling behavior for each model architecture.

Can Chemical Property Prediction Models Extrapolate? Understanding How to Move Towards Generalizable Chemical Foundation Models *Evan Antoniuk[1], Shehtab Zaman[2], Busra Demirci[2], Peggy Li[1], Yu-Ting Hsu[1], James Diffenderfer[1], Ken Chiu[2], Anna Hiszpanski[1], Nikoli Dryden[1], Tal Ben-Nun[1], Bhavya Kailkhura[1] and Brian Van Essen[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Binghamton University, The State University of New York, United States*

Alongside the push towards artificial general intelligence, there has been a surge of interest in the chemical community to develop large-scale chemical foundation models. This goal is motivated by the idea that a single foundation model trained on vast quantities of chemical data can be broadly applied to multiple applications without needing retraining. Although several chemical foundation models have already displayed their proficiency at predicting molecular properties, their capability to generalize across chemical space has yet to be systematically evaluated.
In this talk, I will discuss our work on understanding the capabilities of current state-of-the-art models (both foundation models and otherwise) to extrapolate to new chemistries. From performing large-scale benchmarking of over seven models across ten unique datasets and millions of molecular samples, we find that no existing model has the ability to consistently extrapolate to new chemistry. As a result, we perform various ablation experiments to understand how to provide better generalization capabilities to models. Specifically, we probe how pre-training objectives, multi-task learning, model architecture and molecule representation affect the resulting extrapolation performance. The insights gained from these experiments provide actionable guidance on how the materials community can proceed towards achieving generalizable materials foundation models. In addition, the extrapolation tasks established in our benchmarking provide the materials community with a uniform benchmark for tracking progress in the extrapolation abilities of chemical models.

This work was produced under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Comprehensive Evaluation of Large Language Models for Materials Science— Insights from the MatSciLLM Leaderboard *Vineeth Venugopal and Elsa Olivetti; Massachusetts Institute of Technology, United States*

The MatSciLLM Leaderboard is a large-scale evaluation of large language models (LLMs) specifically tailored to materials science, aimed at guiding researchers in selecting the most suitable models for different tasks in this domain and in answering critical questions about the role of these models in the field. This initiative assesses 23 LLMs across 12 different tasks - for a total of over 250 models - providing a detailed analysis of their capabilities and limitations within the context of materials science. By offering insights into model performance, this work seeks to address the pressing need for AI tools that can support complex materials research and discovery. A key focus of this evaluation is to determine how model size, fine-tuning, and other adaptations impact performance across a range of tasks. Larger models generally exhibit better performance compared to smaller models, and fine-tuned versions of LLMs consistently outperform their base counterparts. Despite these advantages, LLMs still face challenges in certain areas, such as numerical data prediction, where their performance remains suboptimal. Among the models evaluated, Llama3 and Mistral emerged as strong performers across multiple tasks, showcasing their versatility and robustness.
This study also introduces a novel crosstask evaluation, which investigates whether LLMs trained on one specific materials science task exhibit improved performance on other tasks. This analysis raises important questions about whether these models can effectively "learn" materials science through task-specific training. Furthermore, we examine the role of model ensembles in enhancing performance, testing whether combining multiple models can outperform individual large models. This investigation provides valuable insights into the utility of ensemble approaches within materials science applications.
Additionally, we evaluate the impact of data and model size on training effectiveness across 12 distinct tasks, offering a thorough exploration of how these factors influence model performance. This work represents the most extensive evaluation of LLMs in materials science to date, providing critical guidance for researchers and practitioners in the field. The findings underscore the importance of selecting the right model configuration for specific research needs and highlight the potential for further advancements in LLM performance through targeted optimization techniques.

9:30 AM MT04.10.07
Diffusion Generative Modelling with Transformers for Generative Materials Design *Izumi Takahara, Kiyou Shibata and Teruyasu Mizoguchi; The University of Tokyo, Japan*

In recent years, significant progress has been made in developing deep learning-based representation learning and generative methods for materials, accelerating materials exploration and design. For the discovery of inorganic materials with desired properties, inverse design of crystal structures using a generative model has emerged as a promising approach [1]. Crystal structures are composed of multiple types of variables including lattice vectors, atomic species, and atomic coordinates, allowing for various approaches to representing and generating them. Recently, efforts have been made to encode and learn the representation of 3D crystals using Transformers [2,3]. In this presentation, we introduce our approach to leveraging Transformer-based crystal encoding for crystal generation mainly in diffusion models, where we explore suitable conditioning methods for target-aware materials generation [4]. Our model demonstrated high versatility, achieving comparable or superior success rates across various datasets compared to previously reported approaches. We will present the performance of our generative model with a Transformer backbone for the inverse design of crystals, and discuss the implications derived from our models.

Put a Ring on It—Generative Design of Polycyclic Aromatic Systems *Renana Poranne; Technion-Israel Institute of Technology, Israel*

Polycyclic aromatic systems (PASs) are among the most prevalent and impactful classes of compounds in the natural and man-made worlds. Though aromatic systems have captured the fascination of chemists for almost two centuries, a general conceptual framework for understanding and predicting the structure-property relationships of polycyclic systems has not yet been developed. Accordingly, the ability to design PASs with specific properties has remained elusive.
We address this gap using a combination of computational chemistry and data science tools. We established the COMPAS Project—a COMputational database of Polycyclic Aromatic System—which already contains over 500k molecules in three datasets: cata-condensed polybenzenoid hydrocarbons (COMPAS-1), cata-condensed hetero-PASs (COMPAS-2), and peri-condensed polybenzenoid hydrocarbons (COMPAS-3). With COMPAS hand, we demonstrate the first cases of interpretable learning models in the chemical space of PASs. To this end, we developed two types of molecular representation: a) a text-based representation and b) a graph-based representation, which not only achieve higher predictive ability with fewer data, but are also amenable to interpretation – thus allowing the extraction of chemical insight from the model. Using the COMPAS database and our dedicated representations, we implemented the first guided diffused-based model for inverse design of PASs: GaUDI. Our model generates new PASs with defined target properties. In addition to its flexible target function and high validity scores, GaUDI also accomplishes design of molecules with properties beyond the distribution of the training data.

10:45 AM MT04.10.09

Multi-Modal AI for the Design of Functional Porous Materials *Hyunsoo Park and Aron Walsh; Imperial College London, United Kingdom*

Porous materials are increasingly recognized for their potential in energy and environmental applications. Among these, metal-organic frameworks (MOFs) stand out due to their tunable molecular structures and diverse topologies, offering a vast chemical space for exploration. While theoretically, an unlimited number of porous materials can be synthesized, leveraging AI enables more effective navigation of this complex space. We introduce a multi-modal Transformer pre-trained with 1 million hypothetical MOFs, that enables accurate predictions of multiple properties and enhances the transferability of these predictions across various MOFs. This model acts as a robust surrogate, identifying optimal MOF candidates tailored for diverse photocatalytic applications. Our approach significantly accelerates the discovery and deployment of functional MOFs, showcasing the potential of AI in porous materials.

11:00 AM MT04.10.10

Structural Constraint Integration in Generative Model for Discovery of Quantum Material Candidates *Ryotaro Okabe[1], Mouyang Cheng[1], Abhijatmedhi Chotrattanapituk[1], Yongqiang Cheng[2] and Mingda Li[1]; [1]Massachusetts Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States*

Compared to the billions of discovered organic molecules, inorganic materials have long faced the challenge of data scarcity, with only a tiny fraction of possible candidates having been discovered. Recent advancements in machine-learning-based generative models, particularly diffusion models, show great promise for generating new, stable materials. However, challenges remain in integrating lattice types into material generation. Here, we introduce Structural Constraint Integration in the GENerative model (SCIGEN), which sets up constraint and *unconstraint channels and combines them during the diffusion process, generating new structures while maintaining preset lattice constraints. We generate eight million compounds using Archimedean lattices (AL) as prototypes, with over 10% surviving a multi-stage stability pre-screening. High-throughput density functional theory (DFT) on 26,000 compounds shows over 50% were stable at the DFT level. Since the properties of quantum materials are closely related to the lattice types, SCIGEN provides a general framework for generating quantum materials candidates.*

11:15 AM MT04.10.11

Unified Graph Neural Network Model to Accelerate Substitution and Defect Engineering in Halide Perovskites

Maitreyo Biswas and Arun Kumar Mannodi-Kanakkithodi; Purdue University, United States

ABX_3 halide perovskites have been the subject of extensive investigation over the last two decades due to their attractiveness for single-junction and tandem solar cells, light emission, sensors, and photocatalysis. The flexible structure of perovskites and their ability to accommodate both inorganic and organic cations provide a broad spectrum of options for tuning their electrical and optical properties [1]. Despite numerous data-driven efforts, the massive chemical space of perovskites when considering cation/anion-site alloying, point defects, and dopants, combined with the expense of running high accuracy density functional theory (DFT) computations, pose a significant challenge in identifying low energy bulk and defect configurations and designing novel atom-composition-structure (ACS) [2] combinations with multiple desired properties.

We present an autonomous crystal structure prediction (CSP) workflow based on crystal graph-based neural networks (GNNs), where starting from any ABX_3 composition, low energy configurations are devised by identifying suitably alloying elements and likely point defects or complexes. Predictive GNN models are trained on a dataset of > 20,000 perovskite structures generated by our group over the years [3,4], spanning a variety of A/B/X species, different phases and supercell sizes, substitutional alloys, lattice strains and octahedral distortions, native point defects, and dopants from across the periodic table. Applying established methods such as CGCNN [5], M3GNET [6], and ALIGNN [7], we obtain crystal formation energy prediction errors < 13 meV/atom, which is competitive with the state-of-the-art. These predictions are combined with systematic distortion-based geometry optimization [8] (e.g., using the MatGL approach [6]) to design new stable perovskite alloy structures and obtain a complete picture of charge-dependent defect formation energies in them, which further informs their defect tolerance, n-type or p-type nature, and likelihood to be doped a certain way. Furthermore, we incorporate the PU learning approach [9] within our GNN models to predict the likely synthesizability of new compounds, utilizing the experimental data we collected from the literature over the years [4]. Combined with separate predictions of electronic band gap and photovoltaic efficiency [4] as well as systematic hybrid functional calculations, we ultimately discover novel perovskite ACS combinations with desired bulk stability and likelihood of synthesis, defect tolerance and dopability, and suitable optoelectronic properties. This framework will continue to grow with new data and improved models and promises to lead perovskite discovery for the next few years.

Foundation Models and Multi-Agent Systems for Polymer and Catalyst Design *Nathan Park, Tiffany Callahan, Emilio Vital Brazil, Eduardo Almeida Soares, Victor Shirasuna, James Hedrick, Tim Erdmann and Sara Capponi; IBM, United States*

The development of foundation models which can generalize across prediction tasks is imperative for the construction of seamless workflows to enable AI-guided design of novel polymeric materials. Here, we will discuss our efforts in addressing the many challenges of building an effective foundation model for polymers, including strategies for efficient representation of complex materials and construction of relevant benchmarking datasets. In addition to the foundation models themselves, facilitating straightforward interactions between the model and human researchers is a critical aspect in realizing their utility within the experimental research workflows. In this regard, we will discuss how materials foundation models can be incorporated within LLM-powered, multi-agent systems to facilitate not only property prediction but also multimodal retrieval augmented generation (RAG) tasks to provide grounded and salient answers to researcher inquiries. Importantly, these RAG tasks will demonstrate how the combination of chemistry foundation models with LLMs can enable highly challenging queries for polymer topology or leveraging characterization data can be performed—significantly advancing and simplifying critical knowledge retrieval tasks for researchers. Finally, the application of these technologies for development of sustainable materials will also be discussed.

SESSION MT04.11: Machine Learning Potentials for Structure-Properties Prediction
Session Chairs: Jian Lin and Dmitry Zubarev
Thursday Afternoon, December 5, 2024
Hynes, Level 2, Room 210

1:30 PM *MT04.11.01

Enabling Inverse Design of Nanoparticle Photophysics via Deep Learning on Heterogeneous Graphs *Samuel Blau[1], Eric Sivonxay[1], Lucas Attia[1], Benjamin Sanchez-Lengeling[2], Xiaojing Xia[1], Evan W. Spotte-Smith[1], Daniel Barter[1] and Emory Chan[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Google DeepMind, United States*

Deep learning (DL) is commonly employed to accelerate materials design and development. However, to date, few efforts have applied DL to nanomaterials, which lack suitable structural representations and adequate data for model training. We report efforts to overcome these limitations, leveraging DL to optimize the optical properties of heterostructured core-shell upconverting nanoparticles (UCNPs) for applications in e.g. biosensing, super-resolution microscopy, and 3D printing. The nonlinear photophysical properties of UCNPs, which allow for the emission of visible and ultraviolet light from near-infrared excitations, depend on the number of shells, shell thickness, and dopant concentrations. Though kinetic Monte Carlo (kMC) simulations allow for reasonably accurate prediction of UCNP optical properties, high simulation cost has limited the exploration of this vast design space to relatively small, simple systems. Here, we describe the first large-scale dataset of UCNP spectra based on kMC simulations (N > 6000). Training on this dataset, we develop an accurate physics-infused heterogeneous graph neural network and use it to perform inverse design of UCNPs via gradient-based optimization. We identify novel structures with 6.5x higher predicted emission under 800nm illumination than any UCNP in our training set, validated by months-long kMC simulations. Our work reveals new design principles for UCNPs and presents a roadmap for de novo nanomaterial design.

2:00 PM MT04.11.02

Automated COHP Calculations for the Prediction of Stability and Catalytic Activity in Mixed Transition Metal Oxides

Ruchika Mahajan[1,2], Neha Bothra[1,2], Michal Bajdich[1,2] and Kirsten Winther[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States

The materials discovery of effective catalysts for the oxygen reduction and oxygen evolution reactions (ORR/OER) is crucial for the advancement of hydrogen fuel cells and electrolyzers [1]. For this, it is essential to identify affordable and Earth-abundant alternatives to precious metal catalysts that provide both stability and high catalytic activity. Recent studies have shown that the electronic structure of binary bulk transition metal-oxides (TMOs), represented by the crystal orbital Hamiltonian populations (COHP) of the metal-oxygen bond, serves as an accurate descriptor for O and OH adsorption [2]. This further demonstrates that leveraging these bulk descriptors enables efficient catalyst screening without the need for expensive surface simulations [3].

In this talk, we will discuss an extended model of bulk ternary mixed transition metal oxides ($A_xB_yO_z$) and the importance of bond strength between metal d states and oxygen 2p states for predicting their stability and catalytic activity. We will also cover high-throughput COHP [4] calculations using Density Functional Theory (DFT) codes like VASP through the lobster package to analyze these interactions. To handle these high throughput simulations, we developed a python library called AutoCatLab. This library is implemented on finite state machine workflow which consists of several configurable steps including Job scheduling, monitoring and analysing results. In the current configuration, AutoCatLab is configured to compute COHP, handles basic and modified DFT calculations, and analyse the calculation results. I will describe working model of AutoCatLab which automatically deals with subtle aspects of these calculations, including VASP input generation, Job scheduling, output data management, and calculation convergence. This library also further analyse the results through an ASE parser, storing into ASE based SQL database [5]. Additionally, this also supports both CPU and GPU computation with the rescheduling mechanism for failed calculations.

Lastly, our prediction models, such as Gaussian process regression (GPR) and Crystal graph convolutional neural network (CGCNN), will also be discussed in predicting the bulk stability of mixed ternary oxides.

Towards r2SCAN-level Universal Neural Network Potential for Materials Discovery

Chikashi Shinagawa[1], So Takamoto[1], Daiki Shintani[1], Katsuhiko Nishimra[1] and Ju Li[2]; [1]Preferred Networks, Inc., Japan; [2]Massachusetts Institute of Technology, United States

Accurate, universal, and fast interatomic potentials accelerate materials discovery. Neural network potentials (NNP) have initially achieved success in small molecule systems composed of few elements, and have since expanded to systems involving more elements and more diverse systems. Today, some NNPs cover most of the

elements in the periodic table.
Most of these NNPs are trained to reproduce potential energy surface (PES) of density functional theory (DFT) calculation with generalized gradient approximation (GGA) level exchange-correlation functional, such as Perdew–Burke–Ernzerhof (PBE) functional. Improvements in architectures and datasets have reduced errors between GGA-level DFT and NNPs, and the GGA error itself has become more pronounced.
As a meta-GGA level correlation functional, which has more rich expressive power than GGA level functionals, r2SCAN exchange-correlation functional has recently been adopted in DFT calculations, showing improvements in properties like formation energies and densities compared to GGA. In the field of NNPs, some recent studies demonstrate simulations with higher accuracy to real-world properties by using NNPs pre-trained on GGA-PBE and re-trained with metaGGA or higher level data specific to the target materials and structures. However, for efficacy in materials discovery, it is essential to use a universal potential, which can accurately evaluate PES and other properties of a wide range of unknown structures.
We have been developing PFP, which is an NNP aimed at materials discovery, characterized by its universality in reproducing diverse systems, including molecules, crystals, surfaces, and interfaces. We have continually improved both the universality and accuracy of PFP, which now supports most elements in the periodic table. Currently, PFP is trained with our inhouse GGA-PBE level dataset, and its accuracy to real-world properties is limited by the GGA level. Our goal is to refine PFP to reproduce r2SCAN level PES, achieving higher accuracy beyond the GGA level while maintaining its universality. In this presentation, we will show our progress towards r2SCAN level universal NNP and provide several examples of the improvements made possible through these advancements.

2:30 PM MT04.11.04
Support for 96 Elements and Improved Robustness of Universal Neural Network Potential PFP *So Takamoto[1], Chikashi Shinagawa[1], Daiki Shintani[1], Katsuhiko Nishimra[1] and Ju Li[2]; [1]Preferred Networks, Inc., Japan; [2]Massachusetts Institute of Technology, United States*

The concept of a universal interatomic potential that can be applied to various systems without limiting the domain has attracted attention, and is being developed by many groups as a fundamental model of atomic systems. The neural network potential PFP being developed by the authors is characterized by its universality in handling arbitrary combinations of elements in a single model, rather than performing fine tuning for each system. Both dataset expansion and architectural improvements are ongoing, with the aim of achieving both greater universality and accuracy.
In terms of universality, the number of elements supported by PFP has been expanded sequentially with the expansion of the dataset, starting with the initial 45 elements in 2022 and then expanding to 55 and 72 elements, and the PFP currently under development is being expanded to 96 elements, up to the transuranium element Cm (curium), which will cover all elements stably present on earth. In terms of the elements, we have reached an area that can be regarded as truly universal.
Robustness is also important in simulations to ensure that the state does not go to extrapolated regions. In particular, in exploratory tasks such as crystal structure prediction, energetically unstable structures such as those with multiple atoms positioned closer together may be generated, and the ability of the stable inference in such a situation is required. Architectures based on graph neural networks tend to be unstable for compressed structures because the graph representation is excessively dense, and PFP has tackled this problem both in terms of the architecture and the dataset, and has significantly extended the range of stable inference in PFP v6.0.0.

2:45 PM MT04.11.05
Developing ChIMES Machine Learned Interatomic Potentials for Cesium Lead Halide Perovskites Through Hierarchical Learning *Vallabh Vasudevan and Rebecca K. Lindsey; University of Michigan, United States*

Interest in perovskite materials for optoelectronic applications has surged due to their impressive photovoltaic performance demonstrated nearly a decade ago. [1] Initially, research focused on organic-inorganic hybrid perovskites [2], but their relatively poor stability has led to a shift towards the more stable cesium based inorganic lead halide perovskites. [3] While inorganic perovskites offer high conversion efficiency compared to silicon-based materials, they suffer from rapid degradation in the presence of water and relatively poor thermal stability. [4] Recent studies suggest that modifying synthesis protocols, such as solution processing, can enhance material stability, yet the underlying nucleation mechanisms remain poorly understood. [5, 6] Although solution-processing is theoretically highly tunable, the multitude of chemical compounds involved in perovskite synthesis complicates the optimization of governing conditions.

Simulations can offer mechanistic insights to address these challenges. In this work, we present a ChIMES physics-informed, machine-learned model development approach to create interatomic potentials for characterizing cesium-lead halide perovskite. [7–10] Our ChIMES model features a unique hierarchical structure that allows parameter fitting to be broken down into manageable and reusable "bricks." [11] In the present work, this modular approach starts with binary element pairs and systematically builds to a comprehensive cesium-lead halide perovskite model. We demonstrate that training our ChIMES model using randomly perturbed structures can improve the efficiency of model generation compared to similar models generated using complete dynamics runs.

Our approach can enable the efficient development of accurate machine-learned interatomic potentials to probe the effects of halide segregation on the structural properties of the perovskite framework and characterize diffusion pathways that facilitate halide partitioning. The flexible ChIMES framework also allows for the extension of the model to include solvent interactions.

3:30 PM ^MT04.11.06
Molecular Adsorption on Graphene-Based Materials *Ganna Gryn'ova; University of Birmingham, United Kingdom*

Diversely functionalised derivatives of graphene are rising stars in modern materials science due to their structural variability, wealth of attractive physico-chemical properties, relatively low cost, and bio- and environmental compatibility. Their practical applications often involve interactions with small molecular targets (e.g., gases, environmental pollutants, and drugs) via relatively weak non-covalent forces. To rationalise the structure-property relationships and elucidate the design guidelines relevant to the practical applications of graphene-based *materials (GBMs) in sensing and catalysis, we present GRADS (GRaphene ADSorption) – a multiscale workflow and a dataset of ca. 5,000 structures for molecular adsorption on GBMs. GRADS combines molecular dynamics and density functional theory for evaluating the binding energies, charge transfer, and other relevant properties for mono- and bilayer pristine, oxidised, and defected graphene. We demonstrate how GRADS can be used to benchmark computational methods and deduce the structure-property relationships reflecting the influence of stacking, doping, functionalisation, and defects on the adsorption energetics. We suggest that this workflow and the database can be used in machine learning and high-throughput screening for new and improved sensing materials and catalysts.*

Developing a General-Purpose Machine Learning Interatomic Potential for Ge *Ruoyan Jin, Ali Hamedani and Andrea Sand; Aalto University, Finland*

Exposure to irradiation causes damage in semiconductor components, resulting in the degradation of their performance. Germanium is considered as a complementary material to silicon in radiation detection applications. High-purity Ge is commonly used in the fabrication of spectrometers for astrophysics and planetary space missions, as it allows a higher energy resolution at gamma-ray wavelengths than other detection materials [1]. Molecular dynamics (MD) simulations provide the capability to study the dynamics of defect generation and evolution in irradiated materials. The accuracy of the MD simulations depends almost entirely on the quality of the interatomic potential of the material in hand. So far, radiation damage studies in Ge have been performed mostly with Tersoff [2] potential and Stillinger-Weber potentials with different parametrization [3-5]. These empirical potentials show sensible difference in predicting some of the key properties in the description of the damage generation processes [6]. We present a general-purpose Gaussian approximation machine learning interatomic potential (GAP [7]) for Ge, with which we study radiation-induced damage in this semiconductor. In our dataset we cover different crystalline phases, defects, liquid and amorphous phases. We use a two-body and a turboSOAP [8, 9] many-body descriptor to train our potential. The potential shows excellent agreement with DFT in characterizing elastic, thermal and vibrational properties. The formation energies and diffusivity of the point defects are also in very good agreement with the DFT. Through DFT-MD melt-quench simulations, both liquid and amorphous germanium structures are explored, demonstrating good agreement with the DFT radial distribution function. The temperature-pressure phase diagram of Ge is also illustrated, compared to available experimental and DFT results. The high repulsion of the energetic atoms encountered in collision cascades is captured by appending the ZBL [10] repulsive potential. This model demonstrates GAP's capability in describing a material on the atomic scale, laying a foundation for future refinements and advancements.

LightPFP—Accelerating the Development of Task-Specific Machine Learning Potentials Using Universal Potential *Wenwen Li[1], Nontawat Charoenphakdee[1], Yuta Tsuboi[1], So Takamoto[1] and Ju Li[2]; [1]Preferred Networks,*

Inc., Japan; [2]Massachusetts Institute of Technology, United States

Machine learning interatomic potential has emerged as a powerful tool in materials research. While yielding accuracy comparable to ab initio calculations, machine learning force fields significantly enhance computational efficiency. Two categories of machine learning potentials (MLPs), universal and task-specific, have been developed to address different needs.
Universal MLPs, such as PFP, CHGNet, and M3GNet, encompass a wide range of materials, eliminating the need to train models for specific purposes. However, the model size of universal potentials tends to be very large, which makes them computationally inefficient and prohibitive to be applied on large scale simulation. Conversely, task-specific MLPs, including moment tensor potential (MTP) and Allegro, focus on specific materials and applications, necessitating training for each use case. By sacrificing universality, these models tend to be smaller and much faster to compute. Nevertheless, the training procedure is often time-consuming (e.g., weeks or months) because ab-initio calculation of training datasets is typically required.
To overcome the issue of inefficiency in task-specific MLP training procedure, we propose LightPFP, which is a method to train task-specific MLPs leveraging PFP as a universal MLP. By substituting ab-initio calculations with universal MLP to generate training datasets, we can significantly accelerate the model training process to be completed within a few hours. We have verified the discrepancy between LightPFP and PFP to be within a margin of a few meV/atom, ensuring high accuracy. As a result, LightPFP enables the simulation of larger structures with near-DFT accuracy, surpassing the capacity of PFP.
Furthermore, to enhance the stability and expand the applicability of generated machine learning potentials, several techniques have been developed, including model pre-training/fine-tuning, transfer learning to different exchange-correlation functionals, uncertainty estimation, and active learning. Preliminary experiment shows that such techniques can improve the reliability and predictive power of machine learning potentials, facilitating their application in various materials research domains.

4:30 PM MT04.11.09
Hybrid Equivariant Graph Convolutional Neural Networks for Large Scale Atomistic Simulations *Alex Kutana[1], Koji Shimizu[2], Satoshi Watanabe[3] and Ryoji Asahi[1]; [1]Nagoya University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]The University of Tokyo, Japan*

Regression with machine learning models offers a fast and accurate pathway to material property predictions. Equivariant physics-informed neural networks enable faster learning with smaller datasets by imposing appropriate symmetry constraints on the network weights. In this work, we evaluate prediction errors, learning rates, and generalization ability of several architectures of equivariant graph convolutional neural networks (EGCNNs), targeting atom-wise and global tensorial material properties, and report state-of-the-art performance. Atomic structures are represented by graphs, with atoms mapped to graph nodes and neighbor connections to edges, each assigned attributes and features. The core operation is convolution (or, more generally, message passing) on a graph. Node features are updated via message passing from the neighboring nodes along the edges in the convolution block, with messaging and update functions tuned for flexibility and accuracy of representation. The models are trained for end-to-end prediction of tensorial properties from structural input, with features, weights, and outputs conforming to equivariance with respect to the symmetries of the three-dimensional Euclidean space.
We introduce Equivar, a simple EGCNN model for predicting tensors of Born effective charges from the atomic structure. The model is trained with ab initio datasets of oxides, including systems with mixed covalent and ionic bonding. The model shows relative errors of a fraction of a percent to few percent depending on dataset, and linear scaling of computational time with the number of atoms for both training and inference. The training times are 0.493 ms/atom/epoch, and the inference times are 0.340 ms/atom on a single NVIDIA RTX A6000 GPU. We analyze

the learning curves and report the exponents of the empirical power law. Generalization error is seen to decrease faster for small datasets; however, power law scaling continues for the largest dataset size tested (~10^6 atoms), albeit with a smaller exponent.
With accuracy comparable to that of traditional ab initio approaches, Equivar offers a much better scaling and faster evaluation, affording access to larger length and time scales, which allows one to simulate diverse physical phenomena. While the target properties of primary interest are atomic Born effective charges and static dielectric tensors, other direction-depended properties can also be targeted using this universal approach. Combining different models offers a possibility of simultaneously evaluating various properties at a low computational cost. In on-the-fly calculation scenarios, energies and forces are obtained from an EGCNN force field, while other properties (e.g., tensors of Born effective charges) are calculated simultaneously with a different EGCNN. Alternatively, a single hybrid model can be employed for multiple property predictions. We implement and discuss the advantages and disadvantages of each of these approaches, including simplicity of implementation and possibility of model merging and transfer learning.

4:45 PM MT04.11.10

Efficient and Equivariant Graph Networks for Predicting Quantum Hamiltonian and Tensor Properties

Haiyang Yu, Keqiang Yan, Zhao Xu, Alexandra Saxton, Meng Liu, Youzhi Luo, Alex Strasser, Xiaofeng Qian, Xiaoning Qian and Shuiwang Ji; Texas A&M University, United States

Advances in artificial intelligence (AI) are significantly transforming and accelerating discoveries in materials science and enabling our understanding of materials systems across various spatial and temporal scales. Here we focus on the predictions of quantum Hamiltonian and tensor properties of materials, which are particularly important for quantum chemistry, condensed matter physics, and materials science. First we will present QHNet – an SE(3)-equivariant and efficient graph network, which not only obeys the underlying symmetries, but also significantly reduce the tensor products and avoids the exponential growth of channel dimensions with increasing atom types. The results show that our QHNet can achieve comparable performance to the state of the art methods at a significantly faster speed and less memory requirement due to its streamlined architecture. Second, we will present GMTNet – a space group symmetry informed network for O(3)-equivariant crystal tensor prediction. GMTNet is specifically designed for predicting tensor properties of materials such as dielectric, piezoelectric, and elastic tensors. The results show that our GMTNet not only achieves promising performance on crystal tensors of various orders, but also generates predictions fully consistent with the intrinsic crystal symmetries. Finally, we will briefly introudce QH9 – A quantum Hamiltonian prediction benchmark for QM9 molecules, with 130,831 stable molecular geometries, highly valuable for developing machine learning methods and accelerating materials design for scientific and technological applications.

SESSION MT04.12: Novel Algorithms for Materials Science and Engineering

Session Chairs: Jian Lin and Dmitry Zubarev

Hynes, Level 2, Room 210

8:00 AM MT04.12.01

GAN-Based Realistic 3D Multicrystalline Si Structure Generation Using Actual Si Ingot Crystallographic Information

Takumi Deshimaru[1], Kentaro Kutsukake[1,2], Hiroaki Kudo[1], Ryoji Katsube[1] and Noritaka Usami[1];
[1]Nagoya University, Japan; [2]RIKEN, Japan

We have developed a method to generate realistic 3D multicrystalline (mc) structures based on one of the image generation AI; Generative Adversarial Networks (GAN). This was made possible by our original data science approach that can analyze Si ingot at the ingot scale, collecting crystallographic features such as grain boundary distribution, grain shape, crystal orientation, growth direction, and height. Hereby, our GAN-based model can learn and generate a variety of mc-structures containing actual crystallographic features, which are extremely important for understanding the properties and behavior of mc-materials. For example, in Si, crystal orientation is extensively involved in twinning and stress distribution around grain boundaries. Therefore, it is important to elucidate the relationships between mc-structures and properties through extensive exploration for mc-structures that include crystallographic features. However, it has been limited to localized and time-consuming exploration due to the difficulty of mc-structure reproduction. For instance, property estimation is based on mc-structures represented by 3D Voronoi diagram and physical simulations rely heavily on researchers' sense and experience. This is where our method comes into play. Our method can overcome the mc-structure reproduction difficulty and enable faster and more comprehensive mc-structures exploration and analysis.

We used 50 wafers of 15.6 cm × 15.6 cm × 180 µm sliced from a high performance (HP) mc-Si ingot grown via unidirectional solidification method. Alkaline texturing was performed to leave mainly the {111} facets which form a pyramid-like structure. Light illumination on these pyramids results in the appearance of crystallographic orientation-specific reflection patterns. We captured these reflection patterns by a home-made apparatus. As the light rotates around the sample, optical images were captured and integrated into the signal intensity matrix, which we call the "luminance profile". Ingot scale crystal orientation mapping was performed by inputting luminance profiles into our previously developed crystal orientation estimation model that consists of a long short-term memory (LSTM) neural network and two fully connected layers. Our data science approach made it possible to obtain sufficient amount of ingot scale crystallographic feature data for machine learning, which was difficult by conventional measurement such as electron backscatter diffraction (EBSD) due to its slow measuring speed and small area. We adopted one of the GAN models StyleGAN2-ADA to learn crystallographic features since it can be trained effectively with limited data. This is because it applies a method called Adaptive Discriminator Augmentation (ADA), which allows for adaptive data expansion depending on the training process stage. We trained the model using 2500 randomly cropped to 2.6 cm square crystal orientation images from 50 images of 15.6 cm squares. After training, a variety of crystal orientation images can be generated from arbitrary noises. Moreover, we selected one of the conditional GAN models pix2pix to learn growth direction and height features which are especially important for materials grown via unidirectional solidification method. We trained the model using 1500 crystal orientation image pairs equally spaced 180 µm apart along the growth direction. After training, the model learns the growth behavior along the growth direction and can predict the crystal orientation image 180 µm above the input. Finally, realistic 3D mc-Si structure can be generated by combining trained StyleGAN2-ADA and pix2pix. This involves generating the bottom most crystal orientation image from noise and then repeating 180 µm upper crystal orientation image prediction and stacking them. Further analysis of the certainty and accuracy of the mc-structures generated by this method will be reported.

8:15 AM MT04.12.02

Equivariant Machine Learning for Electron Density Predictions *Thomas Koker[1], Keegan Quigley[1], Eric Taw[1,2], Kevin Tibbetts[1] and Lin Li[1]; [1]Massachusetts Institute of Technology, United States; [2]Lawrence Berkeley National Laboratory, United States*

At the root of density functional theory, the first Hohenberg-Kohn theorem states that the ground-state properties of a material can be predicted uniquely by the electron density. We predict this fundamental quantity via an equivariant neural network called ChargE3Net and show that high rotation-order embeddings (up to $l=4$ spherical harmonics) can be used to accurately predict the charge density at any point in the unit cell. When trained on *approximately 120,000 charge density grids from the Materials Project, we show that ChargE3Net generalizes well for bulk inorganic materials across the periodic table and accelerates self-consistent DFT calculations by 26% for non-magnetic materials when used as an initial charge density guess. Using the predicted charge densities in non-self-consistent calculations, we observe that about 40% of materials in a test set achieve <1meV/atom error for calculated potential energies. We show that ChargE3Net still accelerates DFT calculations on a subset of materials obtained from GNoME, further exemplifying its ability to generalize outside of its training set. We explore additional engineering improvements to the model and extensions to magnetic systems.*

8:30 AM MT04.12.03

Advance Materials Research with Atomistic Modeling and Machine Learning *Nicolas Onofrio, Fedor Goumans, Matti Hellström and Paul Spiering; Software for Chemistry & Materials, Netherlands*

In the pursuit of sustainable, high-performance semiconductors, batteries, and optical devices, the development of advanced materials is essential. Tackling the complexities of materials and processes necessitates innovative, data-driven research approaches. The Amsterdam Modeling Suite (AMS) provides a comprehensive framework for simulating materials across multiple levels of theory, integrating atomistic engines (DFT, DFTB, ReaxFF, ML potentials) with a central driver for exploring potential energy surfaces (PES) through molecular dynamics and Grand Canonical Monte Carlo simulations. The combination of the AMS driver with its dedicated Python interface facilitates the automatic screening of materials, optimizing their structural and electronic properties.
Recent developments include a platerform for near-universal machine learning interatomic potentials, and an easy program to fine-tune them for your application. With ParAMS, users can train individual or multiple machine learning potentials from scratch, fine-tune universal models, or actively learn the PES based on target molecular dynamics simulations. Optimized models can be directly used as an engine with the AMS driver. This capability enables the rapid prediction of material properties and reaction mechanisms, accelerating the design and testing of new materials. We will showcase examples related to catalysis and battery modeling.
Our data-driven approach empowers the materials R&D community to surpass traditional development obstacles, enabling accurate material performance predictions and the discovery of new materials and mechanisms, paving the way towards realizing innovative solutions.

8:45 AM MT04.12.04

Multi-Task Learning for Molecular Electronic Structure Approaching Coupled-Cluster Accuracy *Hao Tang[1], Brian Xiao[1], Wenhao He[1], Yao Wang[2], Fang Liu[2], Haowei Xu[1] and Ju Li[1]; [1]Massachusetts Institute of Technology, United States; [2]Emory University, United States*

Machine learning (ML) plays an important role in quantum chemistry, providing fast-to-evaluate predictive models for various properties of molecules. However, most existing ML models for molecular electronic properties use density functional theory (DFT) databases as ground truth in training, and their prediction accuracy cannot surpass that of DFT. In this work, we developed a unified ML method for electronic structures of organic molecules using the gold-standard CCSD(T) calculations as training data. Tested on hydrocarbon molecules, our model outperforms DFT with the widely-used hybrid and double hybrid functionals in computational costs and prediction accuracy of various quantum chemical properties. As case studies, we apply the model to aromatic compounds and semiconducting polymers on both ground state and excited state properties, demonstrating its accuracy and generalization capability to complex systems that are hard to calculate using CCSD(T)-level methods.

9:00 AM MT04.12.05

A Novel Graph Representation and an Improved Transfer Learning Method for Accurate Predictions of the Chemical Properties of Molecules *Joonhyuk Choi and Youngchun Kwon; Samsung Advanced Institute of*

Technology, Korea (the Republic of)

It has been shown that artificial intelligence (AI) models are quite successful to predict chemical properties of molecules and it is crucial to choose a proper molecular representation such as SMILES and a graph in order to improve the performance of the AI models. Recently, graph neural networks (GNNs) have demonstrated superior performance on predicting chemical properties of given molecules and they become prevailing molecular representations. Due to the high dimensionality for data representation with graphs, however, as the number of data points that we need to deal with increases, it demands very large calculation resources and it becomes quite difficult to manage the graph representations to proceed training processes for the AI models. Furthermore, the scarcity of available datasets to predict chemical properties such as retention time of molecules makes development of accurate chemical prediction AI models challenging. To address the first scalability issue with graph-based molecular representations, we propose a sparsified graph representation that regards only heavy atoms in a molecule as nodes and chemical bonds as edges. We show that our proposed representation with an improved message passing and readout functions in a GNN is more scalable to large molecules and provides higher prediction accuracy for NMR chemical shift than generally used graph-based methods. In order to overcome the scarcity problem of training datasets for making an accurate model that predicts retention time for small molecules, we present an improved transfer learning method that learns from a small training data set with a pre-trained GNN. The GNN is pre-trained on the METLIN-SMRT data set and then is fine-tuned on the target training data set for a fixed number of iterations using the limited memory Broyden-Fletcher-Goldfarb-Shanno optimizer. We demonstrate that this proposed method provides better prediction accuracy on numerous chromatographic systems than existing other transfer methods.

9:15 AM MT04.12.06

Quantifying Chemical Short-Range Order in Metallic Alloys *Killian Sheriff, Yifan Cao, Tess Smidt and Rodrigo Freitas; Massachusetts Institute of Technology, United States*

High-entropy materials are metallic or ceramic systems composed of three or more chemical elements mixed in nearly equiatomic concentrations. These design choices lead to substantial chemical complexity which functions as the background against which microstructural evolution occurs, thereby affecting various material properties through chemistry–microstructure relationships. However, computationally capturing and defining this complexity has remained a challenge and is often overlooked. Here, I will discuss how machine learning, group theory, and statistical mechanics, can be employed together to characterize, atom-by-atom, the state of short-range order of high-entropy materials, thereby advancing the quantitative understanding of metallic alloys, and paving the way for the rigorous incorporation of this phenomenon into mechanical and thermodynamic models.

9:30 AM MT04.12.07

Accelerated Quantum Chemical Simulations for Oxygen Evolution Reaction Catalysts Using "PreFerred Potential" (PFP)—A Pathway to Efficient Material Design *Hiroki Kotaka, Yuji Hakozaki, Terumasa Shimada, Yoichiro Kawami, Yoshitatsu Misu, Atsushi Fukazawa and Yusuke Hasegawa; ENEOS Corporation, Japan*

PEM water electrolysis is garnering interest as a promising method for converting and storing renewable energy into hydrogen fuel. Designing efficient the oxygen evolution reaction (OER)catalysts that can operate under the acidic conditions of PEM systems is recognized as a significant challenge. An ideal OER catalyst must exhibit not only high reaction activity and electrical conductivity but also exceptional corrosion resistance. However, candidates that satisfy all these criteria are exceedingly rare. Rutile-IrO2 stands out as the leading catalyst for OER within PEM electrolyzers, yet the scarcity of iridium limits its practicality for large-scale industrial applications. To address this gap, we are using state-of-the-art computational chemistry methods to explore OER catalysts with *alternating Ir that exhibit both enhanced activity, and durability.*

The realm of quantum chemical simulations for heterogeneous catalysis, including OER, has seen remarkable progress due to the relentless contributions of eminent quantum chemists [1-3]. These simulations play a crucial role in propelling computational research forward, aiming to boost catalyst performance. Nonetheless, the substantial computational resources required for such quantum chemical calculations pose a significant hurdle, slowing the advancement of simulation-driven material development.

In this study, we have employed the PreFerred Potential (PFP), a neural network potential which is based on density functional theory datasets [4]. PFP is implemented in MATLANTIS® software and is described as a quasi-atomic potential, which demands fewer computational resources, thus enabling high-precision calculations and remarkably rapid solutions when used for structural relaxation. We have conducted overpotential calculations and screening using computational data for oxygen evolution reaction (OER) catalysts under acidic conditions. Our findings confirm that PFP possesses an interatomic potential with high computational accuracy, comparable to the first-principles calculations, for evaluating OER overpotentials.

Focusing on rutile-RuO2 as, a well-reported candidate material that does not contain Ir, we have performed hetero-metallic doping calculations using PFP. These calculations elucidate the numerical reduction in overpotential due to doping and investigate the appropriate doping levels. Furthermore, we have evaluated the activity of pyrochlore-structured materials containing Ru, identifying better material combinations through overpotential calculations. For each composition, we assessed the surface stability using surface Pourbaix diagrams and compared overpotentials based on adsorption sites, reaction pathways, and molecular orientations [2]. These extensive calculations were made possible by the significant acceleration of structural optimization computations provided by PFP.

Our presentation will suggest effective metal composition ratios for various oxide surfaces, such as rutile, pyrochlore, etc., and demonstrate that PFP is an effective method for rapidly screening potential catalyst compositions. We will illustrate how PFP can be utilized in simulation calculations essential for the theoretical understanding of catalyst activity, thereby offering a valuable tool for the expedited discovery of promising catalyst compositions.

Deconvolving Lithium Diffusion Mechanisms for Solid Polymer Electrolyte Systems Through Graph Neural Network-Enabled Geometric Analysis of Local Structure in Amorphous Polyethylene Oxide Simulations

Pablo A. Leon and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Solid polymer electrolytes (SPEs) have emerged as promising alternatives to conventional liquid electrolytes in lithium battery systems due to their low density, mechanical compliance, and low flammability but are challenged by lower ionic conductivity. Molecular dynamics (MD) simulations can be used to accelerate the design of novel SPEs by allowing for mechanistic understanding of lithium ion diffusion at the atomic scale. It has been determined that lithium diffusion in the most promising polymer candidate, polyethylene oxide (PEO), is limited by lithium's dependence on the polymer's segmental motion. However, the deconvolved contributions of segmental motion and ion hopping to lithium's overall conductivity across a range of polymer systems have not been fully explained. Also, the complex interplay between amorphous polymer structure and lithium diffusion mechanisms is not yet understood.

In this work, we find evidence that local order in the amorphous polymer electrolytes can help elucidate and *explain lithium diffusion mechanisms across a range of polymer chemistries. A combination of local polymer geometry analysis and graph neural network-based atomic environment featurization is used to identify and characterize sites that can be occupied by lithium ions. Additionally, by extracting site-to-site hopping events, the contributions of hopping and segmental motion on lithium diffusion are decoupled and quantified. This analysis was performed on in-house MD simulations run for hundreds of nanoseconds at a range of salt concentrations. By using the developed high-throughput simulation and analysis workflow, lithium salt concentration effects on lithium diffusion were able to be methodically compared, allowing for better understanding of polymer design criteria for novel solid polymer electrolyte systems.*

Modelling Bulk and Edge Phonons in 2D Materials Observed with High-Resolution Transmission Electron Microscopy *Patrick Giese, Mathias S. Nissen, Cuauhtémoc N. Valencia, Stig Helveg and Jakob Schiøtz; Technical University of Denmark, Denmark*

When simulating High-Resolution Transmission Electron Microscopy (HR-TEM) images, atomic vibrations are usually taken into account either by convolving the electrostatic potential with a Debye-Waller factor, or by the Frozen Phonon method. The latter gives the most correct description of the vibrations, as it correctly reflects that the transition time of the electron through the sample is short compared to the atomic vibration time: the calculated image is an average of a sequence of images calculated with slightly perturbed atomic positions. Usually, perturbations are drawn from a normal distribution with a variance calculated with the Debye model.

In a recent publication, Chen et al. were able to measure the vibrational amplitudes of the atoms in a graphite-supported cobalt-doped molybdenum disulfide (MoS_2) nanoparticle, using HR-TEM and exit wave reconstructions [1]. They observe a larger vibrational amplitude of the atoms near the edge of the nanoparticle.

We use machine-learning potentials to study graphite-supported MoS_2 nanoparticles with molecular dynamics (MD). The MD simulations confirm an increase in vibrational amplitude, not only of the undercoordinated atoms right at the edge of the nanoparticles, but also of atoms situated a few lattice constants away from the edge. Simulations of the HR-TEM exit wave show a vibrational signature in the exit wave similar to what was observed by Chen et al., supporting their interpretation that it is induced by atomic vibrations. We interpret the enhanced vibrational amplitudes near the edges as the signature of a phonon edge state, similar to the electronic edge state that has been observed in MoS_2.

The MD simulations were performed using Equivariant Neural Network Potentials trained on Density Functional Theory (DFT) calculations of similar but much smaller systems, using the NequIP [2] package. We demonstrate how a systematic approach to increasing the training set while limiting redundancy can result in a stable and reliable machine learning potential with only a very modest training set of around 400 DFT calculations.

Anharmonic Phonons with Gaussian Processes *Keerati Keeratikarn and Jarvist M. Frost; Imperial College London, United Kingdom*

We provide a method for calculating anharmonic lattice dynamics (http://arxiv.org/abs/2405.05113), by building a surrogate machine-learning model based on Gaussian Processes (GPs). Due to the underlying Gaussian form of a GP, the model is infinitely differentiable. This allows us to train the model trained directly on forces (the derivative of PESs) reducing the evaluations required for a given accuracy. We can extend this differentiation to directly calculate second and third order force-constants using automatic differentiation (AD). For the five model materials we study, we find that the force-constants are in close agreement with a standard finite-displacement approach. We also compare our results with the recent cluster expansion technique implemented in HiPhive.py which requires a larger supercell to achieve the same level of accuracy. Our method appears to be linear scaling in the number of atoms at predicting both second and third-order (anharmonic) force-constants.

11:00 AM MT04.12.11

Finite-Temperature Crystal Structure Prediction with Universal Neural Network Potential and Free Energy Calculation *Kohei Shinohara[1], Takuya Shibayama[1], Hideaki Imamura[1], Katsuhiko Nishimra[1], Chikashi Shinagawa[1], So Takamoto[1] and Ju Li[2]; [1]Preferred Networks, Inc., Japan; [2]Massachusetts Institute of Technology, United States*

Crystal structure prediction (CSP) is a critical process for predicting stable crystal structures in given systems, serving as a crucial prerequisite for harnessing computational atomic simulations. Typically, CSP methods are combined with density functional theory (DFT) calculations to evaluate the formation energy of the candidate structures. However, the efficiency of CSP is greatly hindered by the time-consuming DFT calculations, which limit the exploration of numerous candidate structures.

Recent advancements of neural network potential (NNP) fitted by DFT calculations, offer an efficient approach to CSP thanks to their fast and accurate energy evaluation. Given the interest in multi-component systems in CSP, it is preferable for NNP to exhibit universality across various systems and a strict level of accuracy to capture subtle energy differences in distinct structures. We employed our developed universal NNP called PFP, which was trained with extensive datasets comprising around 59 million structures [1]. The PFP showed 4.2 meV/atom (MAE) in accuracy of the energy above the convex hull among near-the-hull structures up to 10 meV/atom in Materials Project's unary, binary, and ternary systems. We use PFP and a genetic algorithm (GA) based CSP method inspired from the sophisticated multi-objective optimization algorithms [2].

We further extend our analysis to finite temperature as conventional CSP only considers enthalpy at zero temperature. This involves free energy calculation for candidate structures found in CSP. Although the free energy calculations are computationally intensive and require complex workflows, recent developments have led to automated and robust frameworks [3,4]. Similar to these previous works, we employ thermodynamic integration to compute Gibbs free energy and manage the complex workflows with Argo Workflows [5], ensuring robustness and scalability in handling diverse structures in CSP.

For validation, we computed thermal properties using PFP and compared them with empirical potential results [6]. Additionally, we analyzed temperature-dependence of phase stability for near-the-hull structures in CSP search. Our work, combining the universal NNP, GA-based CSP method, and automated free energy calculations, should demonstrate the promise of these methods in materials discovery.

Potential Energy Surface Softening in Universal Machine Learning Interatomic Potentials *Bowen Deng[1], Yunyeong Choi[1], Peichen Zhong[1], Janosh Riebesell[2], Shashwat Anand[3], Zhuohan Li[3], KyuJung Jun[1], Kristin A. Persson[1,3] and Gerbrand Ceder[1,3]; [1]University of California, Berkeley, United States; [2]University of Cambridge, United Kingdom; [3]Lawrence Berkeley National Laboratory, United States*

Artificial Intelligence is increasingly shifting the paradigm of materials discovery. One of the major contributions came from machine learning interatomic potentials (MLIPs), which enabled the chance to scale atomic-level quantum chemical accuracy to large-scale simulations. Recent advancements have seen the emergence of universal MLIPs (uMLIPs) that are pre-trained on diverse materials datasets, providing opportunities for both ready-to-use universal force fields and robust foundations for downstream machine learning refinements. However, the performance of uMLIPs in extrapolating to out-of-distribution (OOD) complex atomic environments remains unclear.

In this talk, we will discuss the limitations and potential improvements of current foundational uMLIPs including M3GNet, CHGNet and MACE-MP-0 through a series of OOD benchmark tests including surfaces, defects, phonons, ion migration barriers, etc. We uncovered a systematic potential energy surface (PES) softening effect characterized by the underprediction of energy and forces in all benchmark tests with all current uMLIPs. We demonstrate that the PES softening issue can be effectively rectified by fine-tuning with a single additional data point. Our findings suggest that a considerable fraction of uMLIP errors are highly systematic, and can therefore be efficiently corrected. Our result provides a theoretical foundation for the widely observed data-efficient performance boosts achieved by fine-tuning uMLIPs and highlights the advantage of next-generation atomic modeling with large and comprehensive foundational AI models.

Progress in Selective Growth of Small-Diameter Single-Wall Carbon Nanotubes from Promoted Catalysts

Placidus B. Amama; Kansas State University, United States

The presentation will focus on recent advances in using high-melting-point metals as promoters of Co and Fe catalysts for the growth of small-diameter single-wall carbon nanotubes (SWCNTs) via chemical vapor deposition. I will also discuss the use of high-throughput experimentation in our research to probe the role of the promoter in SWCNT growth, along with insight into the complex relationship between catalyst promotion, SWCNT diameter, growth temperature, and type of carbon precursor.

11:00 AM NM01.01.02

Vapor-on-Metal Condensation Strategy for Low-Dimensional Carbon-Nitride-Based Material Synthesis *Zihan Song[1,2]; [1]University of Oxford, United Kingdom; [2]Max Planck Institute of Colloids and Interfaces, Germany*

Carbon nitrides (CNs) have attracted widespread attention in the field of energy research due to its tuneable semiconductive property, good physicochemical stability, and easy fabrication. Although a large group of CNs has be reported with different chemical structures, the majority of CNs is basically composed of either heptazine (C_6N_7) or triazine (C_3N_3) units connected by tertiary nitrogen. Different structural units of CNs and their arrangements enables the presents different physiochemical properties. Meanwhile, the morphologies of CN-based materials play a crucial role in determining its properties and performance across various applications. Herein, we proposed a vapor-on-metal condensation strategy for synthesizing two-dimensional (2D) or one-dimensional (1D) CN-based materials on metallic substrates, which are hardly obtained via traditional methodologies.

Triazine-based graphitic CNs are in analogy to the structurally related graphite but has an alternating arrangement of covalently linked carbon and nitrogen atoms. This structure provides an opening of the bandgap (1.6~2.0 eV), while it is not thermodynamically preferential according to theoretical calculation studies. Therefore, the synthesis of triazine-based graphitic CNs through general thermal methods is rarely achieved. In our first study, a planar copper (Cu) foil was used as the substrate for synthesizing 2D triazine-based graphitic CN (t-CN) thin films via thermal vapor condensation at the vapor-metal interface in a simple semi-closed system. This process is operated at a relatively low condensation temperature of 500 °C and achieve a homogeneous centimetre-scale growth of highly crystalline t-CN films with a thickness of ~700 nm. An in-plane periodic crystalline structure of t-CN with AB-stacking mode was confirmed by high-resolution transmission electron microscopy. Cu species homogeneously dispersed in t-CN phase, coordinated with triazine-N in the structural pores, which potentially suppress the formation of heptazine structure. This t-CN film on Cu foil could directly serve as an interphase of an anodeless electrode, improving the uniformity of a dense electrochemical Li deposition on the Cu current collector. As the prospects of this work, the developed vapor-metal interfacial condensation method is applicable for effectively producing high-quality, large-area 2D triazine-based graphitic carbon nitride materials on a planar substrate. The confirmed triazine-based structure provides opportunities to establish clear structure-property relationships of

these carbon nitride materials, paving the way for potentially applications such as energy conversion, membrane separation and optical applications.
One-dimensional hollow materials, in particular nanotubes, have attracted great interests in diverse domains owing to their structural features and corresponding physicochemical properties. Among them, carbon-nitride-based nanotube material, combining the appealing properties of carbon nitride and advantages of its geometric structure, is promising for research and applications in energy and environmental field. Here, a similar thermal vapor condensation route realizes a homogeneous growth of high-aspect-ratio carbon-nitride-based nanotubes (CNNTs) on metallic copper/zinc (Cu/Zn) alloy substrate. The average diameter of CNNTs is in range of 20~25 nm and the corresponding length/diameter ratio is ~100. With systematic investigation, we propose a Zn-assisted diffusion-growth mechanism, which is distinguished from traditional understandings on the growth of nanotubes. Particularly, the growth of CNNTs is highly determined by the chemical structures of precursors and types of metallic substrate. In addition, the chemical composition of CNNTs is tuneable by changing the carbon-nitrogen ratio of precursor molecules. These results provide a feasible synthesis strategy for semiconductive CNNTs and enable further investigation on nanostructure-based applications.

11:15 AM NM01.01.03
Upcycling Low Linear Density Polyethylene Waste into Turbostratic Graphene for High Mass Loading Supercapacitors *Viet Hung Pham[1,2], Yuan Gao[1,2], Ngoc Tien Huynh[1,2], Ki-Joong Kim[1], Congjun Wang[1] and Christopher Matranga[1]; [1]National Energy Technology Laboratory, United States; [2]NETL Support Contractor, United States*

Plastic pollution is triggering a global environmental crisis, prompting research efforts in recycling and upcycling to address the challenge. Upcycling plastic into graphene and porous carbon creates options to manage waste streams by converting the plastic into materials that can be used as electrodes in energy storage devices. Linear low-density polyethylene (LLDPE) is difficult to upcycle because it tends to decompose into light gases and hydrocarbons during thermal processing which limits how easily it can be converted into useful solid carbon materials. In this work, LLDPE was upcycled into a high quality turbostratic graphene using a pre-treatment step to oxidatively crosslink the polymer with the assistance of solid additives (KCl and K_2CO_3) that improve crosslinking by increasing the effective surface area of the polymer melt during processing. After this pretreatment step, the crosslinked polymer could then be carbonized and catalytically graphenized between 400-950 °C without complete decomposition of the material. The LLDPE derived graphene (LLDPE-G) obtained from this process has a Brunauer–Emmett–Teller (BET) specific surface area, up to 1800 m^2g^{-1} and average Raman I_D/I_G and I_{2D}/I_G ratios of 0.85 and 0.57, respectively, indicating high quality graphene. When used as an electrode material in symmetric supercapacitors, LLDPE-G possesses an outstanding specific capacitance up to 175 Fg^{-1} at a mass loading of 20 $mgcm^{-2}$, which is two times the commercial requirement, yielding an excellent areal capacitance of 3.5 Fcm^{-2}. Moreover, LLDPE-G exhibits exceptional cycling stability with a capacitance retention of 95.8% after 100,000 cycles at a current density of 4.0 Ag^{-1}. Additionally, the KCl and K_2CO_3 were recycled and reused over 3 complete cycles to make new LLDPE-G with the material quality and electrocapacitive performance retained and verified after each cycle. Our approach creates new opportunities for upcycling not only waste LLDPE but also other varieties of PE to high value graphene materials for electrochemical energy storage device applications.

11:30 AM NM01.01.04
Bottom-Up Synthesis of Schwarzite Carbon Allotropes from Heptagon Carbon Cycles *Alexey V. Ignatchenko and Degraj Suberi; St. John Fisher University, United States*

Schwarzites represent a class of theoretical carbon allotropes defined by their continuous, negatively curved surfaces exhibiting three-dimensional periodicity. These hypothetical materials are garnering considerable interest *due to their projected high surface area to volume ratio, substantial porosity, tunable electrical conductivity, and exceptional mechanical strength paired with low density. Despite over thirty years of research, attempts to synthesize Schwarzites from gas-phase carbon atoms were not successful and the focus is shifting to other methods, such as zeolite templating and bottom-up synthesis.*

The design of new Schwarzite structures involves the placement of sp2-carbon polygon tiles on mathematically defined triply periodic minimal surfaces. Until recently, Schwarzite designs were dominated by using octagons. In this work, Schwarzite tiling with heptagons will be done for the convenience of the bottom-up synthesis and it will be systematically analyzed and classified by symmetry and topology. For the first time, detailed methodologies for the bottom-up synthesis of various Schwarzites representing gyroid, P, D, CLP, IWP, H, HT, and GW surfaces will be provided, with a trimer of heptagons identified as the central building block in most synthetic approaches. The shift in the synthetic design paradigm lies in creating benzene rings between heptagon rings by connecting pairs of heptagon vertices in a [2+2+2] cyclization as opposed to the current approach for making negatively curved nanographenes by using benzene rings as building blocks.

The bottom-up synthesis using strategically chosen heptagon trimers offers superior control over topology, geometry, and pore size distribution in periodic carbon materials compared to zeolite templating. This approach holds significant potential for advancing the design and functionality of carbon-based structures.

11:45 AM NM01.01.05

Realizing Scalable Chemical Vapour Deposition of Graphene Films on Iron and Steels by In Situ Observations

Bernhard Fickl[1], Werner Artner[1], Daniel Matulka[1,1], Jakob Rath[1,1], Markus Hofer[1], Martin Nastran[1], Raoul Blume[2], Michael Haevecker[2,3], Alexander Kirnbauer[1], Florian Fahrnberger[1], Herbert Hutter[1], Dengsong Zhang[4], Paul Mayrhofer[1], Axel Knop-Gericke[2,3], Beatriz Roldán Cuenya[3], Robert Schlögel[2,3], Christian Dipolt[5], Dominik Eder[1] and Bernhard C. Bayer[1]; [1]Technische Universität Wien, Austria; [2]Max Planck Institute for Chemical Energy Conversion, Germany; [3]Max Planck Society, Germany; [4]Shanghai University, China; [5]Rübig GmbH & Co KG, Austria

Graphene has been suggested as an ultimately thin functional coating for metallurgical alloys such as steels. However, even on pure iron (Fe), the parent phase of steels, growth of high-quality graphene films remains largely elusive to date. We here report scalable chemical vapour deposition (CVD) of high-quality monolayer graphene films on pure Fe substrates and discuss the improvement of graphene growth conditions on steels. To achieve this, we elucidate the mechanisms of graphene growth on Fe substrates using complementary in situ X-ray diffractometry (XRD) and in situ near ambient pressure X-ray photoelectron spectroscopy (NAP XPS) during our scalable CVD conditions. We identify key factors that differentiate Fe from other common graphene CVD catalyst supports such as Ni or Cu. Firstly, that for Fe, carbothermal reduction of persistent Fe-oxides may take place during CVD and secondly, that the kinetic balancing of carbon uptake into the Fe during CVD near the Fe-C eutectoid is critical for monolayer graphene growth because of the complex multi-phased Fe-C phase diagram. Additionally, we establish that the carbon uptake into the Fe during graphene CVD is not only important in terms of growth mechanism but can also be advantageously utilized for concurrent surface hardening of the Fe during the graphene CVD process akin to carburization/case hardening. Our work thereby forms a framework for controlled and scalable high-quality monolayer graphene film CVD on Fe and more complex metallurgical substrates.

Carbon Nanotube using an Autonomous Research System (ARES) *Rahul Rao and Benji Maruyama; Air Force Research Laboratory, United States*

The current materials research process is so slow and expensive, taking decades from invention to commercialization. This has negatively impacted technologically important materials like carbon nanotubes. In order to address this crucial issue, the Air Force Research Laboratory pioneered ARES™, the first autonomous research system for materials development. ARES employs advances in artificial intelligence and machine learning (AI/ML) along with modeling and simulation towards controlled growth of carbon nanotubes. In this talk, we will discuss recent efforts in combining autonomous experimentation with modeling to understand and control the fundamental mechanisms that drive CNT synthesis via chemical vapor deposition (CVD). ARES is one of many emerging materials platforms and self driving labs that are pioneering materials research and speeding up their development.

2:00 PM NM01.02.02

Catalyst Design for the Synthesis of Vertically Aligned and Double-Walled Carbon Nanotube Array Exceeding One-Centimeter Height *Shunsuke Sakurai, Takashi Tsuji, Maho Yamada and Don N. Futaba; National Institute of Advanced Industrial Science and Technology, Japan*

Since metal nanoparticle catalysts often face challenges of catalytic degradation due to structural changes, the design of the catalyst support layer is crucial, especially for the synthesis of vertically aligned carbon nanotubes (CNT forests) from highly dense catalytic nanoparticle arrays [1-3]. Our previous research, which primarily focused on the impact of catalyst support, emphasizes the importance of the double-layer (DL) strategy for the catalyst support layer. DL supports, composed of a top "anchor layer" to impede surface diffusion such as Ostwald ripening, and a high crystallinity "sealing layer" to inhibit subsurface diffusion, have been proposed and demonstrated to elongate the catalyst lifetime for the synthesis of mm-tall single-walled CNT forests [4].
In the present study, we explored the DL catalyst support structure and successfully demonstrated the selective synthesis of DWCNT forests exceeding 1 cm in height in just 60 minutes. The catalyst support was prepared by sputtering an alumina layer (thickness: approximately 1−3 nm) onto pre-annealed SiO_2 layer formed on Si substrate. Sequentially, an iron catalyst film was sputtered onto the catalyst support. The catalyst was then annealed in hydrogen to form catalyst nanoparticles, followed by CNT synthesis using water-assisted catalytic chemical vapor deposition. Observations using an atomic force microscope (AFM) revealed the formation of iron nanoparticle arrays with a relatively low particle density of 3×10^{11} particles/cm^2 after hydrogen annealing. Structural evaluation of the CNT forest revealed a sparse array (0.8×10^{11} tubes/cm^2) of mainly double-walled (56%) CNTs.

Graphene Synthesis on Single-Crystalline Cu(111) Substrate—A Study on Wrinkle Formation and Density
Zhien Wang[1], Jiangtao Wang[1], Zachariah B. Hennighausen[1], Se-Young Jeong[2] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]Pusan National University, Korea (the Republic of)

Chemical vapor deposition (CVD) has emerged as an effective method for synthesizing large-area graphene, yet achieving reproducible synthesis of wrinkle-free, single-crystal graphene remains challenging. Recent studies have shown that wrinkle-free, single-crystal graphene can be synthesized using 500nm single-crystal Cu(111) film on sapphire as substrate. However, the role of Cu(111) thin film in suppressing the formation of wrinkles on as-grown graphene has not been understood thoroughly.
In our study, we developed recipes for single-crystal, large-area graphene on Cu(111) foil and ultra-flat graphene on Cu(111) film/sapphire. Through comparing the wrinkle density of graphene produced by these two methods, we investigated the influences of Cu(111) substrates (thin film vs. foil), and growth parameters towards wrinkle formation. And we compared the respective strengths of these two recipes, which are suitable for different applications. Our stable, highly-reproducible low-pressure (LP) CVD recipe on single-crystal Cu(111) foil produces centimeter-sized, low-defect, single-crystal graphene. While graphene grown on 500nm-700nm Cu(111) film/sapphire is ultra-flat with much fewer wrinkles. This detailed study on wrinkle formation and density holds promise for advancing the understanding and accessibility of high-quality graphene synthesis.

Semiconducting Ratio Modulation of Single-Walled Carbon Nanotubes for Efficient NO_2 Detection at Low-Temperature *Il Jeon; Sungkyunkwan University, Korea (the Republic of)*

This study presents a nitrogen dioxide (NO_2) gas sensor based on single-walled carbon nanotubes (SWCNTs) with varying proportions of semiconducting SWCNTs (s-SWCNTs). The SWCNTs were synthesised using a floating catalyst chemical vapor deposition (FCCVD) method. The purity of the s-SWCNTs was controlled by adjusting the carbon source, reactor temperature, and gas flow rates. The FCCVD-synthesised CNT thin films can be transferred via a simple one-step process without the need for solvents, a significant advantage over conventional CNTs. As reported in our previous publication [S. Kim, et al., Adv. Mater., (2024) 2313830.], sensors utilising FCCVD CNTs demonstrate superior performance in sensitivity, response time, and detection limit among CNT-based NO_2 sensors. Additionally, the optimal operating temperature for these sensors was found to be 150 °C, significantly lower than that of metal oxide-based NO_2 sensors, which typically operate around 400 °C. In this work, we further improved the sensing performance and reduced the optimal operating temperature by controlling the ratio of s-SWCNTs. A higher proportion of semiconducting content increased the binding energy between the gas molecules and the CNT surface, significantly enhancing the sensor performance, even at lower temperatures of 120 °C. A sensor with 94% s-SWCNT exhibited an exceptionally high response (83.2% at 500 ppb) and a fast response time (~8.6 s) compared to previously reported studies [M. Jeon, et al., Appl. Phys. Lett., (2017), 022102.; L. Sacco, et al., Carbon, (2020), 631.]. Conversely, a sample with 87% s-SWCNT demonstrated an extremely rapid recovery (72.8 s). Additionally, the proposed sensor showed superior selectivity compared to other gases and maintained stable properties for up to 6 months. These experimental and theoretical findings suggest that efficient control of s-SWCNT content can pave the way for innovative approaches in various sensor applications in the near future.

3:30 PM NM01.02.05
High Yield Single-Walled Carbon Nanotube Growth with Platinum-Group Metal Based High Entropy Alloy Catalysts *Takahiro Maruyama[1], Shu Matsuoka[1], Kamal Sharma[1], Takahiro Saida[1], Kohei Kusada[2] and Hiroshi Kitagawa[2]; [1]Meijo University, Japan; [2]Kyoto University, Japan*

High-entropy alloys (HEAs), which are solid solutions consisting of five or more elements in an approximately equal atomic ratio [1-3], have attracted tremendous attention in various fields because of their specific properties such

as high hardness and strength, and high thermal and chemical stabilities. In addition, HEAs exhibit unique surface and electronic structures because all surface atoms have different configurations with specific local electronic structures. Such a unique surface structure contains diverse active sites for various catalytic reactions. In the past few years, the catalytic properties of HEA nanoparticles (NPs) have been extensively investigated, demonstrating their high activities in NH_3 *oxidation, oxygen reduction reaction, and ethanol oxidation [4-6].*
In this study, we investigated the catalytic activity of HEA NPs in growth of single-walled carbon nanotubes (SWCNTs). Using HEA NPs composed of five platinum-group metals (5PGM), Ru, Rh, Pd, Ir, and Pt, as catalysts, we succeeded in growing SWCNT via chemical vapor deposition (CVD) with C_2H_2 *feedstock. After CVD growth at 750°C for 10 min, high-density SWCNTs with lengths of 1 mm or more were grown from 5PGM HEA NPs. Transmission electron microscopy (TEM) and Raman spectra showed that the diameters of most SWCNTs grown from 5PGM HEA NPs were less than 1.0 nm, exhibiting the growth of small-diameter SWCNTs. The SWCNT yield with the 5PGM HEA NP catalysts was much higher than those with monometal PGM catalysts (Ru, Pd, Ir, and Pt). In addition, the SWCNT yield was compatible with those grown from Fe and Co catalysts, which are the most common catalysts for obtaining high-yield SWCNTs. Scanning transmission electron microscopy (STEM) and energy-dispersive X-ray spectroscopy (EDS) mapping showed that, even after SWCNT growth, each element was homogeneously distributed in the 5PGM HEA NPs and that their crystal structure was preserved, confirming their robustness in the chemical reaction during SWCNT growth. Our results demonstrate that the 5PGM HEA NPs act as highly active catalysts for obtaining small-diameter SWCNTs, which was realized by unique properties of HEA NPs.*

Spatial Temperature and Composition Inference from FTIR in an FCCVD CNT Reactor *Nicolas Tricard, Zituo Chen, Linzheng Wang and Sili Deng; Massachusetts Institute of Technology, United States*

Carbon nanotubes (CNTs) possess exceptional material properties with transformative potential across various fields. However, their widespread application is hindered by the need for more efficient and pure synthesis methods. Floating catalyst chemical vapor deposition (FCCVD) is a promising technique for mass-producing CNTs, but its efficiency is limited by the deactivation of catalyst nanoparticles due to carbon encapsulation. A lack of in-situ diagnostic tools for detailed internal chemistry and thermodynamics in FCCVD reactors further compounds this issue.

This study introduces a methodology to obtain synthetic Fourier Transform Infrared (FTIR) measurements from Computational Fluid Dynamics (CFD) simulations of an FCCVD CNT reactor. We validate these simulations against experimental data from the literature. Using OpenFOAM CFD software, we model detailed chemistry, including methane pyrolysis and CNT growth kinetics. The Radiant Monte-Carlo ray tracing software provides accurate solutions to the radiative transfer equation, enabling coupled radiation/chemistry modeling and generating incident spectra to an FTIR sampling device. Line-by-line accurate synthetic spectra are produced for gaseous species using the HITRAN and HITEMP databases. Spectral absorption coefficients are also introduced to account for emission and absorption by CNTs.

Our results, compared to literature for both emission-based and absorption-based FTIR, incorporate accurate radiative effects such as the spectral transmittance of quartz containers, boundary reflections, field-of-view restrictions, soot on the walls, and instrument line shape functions to mimic measurement uncertainties. This digital twin of an FCCVD CNT reactor FTIR measurements is then applied to a machine-learning assisted parameter inversion procedure to train chemical rate parameters in the CNT reactor. Additionally, a neural network is applied to obtain radial temperature and composition profiles using FTIR measurements. This approach has significant practical implications, enabling experiments for parameter inversion of chirality-dependent CNT growth kinetics, high throughput experimental testing and data acquisition, and optimal CNT reactor design.

4:00 PM NM01.02.07
Time Resolved Electrical Conductance of Growing CNT Forests Using In Situ SEM Synthesis *Ramakrishna Surya, Prashanth R. Kotha, Minasadat Attari, Kaveh Safavigerdini, Prasad Calyam, Kannappan Palaniappan, Filiz Bunyak and Matthew Maschmann; University of Missouri, United States*

Carbon nanotubes (CNTs) possess exceptional engineering properties that surpass those of conventional materials, making them highly desirable for diverse multi-functional materials, including sensors, flexible electronics, and conductive interfacial materials. Vertically aligned films of CNTs, known as CNT forests or CNT arrays, are frequently synthesized by chemical vapor deposition (CVD) using a thin film catalyst. The ensemble properties of CNT forests are typically degraded when compared to the individual CNTs because of morphological features including waviness, kinks, and inhomogeneities in density. The process-structure relationships for CNT forests are difficult to assess because the CVD synthesis environment is typically enclosed, at high temperature (> 600 °C), requires a controlled gaseous environment, and may be conducted at low pressure.

We have recently developed a procedure to directly observe the synthesis and self-assembly of CNT forests within an environmental SEM. The process uses thin-film MEMS heaters as substrates, upon which a typical catalyst film comprised of Al_2O_3 and Fe are deposited. Acetylene gas is introduced to the SEM chamber to initiate CNT forest synthesis. We observe the catalyst evolution, early growth of independent CNTs, CNT assembly, CNT delamination, and self-termination using this technique.

Digital imaging techniques are applied to the in-situ SEM synthesis sequences to estimate the CNT density as a function of time. CNTSegNet, our image segmentation deep learning network is applied to reduce image noise and to estimate CNT density in individual images. Digital image correlation software is used to track the engineering strain within a growing CNT forest. The Meta Co-Tracker algorithm is used to track the growth profile of CNTs.

The evolving transverse electrical conductance within a growing CNT forest is also measured using pre-fabricated electrodes that span the heated zone of the growth substrates. The conductance initially increases as CNT-CNT contacts accumulate between the electrodes. However, the conductance peaks and decreases at later times due to CNT delamination from the electrode surfaces. Finite element simulation is used to model the evolving CNT forest morphology and predict the CNT delamination stress based on the simultaneous CNT density observation and in-situ electrical conductivity. Simulations predict a delamination force of several nano-Newtons is required to delaminate growing CNTs from the growth substrate, in line with prior experiments conducted after CNT forest synthesis and at room temperature.

4:15 PM NM01.02.08
Continues Synthesis of Free-Standing SWNT Films for Bioelectrode Applications *Qiang Zhang; Honda Research Institute USA, United States*

Thin single-wall carbon nanotube (SWNT) films have garnered significant attention due to their high optical transmittance, electrical conductivity, and mechanical flexibility. High-volume applications in energy devices and electronics have been demonstrated using carbon nanotube films as platform materials. In this work, we developed an advanced floating catalyst chemical vapor deposition (FCCVD) method for the direct production of freestanding SWNT aerosols and roll-to-roll collection. This FCCVD method can produce over 10 m2/h of continuous freestanding SWNT films, which is two orders of magnitude higher than other FCCVD methods, paving the way for a broad range of applications. The typical film thickness is less than 10 nm, and a sheet resistance of about 65 ohms/sq @ 90% optical transmittance has been achieved. This makes the films suitable for direct use as transparent electrodes in energy devices and flexible electronics.
Specifically, the ultra-thin conformal SWNT films have been applied as dry bioelectrodes for surface electrophysiology monitoring. We demonstrate electrocardiogram (ECG), electromyography (EMG), and forehead electroencephalogram (EEG) monitoring on the skin in a tattoo-like form, as well as multifocal electroretinography (ERG) recording on the eyes via a smart contact lens. The CNT electrode design achieves low contact impedance and a high signal-to-noise ratio (SNR), comparable to commercial Ag/AgCl wet electrodes. The ultra-thin form factor and skin attachment reduce susceptibility to motion noise, a common drawback of dry electrodes. Additionally, the dry CNT electrodes offer advantages in terms of cost, flexibility, stability, and biocompatibility.

4:30 PM NM01.02.09
Tailoring the Chemistry and Morphology of Vertically Aligned Carbon Nanotubes Forests, Implications for Smart Electrodes *Lev Rovinsky and Noa Lachman; Tel Aviv University, Israel*

Vertically aligned carbon nanotubes (VACNT) combine three advantageous traits: immense specific surface area, excellent thermal and electric conductivities, and controllable directionality. Thus, VACNT attract attention for anisotropic nanocomposites useful in applications such as supercapacitors, transistors, water purification, thermal management, and dry adhesives. The varying waviness, and high anisotropy VACNT hinders adhesion and therefore processability, thus requires adjustment. Because VACNT structures are susceptible to capillary forces, most wet surface treatments become impractical, leaving only gas-based methods as viable options. The field of gas-based VACNT surface treatment is underdeveloped, with limited control over processes outcome. The introduced methodology enhances the process controllability, enabling gently adjusting the oxygen content on VACNT nanotube surfaces, as well as their nanomorphology and entanglement. The samples are gradually heated to between 430 and 500 °C to weaken the C-C bonds without really breaking them, enabling their adjustment, by introduction of either air or Ar through the reactor. Argon causes removal of excess oxygen contamination and nanotubes straightening, while air enables introduction of additional oxygen functional groups. This method augments the nanocomposite homogeneity, enhancing accessibility towards more active sites for current application performance, amplifying biomedical sensing signal, catalytic activity and heat dissipation. Additionally, by introduction of other gases, unfulfilled predictions could be enabled, and the current state-of-the-art can be expanded.

4:45 PM NM01.02.10
Exotic Core-Shell Nanotubes Synthetized via van der Waals Epitaxy *Vojtech Kundrat[1], Lothar Houben[1], Jakub Zalesak[2] and Reshef Tenne[1]; [1]Weizmann Institute of Science, Israel; [2]Universität Salzburg, Austria*

Inorganic nanotubes from transition metal dichalcogenides (TMDCs) contain various nanomaterials. Mainly studied are WS_2 or MoS_2 nanotubes. Such materials are usually synthesized via high-temperature synthesis, transport, or solvothermal reactions. Yet some members of TMDCs were not successfully obtained in nanotubular form due to collapsing of the structure or other limitations. Van der Waals epitaxy is a key synthetic strategy for *obtaining various 2D heterostructures, including various transition metal dichalcogenides. Thanks to weak interactions between layers, possible lattice strain between divergent compounds is fully relaxed. In other words, heterolayers influence each other physically, mainly as layer alignment, orientations, or different interlayer distances. In the presented methodology, WS_2 nanotubes were mixed with precursor metal oxide and subsequently tellurized, selenized, or sulfidized, reaching multiwall WS_2@MX_2 nanotubes. In such a way, WTe_2, $MoTe_2$, $ReSe_2$, and ReS_2 were deposited on the WS_2 nanotube target. Presented heterogeneous nanostructures were analyzed mainly by transmission electron microscopy and 4D scanning transmission electron microscopy, revealing their complex structures. The prepared nanotubes promise modified electronic properties due to the nanotubular character and also thanks to the 1T'/2H TMDCs junctions.*

High-Throughput Evolution of Near-Infrared Oxytocin Nanosensors Enables Oxytocin Imaging in Mice and Prairie Voles *Natsumi Komatsu, Jaquesta A. Adams, Nicole A. Navarro and Markita Landry; University of California, Berkeley, United States*

Oxytocin is a neuropeptide thought to play a central role in regulating social and emotional behavior. Current techniques for neuropeptide imaging are generally limited in spatial and temporal resolution, real-time imaging capacity, selectivity for oxytocin over vasopressin, and application in young and non-model organisms. To avoid the use of endogenous oxytocin receptors for oxytocin probe development, we employed a protocol to evolve purely synthetic molecular recognition on the surface of near-infrared fluorescent single-walled carbon nanotubes using single-stranded DNA . This probe reversibly undergoes up to a 172% fluorescence increase in response to oxytocin with a Kd of 4.93 μM. Furthermore, this probe responds selectively to oxytocin over oxytocin analogs, receptor agonists and antagonists, and most other neurochemicals. Lastly, we show our probe can image synaptic evoked oxytocin release in live mouse and prairie vole brain slices. Optical probes with the specificity and resolution requisite to image endogenous oxytocin signaling that are readily applicable in different animal model species can advance the study of oxytocin neurotransmission for its role in both health and disease.

5:15 PM NM01.02.12

A New Growth Approach—Alignment van der Waals Epitaxy of Graphene *Shigeya Naritsuka, Yuta Yanase, Yuki Ueda and Takahiro Maruyama; Meijo University, Japan*

This report is concerned with a new technique for synthesis of 2D materials, where precise epitaxy is realized by the help of alignment mechanism between 2D materials and substrate. Graphene attracts much attention from its superior characteristics for realizing excellent future devices. Graphene is conventionally grown on copper foil by CVD and transferred to a certain substrate to fabricate devices. However, graphene is inevitably damaged and contaminated during the process. Therefore, direct synthesis of graphene on an insulator substrate is demanded. CVD has already been studied on SiO_2, sapphire etc. but the quality of graphene is still inferior. To obtain large-scale single crystalline graphene, there are two courses; one is enlargement of single nucleus, the other is connection of individual nuclei with highly-aligned direction. In this report, the latter is introduced to improve the crystallinity of grpahene.
Graphene was synthesized on m-plane sapphire by low-pressure CVD using 3-hexyne as a carbon source [1]. AFM image shows smooth surface of graphene, and Raman spectra do single layer graphene was successfully obtained over the whole surface. X-ray in-plane diffraction spectra shows not only a clear 6-fold symmetry of graphene but also extremely narrow FWHM, which is as narrow as 12''. The value is the narrowest ever reported for CVD graphene and almost equals to that of sapphire substrate. Graphene certainly grew under van der Waals epitaxy but the result indicates presence of special alignment mechanism. A similar phenomenon was reported for carbon nanotubes grown on a sapphire substrate [2]. Carbon nanotubes regularly aligned a certain direction on a sapphire

surface. In our case, X-ray diffraction measurement indicates not only the alignment of the 6-memberd rings but also the uniaxial deformation of the carbon rings in the direction of sapphire [11-20] axis. Namely, [01] lattice constant of graphene was matched with the 1/4 spacing of sapphire a-planes. A strong interaction possibly existed between graphene and sapphire surface, which should align the crystal orientation of graphene nuclei during the van der Waals epitaxy.

SESSION NM01.03: Structure and Properties I
Session Chairs: Shunsuke Sakurai and Ming Zheng
Tuesday Morning, December 3, 2024
Hynes, Level 2, Room 200

8:30 AM *NM01.03.01

One- and Two-Dimensional Molecular Lattices *Stephanie Reich and Chantal Müller; Freie Universität Berlin, Germany*

Two-dimensional monolayers and one-dimensional nanotubes can act as templates and containers for molecules and nanomaterials. We examine the formation of well-controlled molecular lattices inside nanotubes and on atomically flat two-dimensional substrates. We will show how in such lattices the optical molecular excitations couple into collective, delocalized excitons and vibrations. The coupling changes the energetics and dynamics of the collective states giving rise to effects such as superradiance and a strongly enhanced collective Raman response. We will examine how the interaction with the one- and two-dimensional hosts and substrates induce hybridized states with a particular emphasis on changes in the molecule-related response.

9:00 AM *NM01.03.02

Assembly of Single-Wall Carbon Nanotubes Dimers by a DNA Hybridization-based Strategy and Their Metrology *Benjamin Barnes and Jeffrey Fagan; National Institute of Standards and Technology, United States*

The capability to specifically assembly or controllably place an individual single-wall carbon nanotube (SWCNTs) of known (n,m) structure and length is highly desirable for enabling high-value applications including high performance digital logic, sensor arrays, or single photon emitters. Ideally, individual nanotubes should be directable to form controlled structures, or to only assemble in specific locations. Of great promise for achieving such goals is the strategy of assembly using hybridization of single-stranded DNA with a complementary DNA sequence to direct selective assembly of objects to which those DNA strands are attached. Prior efforts have shown that this strategy enables directed placement of SWCNTs at high density and alignment, and in a fashion transferable for the production of active devices. Although these efforts have demonstrated the promise of the method, optimization and improved control are necessary for further implementation. In this talk I will describe efforts to develop the assembly of SWCNT dimers in liquid dispersion via a DNA hybridization scheme as a platform for determining optimized strategies and control of the assembly process. Critically, the measurement of successful dispersion, DNA sequence coating, interaction with complementary DNA sequences and selective assembly with other DNA-SWCNTs is a significant measurement barrier to such efforts. I will describe the use of analytical ultracentrifugation to address this metrology gap and present successful and directed assembly of dimers as a demonstration of the measurement platform.

Defects that Improve Cancer Research and Diagnosis *Mijin Kim; Georgia Institute of Technology, United States*

Investigating the roles of signaling pathways, secreted factors, and immunological components of tumor ecosystems promotes our understanding of the drivers of tumor progression and enables the development of better diagnostics and therapeutic interventions. New measurement technologies through nanoscale engineering can elucidate new insights into tumor ecosystems beyond conventional biochemical and omics-based methods. Fluorescent quantum defects, produced by covalent modifications of single-walled carbon nanotubes, elicit sensitive, bright, tunable emission bands. My studies found that these quantum defects can greatly expand nanosensor capabilities to improve our understanding of tumor ecosystems and develop diagnostic technologies. For improved diagnostics, we developed a quantum defect nanosensor array technology that, coupled with machine learning algorithms, can identify disease fingerprints of ovarian cancer from serum. To investigate disease processes, we developed nanosensors that enable the transient detection and spatial mapping of autophagy in vivo. I will explain how these sensor technologies can benefit bioanalytical research to facilitate biomarker discovery and drug development processes, and address questions in cancer biology.

10:30 AM NM01.03.04

Electrochemically Chlorinated Graphene for Ultrafast NO_2 Detection at Room Temperature *Jaeyeon Oh[1,2], Sungjin Cho[1], Hyeon Kim[3], Donghwa Lee[3] and Yeonhoo Kim[1]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); [3]Pohang University of Science and Technology, Korea (the Republic of)*

Graphene is one of the most promising alternative sensing materials for next-generation applications such as flexible devices, and Internet of Things, since it exhibits high sensitivity at room temperature and stable sensing performance. Meanwhile, graphene has main drawbacks such as slow response and incomplete recovery reaction. To overcome the disadvantages, the functionalization of graphene has been widely explored as graphene have demonstrated a unique advantage in functionalization. Atomically thin carbon nanostructure, consisting entirely of surface, allows surface functionalization to impact the entire structure. As halogen atoms including chlorine are excellent candidates for tuning the surface chemistry, but conventional chlorination methods of graphene typically involve the use of toxic chlorine gas, requiring the advanced reactors or high vacuum systems. The development of efficient and safe chlorination methods has enormous potential for practical sensing application.

Herein, we fabricated chlorinated graphene sensors via a facile electrochemical chlorination process of monolayer graphene using sodium chloride solution. Different voltages and sodium chloride concentration were used to control chlorination levels and investigate changes in subsequent sensing properties. The response and recovery times upon exposure to NO_2 were dramatically decreased after chlorination, from 157 to 38 s and from 1485 to 202 s, respectively. Also, the sensors exhibited high selectivity to NH_3 and NO_2 after chlorination. The selectivity was examined upon exposure to various gases including 5 ppm NO_2, 50 ppm CH_3COCH_3, C_2H_5OH, C_7H_8, H_2, and NH_3. For materials characterization, X-ray photoelectron spectroscopy (XPS), Raman spectroscopy and energy dispersive X-ray spectroscopy (EDS) have been exploited to identify the formation of C–Cl bonds and the presence of chlorine atoms within the graphene structure. Density functional theory (DFT) calculation was performed to discuss the gas sensing mechanism of chlorinated graphene. The theoretical calculation was in agreement with the experimental results. The high sensitivity, selectivity, and enhanced reaction time play a key role in real-time sensing applications, as early-stage gas discrimination is important in various circumstances.

10:45 AM NM01.03.05

Peptide-Functionalized Graphene Biosensors *Yuhei Hayamizu; Tokyo Institute of Technology, Japan*

Gas sensing based on graphene field-effect transistors (GFETs) has garnered significant interest due to their high sensitivity and potential applications in environmental monitoring, healthcare, food, and cosmetic industries. Recent advancements in GFETs aim to establish an artificial sense of smell by mimicking olfactory receptors with electronic devices. While using olfactory receptors on GFETs for odor sensing is straightforward, synthetic molecules that mimic these receptors offer more robust performance. In this presentation, the design of three new peptides is introduced, consisting of two domains: a bio-probe targeting specific molecules and a molecular scaffold [1]. These peptides, rationally designed based on olfactory receptor motifs, self-assemble into a molecular thin film on GFET.

To demonstrate biosensing capabilities, limonene, methyl salicylate, and menthol were employed as representative odor molecules of plant flavors. The peptides exhibited distinct conductivity changes in GFETs upon binding to these odor molecules at various solution concentrations, revealing unique dynamic response signatures [2]. The kinetic response of each peptide showed characteristic time constants during adsorption and desorption, supported by principal component analysis. This demonstration paves the way for future peptide-array sensors with multi-sequence peptides, enhancing odor detection systems' selectivity.

Furthermore, in contrast to the above liquid-phase sensing, gas-phase graphene sensors under environmental conditions were demonstrated by introducing peptide-functionalized graphene sensors that mitigate undesired responses to humidity changes [3]. Humidity plays a significant role in facilitating the selective detection of odorant molecules by peptides, enabling precise and specific detection. The sensors demonstrate notable enantioselectivity, achieving a remarkable 35-fold signal contrast between d- and l-limonene. Additionally, principal component analysis of the obtained data exhibited distinct responses to various biogenic volatile organic compounds, proving their versatility and robustness in odor detection.

By acting as both a bioprobe and an electrical signal transducer, the peptide layer presents a novel and effective strategy for selective odorant detection under normal atmospheric conditions using graphene sensors. This research provides valuable insights into developing practical odor-sensing technologies with broad applications, advancing the field of nanobioelectronics with graphene.

High-Speed Lattice Resolution and Friction Loops on 2D Materials Using a New Interferometric Atomic Force Microscope *Joel Lefever, Aleksander Labuda and Roger Proksch; Oxford Instruments Asylum Research, United States*

Measuring lateral force with lattice resolution is critical for atomic-scale measurements of friction, stick-slip phenomena, and wear reactions, which inform both the tribological and electrical characterization of 2D materials. The atomic force microscope (AFM) is an important tool for nanoscale measurement of friction, down to the level of single atomic defects [1]. Despite these successes, conventional optical beam deflection (OBD) based AFMs have several challenges, including calibration and noise limitations. It is difficult to achieve lattice resolution, especially at high scan speeds, and accurate calibration of the lateral signal is in general possible only with invasive or labor-intensive techniques, all with substantial uncertainty.

In this work, we use a recently introduced AFM [2] with a quadrature phase differential interferometer (QPDI) detector with both an extremely low noise floor and highly accurate positional measurement which enables new capabilities [3,4], including lateral force microscopy at high scan rates. We describe methods to calibrate and measure the lateral force signal using QPDI and apply these methods to measure friction forces on a variety of 2D materials. By positioning the interferometric detection spot along one edge of the cantilever, the AFM takes advantage of the detector's low noise floor to observe stick-slip friction at scan rates that would be difficult or impossible with optical beam AFMs. Alternatively, the detection spot may be placed on the centerline of the cantilever, using interferometric detection in combination with conventional optical beam detection. This variation allows for lateral force imaging without crosstalk from the lateral signal into the normal signal, which reduces the effects of friction and topography on the applied load. The results demonstrate clearly resolvable stick-slip friction over a range of tip speeds up to 2 μm/s and additionally show the variation of friction with applied load.

A major advantage of interferometric AFM is its ability to perform a complete in situ calibration of the lateral force sensitivity without cumbersome sample changes or modifications to the probe. We demonstrate a method based on a combination of our previous method [5] and a new technique for automated, direct measurement of the tip height. We compare the accuracy of this new calibration technique with the wedge calibration method [6]. The methods and results described here pave the way for accurate probing of in-plane frictional and conservative forces including the effect of defects, load, and rate-and-state friction relationships in velocity ranges that were previously difficult or impossible to explore.

Thermal Management Using Carbon Nanotubes Devices with Dynamic Reflectivity *Philip Jean-Remy, Alex Abelson, Tom Nakotte, Sei Jin Park and Anna M. Hiszpanski; Lawrence Livermore National Laboratory, United States*

Materials that have tunable reflectivity and emissivity in the infrared (IR) regime offer a compelling means to reduce buildings' radiative heat losses, and thereby energy consumption. Amongst the types of materials that have been incorporated into electrically driven devices and demonstrated an ability to change their IR reflectivity, carbon nanotubes (CNTs) are amongst the most effective, having a high change in reflectance and excellent cyclability. In this work, we have created electrically-driven devices with tunable reflectance using various types of carbon nanotubes (metallic, semiconducting, mixed), various carbon nanotube geometries (disorganized 2D sheets and ordered vertically-aligned forests), and various device architectures. Through this systematic study, we have elucidated the role that these various factors have on the spectral changes in reflectance and ultimately device performance.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Achieving Carbon Nanotube Encapsulated β-Sn—Direct Observation of the Encapsulation Mechanism by In Situ TEM

George T. Tebbutt[1], Ryan Schofield[1], Shiling Dong[1], Ping-Yuan Lee[1], Christopher Allen[2,1], Barbara Maciejewska[1] and Nicole Grobert[1,3]; [1]University of Oxford, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]WAE Technologies Ltd, United Kingdom

The fabrication of continuous one-dimensional Sn nanocrystals (nanowires) confined within chemically and mechanically robust multi-walled carbon nanotubes (MWCNTs) is highly compelling for high-density energy storage electrodes, electromagnetic absorption materials, and advanced nanoelectronics. Sn is an attractive element to encapsulate for these applications; however, its high vaporization temperature (above 1500 °C in vacuo) and non-wettability towards carbon have made it challenging to encapsulate directly within a highly crystalline carbon nanotube. Here, we present a novel synthesis method to overcome these challenges and achieve β-Sn encapsulation within highly crystalline MWCNTs through a vapor phase transport route.

In comparison to the encapsulation of catalytically active metals for CNT growth (such as Fe, Ni, and Co), where filling is achieved directly in situ with an inherently continuously filled core, the encapsulation of non-intrinsic metals such as Sn occurs post-synthesis of the CNT growth through either a vapor or solution synthesis route. Typically, ex situ encapsulation strategies often yield discrete, non-continuous particles embedded within the nanotube core. The success of encapsulation and the degree of filling are governed by three main factors: the capillarity of the nanotube core, wettability towards the inner carbon surface, and surface tension of the encapsulant, which all control the underlying mechanism of encapsulation. Understanding the interplay between these parameters and how they influence the overall mechanism is key to achieving continuous Sn-filled nanotubes.

To explore these parameters, we present the first-of-its-kind direct observation of the vapor encapsulation mechanism, achieved in situ using transmission electron microscopy (TEM). These findings pave the way for achieving filled nanotubes with non-intrinsic elements introduced through the vapor phase and demonstrate the importance of in situ imaging for providing a holistic understanding of the encapsulation mechanism at the fundamental level.

Beyond encapsulation, we will also exploit the robust and electron-transparent properties of hexagonal carbon as a 'nano-reactor', an emerging frontier for observing complex and dynamic reaction behaviour in situ using TEM at atomic resolution.[1,2]

Fabrication and Measurement of Nanostructures Using AFM Based Nanolithography *Robert Rienstra[1], Nishat Sultana[1], Takashi Taniguchi[2], Kenji Watanabe[2], Curt Richter[3], Nikolai Zhitenev[3], Joeseph Stroscio[3] and Fereshte Ghahari[1]; [1]George Mason University, United States; [2]National Institute for Materials Science, Japan; [3]National Institute of Standards and Technology, United States*

Understanding quantum electronic properties of confined charge carriers in nanostructures can have important implications on the advancement of innovative quantum-based technologies. This is an underexplored area in two-dimensional (2D) material research, primarily due to fabrication challenges. Lithographic patterning and Reactive Ion Etching (RIE) are often used to define these structures. However, etching byproducts, residuals, and edge roughness can create charge localizations and adversely affect electronic performance. In contrast, electrostatic gate defined geometries have been shown to preserve device quality at the cost of increased complexity, imperfect confinement, and imposing the requirement of a tunable bandgap. Presented here is an alternative method of mechanically defining device geometry utilizing AFM based nanolithography and will discuss the methods and techniques used to incorporate the patterned material into van der Waals (vdW) heterostructures. I will also discuss transport measurements of these narrow channels both at zero and high magnetic fields where the interplay between electrostatic and magnetic confinement will be discussed.

Machine Learning Approach to Bioengineering Optical Sensors Based on Carbon Nanotubes *Ardemis Boghossian; École Polytechnique Fédérale de Lausanne, Switzerland*

Fluorescent nanomaterials benefit from tunable bandgaps and associated optical characteristics that are predicted by theory. Their optical characterizations, however, such as absorbance and fluorescence emissions, depend strongly on the environment of these nanomaterials. These measurements can thus vary based on differences in functional modifications, pH, saline concentration, suspension media, and other environmental factors. This environmental sensitivity serves as the basis of nanosensors that optically respond to changes in the nanomaterial's environment. However, the design of these optical nanosensors is limited by the inability to predict the nanomaterial's optical response (or lack thereof) to an environmental change.

This presentation discusses approaches inspired by synthetic biology for developing optical sensors. The presentation focuses on sensors based on the near-infrared fluorescence emissions of single-walled carbon nanotubes (SWCNTs). The SWCNTs are non-covalently functionalized with single-stranded DNA. The optical properties of these DNA-wrapped SWCNTs, including their responsivity and selectivity to different analytes, are tuned in a non-predictable manner by varying the DNA sequence. We develop an approach inspired by directed evolution, an iterative screening technique that is conventionally used to engineer proteins with unknown structure-function relationships, to tune the optical properties of these nanosensors in a guided manner [1-2]. The data collected from this screening approach are used to train algorithms to design diverse screening libraries [3].

These algorithms are further applied to predict DNA sequences that will yield the desired optical responses. Through computationally-assisted directed evolution, we have thus developed a versatile approach for engineering the next generation of rationally designed optical nanotube sensors for diverse applications.

2:00 PM NM01.04.02

Macroscopic and Microscopic Charge Transport in Thin Films of Solution-Synthesized Graphene Nanoribbons *Sebastian Lindenthal[1], Justin D. Earley[2,3], Alejandra Hermosilla Palacios[2], Finn Sebastian[1], Nicolas F. Zorn[1], Andrew J. Ferguson[2], Jeffrey Blackburn[2] and Jana Zaumseil[1]; [1]Universität Heidelberg, Germany; [2]National Renewable Energy Laboratory, United States; [3]Arizona State University, United States*

Graphene Nanoribbons (GNRs) are quasi-one-dimensional nanomaterials with unique optical and electronic properties that depend on their width and edge type. Bottom-up synthesis routes for GNRs offer precise control over these properties and even length but usually yield nanoribbons that also contain some structural defects such as missing phenyl rings or unclosed bonds in an otherwise perfect sp^2*-lattice. Theoretical and experimental studies on on-surface synthesized GNRs have shown that these defects alter the electronic structure of the GNRs. We have recently demonstrated that dispersions of solution-synthesized 9-aGNRs can be subjected to liquid cascade centrifugation to separate defective from pristine GNRs [ACS Nano 2023, 17, 21771] as proven by absorption, photoluminescence and Raman spectroscopy. Defective GNRs showed absorption and emission peaks at higher energies compared to the pristine GNRs, which was also corroborated by time-dependent density-functional theory (TDDFT) calculations.*

So far only few examples of efficient charge transport in devices with thin films of GNRs have been reported. In addition to the required hopping between the individual nanoribbons, defects in the GNR lattice are predicted to significantly impair charge transport. Here, we investigate the impact of such defects on charge transport in thin films of 9-aGNRs and present a simple method to quantify and control the defect density in dense GNR films. We evaluate the macroscopic charge transport in electrochemically doped GNR films using electrolyte-gated transistors and in chemically doped GNR films by 4-point-probe conductivity measurements. We further examine the microscopic charge transport in GNRs depending on defect density by dark microwave conductivity measurements. The combination of these measurements enables us to correlate the defect density of GNRs with their optical and electronic properties.

2:15 PM NM01.04.03

Fluorescent Nanographene-Polystyrene Microlabels for Photonic Applications *Alice Sciortino[1], Marco Reale[1], Emanuele Marino[1], Ermelinda Maçoas[2], Francesco Ciccarello[1], Carlos Cruz[3], Marco Cannas[1], Araceli Campana[3] and Fabrizio Messina[1]; [1]Università degli Studi di Palermo, Italy; [2]Instituto Superior Técnico, Portugal; [3]Universidad de Granada, Spain*

Nanographenes (NG) can be described as graphene fragments displaying strong optical transitions in the visible or near-infrared range due to bandgap opening through quantum confinement on lateral sizes of a few nanometers. NGs can be considered as ideal benchmarks to study the optical response of zero-dimensional nanocarbons, sometimes showing non-trivial photophysics [1,2]. From a functional point of view, NGs often display a very bright fluorescence, and their optical properties can be precisely tailored through precise structural engineering with atomic precision. On these grounds, NGs are ideal building blocks of more complex nanocomposites where they can play the role of efficient light harvesters or light emitters. Here we present the result of our recent study [3] focusing on a nanoribbon-shaped NG displaying visible fluorescence with very high quantum efficiency (QY=65%) [1]. We first carried out a thorough characterization of its photocycle by a combination of steady-state, nanosecond and femtosecond time-resolved optical methods. Then, we coupled these NGs with micrometer-sized polysterene spheres (NG@PS), through a simple self-assembly strategy in solution phase. The resulting NG@PS composites show unique fluorescent properties that are very different from those of the starting NGs and pave the way to new applications of nanographenes. [3] In fact, NG@PS fluorescence displays an entirely new set of narrow resonances due to the coupling of NG optical transitions to the whispering gallery modes of the polystyrene microsphere, acting as an optical microresonator. We argue that these NG@PS are a family of functional nanocomposites which would be potentially suitable for several applications, such as micro-sensing or micro-lasers. More specifically, we show that the finely-structured spectral fingerprints displayed by NG@PS are unique for each individual microparticle, such that NG@PS can be used as luminescent unclonable labels for anticounterfeiting applications.

Identification of Individual Carbon Nanotubes by Near-Field IR/NIR Microscopy *Katalin Kamaras[1,2], Gergely Nemeth[1,3], Daniel Datz[1], Ferenc Borondics[3], Lazar Toth[4], Judit Budai[4], Keigo Otsuka[5] and Shigeo Maruyama[5]; [1]HUN-REN Wigner Research Centre for Physics, Hungary; [2]HUN-REN Centre for Energy Research, Hungary; [3]Synchrotron SOLEIL, France; [4]ELI-HU Non-Profit Ltd., Hungary; [5]The University of Tokyo, Japan*

Scattering scanning near-field optical microscopy (s-SNOM), based on the combination of atomic force microscopy and frequency-dependent light scattering, is an emerging method that combines high spatial resolution with high sensitivity even at long illuminating wavelengths. Its length scale is appropriate to observe nanoscale objects, and carbon nanotubes of 1-2 nm diameter are ideal candidates for such observation.
I will present results in the infrared and near-infrared frequency range obtained on individual carbon nanotubes. Due to the weak scattering cross section, direct observation of localized vibrations is rarely possible, one has to exploit the coupling to collective excitations. In the lowest frequency region, metallic tubes can be detected and distinguished from semiconducting ones due to their free (Drude) electrons. The next step towards determining their chirality is near-infrared excitation where the illuminating laser is resonant with one of the transitions between Van Hove singularities. As the AFM image yields the diameter and the s-SNOM the metallicity (IR) and the electronic transition energy (NIR), the complete information resulting in the chirality is obtained.
The intense field under the tip can also be used to launch and detect the charge distribution inside nanotubes caused by interference of quasiparticles: plasmon-polaritons or phonon-polaritons. I will show examples of such

interference effects in both carbon and boron nitride nanotubes.

3:30 PM *NM01.04.05

Semiconducting Single-Walled Carbon Nanotubes—Stimulated Emission, Electron Spin and Beyond *Xuedan Ma[1,2]; [1]Argonne National Laboratory, United States; [2]Rice University, United States*

Great strides have been made in the understanding of electronic and optical properties of semiconducting single-walled carbon nanotubes (SWCNTs) in the past two decades. With optical transitions at near-infrared wavelengths, and diameter- and chirality-tunable electronic structures, SWCNTs are promising candidates for near-infrared nanolasers. In this talk, I will discuss our recent exploration of stimulated emission from SWCNTs by coupling them to whispering gallery modes supported by polymer microspheres through a self-assembly process. In contrast to the many exciting developments in the excitonic frontier, electron spins, which are ubiquitous in solid state materials and highly relevant to spintronic and quantum information science, in SWCNTs are relatively less understood. In this talk, I will also discuss our recent study of electron spins in SWCNTs.

Measuring Solvent Structure Around Charged Carbon Nanotubes Using Total Neutron Scattering *Adam Clancy[1], Camilla Di Mino[2], Thomas Headen[3], Neal Skipper[1] and Christopher Howard[1]; [1]University College London, United Kingdom; [2]University of Oxford, United Kingdom; [3]ISIS Pulsed Neutron and Muon Source, United Kingdom*

The liquid-phase processing of carbon nanomaterials is a critical step towards their commercial viability, yet the fundamental physics of solvent stabilization has remained elusive. This complexity stems from the minute volumetric fraction of solvent at the nanocarbon interface, the intrinsic disorder in liquids, and the weak X-ray scattering of light elements in most solvents. We have tackled these challenges head-on using the cutting-edge total neutron scattering (TNS). TNS offers a unique light-element-specific scattering probe and the opportunity for isotopic substitution, enabling us to extract multiple constraining datasets for a single nanotube-solvent system.

Leveraging TNS measurements in conjunction with established analysis techniques for pure liquids, we have, for the first time, achieved direct observation of solvent ordering around charged carbon nanotubes. This breakthrough allows us to measure solvent structures with atomistic precision, while charged nanotubes present sufficient concentrations to study their interfaces in their native homogeneous bulk state. We explore a variety of liquid-phase systems, including negatively charged nanotubes dissolved in amides (NMP and DMAc), which are ideal models for nanotube double-layer supercapacitors, and positively charged carbon nanotubes in chlorosulfonic acid. Our findings reveal that in all measured systems, the nanotubes induce strong templating effects on the solvent, forming cylindrical solvation shells and aligning the solvents along their dipoles, with ordering extending beyond these density fluctuations. For anionic nanotube systems, we can directly image the electric double layer, observing sodium counterions at the nanotube surface becoming desolvated as the solvent prefers to solvate the nanotube surface. This insight is invaluable for understanding the behavior of nanocarbons in energy storage applications.

These pioneering measurements underscore the transformative potential of applying TNS to nanomaterial liquid-phase dispersions. We envision that this approach will dramatically advance our understanding of these complex high-aspect-ratio nanomaterials, paving the way for their broader application and societal benefits.

4:15 PM NM01.04.07

Bright Single-Wall Carbon Nanotubes with Luminescent Aryl and Oxygen Defects— Functionalization and Characterization Methods *Finn Sebastian, Simon Settele and Jana Zaumseil; Universität Heidelberg, Germany*

Single-wall carbon nanotubes (SWCNTs) are a promising emitter for in-vivo bioimaging, optical sensing, and optoelectronic devices in the near-infrared (nIR). While SWCNTs show remarkable photostability and high sensitivity towards various analytes, their performance as sensors and nIR emitters is limited by their low photoluminescence quantum yield (PLQY) of 0.5 – 1 % in dispersion. One strategy to overcome this problem is the covalent functionalization of SWCNTs with luminescent defects, leading to red-shifted emission in the nIR and increased PLQYs. The characteristics of the defect emission depend on the type of defect and its binding configuration on the nanotube lattice. Hence, several synthetic strategies have been developed to control the emission wavelength and defect functionality [ACS Nano ***2019****, 13, 9259, ACS Nano* ***2021****, 15, 5174, Nat. Commun.* ***2021****, 12, 2119].*

To achieve a fundamental understanding of the structure-property relationships of luminescent defects, knowledge of their density and distribution along the nanotube is crucial. To this end, we demonstrate a combined approach of Raman spectroscopy and PLQY measurements, which enables the absolute quantification of the density of luminescent defects in SWCNTs with different chiralities and diameters [J. Phys. Chem. Lett. ***2022****, 13, 3542, ACS Nano* ***2023****, 17, 21771]. We now use this metric to compare different types of luminescent defects. Supported by photoluminescence measurements of individual SWCNTs at cryogenic temperature, fundamental differences between oxygen and aryl defects are revealed. Irrespective of the functionalization method, aryl defects appear to act as isolated exciton trapping sites, whereas oxygen defects show a tendency to form local clusters on the nanotube lattice. We combine these findings with insights on the interplay of reaction parameters to obtain oxygen-functionalized SWCNTs with exceptionally high PLQYs (> 3%), thus pushing the limits of nanotube brightness for high-contrast nIR bioimaging beyond the state of the art.*

4:30 PM NM01.04.08

Alternative Doping Strategies for Semiconducting Single-Wall Carbon Nanotube Thin Films for Thermoelectrics *Angus Hawkey, Xabier Rodríguez-Martínez, Aditya Dash, Martijn Kemerink and Jana Zaumseil; Universität Heidelberg, Germany*

Dense films of semiconducting single-walled carbon nanotubes (SWCNTs) are a promising thermoelectric material with high electrical conductivities and power factors after p- or n-doping. To introduce the charge carrier densities required for thermoelectric applications, chemical doping is typically used. However, the remaining dopant counterions are often unstable and residual impurities can affect the doping stability. Here, we present two novel strategies to p-dope thin films of semiconducting SWCNTs that enable the replacement of the dopant counterion with redox-inactive anions from an electrolyte.

First, we employ ion-exchange doping with an excess of several different electrolytes (e.g. [BMP][TFSI]) to systematically vary the exchanged counterion size and investigate its impact on conductivity, Seebeck coefficients and power factors. Larger anions lead to higher electrical conductivities and improved doping stability, while no significant effect on the power factors is observed. These experimental trends can be reproduced by a random resistor model for the nanotube network that accounts for overlapping Coulomb potentials caused by the anions at high doping concentrations leading to the formation of an impurity band whose depth depends on the carrier density and counterion size.

A second new doping method is proton-coupled electron transfer (PCET), which enables tunable p-doping of SWCNTs with the mild oxidant quinone in aqueous electrolyte solutions. At low pH and in the presence of TFSI anions, large-diameter SWCNTs are oxidized and the quinone is reduced to hydroquinone via two-electron/two-proton PCET. The reversible quinone/hydroquinone redox couple further enables precise doping control by tuning the pH of the doping solution. Importantly, the charge transport and thermoelectric properties of PCET-doped and ion-exchange doped SWCNT films are similar to those of chemically doped nanotube films.

4:45 PM *NM01.04.09

Insights of Ultrafast Carrier Dynamics of 2D CdSe Nanoplatelets *Amitava Patra[1,2]; [1]Institute of Nano Science and Technology, India; [2]Indian Association for the Cultivation of Science, India*

Nanomaterials-based light-harvesting systems have been the research subject because they can generate exciton after photoexcitation. A deep understanding of hot carrier (HC) dynamics is crucial to improving the performance of optoelectronic devices by reducing thermalization losses. Here, we investigate the carrier dynamics, energy transfer, and charge carrier dynamics of 2D CdSe nanoplatelets, and perovskite nanocrystals,.[1-7] Ultrafast spectroscopic investigations provide direct insight into the impacts of electron and hole transfer at the interface of hybrid materials for optoelectronic applications. The fundamental knowledge of these photophysical processes is crucial for developing efficient light-harvesting systems.

Electrophoretically Deposited Graphene Oxide on Reusable Acid-Washed Nickel Foam Substrate for Sustainable Capacitive Ion Desalination *Jyotiraman De, Sumit Saxena and Shobha Shukla; Indian Institute of Technology Bombay, India*

Graphene Oxide (GO) comprises unique features that make it a potential material for capacitive deionization (CDI) of brackish and saline water, such as Graphene Oxide's increased surface area providing more ion adsorption sites, the chemical stability of Graphene Oxide across a wide pH and ionic strength range contributing to the longer operational time of the CDI electrodes, the possibility of modification of the Graphene Oxide with various surface functional groups in order to alter the selectivity of the CDI electrode for ions, and the easy dispersibility of Graphene Oxide in various aqueous media and solvents. However, the method of loading Graphene Oxide as an active material on the current collector, as well as the preparation of the current collector before loading the active material, can significantly impact the desalination performance of the system. Hence, exploring an efficient *loading method of Graphene Oxide on a high-charge transfer-capable current collector is required that would inherit a higher electrochemical performance along with a higher salt removal capacity. To mitigate the drawbacks of currently employed materials and methods, we present a facile, scalable, and efficient method of preparing CDI electrodes by electrophoretic coating of GO on acid-washed Nickel foam. The Nickel foam as a current collector was subjected to acid washing with various concentrations of acid, and simultaneous material and electrochemical characterization were conducted to optimize the acid concentration. Further, the deionized (DI) water and acid-washed Nickel foam current collectors were dip-coated and electrophoretically coated with graphene Oxide which, on performing the physiochemical and electrochemical characterization, displayed the specific capacitance and current density in the order electrophoretically coated GO on acid-washed Nickel foam > dip-coated GO on acid-washed Nickel foam > electrophoretically coated GO on DI-washed Nickel foam > dip-coated GO on DI-washed Nickel foam. In comparison to the dip-coated GO on DI-washed Nickel foam, electrophoretically coated GO on acid-washed Nickel foam demonstrates a multi-fold increase in the specific capacitance and current density. We attempted to reuse the current collectors to make the CDI sustainable and cost-effective, and upon experimentation, they demonstrated the same electrochemical properties as a new electrode. The use of three-dimensional electrophoretically coated GO on acid-washed Nickel foam electrodes in a CDI device contributed to the efficient charge transfer ability of the CDI and resulted in a substantial increase in salt adsorption capacity with excellent recyclability and efficient regeneration of the electrodes.*

NM01.05.02

Polyvinyl Alcohol and Multi-Walled Carbon Nanotube Based Electrospun Nanofibrous Scaffolds for Characterization of Proteins

Maeve G. O'Connell and Isaac Macwan; Fairfield University, United States

A recent topic of interest in biomedical engineering and material science is the fabrication of multiwalled carbon nanotubes (MWNT) based electrospun scaffolds using polyvinyl alcohol (PVA) to create porous nanofibrous recognition elements for impedimetric biosensors. The process of synthesizing such scaffolds involved dispersing PVA (10 wt%) and MWNT (0.005 wt%) using controlled stirring and sonication through bath and tip sonication, and further utilizing electrospinning technique with a high-voltage electric field to create random nanofibers (~150nm diameter) out of the dispersion. The experimental protocol was established after several trials of dispersions and electrospinning of control PVA, and PVA with MWNT. The purpose of these trials was to determine the ideal dispersion and electrospinning parameters that would synthesize randomly oriented porous nanofibrous scaffolds with minimal beading and maintaining identical morphology to the control sample in terms of fiber diameter, porosity, and thickness of the scaffolds. For each trial, a viscometer was used to measure the viscosity of the polymer solutions before and after the addition of MWNTs. To examine the morphology of the scaffolds, a scanning electron microscope (SEM) was used, which also evaluated the porosity, fiber diameter, and locations and orientation of the MWNT within the PVA scaffolds. For biosensing applications, the fibers should range between ~50-200 nm, which allows for the best porosity and surface area. Smaller diameter fibers mean a greater surface area to volume ratio, which is vital to maximize the efficiency of biosensors. The control samples and optimized scaffolds with MWNT contained PVA fibers within this diameter range. It is found that MWNT acted as a catalyst for detection within the scaffolds, allowing to produce conductive scaffolds. Quantification of the scaffolds suggested that the established parameters to synthesize PVA/MWNT scaffolds show promising possibilities for applications in impedimetric biosensors.

Currently, the addition of the protein bacteriorhodopsin (bR) containing purple membrane to the PVA/MWNT scaffolds is being investigated to examine how this protein interacts with the PVA nanofibers and MWNT. The bR protein is electrospun with PVA/MWNT dispersions, as well as solely PVA dispersions. Considering the protein is diluted with DI water, the PVA is increased to 12 wt%, to ensure the viscosity is not too low upon the addition of bR. So far, three trials with PVA/bR, and six trials with PVA/MWNT/bR have been conducted. Based on the initial data from these trials, optimized electrospinning parameters have been established to optimize the synthesis *procedure for dispersions containing PVA, MWNT and bR. More trials are anticipated to further confirm the presence of bR within the scaffolds and to electrically analyze the differences between the control and bR containing scaffolds using electrochemical impedance spectroscopy (EIS).*

NM01.05.03

Evaluation of a Porous Nanofibrous Scaffold Comprising Polyvinyl Alcohol and Multiwalled Carbon Nanotubes for Protein Adsorption

Matthew Manduca and Isaac Macwan; Fairfield University, United States

There are several mathematical and physical modeling and simulating tools that are used for evaluating physical properties of nano and biomaterials. This ongoing research project involves the use of reaction bioengineering and transport of diluted species modules within COMSOL to simulate the flow and reactive properties of the protein bacteriorhodopsin through a mesh of polyvinyl alcohol (PVA) nanofibers with and without multiwalled carbon nanotubes (MWNT). The randomly oriented PVA/ MWNT nanofibers are modeled as a mesh on a flat aluminum foil closely mimicking the electrospinning process where such as a scaffold is synthesized in the wet lab. The goal of this study is to understand how concentration and flow of bacteriorhodopsin protein is affected by PVA control scaffold, and that comprising of a composite of PVA/ MWNT providing a link between the reaction kinetics and transport phenomena over the surface of such a biosensing recognition element. It further also accomplishes the purpose of simulating the time factor in a dynamic environment that is needed for the analyte to undergo a change from planar to radial to linear diffusion over such a scaffold. Throughout the simulated experiment, typical conditions of fiber diameter, random orientation, porosity and multilayers are maintained to replicate and confirm the simulated data experimentally. Cylindrical models of randomly oriented nanofibers are created as PVA nanofibers and MWNT on a real scale of 200nm diameters for the nanofibers and 90nm for the MWNT, with a typical length of 5 to 20 µm. A rectangular block around the PVA/ MWNT model served as an air or aqueous environment for the biosensor device. The overall composite model was then meshed using a standard rectangular mesh at the finer level to simulate it and finally integrated to determine the concentration of the analyte and the time required to reach the planar, radial, and linear diffusions respectively. Among the physical attributes, those for the interaction, concentration, velocity, and pressure of the protein were analyzed throughout its trajectory through the PVA/ MWNT scaffold over the aluminum substrate. It is anticipated that the results from this study will be useful in understanding the diffusion-based interaction of bacteriorhodopsin with PVA and MWNT components on a randomly oriented PVA/ MWNT electrospun nanofibrous scaffold.

NM01.05.04

Soft Actuator Based on Carbon-Nanotube-Composite Papers Using Kirigami Technique

Ryodai Toyomasu[1] and Takahide Oya[1,2]; [1]Yokohama National University, Japan; [2]SQIE, Institute for Multidisciplinary Sciences, Yokohama National University, Japan

We propose a unique soft actuator based on carbon nanotube (CNT)-composite papers. In recent years, there are demand for soft actuators that are lightweight, flexible, and compact actuators in medical and welfare applications. Generally, the soft actuators are made of polymer or rubber materials and respond to external stimuli such as electric field, light, temperature, and pH. And they generate a basic motion stretching and shrinking, bending, or twisting. CNT is nano-carbon material that has lightweight, high electrical conductive and large specific surface area. On the other hand, they generally exist at nanoscale and in powder form. Therefore, it is difficult to handle on its own and is used in composites with other materials. For this, we succeeded in developing CNT-composite papers that compose CNT with paper that is a familiar material. We here focus on our CNT-composite paper to develop our soft actuator.

The soft actuator in this study is an ion-conductive soft actuator responding to electric field. It is a three-layered device. It consists of two sheets of CNT-composite papers as electrode layers and one sheet of paper (electrolyte

layer) containing an ionic liquid (only of cations and anions). When voltage is applied to electrodes, each ion moves to the electrode layers and is injected. The size of the cations and anions vary that causes the electrode stretches and the other electrode shrinks. And the soft actuator generates bending motion.
CNT-composite paper is made by following a papermaking method based the traditional Japanese washi papermaking method. First, CNT dispersion is prepared by ultrasonic dispersion and pulp dispersion is also prepared by stirring, and each is mixed. The mixed dispersion is poured into a fine mesh and dehydrated. After that, it is dried by a heat press and the CNT-composite paper completes. It is cut into two sheets of the same size for electrode layers. At the same time, a tissue paper is cut into one sheet of the same size and contain ion liquid as the electrolyte layer. The tissue paper with ionic liquid is sandwiched between two sheets of CNT-composite papers and stacked by pressing and soft actuator based on CNT-composite papers completes.
In this study, Kirigami technique was introduced to our CNT-composite papers to incorporate paper-derived mechanical properties into the soft actuator. In this case, we use a cutter knife for simple fabrication. First, a vertical incision was made in the center of the CNT-composite papers. Next, the soft actuator was constructed using them, and the displacement, which indicates the degree of bending motion, was measured. As a result, we measured displacement of 4 mm. It was higher displacement than previous samples. We thought that this was because the strength of the paper was lowered by making vertical incision in the CNT-composite papers.
Since improvement in displacement was observed by making the vertical incision, we then considered making horizontal incision. First, horizontal incisions were made in CNT-composite papers at equal intervals to give the paper flexibility. Next, the soft actuator was constructed using them, and the displacement was measured as described above. As a result, we measured displacement of 1 mm. This was a lower than we had expected. However, at this time, we confirmed that the soft actuator was not bending in a two-dimensional direction, but rather twisting in a three-dimensional direction. We thought that by horizontal incisions, this motion was induced by the transition from in-plane deformation to out-of-plane deformation. Until now, few soft actuators have both bending and twisting motions have been reported for polymer materials and responding to electric field. This soft actuator was found to be an excellent soft actuator that can be used for twisting motion as well as bending motion by selective incision in our CNT-composite paper.

Graphene-Mediated Surface-Enhanced Raman Spectroscopy (G-SERS) for Biomolecule Detection

Takashi Uchino[1], Yanjun Heng[1], Ryoma Kumagai[1], Shigenobu Kasai[2], Hirokazu Fukidome[2], Akira Satou[2] and Taiichi Otsuji[2]; [1]Tohoku Institute of Technology, Japan; [2]Tohoku University, Japan

Surface-enhanced Raman spectroscopy (SERS) has attracted attention in biosensor applications because the technique allows high-specificity label-free detection. Traditionally, gold and silver nanoparticles have been used in SERS substrates, but these metals have technical issues such as biocompatibility and degradation. At the same time, two-dimensional materials, such as graphene, h-BN, and MoS_2, have been explored as a new platform for SERS substrates. Graphene especially has the advantage of being a non-metal with excellent biological compatibility, uniformity, and hydrophobicity.
We developed highly sensitive graphene-mediated SERS (G-SERS) substrates composed of a mica substrate covered with monolayer graphene and a silver nanohole structure on the backside. We discovered that the Raman peak intensity observed with the mica surface exposed (far-side excitation) was twice as high as that observed with the Ag surface exposed (near-side excitation). In addition, the graphene-based SERS substrates had stronger Raman signals than the mica/Ag substrates without graphene.
We also investigated the sensitivity of G-SERS substrates regarding substrates, graphene structure, and annealing effects. We found that hydrogen-annealed monolayer G-SERS substrates exhibited the highest sensitivity, comparable to SERS substrates consisting of gold or silver nanoparticles.
Furthermore, we examined hybrid SERS substrates, consisting of Ag/mica substrates coated with monolayer

graphene films. This structure aimed to improve SERS sensitivity and transform the surface from hydrophilic to hydrophobic to form a sandwich enzyme-linked immunosorbent assay (ELISA). ELISA is a powerful technique for detecting trace amounts of biological substances [1-3]. In this method, solid substrates are modified with antibodies that selectively capture the corresponding antigen molecules. Subsequent binding of enzyme-labeled secondary antibodies to the antigen-antibody complex leads to a sandwich-like structure. The enzyme label, usually horseradish peroxidase (HRP), is typically detected by measuring the absorbance of the enzyme reaction products.

We used the SERS substrates with ELISA to detect interleukin-6 (IL-6), an inflammatory cytokine closely associated with bovine mastitis. While we have previously detected the somatic cell count in raw milk by a simple electrochemical method, IL-6 has never been detected [4]. The SERS substrates detected trace amounts of HRP combined with IL-6 at a level as low as 50 pg/mL. This technique not only increased the precision of IL-6 detection but could also improve biomolecule detection.

Molecular Domain Modulated High Quantum Yield Nitrogen-Doped Carbon Dots (NCDs) and Their Application in the Fluorescence Based Sensing of Bilirubin and Cu^{2+} in Aqueous Medium

Rajarshi Basu and Amita Pathak; Indian Institute of Technology Kharagpur, India

Carbon dots have emerged as promising optical sensing probes for their remarkable photoluminescent properties. However, a comprehensive understanding of the structure-property relationship, particularly regarding the influence of different molecular domains, remains limited. In this regard, our study addresses this critical challenge by elucidating the transformation of H-bonded molecular clusters (IPCA/HPPT dominated fluorophores) in dual emissive (blue/green) NCD1 into aggregated molecular fluorophores (HPPT dominated) passivated on amorphous carbon nanodots in single emissive (green) NCD2 that holistically influenced the detection of both the Cu^{2+} ions and bilirubin (BR), focusing on the insufficient understanding of their underlying structure-property relationship. In this work, we have employed a bottom-up carbonization technique to synthesize two NCDs (NCD1 & NCD2), by varying the synthesis temperature, allowing control over the subpopulations of intrinsic domains such as crystalline-like, amorphous, and molecular domains. A remarkably high quantum yield of 80-85% has been observed for both the NCDs, which is explained based on their inhomogeneous distribution of fluorophores in molecular domains. Depending on the synthesis temperature, we can alter the natures of molecular domains/ constituents of NCDs revealed through a synergistic combination of time-resolved and steady-state optical spectroscopy, XRD, HRTEM, FTIR, XPS, and Raman analysis. Depending on the synthesis temperature, we can alter the natures and population of molecular domains/ constituents of NCDs revealed through a synergistic combination of time-resolved and steady-state optical spectroscopy, XRD, HRTEM, FTIR, XPS, and Raman analysis. The primary photophysical process involved in Cu^{2+} sensing is an electron transfer mechanism associated with dynamic quenching, while BR sensing relies on static quenching. Preliminary evidence suggests the electron transfer mechanism in Cu^{2+} sensing is mildly influenced by the molecular domain nature, whereas for static quenching process passivated molecular domains in CNDs take precedence over H-bonded molecular cluster domains linked to a crystalline component. Conversely, in BR sensing, static quenching dominates, driven by disordered domains prevailing over hydrogen-bonded molecular cluster domains coupled to a crystalline component. The modes of static quenching have been further elucidated based on the isosbestic point and *volume of sphere model.*

NM01.05.07

Catalyst-Free Direct Growth of Graphene on Silicon at Low Temperature Using HPPS Plasma *Yuto Oishi[1], Masanori Shinohara[1], Fumihiko Maeda[2] and Takashi Matsumoto[3]; [1]Fukuoka University, Japan; [2]Fukuoka Institute of Technology, Japan; [3]Tokyo Electron Technology Solutions Limited, Japan*

Graphene is a 2D material, is composed of carbon hexagonal ring structures. It has many useful properties, especially low resistivity. It is a promising material for LSI wiring to replace Cu on semiconductor devices. For this purpose, it is required to grow graphene on Si-Chips, without catalysts at low temperatures. Previous study indicates that high density plasma is suitable to catalyst-free direct graphene growth on Si. High power pulsed sputtering (HPPS) plasma generated at carbon target is focused as a plasma source for PECVD methods because HPPS generates high density plasma. HPPS have been attractive as new sputtering method in these days. HPPS-plasm enhanced CVD has been adopted for graphene direct growth on a Si substrate without catalyst.
HPPS-plasma was generated by applying direct voltage of 850 V for 20 μs at a frequency of 500 Hz to the carbon target set in the chamber pressure of 1.3 Pa, after the chamber was fed with styrene (C_8H_8) at 0.75 sccm and hydrogen at 15 sccm. The native oxide covered Si substrate set in the chamber as a substrate was heated at 550 degrees C or less with resistive heating, while its surface was monitored with a pyrometer. The deposition time was changed from 10 min to 20 min or long. The grown films are characterized with Raman spectroscopy, SEM (scanning electron microscope), and TEM (transmission electron microscope).
Every Raman spectrum of the film obtained at 550 degrees C has D band, D' band, G band, and 2D band which are characteristic to a hexagonal ring structures like graphene, carbon nanowalls and so on. SEM images of sample surfaces do not show whisker structures characteristic to carbon nanowalls in every sample. The images show plain surface but mosaic-like pattern, indicating that island growth occurred.
Every TEM image of the film obtained at 550 degrees C show multi-layer structures, indicating that Multi-Layer Graphene (MLG) was grown on Si. TEM images of the sample grown for 10 min shows several layers, but clearly shows islands. TEM images shows that around 10 layers are grown for 15-min growth and around 30 layers are grown for 20-min growth. From TEM images, it is suggested that after islands are formed in the early growth region (less than 15 min), the layer structures are formed. Island growth of MLG stems in the sample of 550 degrees C. The precursors generated in styrene plasma would not move to edge of the graphene formed on Si. The precursors might be large molecular weights. TEM images also show the interlayer is formed between MLG and Si crystal. Thickness of the interlayer is 1.82, 2.66 and 2.45 nm at the sample grown for 10 min, that for 15 min and that for 20 min, respectively. The interlayer is due to carbonized silicon oxide layer, and the layer is changed with the growth time.
We succeeded in the MLG growth at 550 degrees C on Si substrate without catalysts, with HPPS-plasma CVD using styrene as carbon source.
Part of this study is supported by KAKENHI (23K03372) and by funding from Fukuoka University (GR2305).

NM01.05.08

Development of Gas Sensor Using Carbon-Nanotube-Composite Paper with Metal Particles *Shuntaro Kubo[1], Koya Arai[2] and Takahide Oya[1,3]; [1]Yokohama National University, Japan; [2]Mitsubishi Materials Corporation, Japan; [3]SQIE, Institute for Multidisciplinary Sciences, Yokohama National University, Japan*

We propose a "paper gas sensor" based on carbon-nanotube (CNT)-composite paper (CNTCP) with metal particles.

Gas sensors are extremely important devices that enable us to have a safe and healthy life by detecting various *gases, such as combustible hydrogen, ammonia, nitrogen dioxide and carbon monoxide, which are toxic to the human body. Therefore, gas sensors are required to have high sensitivity and fast response. CNTs are known to have high sensitivity for specific gases, and their use as gas sensors has attracted much attention. However, CNTs are usually powdered and nanoscale materials. Therefore, it is difficult to handle them by themselves. For this, we here aim to develop a gas sensor using CNTs by utilizing CNTCP, which is easy to manufacture and process, inexpensive, and lightweight, and which is a composite of CNTs and paper.*

The reaction mechanism of CNTs to gases is based on the physical adsorption of gases and CNTs. This causes electric charge transfer between the CNTs and the gas molecules, which changes the electrical state of the CNTs. As a result, conductivity of the CNTs changes.
Currently, there are issues with our CNTCP reacting with various gases and not being able to detect only the targeted gas, and low sensitivity. Therefore, to improve these issues, metal particles are added to CNTCP and their reactions with gases are evaluated. In, this study, we use zinc oxide as metal particles. It is widely used as an n-type semiconductor and is also used as a gas sensor. The reaction mechanism of it with gas is also due to electric charge transfer by physical adsorption with gas molecules. Therefore, we expected that by adding zinc oxide particles to the CNTCP and adhering it to the surface of the CNTCP, the change in the electrical state of the zinc oxide would influence the CNTs and be evaluated as a change in the resistance of the CNTCP.

A CNTCP fabrication method is based on the "Japanese-washi-papermaking method." First, a CNT dispersion is prepared by ultrasonically dispersing NC7000, a multi-walled CNT, and Sodium Dodecyl Sulfate (SDS) as dispersant in pure water. Next, the pulp dispersion is prepared by dispersing pulp (raw material of paper) in pure water. CNTCP is then prepared by mixing these dispersions, pouring them into a papermaking device, dropping the water, and heat pressing. After that, it is cut into appropriate size, soaked in 0.1 mol/L of nitric acid for 1 hour to remove SDS. Finally, the dispersion prepared with zinc oxide is added to the CNTCP.
To evaluate the response to gases, the fabricated CNTCP is connected to a 4-terminal resistance measurement device and placed in a container. In this study, oxygen, carbon dioxide, and hydrogen gases of 99% purity are used, and each is introduced into the container, and the resistance change of the CNTCP is monitored. As a comparison, we also made the CNTCP without zinc oxide and conducted similar measurements.

The reaction of the CNTCP with zinc oxide with each gas changed comparing with the CNTCP without zinc oxide. In particular, in the reaction with oxygen, the resistance of the CNTCP decreased after the introduction of oxygen gas in the previously fabricated CNTCP, but the addition of zinc oxide caused an increase in resistance after the introduction of the gas. This suggests that the reaction of zinc oxide with the gases is different from the reaction that occurs between the CNTs and the gases. Thus, the reaction of the CNTCP can be altered simply by adding zinc oxide, which means that the gas to be detected may be selected by the addition of metal particles.

The next step in this research is to improve the sensitivity and selectivity of CNTCP to gases by changing the type of metal particles added. we believe that our CNTCP can be used as a gas sensor for each target gas in the near future.

NM01.05.09

Carbon Nanotube Thin Film pn Junction Diode with High Temperature Tolerance Using Chemical Dopants

Yuki Matsunaga[1], Haruki Uchiyama[1], Haruka Omachi[2] and Jun Hirotani[3]; [1]Nagoya University, Japan; [2]Wakayama Medical University, Japan; [3]Kyoto University, Japan

Chemical doping for carbon nanotubes (CNTs) is one of the most reliable approaches for controlling the electron/hole carrier quantities in CNTs. However, typical dopant molecules are desorbed from CNTs under these *harsh high-temperature and/or high-vacuum conditions during the device fabrication processes such as photolithography, the deposition of metal electrodes, and dielectric film formation. Therefore, the degradation of dopants during these processes limits the fabrication procedures of devices.*

We recently reported that 1,4,5,8,9,11-hexaazatriphenylenehexacarbonitrile (HATCN) is a good p-dopant for CNT-TFTs.[1] *We found that CNT-TFTs doped with HATCN exhibited an excellent on/off ratio even after heating up to 200 °C. On the other hand, for n-type doping, Nonoguchi et al. demonstrated that a composite of potassium hydroxide (KOH) and benzo-18-crown 6-ether (CE) is effective for CNT-based thermoelectric devices, which can withstand heat up to 150 °C in Seebeck coefficient measurements.*[2] *To overcome the thermal stability problem, we developed a new device fabrication process using temperature-tolerant p-type and n-type dopants to maintain chemical doping onto the CNT thin film. In this study, we fabricated CNT thin film pn junction diodes using a combination of HATCN and KOH/CE.*

Prior to the fabrication of the CNT pn junction diodes, CNT-TFTs were fabricated using purified semiconducting CNTs (s-CNTs). Because the as-grown CNTs synthesized via arc discharge (Meijo Arc SO type, Meijo Nano Carbon) contain both metallic and semiconducting characteristics, they were purified using an aqueous two-phase extraction method, as previously reported.[3] *The thin film of s-CNTs was then formed using the drop-cast method. The heavily doped* p^+*-Si substrate, which has a 100 nm-thick thermally grown* SiO_2 *layer and a back gate electrode, was functionalized with poly-L-lysine (Peptide Institute, Inc.). The as-prepared s-CNT dispersion (600 µL) was dropped onto the substrate to cover the entire surface. The substrate was rinsed with DI water and subsequently immersed in hot DI water (80 °C) for 1 min to remove the surfactant of CNTs and impurities.*

After obtaining suitable CNT–TFTs, we fabricated the CNT pn junction diodes. First, the CNT-TFTs were spin-coated with a 50 mM KOH/CE solution to demonstrate the device fabrication process in a high-temperature environment, as in the case of HATCN. The n-type doped CNT channel region requires passivation with oxide films before spin coating the p-type dopant solution. Therefore, the n-doped devices were covered with a 40 nm Al_2O_3 *film by atomic layer deposition (ALD). After the deposition, half of the* Al_2O_3 *on the channel of the CNT-TFTs was covered with photoresist using photolithography, and the exposed* Al_2O_3 *part was etched with a tetramethylammonium hydroxide solution (Microposit, MF CD-26 Developer) for 15 min. The photoresist covering was removed using an organic solvent to remove the n-type dopant of KOH/CE and to refresh the CNT surfaces. The devices were then doped with a 3 mM HATCN solution in a glovebox to remove the extra doping effect from oxygen and moisture.*

To evaluate the thermal stability of the fabricated pn diodes, we measured the I_{DS}-V_{DS} *characteristics of the diode after heating to 200 °C for 30 min, 100 min, and 300 min. The pn diode device with a channel length of 20 µm was evaluated at room temperature. The fabricated device exhibited stable behavior even after heating to 200 °C for 300 min.*

NM01.05.10

Developing Electrical Conductive Pastes for Screen-Printing on Textile

Ernesto A. Aguayo Calderon; CNyN-UNAM, Mexico

Introduction

The wearable devices correspond to a current technology that has caught great attention for further development. Nanotechnology with the different nanostructures with diverse physicochemical properties that has been able to accumulate, could contribute to diversify the development of this technological applications corresponding to the *wearable devices in textiles. Specifically, carbon nanotubes are currently in a mature enough stage, after several decades of academic research, to be considered for their applications in technological implementations. On this sense, it is well known the great electrical conductivity, mechanical flexibility, low density and low weight characteristics of the carbon nanotubes. A next step into technological applications, in the wearable devices route, could be to incorporate them in inks or pastes for different printing technologies such as screen-printing, ink-jet or spray-jet among others. This could impact in textiles with electrical conductive patterns, hydrophobic properties or even thermal management. The present work present the development of electrical conductive inks/pastes for screen-printing into textiles. Moreover, the adherence, stability on the textile and textile electrical conductivity were evaluated trying to show valuable data of their performance to be considered for their future technological application.*

Methodology

A methodology was developed for incorporating single-wall carbon nanotubes (SWCNTs) as nanostructured pigment into a water-based screen-printing paste. The formulation of carbon nanotube pastes/inks was optimized using two different surfactants to achieve homogeneous dispersions of CNTs at a relatively high concentration (10 mg/mL) in water, necessary for attaining the viscosity required in the screen-printing process. Once the optimized formulation was achieved, various patterns were printed on polyester-cotton textiles, and their stability was evaluated under different pH water environments.

Comparisons were made among different inks, varying preparation times, to select an ink that suited the project's goals. Physical properties such as adhesion and viscosity, which influence the ink's and the serigraphy materials' lifespan, were taken into account. Furthermore, the ink's print quality and its resolution capabilities on different serigraphy mesh counts were evaluated to assess effectiveness and scalability.

Results

In this work, we will present our results on the formulation and optimization to achieve a screen-printing paste incorporating SWCNTs as electrical conductor pigment. The empirical characterization of its viscosity will be conducted by microscopically imaging the cross-sectional profiles of printed patterns on different substrates, including polyester-cotton textiles. We will also present the adherence stability to the textile, performance, and electrical characteristics of the patterns on the textile after exposure to various aqueous pH environments and different washing cycles. These combined results demonstrate the feasibility of imprinting textiles with electrically conductive paths that could serve as interconnects for wearable devices.

Conclusions

An electrical conductive screen-printing paste was successfully developed and its application for printing on textiles was demonstrated. Moreover, the stability performance in adherence of the printed patterns on textiles makes the SWCNTs based screen-printing pastes presented feasible for applications to engrave electrical interconnects for wearable devices on textiles.

High-Performance and Flexible Thermoelectric Generator Based on a Robust Carbon Nanotube/BiSbTe Foam Young Hun Kang and Mijeong Han; Korea Research Institute of Chemical Technology, Korea (the Republic of)

The growing demand for wearable power generation system has led to research interest in organic thermoelectric (TE) materials due to their flexibility and ease in processability. Even though organic TE materials with thin film geometry have enough flexibility, organic TE generator with vertical structure has difficulty in compression or bending due to its lack of enough mechanical strength and durability. Furthermore, their low electrical conductivity and Seebeck coefficient is still challenge for use as practical TEGs with high power output.
In this study, we developed the hybrid CNT/$Bi_{0.45}Sb_{1.55}Te_3$ (BST) foam using the rapid solvent evaporation method and sepcifically investigated the influence of the adding BST nanoparticles (NPs) into CNT foams on thermoelectric and mechanical properties of the CNT/BST foams. The BST NPs were easily alloyed and crystallized within the CNT foam at a relatively lower temperature of 300 degree, significantly improving electrical conductivity and Seebeck coefficient of CNT/BST foams, simultaneously. Especially, the numerous junctions between CNTs and BST NPs within the CNT/BST foam could enhance the mechanical robustness by uniformly distributing the applied stress to the 3D networks of CNT/BST foam. Finally, we demonstrated a flexible vertical TEG consisting of 20 p-n pairs using p-type CNT/BST foam and n-type CNT/Ag_2Se foam. The fabricated TEG showed a relatively high output power of 15.7 μW at a temperature difference of 17 K and a low internal resistance of 12.3 Ω. Furthermore, the flexible TEG maintained the stable electrical resistance even after 10,000 cycles of bending with a bending radius of 25 mm.

NM01.05.12

Microstructural Origin of Non-Monotonic Piezoresistivity in CNT/Epoxy Nanocomposite Ting-yui Wong, Tao Yu and Fangxin (Frank) Zou; The Hong Kong Polytechnic University, Hong Kong

One basic requirement for the use of a piezoresistive material for strain sensing is that the material exhibits a monotonic resistance change response when subjected to mechanical deformation. Polymer nanocomposites such as CNT/epoxy, which possesses piezoresistive properties, have attracted considerable interest for strain sensing. However, both monotonic and non-monotonic piezoresistive behaviours have been observed in CNT/epoxy nanocomposite but the fundamental causes remained debatable. Our previous work established that the monotony of the piezoresistive behaviour in CNT/epoxy nanocomposite displays a dependence on curing temperature (Compos. Commun., 2023, 39: 101557). Nevertheless, the underlying microstructural mechanism was still ambiguous and required further investigation.

In this study, we investigate the microstructural origin of the non-monotonic piezoresistivity in CNT/epoxy nanocomposite through a combination of numerical simulations and experimental investigations. Coarse-grained molecular dynamic (CGMD) simulations illustrate the influence of curing temperature on the movement of CNTs during annealing and hence changes in nanofiller network configuration. Supported by experimental evidence including FESEM images and electrical conductivity measurements, this dependency is attributed to thermal-activated diffusion of CNTs in the viscous epoxy matrix. CGMD simulations are further used to compute the movements of CNTs during mechanical deformation, which are transformed into equivalent resistor network for the calculation of electrical resistance. The simulation results reproduce the experimentally observed curing *temperature dependence of the piezoresistive behaviour, suggesting that curing temperature influences the initial inter-nanotube junction geometry, leading to different movement trends and events that change the inter-nanotube junction geometry in response to tensile deformation. This finding provides evidence supporting the correlation between thermal and strain-controlled inter-nanotube junction geometry and the piezoresistive behaviour of CNT/epoxy nanocomposite. This study offers molecular insight for the key mechanism in the non-monotonic piezoresistivity of CNT/epoxy nanocomposite and enhances the understanding of piezoresistive polymeric materials.*

High-Throughput Calculation of 2D Carbon Allotropes *Vincent Meunier[1], Eduardo Costa Girão[2], Lilac Macmillan[1], Jodie Roberts[1] and Natalya Sheremetyeva[1]; [1]The Pennsylvania State University, United States; [2]Universidade Federal do Piauí, Brazil*

We systematically calculate the electronic and phononic properties of over 60 two-dimensional (2D) carbon allotropes. To accomplish this, we developed a graph theoretical method introducing the embedding tensor, enabling the discovery and characterization of three folded carbon allotropes. Additionally, we propose a unified taxonomy for sp2 nanocarbon allotropes in 2D, where each structure is assigned a unique symbol representing its geometry.

This naming scheme is demonstrated for all structures described in the literature and illustrated for several other topologically-allowed sp2 carbon systems. The symbol provides straightforward access to geometric features like polygon count and arrangement. It facilitates classifying reported structures, many of which had arbitrary names assigned by different authors.

The naming convention enables a systematic study of vibrational properties, allowing the search for unique features like topological phonons and determination of finite-temperature free energies. Calculations combine density functional theory (DFT) with a machine-learning force-field ("GAP") for faster computation.

Overall, our work provides a comprehensive framework for understanding the diverse properties of 2D carbon nanostructures through a novel topological perspective.

9:00 AM NM01.06.02
Exploration into Interstitial Crosslinks Capable of Strengthening Boron Nitride Nanotube Bundles *Nicholas Tjahjono[1], Evgeni Penev[1], Vesselin Yamakov[2], Cheol Park[3] and Boris I. Yakobson[1]; [1]Rice University, United States; [2]Analytical Mechanics Associates, United States; [3]NASA Langley Research Center, United States*

Boron nitride nanotubes (BNNTs) are promising strong, lightweight, and piezoelectric nanomaterials that can be used in applications ranging from vibration sensing to resilient aerospace materials with radiation shielding capabilities [1]. However, the superior mechanical properties of individual nanotubes [2] and ultrahigh interlayer *friction within multi-walled BNNTs [3] have yet to be manifested in practical macroscale BNNT bundles: despite their partially ionic B-N bonds, synthesized BNNT bundles [4] have not exhibited strengths substantially higher than carbon nanotube bundles.*

Here, we use ab initio calculations to search for interstitial species that can strengthen BNNT bundles via the formation of interlayer crosslinks. Density-functional theory (DFT) calculations indicate that small species present in the laser ablation synthesis of BNNTs [5,6], such as BN dimers, form stable links between h-BN bilayers, with binding energies greater than 2 eV. Additional ab initio molecular dynamics (AIMD) and DFT calculations suggest that larger species found during BNNT purification [7] (such as deprotonated forms of boric acid), can form covalent bridges within small-diameter BNNT bundles. Full enumeration of low-energy interstitial configurations within various h-BN bilayer stacking modes reveals that some interstitials prefer to bridge the layers in their ground states. The results demonstrate not only the recoverability and stability of these links under shear, but also the potential for high friction [8] as bound interstitials interact or transition between their ground states. Moreover, this suggests that links can strengthen BNNT bundles by orders of magnitude, thereby bolstering BNNT fibers up to the long-sought intrinsic strength of individual tubes, in the range of tens of GPa [2].

This work was supported by the NASA grant 80NSSC21K1299.

Exploring the Configurational Space of Amorphous Graphene with Machine-Learned Atomic Energies

Zakariya El-Machachi, Mark Wilson and Volker L. Deringer; University of Oxford, United Kingdom

Two-dimensionally extended amorphous carbon ("amorphous graphene") is a prototype system for disorder in 2D, showing a rich and complex configurational space that is yet to be fully understood. In this contribution, we explore the nature of amorphous graphene with an atomistic machine-learning (ML) model. We create structural models by introducing defects into ordered graphene through Monte-Carlo bond switching, defining acceptance criteria using the machine-learned local, atomic energies associated with a defect, as well as the nearest-neighbor (NN) environments. We find that physically meaningful structural models arise from ML atomic energies in this way, ranging from continuous random networks to paracrystalline structures. Our results show that ML atomic energies can be used to guide Monte-Carlo structural searches in principle, and that their predictions of local stability can be linked to short- and medium-range order in amorphous graphene. We expect that the former point will be relevant more generally to the study of amorphous materials, and that the latter has wider implications for the interpretation of ML potential models.

From Chiral-Specific CNT to Flat, Wrinkled, Tubular hBN—Growth and Electronics, In Theory *Boris I.*

Yakobson; Rice University, United States

Following the broad scope of the symposium, we will first discuss the "Holy Grail", long stading challenge of carbon nanotube research: how to synthesis nanotubes aof a desired chral symmetry, in order to have uniform electronic and optical properties. Recent ideas based on evolutionary selection can achieve it, in principle, while significant technical hurdles must be overcome yet.

We will then turn to other material for which chirality seems not being an issue, hexagonal boron nitride always an insulator, either tubular BNNT or planar hBN. What chemical precursors are needed as building units and how do they form in the gas phase of CVD varieties? For bilayer hBN, an intriguing possibility of creating new electronic properties by its undulation can also be of further great interest, to be discussed if time permits.
Supported by the DOE BES grant DE-SC0012547) and in part (BL hBN electronics) by the ONR grant N00014-22-1-2788.

First-Principle Analysis of Iron-Doped Hexagonal Boron Nitride Nanosheet as a Single-Atom-Catalyst for Water Splitting Under Extreme Conditions *Samira Ghanbarzadeh and Jihong Ma; The University of Vermont, United States*

This study presents a density functional theory (DFT) analysis of the performance of single-atom catalysts for water splitting under extreme conditions. We used iron (Fe) atom doped in two-dimensional hexagonal boron nitride nanosheets (BNNS) as an example and investigated its potential as an electrocatalyst for the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER). We addressed the challenges of high overpotential and low catalyst stability associated with these reactions through detailed investigations of band edge alignment, electronic structure, and overpotential. Specifically, we compared the effect of different concentrations of Fe doped in BNNS with various vacancy types. Our study reveals that the density of doped Fe atoms significantly influences the HER process such that mono-vacancy Fe-BNNS with a Fe concentration of 9.09% exhibits favorable HER performance, characterized by a Gibbs free energy change (ΔGH^*) of -0.22 eV. While in double-vacancy structures, reduction in Fe concentration adversely affects the performance. The findings underscore the critical role of Fe doping density in modulating the catalytic efficiency of BNNS for HER and OER, offering valuable insights for the design of advanced electrocatalysts for sustainable energy applications.
By employing the transition state theory, we have also examined the kinetics of the water-splitting process and found out that BN-vacancy Fe-BNNS compared to B-vacancy with a Fe concentration of 3.2% demonstrates low activation energy barriers of 0.83 eV for HER and 0.59 eV for OER, suggesting high catalytic activities. To assess the thermal stability of Fe@BNNS catalysts, we conducted ab initio molecular dynamics (AIMD) simulations at 500 K. Over a simulation period of 10 ps, our observations revealed no significant structural distortions or diffusion of transition metal TM atoms following thermal treatment. These findings underscore the inherent stability of Fe@BNNS catalysts, positioning them favorably for applications in water electrolysis. Their ability to maintain structural integrity under thermal stress highlights their potential as reliable catalysts for sustainable energy conversion processes.

Functionalization of Nanoporous Hexagonal Boron Nitride in Water—What Sticks at Nanopore Edges and Its Implications for Selective Desalination *Sagar Ghorai, Dhondi Pradeep and Ananth Govind Rajan; Indian Institute of Science, India*

Heteropolar two-dimensional (2D) materials, such as hexagonal boron nitride (hBN), are promising candidates for *seawater desalination and osmotic power harvesting. The significant electrostatic interactions that are operative in their vicinity allow the modulation of interfacial properties and nanoscale transport phenomena. Although nanopores would be terminated by various functional groups in aqueous environments, previous studies have considered bare nanopores in hBN. Here, we conduct accurate ab initio molecular dynamics studies of hBN nanopores surrounded by water molecules. Our simulations highlight a high propensity for H and OH functionalization at boron edges, while nitrogen edge atoms are primarily functionalized with H and occasionally with O, highlighting a potential route to selective membranes. We demonstrate the role of the Grotthus mechanism during the functionalization of hBN edges in water and show that functionalized pore atoms are inert for further reactions. We use this knowledge to develop a high-fidelity force field for B-H, B-OH, N-H, and N-O functionalization of hBN nanopores by combining quantum-mechanical calculations for structural optimization, charge determination, and potential energy surface fitting. We show that N-H terminated nanopores are excellent for the rejection of boron, a difficult-to-remove contaminant found in seawater. Additionally, the introduction of N-O groups allows a counter-intuitive increase in both water flux and ion rejection. We also establish a link between the magnitude of the charge difference in the edge atoms and higher salt salt rejection. Overall, our work provides rich mechanistic insights into nanopore functionalization, advances highly accurate models to simulate functional groups at nanopore edges, and demonstrates surprising new findings for boron and salt rejection from seawater, thereby significantly advancing the use of nanoporous 2D materials for membrane separation applications.*

11:00 AM NM01.06.07
Enhanced Heat Transfer Between Graphene and Water by Basal-Plane Oxidation— A One-Order-of-Magnitude Improvement *Haoran Cui and Yan Wang; University of Nevada, Reno, United States*

Heat transfer between graphene or carbon nanotubes (CNTs) and water is pivotal for various applications, including solar-thermal vapor generation and the advanced manufacturing of graphene/CNT-based hierarchical structures in solution. In this study, we employ a deep-neural network potential derived from ab initio molecular dynamics (MD) to conduct extensive simulations of graphene-water and CNT-water systems, varying the levels of oxidation (carbon/oxygen ratio). Remarkably, our findings reveal a more than one-order-of-magnitude enhancement in heat transfer upon oxidizing graphene or CNTs, underscoring the significant tunability of heat transfer within this system. Through comprehensive atomistic investigation, we elucidate how oxide functional groups facilitate heat transfer between graphene and water.

11:15 AM NM01.06.08
Thermal Probe of Fractional Quantum Hall States in Bilayer Graphene *Nishat Sultana[1], Robert Rienstra[1], Takashi Taniguchi[2], Kenji Watanabe[2], Nikolai Zhitenev[3], Joeseph Stroscio[3] and Fereshte Ghahari[1]; [1]George Mason University, United States; [2]National Institute for Materials Science, Japan; [3]National Institute of Standards and Technology, United States*

Measuring thermodynamic properties such as thermoelectric power (TEP) of a system can offer a way which is distinct from other techniques, particularly when it comes to studying fractional quantum hall states at half-filled Landau Levels (LLs). It has been shown that in a clean, non-interacting 2D electron system, TEP is proportional to the transport entropy of the 2D electron system. In the presence of a high magnetic field for strongly interacting electrons, the relation between TEP and entropy remains the same, which was also proved in previous works. This characteristic makes TEP a powerful measurement technique for studying statistical properties of FQH states, as the entropy carried by non-Abelian quasiparticles is predicted to be anomalously large. In our work, we perform magneto-TEP measurements of high-quality Bernal stacked bilayer graphene (BLG) because BLG has recently emerged as a new platform to study even denominator states. In our experiment, we observed well-developed FQH states even at a relatively low magnetic field. Our result indicates that thermopower as a measure of entropy *is more sensitive to probe FQH states than resistivity measurements. We also perform temperature and magnetic field dependence to further study the observed FQH states.*

SESSION NM01.07: Theory and Simulation II

1:30 PM *NM01.07.01
Computational Modeling of Various Nanomaterials for Electrocatalytic Energy Applications *Swapan K. Pati;*
Jawaharlal Nehru Centre for Advanced Scientific Research, India

Current research in materials science encompasses either production or storage of renewable energy or development of green research protocols. In this respect, I shall discuss computational modeling of several nanomaterials for electrocatalytic reactions, namely, bifunctional electrocatalysts and water splitting cathodic reaction, i.e. oxygen evolution reaction (OER) and oxygen reduction reaction (ORR), and hydrogen evolution reaction (HER). I shall discuss the bifunctional electrocatalytic activity of transition metal (Co/Rh/Ir) and N co-doped graphene (G) system with varying N concentrations using first principles calculations. The TM-N_4@G systems are found to be highly efficient bifunctional electrocatalysts and we find DG_{OH^*} to be a good descriptor in designing superior bifunctional electrocatalysts [1]. I shall also talk on the bifunctional electrocatalytic reactions in a Co-pyrophosphate, where we find that the bifunctional activity is rooted in the Co active site with CoO_5 local coordination in the (110) surface and the bulk oxygen makes way for the intermediate to bind with Co to give rise to superior overpotential values for both oxidation and reduction reactions [2].
For electrocatalytic HER in acidic media, I shall discuss the SiPF-tetrazine covalent organic framework (COF) which exhibits superior HER catalytic activity with DG_{H^*} values being almost zero [3]. The superior HER activity found in two nanoclusters, namely, $Ni_{73}Mo$ alloy electro-deposited on Cu nanowires and Ni_5Mo-hydroxide on Ni foam will be discussed [4-5]. In both the cases, through DFT calculations, we find that there is an unorthodox intra-lattice 'inverse' charge transfer from Mo to Ni. In fact, the undercoordinated Mo-centre pushes the Mo 4d-orbitals closer to the Fermi level in the valence band region while Ni 3d-orbitals lie in the conduction band facilitating the inverse charge transfer from the electron-rich Mo-centre to the electron-poor Ni-centre. I shall also discuss the all-pH HER electrocatalytic activity found in an interconnected NiV-LDH - CoP nanowire heterostructure. From our DFT calculations through Bader charge analysis, we find the higher concentration of charge carriers at the heterointerface and the transfer of fractional electronic charge from the hole-enriched NiV-LDH to the electron rich CoP surface at the heterointerface [6]. The stability of the hosts, surface types, selectivity, detailed mechanism, d-orbital centre, overpotential values and many other quantities relevant for the robust prediction and explanation of experimental data in each of these systems will be discussed.

Electronic, Mechanical and LIB Anode Performance of TPDH-Nanotubes—From Ab Initio to Classical Molecular Dynamics Simulations *Juan R. Gomez Quispe[1], Bruno Ipaves[1], Douglas S. Galvao[2] and Pedro A. Autreto[1]; [1]Universidade Federal do ABC, Brazil; [2]Gleb Wataghin Physics Institute, Brazil*

Tetra-Penta-Deca-Hexa-graphene (TPDH-gr) is a new 2D carbon allotrope with attractive electronic and mechanical properties [1]. It is composed of tetragonal, pentagonal, and hexagonal carbon rings. When TPDH-graphene is sliced into quasi-one-dimensional (1D) structures like nanoribbons, it exhibits a range of behaviors, from semi-metallic to semiconducting and unconventional ionic diffusion pathways for lithium ion batteries (LIB) anode application [2]. An alternative approach to achieving these desirable electronic properties is the creation of nanotubes (TPDH-NTs), which present a more reactive sites compared to TPDH-gr. In the present work, we carried out a comprehensive study of electronic, mechanical and LIB anode performance of TPDH-NTs combining Density Functional Theory (DFT) and Classical Reactive Molecular Dynamics (MD). Our results show structural stability and a chiral dependence on mechanical properties. Similarly to standard carbon nanotubes, TPDH-NT can be metallic or semiconductor. MD results show Young's modulus values exceeding 700 GPa showed a rigid behavior, except for nanotubes with very small radii. However, certain chiral TPDH-NTs (n,m) display values both below and above 700 GPa, particularly for those with small radii. The analyses of the angle and C-C bond length distributions underscore the significance of the tetragonal and pentagonal rings in determining the mechanical response of TPDH-NTs (n,0) and (0,n), respectively. On the other hand, we corroborated a TPDH-gr as a promising anode material for LIB applications, with a high theoretical capacity of C = 1116 mA h/g and low diffusion barriers (< 0.20 eV), closed to graphene values [3]. These results indicate that applicability of TPDH-NTs as an anode of LIB can be improving the diffusion lithium ion, due to curvature effects and chirality. Therefore, all these results show that TPDH-NTs could be possible candidates to be applied as an anode in lithium ion batteries.

Designing Carbon Allotropes—Marrying Schwarzites and Nanotubes *Degraj Suberi; St. John Fisher University, United States*

The outlook for expanding the carbon allotropes family includes a range of sp2-carbon structures, such as negatively curved nanographenes and still hypothetical Schwarzites. A bottom-up approach for periodic materials synthesis involves connecting various fragments such as nanographenes and nanotubes through covalent bonding. The bottom-up method allows for greater control over the diameter and length of nanotubes, as well as geometrical parameters of the molecular architecture.

In this theoretical study we explored an idea of assembling one-dimensional synthetic nanotubes of a uniform size into a highly ordered porous three-dimensional periodic structures to fully exploit their potential for creating next generation materials with controllable electronic and mechanical properties.

To achieve this, covalent binding can be employed to join nanotubes and negatively curved hydrocarbon elements serving as connectors. In this context, a typical Schwarz P-surface chamber with matching openings can serve as a six-way connector for nanotubes of the same diameter. Various other Schwarzites, such as G, D, H, HT, CLP, and GW were exploited as connectors for nanotubes. The created molecular architectures retained the symmetry of the parent Schwarzite. The geometry was optimized, electronic and elastic properties were estimated by DFT calculations. Porosity and materials density ranges have been widely extended through the choice of the nanotube's length. The design included specific tiling by heptagons and octagons for several dozen Schwarzites which will guide bottom-up synthesis of new materials particularly suitable for various applications such as gas storage, adsorption, membranes, lithium batteries, and supercapacitors.

By leveraging the unique properties of Schwarzite structures and nanotubes, this approach may open new possibilities for advanced material design and application, paving the way for innovative solutions in energy storage and material science.

Correlation Between Rashba Spin Splitting and HER Activity Enhancement in Two-Dimensional Layered Nanostructures *Sudip Chakraborty; Harish-Chandra Research Institute, India*

We address the fundamentals and possible implications of Rashba phenomena particularly for heavy element-containing non-centrosymmetric ultrathin two-dimensional nanostructured catalytic materials. It aims to shed light on the application paradigm of these exciting phenomena in the field of catalytic reaction mechanism, specially the photocatalytic water splitting which strongly depends on HER. The experimental realization along with the theoretical prediction of these phenomena in the emerging family of 2D materials could open up a new direction for modulating the charge carrier recombination probability. The influence of external parameters like hydrostatic pressure, uni and bi-axial strain are expcted to change the Rashba splitting factor, which essentially suppresses the recombination rate. Our work would provide a possible roadmap of materials design and the effect of external stimuli on the plethora of 2D materials for extensive energy scavenging with the focus on catalytic reaction mechanism. We have employed electronic structure calculations along with Spin-Orbit-Coupling to envisage the spin-splitting qualitatively and quantitatively from the bandstructure and spin-texture. Our atomistic modelling entails better understanding of the HER and make reliable advancements to expanding field of water splitting. Our aim is to create intermediate electronic states through Rashba band splitting, where electrons can stay and subsequently start HER mechanism. Therefore, we have performed the adsorption free energy analysis to form the reaction coordinate that maps all the reaction intermediates in order to find the corresponding overpotential along with the band structures of novel 2D materials to envisage the Rashba like band splitting through the external strain.

4:00 PM NM01.07.05
Confined Electrocatalysis in Carbon Nanotubes *David Zitoun[1], Samuel Hardisty[1], Anthony Kucernak[2] and Manoj Shanmugasundaram[1]; [1]Bar-Ilan University, Israel; [2]Imperial College London, United Kingdom*

Nano-confinement of electrocatalytic reactions is a promising strategy to influence the reaction kinetics and selectivity. The degree of confinement affects both electronic and mass transport parameters and breaks the scaling laws of surface activity in electrocatalysis.

Encapsulation of Pt nanoparticles in carbon nanotubes (CNTs) has previously shown excellent hydrogen oxidation reaction (HOR) performance and durability in corrosive electrolyte due to the high selective diffusion of the species H^+ and H_2 vs. the corrosive anions Br^- and Br_3^-.[1] A slightly different approach has been followed to encapsulate Pt SAC in CNT which demonstrates a high selectivity towards HOR vs. oxygen reduction reaction (ORR) in acidic medium.[2]

Herein, a strongly confined system has been designed and synthesized to demonstrate the nanoconfinement effects on HOR in alkaline medium. CNTs with inner diameter as low as 14 Å have been filled with a Pt single atom catalyst (SAC). The kinetics of the HOR reaction in alkaline are slowed down by the confinement effect, with a high overpotential observed for Pt SAC in CNT compared with a non-confined Pt catalyst. This effect was observed to a lower extent in Pt SAC in CNT with a larger diameter. On the other hand, nanoconfinement does not slow down the kinetics in acidic medium for any of these three types of catalyst. This phenomenon can be explained by the mass transport limitations of OH^- in 14 Å CNT, affecting the Heyrovsky rate determining step in alkaline medium; density functional theory calculations confirm the energy barrier for OH^- to diffuse in the CNT.

The Impact of Morphology and Crystal Orientation of the Metal Substrate on the Reactivity of Graphene with Nitrene *Jia Tu and Mingdi Yan; University of Massachusetts Lowell, United States*

Effective methods for the covalent functionalization of graphene are scarce due to the low chemical reactivity of graphene. As such, reactions of graphene primarily involve reactive intermediates such as free radicals, carbenes and nitrenes. We developed the covalent chemistry of graphene using nitrenes generated from perfluorophenyl azides (PFPA). We have shown that the reactivity of graphene with the electron-deficient perfluorophenyl nitrene can be enhanced by a metal substrate, achieved through increased electron density of graphene by the electron donating metal such as Ni and Cu. In this work, we investigate the impact of morphology and crystalline lattice structure of the metal substrate on the reactivity of graphene towards PFPA. Cu was used as the model substrate, and the reactions of PFPA with graphene supported on polycrystalline Cu (pCu), electropolished pCu, Cu(111), and silicon wafers (SiO_2/Si) were carried out. Raman spectroscopy was employed to analyze the vibrational changes of graphene before and after functionalization, using the intensity ratio of D and G peaks, I_D/I_G, as the indicator for the extent of reaction. We found that graphene supported on Cu(111) exhibited the most enhanced reactivity towards PFPA. The detailed studies and results will be presented.

4:30 PM NM01.07.07

Interfacial Characteristics of Ice-Supporting Substrates via Molecular Dynamics Simulations *Emmanuel Skountzos, Ashwin Ravichandran and John W. Lawson; NASA Ames Research Center, United States*

Ice accretion on critical infrastructure and equipment, including aircraft, wind turbines, solar panels, and power lines, poses significant risks to operational safety and incurs substantial economic losses annually.[1] Traditional active de-icing methods, such as mechanical vibration, thermal heating, and chemical spraying, have demonstrated efficacy but suffer from drawbacks including high energy consumption, environmental concerns, *and operational inefficiencies.[2] Consequently, there has been a shift towards exploring passive anti-icing solutions, such as icephobic coatings, which offer an environmentally friendly and energy-independent means to mitigate ice formation and facilitate its removal. These coatings, by reducing ice adhesion strength to below critical thresholds, enable ice shedding through natural forces like wind and gravity.[3]*

The present work focuses on characterizing the low ice adhesion properties of various substrates through molecular descriptors. We follow the hypothesis that has been previously speculated in several experimental works[4,5] according to which a disordered, liquid-like layer (QLL) of water at the substrate/ice interface is developed, which in turn acts as a self-lubricant reducing the ice adhesion strength and enhancing the material's icephobicity. To put this idea into the test, we conducted exhaustive molecular dynamics (MD) simulations on ice, supported by different types of substrates, such as graphite, a boron nitride sheet, and a cross-linked polymer epoxy matrix. Our findings reveal that the ice structure becomes disordered near the interface for all substrates, with a more pronounced effect in the polymer substrate. Detailed analysis showed that this is directly correlated to the development of hydrogen bonds between the interfacial water molecules and the polymer substrate's polar atoms, which was found to induce a more intense disruption of interfacial ice's crystal structure, promoting thus the formation of a thicker QLL. Our detailed analysis showed that there are specific atoms of the polymer substrate that interact more intensively with the water molecules of the crystal ice, providing thus important guidance towards the fabrication of polymer coatings that exhibit the necessary nanoscale chemical formulae that can result in very low ice adhesion strengths.

Modulating the Nitrogen Species of N-Doped Graphene—A Step Forward Towards Improving the Selectivity of Electrochemical Reactions *José M. Ruiz-Marizcal[1,2], Miguel A. Amezcua[1], Jose I. Paez-Ornelas[1], Noe Fernandez-Escamilla[3], Carlos Belman[1], Rodrigo Ponce[1], Noboru Takeuchi[1] and Jose M. Romo-Herrera[1]; [1]Universidad Nacional Autónoma de México, Mexico; [2]CICESE; Posgrado en Nanociencias, Mexico; [3]Universidad Autónoma de Nuevo León, Mexico*

Global challenges such as alternative clean energy sources and environmental remediation issues can find some options with electrochemical reactions. Nitrogen doped (N-doped) graphitic nanostructures have been emerging as promising candidates to overcome precious metal electrocatalysts drawbacks such as increasing costs and scarcity and even some corrosion effects by side-products, due to the Earth-abundant availability of carbon and their chemical stability.

The N-doping of graphitic nanostructures commonly includes different nitrogen species such as pyridinic nitrogen, pyrrolic nitrogen and graphitic nitrogen. Each of such different nitrogen species sites present different properties and therefore electrochemical activity and they could even dictate different reaction pathway. For instance, for the Oxygen reduction reaction, it has been shown that pyridinic nitrogen favors the 4-electron pathway while the graphitic nitrogen favor the 2-electron pathway [1-2]. Then, to be able to modulate the proportion of nitrogen species in N-doped Graphene becomes a challenge of paramount importance in order to improve its selectivity as electrocatalyst for important electrochemical reactions.

Here, we will start showing some evidence in the selectivity dependence on different nitrogen species for the

Oxygen reduction reaction (ORR) and the Iodide reduction reaction (IRR) for N-doped graphitic carbon nanostructures. Then, we will describe experimental and DFT calculations results on the understanding of the N-doping process by post-synthesis treatments using graphene oxide as precursor; this results show the feasibility of two different approaches for modulating the nitrogen species proportions in N-doped graphene. Following, we will show the effect of this nitrogen species proportion modulation on the ORR selectivity for N-doped graphene as the electrocatalyst. We will end up discussing alternative N-doping approaches with a special emphasis on nitrogen species proportion modulation.

Formation Mechanism of Hierarchically Porous Graphitic Aerogel and Their Application in EMI Shielding

Mohd Shaharyar Wani, Yusuf Jimoh, Paul Prucnal and Craig Arnold; Princeton University, United States

Hierarchically porous graphitic sheet-based aerogels (HGAs) have garnered significant attention due to their diverse applications in water purification, energy storage, electromagnetic interference (EMI) shielding, and other fields. However, current fabrication methods face sustainability and scalability challenges. This study introduces the formation mechanism of a novel, green synthesis approach for HGAs using naturally available protein precursors. Through in-situ characterization techniques, we elucidate a self-foaming mechanism during controlled pyrolysis. In this process, protein precursors undergo softening, gas evolution, and foaming, followed by carbonization and graphitization, resulting in a hierarchically porous graphitic aerogel with an integrated framework of sheets and fibers. By systematically exploring processing-structure-property relationships, we tailored critical material performance metrics, including density, porosity, and electrical conductivity. The bio-derived HGAs exhibit exceptional EMI shielding performance, with a specific shielding effectiveness per unit thickness (SSE/t) exceeding 16,400 dBcm^2/g, surpassing previously reported carbon and graphene aerogels. This work paves the way for scalable production of HGAs in next-generation technologies, offering a promising solution for various applications, including high-performance EMI shielding.

NM01.08.02

Anisotropy and Stress-Assisted Thermal Activation Kinetics of Graphene Fracture *Cangyu Qu[1], Diwei Shi[2], Li*

Chen[2], Zhanghui Wu[2], Jin Wang[2], Songlin Shi[2], Enlai Gao[3], Zhiping Xu[2], Quanshui Zheng[2] and Robert W. Carpick[1]; [1]University of Pennsylvania, United States; [2]Tsinghua University, China; [3]Wuhan University, China

We have experimentally determined the fracture toughness anisotropy of graphene, showing that the zigzag (ZZ) direction has slightly lower fracture energy than the armchair (AC) direction. This provides an experimental benchmark for widely scattered theoretical predictions, and provides constraints for future models of graphene fracture. We then demonstrate that fracture initiation of graphene is a stress-assisted thermal activation process, and determine the activation energy and activation volume for the process by using Eyring kinetics. These precise measurements are facilitated by exploiting the mechanical exfoliation process used to fabricate graphene, which naturally produces an enormous number of single- and few-atomic height steps on the parent graphite sample's surface. These steps are a vestige of fracture events occurring in single- and few-layered graphene planes during exfoliation, and as such provide a previously untapped, convenient, and versatile platform for quantitatively determining graphene's fracture behavior. The measurements are performed using atomic force microscopy (AFM) to image or manipulate these step edges. For investigating facture anisotropy, AFM was used to image the geometry and orientations of the steps with lattice resolution. Two distinct categories of steps were observed depending on the exfoliation direction and local lattice orientation: parallel groups of straight steps well-aligned with local ZZ directions, and steps comprising nanoscale ZZ and AC segments. A fracture mechanics analysis of the microscale morphology and statistics of directions of these steps yielded an experimental measurement of the anisotropy ratio of graphene's fracture toughness G such that G_{ZZ}/G_{AC}=0.971, i.e., ZZ direction has a slightly lower fracture toughness than AC direction. To study the kinetics of fracture initiation, AFM was then used to cut single- and few-layered graphene at those step edges as a function of applied stress and temperature. The results support the hypothesis that fracture initiation is a stress-assisted thermal activation process, offering new physical insights into this phenomenon. In addition to these scientific insights, the AFM-based methodology itself is new. It permits high spatial resolution (sub-nanometer) measurements with facile sample preparation, high throughput due to the typically high areal density of steps, and quantitative measurements applicable to fracture mechanics models. Thus, it is a powerful tool for investigating the nanoscale fracture of graphene and other 2D materials.

NM01.08.03

Direct Capture and Photothermal Release of Toluene by Nanostructured Hard Carbon Monolith *Subham Yadav; Indian Institute of Technology Bombay, India*

Volatile organic compounds (VOCs), such as toluene, benzaldehyde, alcohols, and aromatics, pose a significant threat to both terrestrial and aquatic ecosystems. Therefore, it is essential to develop efficient and sustainable capture and recovery pathways to create a biologically suitable environment. Various adsorbents, including activated carbon, CNT composites, and graphite, have been explored, but the release of VOCs from such adsorbents requires the use of electrical energy for heating, which increases the carbon footprint of the entire process. Moreover, the release process can alter the adsorbent's microstructures and decrease VOC capture efficiency. Our approach aimed to address both aspects by utilizing a porous hard carbon nanomaterial with a unique solar-thermal conversion property which made the entire capture-release process more sustainable and efficient without altering the adsorbent material's characteristics. By leveraging the advantages of ice-templating and chemical vapor deposition processes, a carbon coated silica monolith structure (dNCF-ML) was fabricated with 50% toluene vapor adsorption efficiency at low inlet pressures of 767 Pascal and efficient release under light irradiation.

For Mom and Baby Wellness, An Electrochemical Enzymatic Biosensor for Quantification of Glucose in Breast Milk Based on Laser-Induced Graphene Electrodes *Abdulrahman Al-Shami, Haozheng Ma, Melissa*

Banks, Farbod Amirghasemi, Mona Abdelmonem, Ali Soleimani, Sina Sina Khazaee Nejad, Victor Ong and Maral Mousavi; University of Southern California, United States

Beyond the fact that human breast milk is nature's perfect food for newborns, it is also a rich biofluid containing potential biomarkers for various health conditions of breastfeeding moms. The field of breast milk analysis has witnessed the introduction of various products designed to support breastfeeding management. The U.S. Food and Drug Administration (FDA) has, for instance, authorized devices like the Miris Human Milk Analyzer for use in hospital settings to quantify breast milk nutrients. However, these instruments use infrared analyzers that are often large, expensive, and frequently require specialized training. Consequently, accessibility for parents in the home setting is limited and use is generally restricted to hospital laboratories and milk banks. Breast milk's glucose content presents a complex challenge for infant development. It's vital for brain development and growth, but high levels in overweight mothers raise concerns about perpetuating childhood obesity. Conversely, mothers with gestational diabetes have lower milk glucose, putting babies at risk of hypoglycemia (low blood sugar) with potential long-term consequences. In this work, we present a point-of-care glucose electrochemical biosensor for glucose level detection in breast milk. The electrochemical electrodes were fabricated using, a precise, cost-effective, fast, scalable, safe, and highly reproducible laser-engraving method on polyimide film. we used Prussian blue PB as a mediator in the enzymatic sensor to enhance the reduction of hydrogen peroxide H2O2 that results from glucose and glucose oxidase reaction. PB helps in efficient hydrogen peroxide reduction at low electrochemical potential values leading to improved sensitivity and selectivity for enzymatic biosensors. PB was electrochemically deposited on the LIG surface. The GOx enzyme was deposited on the LIG+PB within a cocktail of bovine serum albumin BSA, glutaraldehyde GA, and Nafion. GA works as a crosslinker for GOx and BSA to provide a homogeneous and biocompatible membrane to maintain the functionality of the enzyme and improve its performance characteristics. This biosensor achieved high sensitivity and a low detection limit, allowing for accurate glucose measurement in complex samples like breast milk. The developed sensor exhibited robust accuracy in directly detecting glucose concentrations (96.8-104.1%) in real human milk samples collected at various stages of lactation (1st, 6th, and 12th months). These results highlight the potential of this technology for effective and non-invasive glucose monitoring in breast milk for moms and babyies wellness.

Multifunctional Free-Standing Thermoelectric Nanocomposite Foams with Acoustic Properties

Rui Yang (Sunny) Liu[1], Yu-Chen Sun[1], Szu-Ling Liu[1], Weiqing Fang[1], Terek Li[1], Yadienka Martinez-Rubi[2], Michael Jakubinek[2], Behnam Ashrafi[2], Christopher Kingston[2] and Hani E. Naguib[1,1]; [1]University of Toronto, Canada; [2]National Research Council, Canada

The thermoelectric effect (TE) represents a remarkable physical process that facilitates the direct conversion of thermal and electrical energies. This effect is notable for its inherent reversibility, and it has been extensively utilized in various technological applications, such as solid-state refrigeration/heating devices and temperature sensors. The efficacy of thermoelectric materials is fundamentally influenced by a constellation of material-dependent parameters, including electrical conductivity, thermal conductivity, and the Seebeck coefficient. The pursuit of optimal thermoelectric materials is driven by the need to achieve high electrical conductivity and Seebeck coefficient while maintaining minimal thermal conductivity. In recent times, the focus of thermoelectric research has undergone a significant shift, gravitating towards polymer-based nanocomposites as opposed to traditional semiconductor-based formulations. This trend is propelled by the inherent versatility of polymeric materials in customizing and manipulating their electrical and thermal conductivities. Furthermore, advantages such as enhanced mechanical pliability, lower fabrication costs, and improved manufacturability have been instrumental in directing the development of polymeric thermoelectric nanocomposites. The domain of engineered nanocomposites offers a platform for further refinement of material characteristics and thermoelectric

efficiency. This is accomplished through the strategic integration of various micro- or nanostructures and secondary nanoparticles. Importantly, the incorporation of highly conductive fillers such as carbon nanotubes (CNTs) and graphene nanoplatelets (GNPs) is central to enhancing electrical conductivity. Utilizing their high aspect ratios, a small concentration of these fillers can significantly alter the overall conductivity at the macroscale, predicated on the formation of a strong interconnective conductive network within the nanocomposite matrix. Additionally, the incorporation of microstructures into the nanocomposite framework provides avenues for modulating thermal conductivity. For example, introducing cellular structures can substantially hinder thermal transfer, thereby enhancing thermoelectric performance. This research is at the vanguard of innovation, presenting a novel fabrication methodology for thermoelectric nanocomposite foams. This technique employs thermally responsive expandable microspheres integrated with thermoplastic polyurethane (TPU)-coated CNT structures. Empirical results from this study highlight the effectiveness of this approach, showcasing the production of nanocomposites with exceptional electrical conductivity. Notably, the thermal conductivity of these nanocomposites is on par with that observed in aerogel-based nanocomposites, indicating a promising pathway for developing highly efficient polymer-based thermoelectric materials with broad technological ramifications. We also evaluated the compressive stiffness, mechanical stability, and potential for sound absorption of the nanocomposite foam. With this unique combination of thermoelectric, sound absorption, and mechanical properties, the engineered thermoelectric foams show great potential for aerospace applications, where high-temperature gradients and mechanical vibration/noise are prevalent simultaneously. This research is at the vanguard of innovation, presenting a promising pathway for developing highly efficient polymer-based thermoelectric materials with broad technological ramifications.

NM01.08.06

Stability and Electronic Structure of Double-Walled Transition Metal Dichalcogenide Nanotubes *Daniel S. Vadseth[1], Joshua Brown[2], Shigeo Maruyama[3] and Alister Page[1]; [1]The University of Newcastle, Australia; [2]University of New South Wales, Australia; [3]The University of Tokyo, Japan*

The groundbreaking discovery of a new class of materials, one-dimensional (1D) van der Waals (vdW) heterostructures [1], has opened the door for studying a range of novel physics, material properties, and exciting applications. With two dimensions in the sub 10 nm scale and near limitless material combinations of nanotube (NT) layers, 1D vdW heterostructures have demonstrated novel physics and material properties such as interlayer excitonic coupling [2], charge transfer, and importantly, tunable optoelectronic properties [3]. That layers in 1D vdW materials are connected via vdW forces alone highlights the need for a better understanding of the interactions between NT layers, and how it affects properties.

In this study density functional theory (DFT) and the density functional tight binding method GFN1-xTB were used to systematically investigate how vdW interactions between NT layers of transition metal dichalcogenide (TMD) double-walled (DW) NTs affect stability and electronic properties. The strength of vdW interactions were modulated by increasing the intertube separation gradually, and the stability, band structure, rotational and translational potential energy surfaces and vdW interaction energies were calculated using DFT and GFN1-xTB. It was found that the vdW forces have a stabilizing effect on DWNTs, and that the magnitude of the vdW forces depend on the chalcogenide, not the transition metal. The vdW interactions facilitate band gap changes of up to 0.3 eV, without changes to the tube chirality, due to radial compression of the inner-tube.

AI-Based Chirality Classification for Carbon Nanotubes *Rui Iwasaki, Tatsuya Takakuwa, Hirotaka Inoue and Takamasa Onoki; Sumitomo Electric Industries, Ltd., Japan*

Carbon nanotubes (CNTs) possess exceptional properties such as high conductivity, lightweight, high strength, and excellent heat dissipation, making them ideal for advanced material applications. A significant challenge in CNT research is controlling chirality, which directly influences their electrical properties, distinguishing between metallic and semiconducting CNTs. Traditional chirality classification methods, involving the analysis of diffraction images obtained through Transmission Electron Microscopy (TEM), are complex and labor-intensive. To address this challenge, we developed an AI approach aimed at automating the chirality classification process. The AI was trained on a comprehensive dataset of simulated diffraction images representing various CNT chiralities and tilt angles, ensuring robust training. In tests using experimental TEM images, the AI achieved a classification accuracy of 97%. This high accuracy enables a more efficient classification process. This approach not only enhances the efficiency of CNT research but also opens new avenues for leveraging machine learning in materials science. It addresses complex challenges in materials characterization and advances the broader field of nanotechnology and advanced materials research.

NM01.08.08

Controllable Interlayer Shielding Effect in Twisted Multilayer Graphene Nanoflakes *Xian Wang and Yunpeng Lu; Nanyang Technological University, Singapore*

When multilayer graphene (MLG) is subjected to a vertical electric field, electrons traverse across the layers and its interlayer electrical conductance and shielding effect exhibits remarkable diversity, leading to exotic phenomena and diverse applications in photoelectric devices. The rearrangement of electrons induced by this external field is aptly described by polarizability, which quantifies the electronic response to the applied field. In this work, we have developed a polarizability decomposition scheme based on field-induced electron density variations computed using a first-principles approach. This scheme allows us to isolate the inter- and intra-layer contributions from the total polarizability of twisted multilayer graphene (TMG) nanoflakes. The inter- and intra-layer counterparts reflect the charge transfer (CT) and field shielding effects among the layers, respectively. While the strongest shield effect is observed between the outermost two layers, the largest CT change is noted in the outermost layers, but small or nearly zero CT changes in the inner layers. Significant CT and shielding effects are observed not only in strongly coupled Bernal stacking, but also in the structures misaligned from full-$(AA)_N$ stacking by a small and size-dependent twist angle. The dielectric behaviors of the TMG nanoflakes of a few layers are layer-dependent and different from those of typical dielectrics. Moreover, both the shielding and CT effects exhibit variation with thickness, twist angle and disc size, suggesting controllable conductive/dielectric conversion in the vertical direction. Considering the inter- and intralayer polarizability, our study addresses the precise modulation of interlayer conductance and shielding effect for TMG nanoflakes, essential for microstructure design and performance manipulation of MLG-based photoelectric and electrochemical devices.

NM01.08.09

Production and Electrical Characterisation of Phosphorene Nanoribbons (PNRs) *Eva Aw[1], Loren Picco[2], Oliver Payton[2], Stacy Moore[2,3], Fengfei Zhang[1], Adam Clancy[1], Thomas Miller[1] and Christopher Howard[1]; [1]University College London, United Kingdom; [2]Bristol Nanodynamics Ltd., United Kingdom; [3]University of Bristol, United Kingdom*

In our fast-paced technological world, the demand for more powerful yet smaller devices has fueled the need for *nanomaterial innovation. To meet this demand, precise chemical doping techniques can be employed to tailor the properties of low-dimensional materials and facilitate their integration into functional films, electrodes, and spin-based electronics.*

Phosphorene nanoribbons (PNRs), a nanomaterial synthesized by our research group at UCL [1], are predicted to exhibit exotic properties, including the Seebeck effect, tunable layer-dependent electronic, optical and ionic transport properties. Recent experiments have demonstrated room-temperature magnetism [2] in PNRs and their ability to enhance hole mobility in solar cells [3]. By combining the flexibility and unidirectional properties of nanoribbons with the high surface area and anisotropic properties of 2D phosphorene sheets, PNRs are expected to exhibit high conductivity due to the 2D confinement of electronic movements and edge effects.

This work focuses on the synthesis of PNRs using a two-step method. Firstly, black phosphorus is intercalated with alkali metal ions, followed by exfoliation to form stable liquid dispersions of PNRs with few-layer thicknesses and 4-50 nm widths uniform along their lengths [4]. This scalable approach allows us to isolate high quality individual PNRs from bulk black phosphorus. In collaboration with Bristol Nanodynamics Ltd., I am using a recently developed high-speed scanning probe microscope, Vector Dynamic SPM, to characterise the local charge distribution of PNRs [5][6].

Vector is an advanced characterization instrument specialising in rapid, high-resolution mapping and nanoscale surface characterisation. This technique enables simultaneous topography and conductivity measurements, providing valuable insights into the spatial maps of conductivity. By analyzing these maps, we can derive insights on how the electronic band structure of PNRs varies with their dimension and number of layers.

Advanced Nanostructured Energy Storage—Graphene Oxide with Niobium-Manganese Oxides for High-Performance Supercapacitors

Danilo Alves Oliveira and Jose Roberto Siqueira Junior; Universidade Federal do Triângulo Mineiro, Brazil

Nanostructured films have garnered significant attention in energy storage applications, particularly within the domain of supercapacitors. Carbon and metal oxide-based materials have attracted considerable interest due to their potential across a wide array of technological applications in energy storage. A promising approach involves integrating various metallic oxides into graphene oxide matrices. In this context, our research focuses on the fabrication of Layer-by-Layer (LbL) and Langmuir-Blodgett (LB) films comprising graphene oxide and metal oxide nanoparticles embedded within electrodes. These films serve as customized interfaces with the capability to function effectively in supercapacitor devices.

Thus, we explored the incorporation of different metal oxide nanostructures, including MnO_2 *and* NbO_2 *into* *graphene sheets. These were combined with polyelectrolytes for LbL film formation or phospholipids for LB film formation. Here, we present insights into the fabrication techniques and characterization methods employed to develop strategies for modifying conductive electrodes. Additionally, we discuss the advantages of arranging graphene oxide and metallic oxides in LbL or LB fashion films, highlighting their potential properties for exploitation in supercapacitor devices.*

In particular, we focused on enhancing an indium tin oxide (ITO) electrode by applying films containing a combination of the positively charged polyelectrolyte polyethyleneimine (PEI) and the negatively charged polyelectrolyte graphene oxide (GO), alongside metallic oxides like manganese oxide (MnO_2) and niobium oxide (NbO2), using the Layer-by-Layer (LbL) method. Following the fabrication of the films, graphene oxide was electrochemically reduced to yield reduced graphene oxide (rGO).

Cyclic voltammetry analysis revealed that the PEI/rGO system exhibited a capacitance per unit area of 20.42 mF cm^{-2}. In comparison, the PEI/rGO-MnO_2 system demonstrated 36.57 mF cm^{-2}, and the PEI/rGO-NbO_2 system showed 30.14 mF cm^{-2} when utilizing a 1 M potassium chloride electrolyte at a scan rate of 1 mV s^{-1}. Through galvanostatic charge and discharge measurements, specific capacitance values of 144.85 F g^{-1} and 183.77 F g^{-1} were attained for systems containing manganese and niobium, respectively, compared to 29 F g^{-1} for the PEI-rGO system, under a fixed current of 20 microamperes.

Remarkably, by combining both manganese oxide and niobium oxide, the capacitance per unit area surged to 119 mF cm^{-2}, while the specific capacitance soared to 353 F g^{-1}. In terms of long-term stability, all films exhibited negligible capacitance loss, with none exceeding 2.57% after 10,000 cycles. These findings underscore the feasibility of integrating these materials via the LbL technique, elucidating the synergistic interplay between manganese oxide and niobium oxide as a potential energy storage system.

NM01.08.11

Au Substrate Effect on Thermal and Mechanical Properties in Biphenylene-Like Graphyne *Willian Fábio Radel and Marcelo L. Pereira Junior; Universidade de Brasilia, Brazil*

Nanomaterials comprise a vast class of materials that have attracted significant attention from the scientific community due to advancements in nanotechnology. In particular, following the synthesis of graphene in 2004, two-dimensional systems have shown promise in various areas of great importance for societal advancement, including new membranes for electronics, water treatment, adsorption of harmful gases, and more. Carbon-based nanomaterials commonly exhibit mechanical, electrical, thermal, and optical properties of interest for these applications. Beyond graphene, many other systems have been theoretically proposed and subsequently synthesized in recent years. Among the carbon allotropes, the biphenylene network (BPN) was recently synthesized and has garnered considerable attention for its comprehensive characterization and potential applications. Similarly, gamma-graphyne (gamma-GY) was also recently synthesized, consisting of a system derived from the insertion of acetylenes into the bonds of graphene, with benzene rings connected by these links. Here, we propose combining both ideas, preserving the benzene ring of BPN while inserting acetylenes into all other system bonds. In our study, four biphenylene-derived systems are considered, and their mechanical and thermal properties are obtained. Using the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) software, our simulations employed reactive molecular dynamics. The Adaptive Intermolecular Reactive Empirical Bond Order (AIREBO) potential was used, following extensive testing of other force fields such as REBO, ReaxFF, and Tersoff. For better accuracy in the simulations, the cutoff radius of the potential was adjusted based on results from previous literature. The systems were simulated with and without a gold substrate for comparison. Our protocol initially involves optimization at 0 K, followed by two system equilibration/thermalization stages. First, the isothermal-isobaric ensemble (NPT) was employed for 100 ps, with zero pressure and room temperature, to eliminate residual stresses in the investigated systems. The systems underwent an additional 100 ps of simulation using the canonical ensemble (NVT) to ensure room temperature. A time step of 0.1 fs was used, and for each *system, several simulations with different initial velocities were considered to obtain a better statistical description of the properties. From the prepared systems, two separate protocols were applied. In a heating simulation, the system temperatures were gradually increased from 300 K to 5000 K in a thermal bath, calculating the potential energy and system temperature throughout the simulation. The heat capacity was calculated as a function of temperature using a post-processing code. In our results, the specific heat of the systems ranged from 2100 to 2500 J/(kg K) for the suspended systems, slightly decreasing in the presence of the substrate. The phase changes of the systems and the melting patterns were also obtained. Regarding mechanical properties, the monolayers were subjected to strain up to 50% of their original size, using the NPT ensemble again to observe the Poisson effect in the systems. In all cases investigated here, fracture occurred with around 11% deformation. Young's modulus varied from 190 to 380 GPa without the substrate, depending on the direction and number of acetylene pairs inserted into the bonds. With the Au substrate, complete fracture occurred at slightly lower strains than the suspended system. Young's modulus ranged from 270 GPa to 430 GPa, indicating that the aggregated system is more rigid due to the lack of degrees of freedom for atomic bond rearrangement. In all cases, the fracture pattern was verified to understand the thermomechanical properties of these systems.*

NM01.08.12

Exploiting Optical Asymmetry in N-Doped Chiral Carbon Dots and Their Application in Fluorescence OFF-ON Sensing of Hg^{2+} and L-Cysteine *Angana Bhattacharya and Amita Pathak; Indian Institute of Technology Kharagpur, India*

Chiral carbon dots (CCDs) have emerged as a novel class of carbon-based functional materials with unique optical properties and potential applications in biology, chemistry, and medicine. This study presents the synthesis and characterization of blue-emissive nitrogen-doped chiral carbon dots via thermal pyrolysis of citric acid and D/L-Aspartic acid (N-CCDs: D-NCD, D-Aspartic acid as symmetry breaking (SB) agent &L-NCDs, L-Aspartic acid as SB agent). These water-soluble nanoparticles exhibit exceptional photostability, low toxicity, and strong biocompatibility. Our comprehensive investigation into the origin of chiroptical activity, as confirmed by circular dichroism (CD) spectroscopy, reveals a synergistic effect of intrinsic chirality, chiral precursors on the N-CCDs surface, and hybridization of lower energy levels within the chiral chromophore embedded in the N-CCDs. Quantitative analysis of optical asymmetry using the Kuhn asymmetry factor (g) shows that D-NCD exhibits a higher g value ($1.03x10^{-4}$) compared to L-NCD ($1.13 x10^{-5}$) at 325 nm. We explore the structure-activity relationship between the originated optical asymmetry and sensing behavior, demonstrating the potential of N-CCDs as chirality-based fluorescent probes for selective detection of Hg^{2+} and L-Cysteine. Our findings reveal that N-CCDs serve as a fluorescent turn-off probe for Hg^{2+} detection, where oxygen-rich functional groups on the N-CCD surface bind to Hg^{2+} ions, resulting in fluorescence quenching through non-radiative electron transfer. Interestingly, we observe a negligible effect of chirality on Hg^{2+} sensing, as evidenced by similar LOD values for D- and L-NCDs. In contrast, N-CCDs act as a fluorescent turn-on probe for L-Cysteine detection, with a significant enhancement in fluorescence intensity observed for D-NCD compared to L-NCD. This preferential stereoselective interaction, which has been explained based on homo/heterochiral interaction, is confirmed by CD spectroscopy and ITC experiments. These findings offer promising opportunities for the application of N-CCDs in developing highly sensitive optical sensing devices, exploring chiral recognition phenomena in biological systems, and advancing the field of chiral nanomaterials for various technological applications. Future work will focus on optimizing the synthesis of N-CCDs for enhanced chiroptical properties and exploring their potential in a wider range of sensing and biomedical applications.

Arc Discharge in Methane with Metal Electrodes—Synthesis of Metal Catalyst and Carbon Nanomaterials

Stanislav Musikhin, Yevgeny Raitses and Valerian Nemchinsky; Princeton Plasma Physics Laboratory, United

States

A direct current (DC) arc discharge is a widely used method for large-scale production of metal nanoparticles, core-shell particles, and carbon nanotubes [1]. Maximizing the desired product quality and yield requires optimization for metal catalyst particle concentration and size.
Here, we deploy an industrially relevant and sustainable approach of the DC arc between metal electrodes in methane atmosphere [2] and explore the growth of iron nanoparticles. Iron nanoparticles are produced by the evaporation of a steel anode, while methane serves as a carbon source. The arc and electrodes are characterized using high-speed imaging, optical emission spectroscopy, and thermal imaging. TEM and EDS analysis of the obtained nanomaterials suggests that products of methane decomposition adsorb to iron clusters, gradually forming a carbon shell and thus, inhibiting metal particle growth until it is fully encapsulated, at which point its growth is ceased. Experimental observations are elaborated using an aerosol growth model with an included hydrocarbon environment. We claim that the alone effect of the carbon shell formation is sufficient to obtain ultra-fine metal nanoparticles of only a couple of nanometers in size. The results demonstrate the path to manipulate metal particle size in a hydrocarbon arc environment, which is a crucial parameter for the predictable synthesis of core-shell nanoparticles and carbon nanotubes [3].

This work is supported by the U.S. Department of Energy through contract DE-AC02-09CH11466.

Enhanced Thermoelectric Performance of 2D Materials—A Comparative Study of MXene and TMDCs

Rohit Kumar and Bhaskaran Muralidharan; Indian Institute of Technology Bombay, India

Advanced materials are vital for high-performance thermoelectric (TE) devices, overcoming the limitations of conventional materials. Two-dimensional (2D) materials like MXenes and transition metal dichalcogenides (TMDCs), such as molybdenum disulfide (MoS_2), show promise due to their unique properties. This study explores the TE potential of pristine monolayer Ti_3C_2 MXene and bulk 2H and monolayer MoS_2 using first-principles density functional theory and a semi-classical Boltzmann transport approach under the constant relaxation time approximation and rigid band approximation [1, 2]. We analyze key transport parameters, including electron thermal and electrical conductivities, Seebeck coefficients, power factor, and figure of merit [2]. Our results reveal distinct electronic structures and superior TE performance for both materials. Ti_3C_2 MXene exhibits unique thermal and electrical transport features, while MoS_2 shows high Seebeck coefficients (up to 1550 μV/K) and ultrahigh power factor values (up to $9.21 \times 10^{11}\ Wm^{-1}K^{-2}s^{-1}$). We demonstrate that the semiconductors are highly efficient in TE power generation, as indicated by their high figure of merit values. However, their low thermal conductivity restricts their effectiveness in TE cooling applications. On the other hand, metals are excellent for cooling due to their high thermal conductivity but are generally inefficient for power generation due to their low Seebeck coefficient and high thermal conductivity. Consequently, semimetals and functionalized MXenes are anticipated to provide a well-balanced performance for both TE power generation and cooling applications. Therefore, our comprehensive analysis provides benchmarks for experimental validation and guidelines for improving TE performance, highlighting the potential of MXenes and TMDCs for advanced energy device applications.

Enhanced Sensitivity and Recovery Time of ZnO/SWCNTs-Based Nitric Oxide Gas Sensor Utilizing Photo-Stimulated Desorption Method at Room Temperature Environment

KyungEun Kim, RyangHa Kim, Beomsu Jo and YoungLae Kim; Gangneung-Wonju National University, Korea (the Republic of)

Nitric oxide (NO) is a colorless, odorless gas that is highly reactive with oxygen in the air. NO gas causes environmental problems and explosions in both life and industrial settings; therefore, NO gas detection is necessary to prevent these issues. Previous research has focused on detecting NO gas using sensors that typically operate at high temperatures, between 160 and 300°C. Sensors operating at high temperatures require high power consumption and are not portable, making it necessary to develop NO gas sensors that can operate at room temperature. Single-walled carbon nanotubes (SWCNTs) have a large specific surface area, excellent thermal conductivity, and high tensile strength, making them suitable for use in wearable sensors. Zinc oxide (ZnO) possesses excellent physical and chemical properties, along with advantages such as chemical stability, environmental friendliness, and low synthesis cost. In this work, a ZnO/SWCNTs-based NO sensor will be fabricated to provide a rapid and excellent response and recovery rate to NO gas, even at room temperature. The NO sensor based on pristine SWCNTs exhibited a response of 4.17% at an NO gas concentration of 50 ppm. However, the NO sensor based on ZnO-decorated SWCNTs showed a significant improvement with a response of 32.94% at the same concentration, an enhancement of 28.77%. Despite this improvement, the recovery rate was low. To address this issue, an external light source was used, resulting in remarkable changes. Using a UV light source (405 nm) led to fast recovery rates, a phenomenon attributed to photostimulated desorption (PSD). The recovery time was reduced from over 2400 seconds to 83 seconds at an NO concentration of 100 ppm, a reduction of over 2317 seconds. Therefore, utilizing the high sensitivity and recovery rate of the NO gas sensor based on ZnO/SWCNTs developed in this study, it can prevent atmospheric pollution and explosion accidents caused by NO gas leakage even at room temperature.

Nickel-Based Metal-Organic Framework (NiMOF) Decorated Single-Walled Carbon Nanotube (SWCNT) Fiber Electrolyte-Gated Field-Effect Transistors for Glucose Sensors

Van Ky Nguyen and WiHyoung Lee; Konkuk University, Korea (the Republic of)

In this study, we present a novel approach for glucose sensing using single-walled carbon nanotube (SWCNT) fibers coated with nickel metal-organic framework (NiMOF). The SWCNT fibers, characterized by sub-micron size graphene nanosheets and oxidative functional groups, provide an ideal substrate for the attachment of NiMOF molecules, enhancing the sensor's performance. We demonstrate the fabrication and characterization of electrolyte-gated field-effect transistors (EGFETs) based on NiMOF-SWCNT fibers for glucose detection. Using NiMOF-SWCNT fiber electrolyte-gated field-effect transistors for glucose sensing offers several advantages. The transistor structure provides low operating voltage, local amplification, and a high signal-to-noise ratio, making it suitable for direct contact with skin, where sweat can serve as an electrolyte. SWCNT fibers, which can be woven into fabrics or flexible platforms, serves as the substrate for the sensor. The NiMOF acts as nanozyme for nonenzymatic glucose sensors, eliminating the need for complex enzyme immobilization process.

NM01.08.17

Enhanced Detection of Hydrogen Sulfide Gas Using TEMPO-Functionalized Single-Walled Carbon Nanotube Electrochemical Sensors *RyangHa Kim, KyungEun Kim and YoungLae Kim; Gangneung-Wonju National University, Korea (the Republic of)*

Hydrogen sulfide (H_2S) is a toxic gas characterized by its corrosive and flammable properties, commonly found in hot springs, volcanic regions, and certain food sources. It is distinguished by its distinctive rotten egg odor and is typically produced through the bacterial decomposition of organic matter in oxygen-deficient environments. This gas is generated in industrial settings such as sewage treatment plants and slaughterhouses, and is a byproduct in various industrial processes including gas treatment, wood pulp processing, elemental sulfur production, and wastewater treatment. Due to its higher density compared to air, H_2S can rapidly accumulate in confined spaces such as tunnels and mines, posing significant risks of explosion and asphyxiation. At low concentrations, H_2S causes irritation to the eyes and respiratory system. It can be detected by its rotten egg smell; however, at concentrations exceeding 100 ppm, it can lead to olfactory fatigue, increasing the risk of accidents. Higher concentrations (>500 ppm) can cause severe lung damage and potentially fatal asphyxiation.

In this work, we introduce an electrochemical sensor designed to detect H_2S gas in the concentration range of 0.01 ppm to 100 ppm. This sensor leverages single-walled carbon nanotubes (SWCNTs) functionalized with 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) to enhance sensitivity. SWCNTs, defined as one-dimensional materials with hexagonal carbon structures, exhibit high aspect ratios and conductivity, resulting in low power consumption, high elasticity, and thermal conductivity, which confer thermal and chemical stability. The porous structure of SWCNTs is particularly suitable for gas sensing applications. Specifically, the chemical resistance of gas sensing related to surface reactions benefits from the substantial surface area and the significant quantity of atoms present on the nanostructured material surfaces. This leads to pronounced changes in the electrical signal even at very low gas concentrations, thereby enhancing sensitivity. In nanostructured materials, a considerable proportion of surface atoms are unscreened, resulting in high surface energy and strong molecular forces. This facilitates the adsorption or chemical bonding with gas molecules more readily than bulk atoms, enabling room temperature gas detection using nanostructured materials.

The fabrication process involves a simple method for forming the sensor surface, demonstrated through the deposition of SWCNTs using drop-coating techniques. The TEMPO-functionalized sensor exhibits a sensitivity improvement of 201.056% at 0.01 ppm compared to the pristine SWCNTs sensor. Gas sensing measurements were conducted using a Gas Probe Station, and the sensor's response was analyzed. The results indicate that the developed sensor holds promise for real-time, low-concentration detection of H_2S gas at room temperature.

Insights into Growth Mechanisms and Kinetics of VACNTs via SiC Decomposition for Field Emission Applications *Erhan Gurpinar[1], Ayse Doga Oren[1], Tyson Back[2], Jonathan Ludwick[2,3], Marc Cahay[3] and Goknur Cambaz Buke[1,1]; [1]TOBB University of Economics and Technology, Turkey; [2]Wright-Patterson Air Force Base, United States; [3]University of Cincinnati, United States*

Vertically aligned carbon nanotubes (VACNTs) have attracted significant interest due to their high aspect ratio, mechanical strength, and thermal stability which is also making them promising candidates as a field electron emitters. While chemical vapor deposition (CVD) is commonly used to produce VACNTs, CVD process causes several challenges such as substrate adherence, catalyst impurities, poor alignment control, and contact resistance between the emitter and substrate.

We used an alternative approach for the formation of VACNT through high-temperature vacuum decomposition of

SiC. The VACNT growth mechanism and kinetic factors were investigated to design and produce aligned CNT structures using SiC decomposition. Our optimization studies explored strategies to improve the control over the CNT array lengths. Field emission results have been correlated with electron optic microscopy analysis and Raman spectroscopy results to elucidate electron emission mechanisms.

Strain-Driven Magnetic Transition of Intercalated Pressure-Stabilized Cobalt and Cobalt Oxide Nanoparticles in Linked Graphene Oxide Nanoscale Reactors

Nikita Sugak[1], Joseph C. Prestigiacomo[2], Jennifer Girard[3], Swathi Ganjigunteramaswamy[4], Haiyan Tan[5], Shize Yang[3], Manoj Kolel-Veetil[2], Shomeek Mukhopadhyay[3], Michael Osofsky[6] and Lisa Pfefferle[3]; [1]Northeastern University, United States; [2]U.S. Naval Research Laboratory, United States; [3]Yale University, United States; [4]NOVA Research, Inc., United States; [5]University of Connecticut, United States; [6]Towson University, United States

The study of the evolution and metamorphosis of nanoparticles under high pressure and in nanoscale confinement is a rapidly developing field that promises a diverse range of fundamental research and application opportunities. Here, we demonstrate how a linked and strained graphene oxide (GO)-based confinement system, functioning as a nanoscale reactor at high pressures, allows the evolution of the magnetic properties of an in situ generated composite cobalt (Co) nanoparticle system and further enables the retention of such properties when the pressure of the system is returned to ambient. We posit that this phenomenon is due to an 'induced pressure' created by strain, on the flexible planes of the 2D GO system, by the intercalated Co-based nanoparticles. For graphene/GO this strain is characterized by shifts in the Raman "G-band". Specifically, the studied system comprises in situ generated Co-containing nanoparticles confined between linked GO layers upon pressurization between 0 and 25 GPa. After quenching to ambient pressure, each of these samples exhibited innate ferromagnetic behaviors, demonstrating that our confinement system can be used to 'lock in' phase changes created by the application of transient high pressure. Importantly, while the unpressurized sample exhibited antiferromagnetic Co_3O_4 nanoparticles of ~4 nm size, the samples pressurized to 10 GPa and 25 GPa, presented ferromagnetic order on the shell of an antiferromagnetic core of Co_3O_4 and CoO.

NM01.08.20

Current Enhancement in a Graphene/GaAs Schottky Barrier Photovoltaic Device with InAs Quantum Dots (QD) in the Depletion Region

Argyrios Varonides; University of Scranton, United States

Ab-initio calculations are proposed for an explicit derivation of tunneling current in a Graphene/n-GaAs Schottky-Barrier diode (SBD). The semiconductor chosen is n-type GaAs bulk layer with energy band bending at the interface, where electron and hole accumulation is feasible. Under forward bias, electrons from the graphene and the semiconductor reservoirs cross the SB junction by tunneling in both directions. Selective n-type doping of the GaAs layer pins the Fermi level on the conduction band edge. Mobile photoelectrons, from both sides and with energies near the GaAs Fermi level, cross quantum mechanically the SBD junction with non-zero probability and generate net current. We derive from first principles the photocurrent and show the diode-like behavior of this hybrid Schottky junction to be of the form $J(TU) = A^{**} T^2 |t| \exp(-2qV/kT) (\exp (qV/nkT -1))$, with a new Richardson constant A^{**}, a WKB transmission probability $|t|$. Tunneling at such conditions is called field emission (FE) through the SB quantum barrier. Field emission current substantially reduces due to ideality factor variations from sample to sample. We compute tunneling current at different temperatures T and various ideality factor values. Tunneling current drops significantly, for instance, from 164.2nA/cm2 (300K, n = 1) to 74.5nA/cm2 (300K, n = 2.0). Probing further, we explore the advantage of quantum dot insertion in the depletion region of the semiconductor. Such

quantum traps offer possibilities for photocarrier capture in the depletion layer. Electrostatic field and thermionic emission force excess electrons to escape and form excess current. We therefore propose a device design ***Gr/i-GaAs/InAs-QD/n+-GaAs*** *Schottky diode with InAs (gap energy 0.36eV) quantum dots (QD) inserted in the depletion region of the i-GaAs layer grown on a bulk n-n+- GaAs double layer. Tuned QD insertion, in the intrinsic depletion region (a) widens the optical gap or the energy distance between electron-hole QD eigenstates to more than 1eV indicating absorption advantage at desired wavelengths with several QDs (b) reduces impurity scattering and (c) thermionically emits excess photoelectrons to the conduction band. Total current components emanate from (a) the hybrid Schottky barrier region via thermionic emission (b) via tunneling through the SB potential barrier Field emission) and (c) via QD electron emission in the conduction band of the semiconductor. We show substantial current increase in a novel graphene-based Schottky/QD diode, leading to potential high current photovoltaic devices or high responsivity infrared photodetectors IPs) (e.g. QWIPs or QD-IPs). Based on our calculations, we make a case for current enhancement in hybrid Schottky diodes by proposing multi-QD insertion in the depletion region for current enhancement and for different alloys (GaN for space applications).*

NM01.08.21

Biopolymer-Graphene Aerogel Sorbent Materials for Extraction of B-Blockers from Aqueous Environmental Samples

Androniki Rapti[1], Konstantinos Maroulas[2], Eleni Evgenidou[1,1], George Kyzas[2], Dimitrios Bikiaris[1] and Dimitra A. Lambropoulou[1,1]; [1]Aristotle University of Thessaloniki, Greece; [2]Democritus University of Thrace, Greece

The global consumption of human pharmaceutical compounds is steadily increasing. These compounds are often excreted from the human body with minimal or no alteration to their chemical structure, causing them to frequently appear in urban wastewaters. Beta-blockers are a class of pharmaceutical compounds, among others, that are not effectively removed during wastewater treatment. The overconsumption of these drugs can cause a very serious environmental threat since their presence is ubiquitous in the aqueous matrices. Hence, the design and synthesis of novel high-performance extraction materials towards effective isolation, preconcentration and subsequent determination of low amounts of these drugs is still a challenge in sample preparation. Environmentally friendly adsorbent materials, such as biopolymer graphene aerogel (GA) has recently gained attention as a promising sorbent in extraction due to its high specific surface area, excellent mechanical properties, and unique physicochemical properties. GA as an SPE sorbent has been demonstrated to show high adsorption capacity, fast kinetics and good reusability. In this context, current study investigated the synthesis, characterization, and efficacy of two new graphene aerogel sorbent materials for the determination of beta-blockers (atenolol, pindolol, bisoprolol, propranolol, metoprolol, timolol) in wastewater and aqueous samples. Four different materials of chitosan (CS)/polyvinyl alcohol (PVA) were synthesized using an increasing quantity of graphene oxide and reduced graphene oxide (0.1% and 0.5%). Glutaraldehyde (GLA) has been used as cross-linking agent. Aerogels were obtained through the freeze-drying method and they went through hydrophobic modification. The composites were characterized by Fourier transform infrared spectroscopy (FT-IR), X-ray diffraction (XRD), Brunauer-Emmet-Teller (BET), scanning electronic microscopy (SEM). Additionally, their mechanical properties were tested. SEM and BET analysis confirmed the porous structure and high surface area of aerogels. Based on these findings, the four materials demonstrate high effectiveness as adsorbents for removing drug residues from aqueous environments. Among them, the highest adsorption capacity was exhibited by the composite with the highest concentration of rGO (0.5%), and this material was selected for further investigation. A study of the performance of the sorbent materials and the optimization of the parameters affecting the extraction stages were carried out using a liquid chromatography system of mass spectrometry. All recoveries ranged between 65-97%. The LODs and LOQs of the proposed method ranged between 0.04 to 0.22 μg/L and from 0.125 to 0.72 μg/L for all substrates, respectively. The linearity was satisfactory, with the coefficients of determination ranging from 0.99 to 0.999, while the relative standard deviation for repeatability and reproducibility of the method ranged between 4.4% to 13.7%, and from 4.6% to 12.2%, respectively. The established method was proved to be

simple, highly sensitive and accurate. The adsorbent could be reusable up to 5 cycles without any performance decrease, which provides economic strategy and little waste generation.

NM01.08.22

Two-Dimensional Diamond-Like C_4X_2 (X = B or N) for Hydrogen Evolution Reaction Catalyst *Bruno Ipaves[1], João F. Justo[2], James M. de Almeida[3], Lucy V. C. Assali[2] and Pedro A. Autreto[1]; [1]Universidade Federal do ABC, Brazil; [2]University of São Paulo, Brazil; [3]Center for Research in Energy and Materials, Brazil*

Graphene is the most important two-dimensional (2D) material, characterized by a zero-gap semimetal structure composed of honeycomb carbon with sp^2 hybridization. As graphene represents the foundational unit for various other nanomaterials such as fullerenes, nanotubes, graphite, and single-layer diamond (2D diamond), its properties can significantly alter through doping and functionalization with diverse types of atoms and by integrating with other different 2D systems [1, 2]. Recent advancements in synthesizing and characterizing 2D materials have brought substantial attention to 2D diamonds, showcasing promising applications across various fields, including batteries, quantum computing, nano-optics, and nanoelectronics. In this vein, we investigated the structural, thermodynamic, dynamic, elastic, and electronic properties of diamond-like C_4X_2 (X = B or N) systems [2]. Our findings reveal that the C_4X_2 systems exhibit stiffness akin to that of diamond. Moreover, while C_4N_2 nanosheets demonstrate wider indirect bandgaps, C_4B_2 systems exhibit narrower direct bandgaps when compared to pristine 2D diamonds. Notably, our current results underscore the potential of these systems as efficient catalysts for the hydrogen evolution reaction.

Study of the Luminescence Properties of Polyvinyl Alcohol/Graphene Quantum Dots Nanocomposites

Beatriz Rodríguez Fernández[1], Ganna Kovtun[2], Dhanumalayan Elumalai[3,2], Shaik Kaleemulla[3], Girish Joshi[2,4], Pedro Hidalgo[1], Bianchi Mendez[1] and Teresa Cuberes[2]; [1]Universidad Complutense de Madrid, Spain; [2]Universidad de Castilla - La Mancha, Spain; [3]Vellore Institute of Technology, India; [4]Institute of Chemical Technology Mumbai, India

Graphene quantum dots (GQDs) are an appealing system due to their non-zero band gap, which allows luminescence, and size-dependent physical properties, attributed to quantum confinement and edge effects. In particular, GQDs suspended in liquid exhibit luminescence under UV light and photoluminescence (PL) emission depending on their size and properties. Furthermore, these GQDs can upgrade the electrical and optical properties of polymers films, such as those made with polyvinyl alcohol (PVA). In this sense, nanocomposites formed by the inclusion of GQDs in a PVA matrix are currently attracting strong interest, and the study of the correlation between structural and optical properties is necessary.

In this work, we present the characterization results of PVA/GQDs composites with different GQD concentration. The study encompasses both structural, surface and photoluminescence results in order to shed some light of the luminescence mechanisms in the nanocomposite, including the role of GQDs in these processes. This understanding will be of paramount importance in the development of PVA/GQDs composites in a wide range of applications in the field of nanophotonic or biotechnology.

Reduced Graphene Oxide with a Peptide Aptamer Receptor for Reproducibility of Electronic Noses *Yong Kyoung Yoo, Min Hyeong Mun, SangMin Seok, Yong Beom Seo and Ho Seung Song; Catholic Kwandong University, Korea (the Republic of)*

A key requirement for bio/chemical sensors and electronic nasal systems is the ability to detect specific targets with high selectivity and reproducibility at room temperature. In this work, we present a reduced graphene oxide (rGO)-based gas sensor functionalized with a peptide receptor to detect dinitrotoluene (DNT), a byproduct of trinitrotoluene (TNT). We fabricated multi-arranged rGO sensors using spin coating and standard microfabrication techniques. We then processed the rGO using photolithography and etching. We prepared a DNT non-specific binding peptide (DNT-bp, sequence: His-Pro-Asn-Phe-Ser-Lys-Tyr-Ile-Leu-His-Gln-Arg-Cys) and a DNT non-specific binding peptide (DNT-nbp, sequence: Thr-Ser-Met-Leu-Met-Ser-Pro-Lys-His-Gln-Ala-Cys) to serve as a high-specificity and control receptor, respectively. By measuring the differential signal between DNT-bp and DNT-nbp functionalized rGO sensors, we demonstrated that 2,4-dinitrotoluene (DNT) specifically binds to the DNT-specific peptide surface with high sensitivity and selectivity. The differential signal approach effectively eliminated unwanted electrical noise and environmental influences. The sensor exhibited a sensitivity of $27 \pm 2 \times 10^{-6}$ ppb (parts per billion) for the slope of resistance change versus DNT gas concentration of 80, 160, 240, 320, and 480 ppm. Upon sequential exposure to DNT vapor (320 ppb), acetone (100 ppm), toluene (1 ppm), and ethanol (100 ppm), the rGO sensor signal change was 6400×10^{-6} per ppb for DNT and was unresponsive to other gases, indicating highly selective performance. This rGO-based sensor platform not only demonstrates high sensitivity and selectivity for DNT detection, but is also highly reproducible. In addition, the sensor surface can be easily regenerated by purging with N_2, ensuring consistent performance over multiple uses.

Nanocomposite-Structured Materials for the Design of Chemiresistive Sensing Interfaces *Lidia G. Gebre[1], Guojun Shang[1], Dong Dinh[1], Madelyn Lee[1], Ielyzaveta Antonova[1], Seyed Danial Mousavi[1], Jin Luo[1], Susan Lu[1], Cate Wisdom[2], Zakiya Skeete[3], Tony Yuan[2] and Chuan-Jian Zhong[1]; [1]Binghamton University, The State University of New York, United States; [2]Uniformed Services University, United States; [3]Pacific Northwest National Laboratory, United States*

The ability to tune the chemical sensing interfaces with the desired intermolecular interactions is critical for the development of highly sensitive and selective sensor arrays. Such sensor arrays for useful for the detection of volatile organic compounds (VOCs) released from different industrial processes or environmental sources. Exposure to toxic VOCs poses a major risk to human health. Current methods of detecting VOCs in air lack the sensitivity and selectivity for accurate assessments, and there is an increasing need for the development of highly sensitive and selective sensors. We have been developing nanocomposite sensing interfaces to address this need. In this presentation, we will describe recent results in the fabrication and preparation of nanocomposite-structured sensing interfaces derived from graphene, polymer, and nanoparticle materials. The nanocomposite interfaces exhibit controllable electrical conductivity and high surface-to-volume ratio, and the chemiresistor sensor arrays with such interfaces show promises for sensitive detection of VOCs. The data are also analyzed using pattern recognition methods to enhance selectivity. Intermolecular interactions of VOCs with the nanocomposite structures will also be discussed.

Functionalized Graphene-Like Materials via a One Pot Reaction Enabling Pore Size and Functional Groups Modification

Kira C. Kirkham, Alathea Davies, Michael Wenzel, Bhausaheb Dhokale, Masoumeh Mahmoudi Gahrouei, Bruce Parkinson, Laura de Sousa Oliveira and John Hoberg; University of Wyoming, United States

Graphene is a material characterized by its superior electrical conductivity and exceptional mechanical strength. However, post-reduction or functionalization processes typically result in a significant loss of these enhanced properties. In this work, we introduce a novel class of graphitic materials that exhibit tunable functionalities and pore sizes, excellent thermal stability and modifiable band gaps. These highly ordered Covalent Organic Frameworks (COFs) are synthesized via a Pictet-Spengler polymerization reaction.

NM01.08.27

Laser Synthesis of Single Wall Carbon Nanotubes with Furnace Near the Eutectic Temperature for Ni-C/Co-C

Tomasz S. Mazur and Brian J. Landi; Rochester Institute of Technology, United States

Single Wall Carbon Nanotubes (SWCNTs) have brought great interest due to their exceptional electronic and physical properties in applications including photovoltaics, lithium-ion batteries, and integrated electronics. The impact of electronic type and diameter on device performance is largely influenced by the ability to precisely control SWCNT intrinsic properties during synthesis. The predominant synthesis methods have been chemical vapor deposition, laser vaporization, and arc discharge. Laser vaporization is of particular interest due to the resulting high quality of SWCNTs produced, as well as the ability to systematically control the accompanying diameter distribution through catalyst selection, carrier gas, and furnace temperature.

Results in the literature show that synthesis temperatures ranging from 700-1200 °C have demonstrated a direct correlation to mean SWCNT diameter. The utility of different carrier gases with a range of thermal conductivities can further alter the cooling dynamics to modify the type of SWCNT chirality and SWCNT diameter during laser synthesis. Conventional laser vaporization synthesis for Ni-C and Co-C systems has been primarily studied at furnace temperatures around 1100-1200 °C, where typical quartz tube furnace systems are stable. Synthesis at higher temperatures near the eutectic point of the catalyst system (~1320 °C) are expected to increase SWCNT diameter as well as other physical properties like length and purity given the extended time in the growth phase.

In the present work, an advanced pulsed laser vaporization setup is used. It incorporates high temperature stability furnace tubes (e.g. mullite, SiC, etc.) and complementary endcaps to surpass temperature limitations of a typical quartz tube, realizing temperatures up to 1400 °C . The physical properties of the SWCNT soot synthesized in both argon and helium gas environments over a range of temperatures will be compared. The quality of the as-produced raw SWCNT soot is characterized by thermogravimetric analysis, scanning electron microscopy, and optical absorption spectroscopy to determine a purity level relative to the conventional materials synthesized at 1150 °C. The diameter distributions are analyzed using Raman spectroscopy to establish the fundamental diameter relationship with temperature. Overall, this work will summarize the physical implications of conducting laser synthesis with furnace temperatures near the eutectic temperature for Ni-C/Co-C systems.

NM01.08.28

Ultrasonic Welding of Nanostructured Carbon Conductors to Reduce Contact Resistance with Metallic Foils

Daniel L. Broderick, Samuel J. Boyd, Jamie E. Rossi, Alexander C. Tomkiewicz and Brian J. Landi; Rochester Institute of Technology, United States

Electrochemical devices such as batteries, fuel cells, and capacitors which employ nanostructured carbon conductor electrodes require a low contact resistance connection with metallic foils for termination. Techniques such as soldering and crimping have limited utility in bonding planar electrodes with foils, whereas ultrasonic welding has emerged as a viable technique for creating robust nanostructured carbon metallic connections via *solid-state welding. Emerging nanostructured carbon materials include carbon nanotubes (CNTs) and graphene sheet materials due to their mechanical strength, and thermal and electrical conductivity. Characterization of the interface between nanostructured carbon materials and metallic foils is an emerging field of interest where optimization to improve device performance through modification of the electrical and physical connection is critical.*

The current work investigates two simultaneous strategies to enhance the electrical contact via chemical doping of CNTs with potassium tetrabromoaurate ($KAuBr_4$) and ultrasonic welding to Cu foil. The specific contact resistivity was measured using the transfer length method (TLM) to evaluate laser cut CNT rectangular ribbons with geometrically sequenced tabs (RGT) having ultrasonically welded Cu contacts with and without selective doping isolated to the contact region. $KAuBr_4$ doped CNT-Cu samples had a specific contact resistivity that was more than 50% lower than the purified CNT-Cu samples. Doped CNT-Cu ultrasonic welds reduced the extent of Joule heating beyond the contact region when applying increasing current to failure in a 2-terminal test structure. The advantage of chemical doping has been further validated on test articles that were scaled up from a rectangular ribbon geometry used in TLM characterization to an area of 6 cm x 8 cm, which is consistent with battery electrode form factors. Selective doping (confirmed using emissivity measurements to spatially profile dopant location) of the CNTs prior to ultrasonic welding showed a 1.5x reduction in peak temperature of the contact for each form factor analyzed.

Additionally, ultrasonic welding of graphene sheet conductors to Cu foil was also demonstrated. A series of displacement amplitudes with constant applied energy and pressure values were evaluated to determine optimal welding conditions. A purified and $KAuBr_4$ doped CNT interlayer was introduced between the graphene sheet and Cu foil to determine the impact on weld properties. Mechanical testing of various ultrasonic weld conditions demonstrated that a CNT interlayer improved the tensile strength of welded samples. Electrical characterization of graphene-CNT/Cu foil samples with and without $KAuBr_4$ doping show a consistent reduction in specific contact resistivity when $KAuBr_4$ doping is introduced. Morphological characterization at the weld interface was performed for graphene-CNT/Cu foil conductors via scanning electron microscopy and elemental mapping. These results show the spatial influence of the chemical dopants within the CNT interlayer and how the nature of the material interactions affect the ultrasonic weld interface between nanostructured carbon conductors to metallic foils.

NM01.08.29

Angular Dependence of Four Mechanical Properties of Graphynes *Guilherme B. Kanegae[1] and Alexandre F. Fonseca[1,2]; [1]Universidade Estadual de Campinas, Brazil; [2]California Institute of Technology, United States*

In 1987, Baughman, Eckhardt and Kertesz proposed the existence of 7 sets (or "families" as we call them) of novel two-dimensional carbon allotropes called "graphynes". These allotropes are composed of acetylene chains of length n, [–C≡C–]n, and connected by aromatic rings or sp^2 carbon-carbon bonds [1]. Although graphdiynes (GYs with n = 2) [2] and graphtetraynes (GYs with n = 4) [3] have been synthesized several years ago, the densest form of GY with n = 1 was only recently synthesized by several groups [4-6]. This result is significant given that graphyne has been considered a potential candidate to replace graphene in certain applications [7]. In 2022, we conducted [8] a comprehensive computational study to predict the mechanical properties of 70 GYs, 10 GYs (for 1 ≤ n ≤ 10) of each original family proposed by Baughman, Eckhardt and Kertesz. The elastic compliances C_{ij} of all structures were obtained from molecular dynamics calculations, and the following mechanical quantities were obtained from them along two main directions: the Young's modulus, shear modulus, Poisson's ratio and linear compressibility. In this work, we present the angular dependence of the four mechanical quantities on the direction of application of the tensile stress. First, the rules for transforming the elements C_{ij} of the elastic compliance tensor under rotation of an angle θ in the GY structure plane were revised and applied. The resulted equation $C'_{ij}(\theta) = R(\theta) \bullet C_{ij} \bullet R^{-1}(\theta)$, with R(θ) being the rotation matrix by angle θ [9], was used to generate the polar plots of all mechanical quantities of the 7 GY families (for 1 ≤ n ≤ 10). As demonstrated by Huntington [10], the *shear modulus is independent of θ, and thus the corresponding polar plots exhibit only circles. Additionally, for the symmetric GY structures, or the families known in the literature by the Greek letters γ-, β- and α-GYs (which correspond to our designated GY families 1, 4 and 7, respectively), also exhibit circular results, as expected. However, the most intriguing results are observed for the non-symmetric GY families. We show that the Young's modulus can vary by up to a factor of ten depending on the direction of the applied tensile stress. Furthermore, the Poisson's ratio can be altered from values less than one to values greater than two for some of the asymmetric GY families. The linear compressibility of asymmetric GYs presents even more intriguing results. For instance, the known 14,14,14- and 14,14,18-GYs present a change in sign of their linear compressibility, from positive to negative as the angle is altered. This indicates the existence of directions along which the linear compressibility of these structures is null. The nonlinear dependence of the elastic moduli and Poisson's ratio on n contrasts with the linear dependence on n of the linear compressibility in both symmetric and asymmetric GYs. We discuss potential applications of these distinctive properties of different GYs.* *The authors would like to acknowledge the support and grants provided by the São Paulo Research Foundation (FAPESP) (#2020/02044-9 and #2023/02651-0), the Brazilian Agency CNPq (#303284/2021-8) and by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior-Brasil (CAPES)-Finance Code 001.*

Studies of Graphene in Pink Quarry of Huichapán in the Hidalgo State of México *Jael Villegas Roa[1], Elizabeth Chavira[2], Omar G. Morales[2], Patricia E. Altuzar[2], Isela Padilla[2], Armando Reyes[2], Adriana Tejeda[2], Omar Novelo[3] and Elsa Chavira[4]; [1]Instituto Tecnológico Superior de Huichapan, Mexico; [2]Universidad Nacional Autónoma de México, Mexico; [3]Universidad Nacional Autónoma de México, Instituto de Investigaciones en Materiales, Cd. Universitaria,, Mexico; [4]Benemérita Universidad Autónoma de Puebla, Mexico*

Study focuses on the reuse of quarry waste deposits located in Maney, Huichapan municipality in Hidalgo, state of Mexican republic, in architectural applications, considering various physical and mechanical properties. Volcanic rocks, primarily composed of silicon dioxide (SiO_2), also contain a variety of other chemical compounds that influence their characteristics. One of the main reasons it is essential to efficiently reuse these waste materials is the multitude of variables to be considered. These include the chemical composition of volcanic rocks, the nanometer-sized grain of the waste, hardness, durability, and color. The nanometer grain size of these residues allows for specific applications in various forms: powder, laminates, and meshes, utilizing nanotechnology alongside characterization methods such as Infrared and Raman Spectroscopy. In an effort to reduce environmental impact, effective utilization of these waste materials is crucial.

The dust from pink quarry obtained when cutting a large piece of quarry is already nanometric (1.123- 8 nm) and has been characterized through thermal analysis, providing information about its dehydration and decomposition. Additionally, the mixture of pink quarry with carbon nanotubes was evaluated at different compositions (15%, 30%, and 45%). Powder X-ray diffraction, XRD, allowed us to determine the quarry's composition and the purity of the graphite (Sigma-Aldrich, 99.999%), whereas charcoal was obtained through pyrolysis. XRD allowed us to determine the preferential orientation of graphite via Ion Devastation process in methanol. The charcoal was also exposed to ionic devastation in alcohol. Diffractograms revealed the preferential orientation of planes corresponding to the formed nanotubes. Furthermore, infrared, Raman, and photoluminescence spectroscopy studies, and electrical characterizations were conducted. Our experimental findings pave the way to obtain quarry powders at the nanometric level with potential technological application, where the implementation of nanotubes, provides hardness to the composite material, making it suitable for high-impact flooring.

Graphitization of Amorphous Carbon Film Based on (111)-Oriented Metal Films

Ik-Soo Kim, Joosung Oh, Woosung Cho, Huisim Moon and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

Single crystal metal film has been widely used in two-dimensional materials such as metal chalcogenide, graphene, and h-BN synthesis. Graphene among those materials has been used in active layers for sensors, membranes for flexible electrodes, or heat sinks due to its large surface area, high optical transmittance, and high thermal conductivity. To achieve a high-quality graphene mono-, or multilayers, previous studies required precise vacuum control and a high-temperature annealing process. On the other hand, we focus on easy fabrication through rapid thermal annealing. A thermal conversion method was used to obtain amorphous carbon (a-C) films to be used as graphene seeds from the carbonization of polymers. After that, the metal film was thermally evaporated on the a-C layer to form a metal/a-C/substrate structure. The evaporated polycrystalline metal film can be aligned in the (111) direction through the rapid thermal annealing process, and simultaneously, the transformation from a-C to graphene can occur due to the interaction between the (111)-oriented metal film and the a-C layer. We will investigate whether graphene formation is possible through the above method.

NM01.08.32

Synthesis of Nitrogen-Doped Graphene Quantum Dots for High Efficiency Self-Powered UV Photodetector

Muhammad Shehzad Sultan[1], Angela Luis Matos[1], Bianca S Umpierre Ramos[1], Daniela D Negron Negron[1], Luis O. Ramos Alers[1], Wojciech Jadwisienczak[2], Brad R. Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]Ohio University, United States

*We report a straightforward bottom-up approach for the synthesis of high-quality nitrogen-doped graphene quantum dots (NGQDs). This approach is cost-effective, environmentally friendly, and suitable for production of high quality NGQDs on large-scale. The as-synthesized NGQDs have high crystalline quality with an average size of 3.26 nm, are water soluble, and show strong fluorescence. The UV-vis spectra indicate that N-doping introduces new energy levels into the electronic structure of graphene, which tune the optical properties resulting in photoluminescence quantum yield (PLQY) of 73%. The NGQDs show excitation wavelength-dependent fluorescence with a maximum excitation and emission at 340 and 431 nm, respectively. Using the as-synthesized NGQDs, we fabricated a high-efficiency fast-response self-powered UV photodetector. Under the illumination of 365 nm UV light with power density of 25 mW/cm, the NGQD photodetector shows a high photoresponsivity of 37 A/W, detectivity of 1 * 10 Jones, and external quantum efficiency (EQE) of 12.6 * 10 %. This UV photoresponse is fast, with rise time of 0.29 s and fall time of 0.33 s. This work paves the way for the development of graphene-based high-performance optoelectronic devices.*

SESSION NM01.09: Devices and Applications I
Session Chairs: Yutaka Ohno and Shunsuke Sakurai
Thursday Morning, December 5, 2024
Hynes, Level 2, Room 200

8:30 AM *NM01.09.01
Printing, Recycling and Scaling Transistors with Nanomaterial Inks *Aaron D. Franklin; Duke University, United States*

Additive printing of electronics directly onto any surface has been sought for decades. Despite significant progress, reports on fully direct-write printed electronics continue to rely on excessive thermal treatments and/or fabrication processes external from the printer. What's more, the dimensional scalability of these printed devices remains limited to the micron regime and typically >10s microns for fully printed transistors. In this talk, recent progress towards recyclable and scalable print-in-place electronics will be discussed; print-in-place involves loading a substrate into a printer, printing all needed layers, then removing the substrate with electronic devices immediately ready to test. Inks from various nanomaterials make this possible, including semiconducting carbon nanotubes (CNTs), conducting graphene, and insulating crystalline nanocellulose. Using an aerosol jet printer, these nanomaterial-based inks are printed into thin-film transistors (TFTs) using a maximum process temperature of 70 C. Complete recyclability of these print-in-place transistors has been achieved, demonstrating the environmental sustainability of this additive manufacturing approach. The same set of carbon-based inks is shown for use in all-aqueous (completely water-based) printed CNT-TFTs, eliminating dependence on processing with hazardous chemicals. Finally, the use of a capillary flow printer will be shown to enable the direct-write printing of submicron transistors having performance competitive with commercial TFT technologies that rely on cleanroom-based fabrication.

9:00 AM *NM01.09.02
Reduction of Low-Frequency Noise in Flexible Carbon Nanotube Thin-Film Transistors with Inorganic Polymer Insulator *Yutaka Ohno; Nagoya University, Japan*

Carbon nanotube (CNT) thin-film transistors (TFTs) possess high mobility and mechanical flexibility, making them promising for flexible electronics applications. While there have been reports demonstrating analog circuits such as analog front-ends using CNT TFTs [1], reducing noise in the low-frequency region (<1 kHz) is critical for the measurement of physiological signals from human body such as ECG and EEG. In this study, we report the fabrication of flexible CNT TFTs using inorganic polymer as the gate insulator, which is expected to have low trap density, and the evaluation results of low-frequency noise.
We fabricated bottom-gate CNT TFTs on polyethylene naphthalate (PEN) substrates using a self-aligned process. The inorganic polymer gate insulator was formed from perhydropolysilazane [2] as a precursor, by spin-coating and low-temperature annealing at 90 degC. The thickness was 400 nm. After applying poly-L-lysine to the surface of the inorganic polymer, we immersed it in a semiconductor CNT dispersion solution (0.5% sodium cholate aqueous solution) to form a high-density and uniform CNT thin film. The channel length and width of the TFT were both 100 μm.
The CNT TFTs with the inorganic polymer insulator exhibited a high on-current (0.2 mA/mm) and a steep subthreshold swing (130 mV/dec). The noise power density of low-frequency noise was approximately 50 %

reduced compared to the devices with the conventional low-temperature ALD Al_2O_3 insulator. This suggests that the inorganic polymer insulator has a lower trap density, which is a noise source, compared to the Al_2O_3.

Functional Optoelectronic Devices Based on Strained Monolayers and Heterostructures *Jiang Pu; Tokyo Institute of Technology, Japan*

Atomically thin transition metal dichalcogenides (TMDCs) and their heterostructures are attractive for functional optoelectronic applications due to their diverse bandgaps and band offsets, robust exitonic emission and absorption, and unique quantum (spin-valley) properties [1]. In particular, recent demonstrations of symmetry control/engineering in TMDCs provide an interesting approach to invoke new optoelectronic functionalities such as bulk photovoltaic effects [2]. Here, to directly control the crystal structure/symmetry of TMDCs, we focus on the strain effects because of excellent mechanical flexibility of monolayers. We can directly modulate band structures and band alignments in TMDCs and their heterostructures by the strain-induced lattice structure/symmetry modulation, which yields distinctive device functionalities, including in anomalous photovoltaic effects, robust chiral light emission, and wide-range optical modulation [3-6].
In this talk, we mainly focus on three functional devices which utilize the strain effects. First one is the room-temperature electrical tunable chiral light-emitting devices using strained monolayer TMDCs [3]. We can effectively control circularly polarized light emission by strain-induced band structure evolution. Second is the in-plane heterostructure devices, which also create room-temperature chiral light emission via strain effects at junction interfaces [4]. Third is the alloy devices with composition gradient. We can realize continuous color-tunable light emission and anomalous photovoltaic effects accordingly to the spatial composition distribution [5,6]. Moreover, we also introduce recent advances of direct control of Moiré pattern in TMDC heterostructures by strain effects.

SWNTs for Enhancing Performance and Sustainability of Electrochemical Energy Conversion Devices *Alisa Bogdanova, Polina Kalachikova, Filipp Obrezkov, Farhan Ali, Olli Sorsa and Tanja M. Kallio; Aalto University, Finland*

Drastically increasing demand for various energy conversion and storage devices poses a tremendous pressure for improving their architecture to meet circular economy principles. This stems from already recognized mismatch between the anticipated demand for nonrenewable minerals and their supply for constructing these devices. Electrodes where electrochemical reactions occur are one of the decisive components for achieving high efficiency and long lifespan in each electrochemical energy conversion device despite of their widely different characteristics. Thus, development of efficient and durable electrodes which enable reduced utilization of critical

elements is essential.
Single-walled carbon nanotubes (SWNTs) featured by such desired properties as high electrical conductivity and excellent mechanical and (electro)chemical durability appear as an attractive electrode component for striving for the above-mentioned goals. Here, we present different approaches for preparing 3D SWNT containing composite electrodes for lithium batteries and hydrogen reactions in electrolysers and fuel cells. Our investigations focus on understanding implications of incorporating SWNTs in the electrodes. The origin of the favorable properties and effects brought by SWNTs have been investigated using various structural analysis methods and in-situ electrochemical characterizations. The relevance of adding SWNTs in the composite electrode structure is verified by integrating the electrodes laboratory scale electrochemical cells which are subjected to testing conditions relevant to end applications.
The main benefits of SWNTs incorporation in lithium batteries include improved cycle life and energy efficiency [1. 2], which is essential from both economic and sustainability perspective. On the other hand, for hydrogen economy electrodes utilizing efficiently scarce and valuable nonrenewable metals for electrolyzing the hydrogen conversion reactions are inevitably required. Utilizing SWNTs to support the catalytically active noble metals enables efficient metal utilization while hindering ageing [4-5].

Redesigning DNA's Electronic Blueprint—Crafting Metallic DNA-CNT Junctions for Novel Bioelectronics *Bo Liu and Joshua Hihath; Arizona State University, United States*

DNA, traditionally recognized for its role in genetic information storage, has emerged as a promising building block for bioelectronics due to its inherent programmability and self-assembly capabilities. However, its insulating nature poses a challenge to efficient charge transport. This research introduces a novel approach to redesigning DNA's electronic blueprint by crafting metallic DNA-carbon nanotube (CNT) junctions.
By incorporating metal ions (Ag^+, Hg^{2+}) into the DNA structure and precisely interfacing it with metallic CNTs, we engineer hybrid nanostructures with enhanced electronic properties. Notably, we demonstrate the ability to

modulate conductivity and charge transfer efficiency within these hybrid junctions by manipulating the interface pH, which induces a reversible Ag^+/Hg^{2+} ion exchange process.
The tunability and enhanced conductivity of these DNA-CNT hybrids pave the way for the development of a new generation of bioelectronic devices, including but not limited to biosensors, bio-transistors, and bio-integrated circuits. Moreover, this system provides a unique platform for investigating fundamental questions in single-molecule bioengineering, with the potential to drive breakthroughs in various single-molecule research areas.

Exchange Coupling Effects on the Magnetotransport Properties of Ni-Nanoparticle-Decorated Graphene

Erick Arguello[1,2], Pedro Ducos[1], Zhaoli Gao[3,4], Alan T. C. Johnson[3] and Dario Niebieskikwiat[1]; [1]Universidad San Francisco de Quito, Ecuador; [2]Carnegie Mellon University, United States; [3]University of Pennsylvania, United States; [4]The Chinese University of Hong Kong, Hong Kong

We characterize the effect of ferromagnetic nickel nanoparticles (size ~6 nm) on the magnetotransport properties of chemical-vapor-deposited (CVD) graphene. The nanoparticles cover ~10-15 % of the graphene area, and were formed by thermal annealing of a thin Ni film evaporated on top of a graphene ribbon. The magnetoresistance (MR) was measured while sweeping the magnetic field at different temperatures, and compared against measurements performed on pristine graphene. For our analysis, we fitted the MR curves in terms of existing models for the electronic transport in graphene. Our results show that, in the presence of Ni nanoparticles, the usually observed zero-field peak of resistivity produced by weak localization is widely suppressed (by a factor around 3), most likely due to the reduction of the dephasing time because of the increase in magnetic scattering at small fields. On the other hand, the high-field magnetoresistance is amplified by the contribution of a large effective interaction field B_{ex} ~15-20 T, arising from a strong magnetic interaction of the graphene with the saturated magnetization of Ni. These results are discussed in terms of a local exchange coupling, J ~6 meV, between the graphene π electrons and the 3d magnetic moment of nickel. Interestingly, this magnetic coupling does not affect the intrinsic transport parameters of graphene, such as the mobility and transport scattering rate, which remain the same with and without Ni nanoparticles, indicating that the changes in the magnetotransport properties have a purely magnetic origin.

11:30 AM NM01.09.07

Aerosol Jet Printed Carbon Nanotube-Poly(3-hexylthiophene) Bilayer Thin-Film Phototransistors with High Responsivity

Zahra Bahrami, Kevin Schnittker and Joseph Andrews; University of Wisconsin–Madison, United States

Phototransistors (PTs) are crucial for integrating light detection with signal amplification, leveraging the photogating effect to modulate channel conductance by adjusting the charge carrier density in the active channel of field-effect transistors (FETs) under illumination [1,2].
Hybrid material phototransistors, combining inorganic and organic components, achieve enhanced sensitivity and efficiency due to the high carrier mobility of inorganic materials and the excellent light absorption and adjustable bandgap of organic materials [3,4]. Conjugated Poly(3-hexylthiophene) (P3HT) is widely utilized in optoelectronics owing to its flexibility, high absorption coefficient, and cost-effectiveness, while carbon nanotubes (CNTs) are notable for their superior electrical and optical properties derived from their one-dimensional structure [5]. The low-temperature, solution-processable nature of CNT and P3HT composites makes them ideal for a range of cutting-edge, low-cost, flexible, and large-area light detection applications. These include process monitoring, biomedical imaging, night vision, and wearable electronics, which benefit from diverse printing techniques such as spray coating, screen printing, aerosol jet printing, inkjet printing, and layer-by-layer assembly [6-8].
In this study, we present a simplified and cost-effective process for fabricating bilayer CNT/P3HT ink-based

phototransistors using aerosol jet printing. We aim to investigate their potential in high-responsivity printed optical detection devices, with a focus on further optimization and scalability for printed and flexible electronics applications.

Our findings reveal that the printed devices exhibit exceptionally high photoresponsivity, achieving 1.57 x 10^3A/W under forward bias and 5.23 x 10^4 A/W under reverse bias at a wavelength of 470 nm. This remarkable photoresponsivity is primarily due to the high light absorption characteristics of the conjugated polymer, combined with the excellent mobility provided by the underlying CNT network. Furthermore, we assessed the device's detectivity by analyzing its noise profile at 10 Hz across various V_{GS} values. The device's maximum detectivity reaches approximately 6.22 x 10^8 Jones under forward bias and 2.05 x 10^{10} Jones under reverse bias. These results indicate that the aerosol jet-printed P3HT/semi-CNT bilayer platform is a promising approach for advanced large-area, flexible photodetection applications.

2D Materials as Versatile Coatings for Engineered Metal Powders in Additive Manufacturing Thermal Devices

Apostolos Koutsioukis, Ruan Siyuan, Shuo Yin, Rocco Lupoi and Valeria Nicolosi; Trinity College Dublin, The University of Dublin, Ireland

The development of nanotechnology combined with additive manufacturing has significantly transformed the electronics industry. The transition from analog to digital technology through microchips in sectors such as computing, automotive, aerospace, and general electronics ‘operation has introduced a major challenge: heat dissipation. Data centres, for instance, are estimated to use 40% of their total energy to address thermal management issues. This underscores the urgent need for new functional materials with high thermal conductivity to develop effective heat dissipation devices.

Traditionally, metal powders, especially copper, have been the go-to materials for this purpose due to their excellent thermal properties. Moreover, metals have been crucial to industrial innovation from the Bronze Age to modern times, serving as vital components in various industries. However, they come with drawbacks, including high cost and limited scalability.

Recently, 2D materials such as graphene, hexagonal boron nitride (hBN), and MXenes have revolutionized nanotechnology due to their extremely and diverse chemical, mechanical and electrical properties inherent in their atomic- structure. Especially, graphene, hexagonal boron nitride (hBN) with their thermal properties emerged

as promising alternatives in the heat dissipation field. Combining 2D materials, such as graphene and HBN with extremely thermal properties, with metal powders can significantly enhance their properties, expanding the possibilities for applications in diverse fields.
*However, an efficient and versatile preparation method to use 2D nanosheets to coat metal powders are still in its infancy. In this talk, we will introduce a new 3D printing toolbox that integrates 2D materials with metal powders (**2D**MMCs), aligning seamlessly with established large-scale manufacturing methods.*
In this talk, we will introduce a new 3D printing toolbox that integrates 2D nanosheets with metal powders based on ball milling technique, aligning seamlessly with established large-scale manufacturing methods. We will discuss our innovative approach and the characterization of these composites based on our advanced microscopy and spectroscopical studies. Our findings demonstrate the potential of these composites in addressing the thermal management challenges in electronics. We believe this new approach not only enhances the thermal properties of metal powders but also offers a scalable and cost-effective solution for next-generation electronics.

Advanced Carbon Nanotube Composites—From Material Design to Commercial Applications *Naoyuki Matsumoto; National Institute of Advanced Industrial Science and Technology, Japan*

At AIST, our mission is to bridge invention and industry and contribute to society through the development of new technologies. In line with this mission, our team has devoted significant efforts in recent years to the development of carbon nanotube (CNT)-polymer composites, focusing primarily on rubber and resin, using our proprietary "super growth" CNTs [1] along with other commercially available single and multi-walled CNTs [2]. We have successfully developed and commercialized CNT rubber composites (O-rings) with exceptional durability, high heat resistance and high-pressure resistance, as well as CNT resin composites using PEEK, a super-engineering plastic, with excellent heat and impact resistance [3]. These fabrication technologies pave the way for the application of these materials in manufacturing and mainstream applications, thereby fulfilling our mission to advance materials and technology development for the benefit of society.

However, the number of research papers on CNT composites has declined in recent years. In addition, the demand for CNT composites in specific applications remains at around 15%, significantly lower than the 70% seen in battery applications. This decline can be attributed to the lack of "killer properties" or applications for CNT composites that justify their cost. In other words, the days of simply mixing CNTs into resins, rubbers and metals are over. To overcome this challenge, it is critical to optimize material design, manufacturing processes, and evaluation techniques, which requires a deep understanding of CNT properties.

In this presentation, I will discuss our research and development efforts on CNT rubber/resin composites, highlighting material design methodologies, manufacturing process technologies, and evaluation techniques. In particular, I will illustrate the importance of material design using our research on CNT/aluminum nitride (AlN)/rubber composites as an example [4]. Regarding the manufacturing process, I will describe the property *optimization achieved in CNT-rubber composites that we have already commercialized. Finally, I will present the nanoindentation technique used for process and property optimization [5]. By integrating these three methods and techniques, I will provide examples of the discovery of new "killer applications" for CNT composites.*

Carbon Nanodots as Active Media for Tunable Laser and Random Laser Applications *Ashim Pramanik[1], Antonino Madonia[1], Marco Reale[1], Gianluca Minervini[2], Annamaria Panniello[2], Marinella Striccoli[2], Marco Cannas[1], Alice Sciortino[1] and Fabrizio Messina[1]; [1]Università di Palermo, Italy; [2]Consiglio Nazionale delle Ricerche, Italy*

After making their appearance at the beginning of the century as a newborn in the wide family of carbon-based nanomaterials, carbon dots (CDs) are now well-established as zero-dimensional C-based nanoparticles capable of bright and tunable visible fluorescence. Because of their fascinating optical properties, very uncommon in other C-based nanomaterials such as CNTs and graphene, CDs are very appealing for light emitting devices and several other applications in photonics and photochemistry. Broadly speaking, CDs can be seen as a carbon-based equivalent of inorganic quantum dots, endowed with specific advantages due to their water solubility, ease of functionalization, low cost, low toxicity, and lack of rare or critical chemical elements. However, the optical response of CDs still needs to be optimized to fulfill the requirements of many real-world applications. In particular, only a few types of CDs are capable of optical gain, still limiting their use as active media in lasers.

In a series of recent works [1-3], our group has demonstrated the use of CDs as versatile active media for laser and random laser action. We used different synthesis routes to obtain various types of CDs capable of bright fluorescence and optical gain in the green and red region of the visible spectrum. Aqueous solutions of these CDs are shown to behave as active media inside Fabry-Pérot-like optical resonators, yielding an efficient narrowband and directional emission very similar to that of a dye laser [1,2]. In addition, we recently demonstrated [2-3] that the same CDs can also be used as active media in random lasers (RLs). RLs are a class of devices which are attracting a growing interest in photonics as laser-like sources featuring specific benefits over traditional lasers for some applications, such as speckle-free imaging and omnidirectional emission [3]. Our CD-based RLs characteristically display ultra-narrow (~ 0.70 nm) emission lines over a comparatively broader (~10 nm) background. The relative weight of these two types of emissions can be controlled by an appropriate choice of experimental conditions, allowing to tune the characteristics of RL light.

The results demonstrate the potential of CDs as a viable alternative to environmental unfriendly, scarce, or chemically unstable nanomaterials as laser gain media with customizable emissions.

Demonstration of High Detectivity of Microbolometer Array with High-Purity Semi-Conducting CNT Networks
Tomo Tanaka[1,2], Masahiko Sano[1], Masataka Noguchi[1,2], Takashi Miyazaki[1,2], Toshie Miyamoto[1,2], Megumi Kanaori[2]

and Ryota Yuge[1,2]; [1]NEC Corporation, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

Uncooled infrared sensors of bolometer type have a wide range of applications such as security, military, food inspection, health care, and automotive night vision system. Currently, the highly sensitive device development is the key issue for further expansion of demand. The bolometer is an infrared detector of long wave infrared (LWIR) region for radiant heat by means of an infrared absorber having a temperature sensitive electrical resistance material. Infrared radiation strikes the absorber material heating it and thus changing resistor material resistance. Therefore, bolometer's performance is strongly limited by temperature coefficient of resistance (TCR) of the resistor. The conventional resistor is generally based on vanadium oxide (VO_x) with TCR of about -2%/K[1] and an outstanding resistor is essential to achieve highly sensitive infrared detectors. Recently, single-walled carbon nanotubes (SWCNTs) have been expected as promising materials with high TCR and high chemical stability. We have reported that semi-conducting SWCNT networks extracted by the "Electric-field inducing Layer Formation (ELF)" method[2] show high TCR which is close to -6%/K[3]. The pristine SWCNTs are fundamentally a mixture of both semi-conducting and metallic SWCNTs. The ELF method is the remarkable promising technique to extract semi-conducting SWCNTs with high purity, which show stable device performance and excellent electrical transportation property. Previously, we showed TCR of semi-conducting SWCNT network was responsible for the increased sensitivity of the microbolometer. We have established a fabrication process for Video Graphics Array (VGA) format microbolometer focal plane allays (FPAs) with semiconducting SWCNTs[4]. And the responsivity of a single pixel in FPAs as test element group (TEG) was estimated to be over 10^5 V/W at 0.2 V bias voltage. This is about three times higher than that in FPAs with VO_x [4].

In this study, the low-frequency noise of the TEG adjacenet to the FPA was measured, and the black body detectivity, D was estimated. Device chip which was mounted on the ceramic carrier was installed and infrared-shielded in a vacuum dewar. For the low-frequency noise measurement, bias voltage was applied in series with a load resistor and the TEG. The lectric potential between the TEG and the load resistor was amplified by a current amplifier, and the frequency dependence of the noise power density was obtained by a signal analyzer. At frequencies up to 200 Hz, the noise power density was inversely proportional to frequency. This shows that the noise component is dominated by 1/f noise at the operating frequency of a typical microbolometer camera. The D* calculated from the noise and the responsivity was equal to or better than microbolometer using VO_x fabricated by a similar fabricating process.*

In conclusion, we showed the high-purity semi-conducting SWCNT networks extracted by ELF method effectively work for higher detectivity of microbolometer FPAs. To further increase detectivity, we will improve the TCR and reduce the 1/f noise in the semi-conducting CNT networks.

Revolutionizing Multifunctional Subaquatic Apparatus via Advanced Structural Engineering of Nanocarbon Materials *Huajian Li, Xingzi Xiahou, Sija Wu, Chen Chen and Ming Xu; Huazhong University of Science & Technology, China*

A paradigm shift is underway in underwater technology, driven by advanced nanocarbon structural engineering. The age-old challenge of effective underwater adhesion is conquered with a novel approach – a one-way valve design that deftly channels residual liquid away from the adhesion interface, ensuring robust locking and substrate sealing. Crafted from low-dimensional materials like CNT, Graphene, and MXene, this adhesive material features a high-aspect-ratio vertical channel for swift water transport and multiple mesopores that enhance liquid storage efficiency. A remarkable adhesive strength of 216.5 ± 5.5 kPa is achieved, surpassing the 100 kPa benchmark for underwater adhesives. Cycling endurance soars to an unprecedented 100,000 cycles, while a rapid 1.5-second adhesion cycle time sets a new standard. Mechanistic insights unveil the synergy between submicron vertical channels and surface cup area fractions, amplifying adhesion prowess. Shifting focus to pressure sensors, a groundbreaking self-adhesive sensor emerges, combining aligned and nonaligned carbon nanotube components. It detects pressures as low as 18 mPa with remarkable linearity, while the nonaligned component ensures effective underwater adhesion and secure fixation. This sensor extends the detectable pressure range by four orders of magnitude, akin to air applications. Fusing artificial neural networks with the sensor achieves flawless underwater target recognition. This transformative narrative marks the dawn of a new era in multifunctional subaquatic technology, driven by ingenious nanocarbon structural engineering.

Response Properties of NO_2 Gas Sensors Based on Ambipolar Carbon Nanotube FETs with Various Accumulation Amount *Masafumi Inaba[1], Haruka Omachi[2], Michihiko Nakano[1] and Junya Suehiro[1]; [1]Kyushu University, Japan; [2]Wakayama Medical University, Japan*

Carbon nanotubes (CNTs) are promising materials for gas sensors because of their large specific area and high sensitivity to charge differentiation. In CNT-based field-effect transistors (FETs) for gas sensing, we should consider the exact point of gas sensing; CNT channel, CNT/metal electrode contact, and CNT/CNT junctions. The potential modulation in the CNT channels and Schottky barrier height modulation at the CNT/metal electrode contact induced by the gas adsorption influence the electric current properties. Boyd et al.[1] reported that the device current increased with the total amount of CNT/CNT junctions in a device. In this study, we fabricated ambipolar CNT-FETs by the dielectrophoretic assembly varying the amount of CNTs to investigate and compare these effects on NO_2 gas exposure through electrical properties. We exposed CNT FET gas sensors to N_2 gas containing 100-ppb NO_2. For devices with low CNT amount, two different responses were observed in the electric properties: A steady current shift in the positive direction in the hole-conduction region because of the channel potential modulation; an abrupt decrease in transconductance in the electron-conduction region because of the Schottky barrier modulation [2]. For devices with a large amount of CNTs, in which a network-like structure of CNTs was observed near the electrodes, increased current in both electron and hole conduction regions was observed compared with that for the device with a small amount of CNTs. This response is consistent with that of CNT/CNT X-type contacts, which have high resistance before NO_2 adsorption [3]. Evaluation of time constants revealed that

CNT/electrode contacts and CNT/CNT X-type contacts exhibited high NO_2 adsorption and desorption rates, respectively.

Multiplex Sensing Platform for Predictive Biomarkers in Vascularized Composite Allografts Using Porous Laser-Engraved Graphene

Atul Sharma[1,1], Nafize Ishtiaque Hossain[1,1], Vijay Gorantla[2], Yalcin Kulahci[2], Anvesh Naga Kodali[2], Omer Faruk Dirican[2], Wensheng Zhang[3], Casey M Sabbag[3] and Sameer Sonkusale[1,1]; [1]Tufts University, United States; [2]Atrium Health Wake Forest Baptist Medical Center, United States; [3]Uniformed Services University, United States

Over two decades, vascularized composite allotransplantation (VCA) has been a promising solution for severe tissue deficits. However, the reliance on graft biopsies for monitoring and treatment guidance is hampered by invasiveness and sampling errors. To address this, we propose a novel, low-cost, portable, flexible, miniaturized, and site-of-care (SOC) platform for multiplex sensing of predictive biomarkers (e.g., interleukin 6 (IL6), lactate) and pH. This platform can detect instances of VCA rejection before apparent clinical signs of immunogenic reactions such as inflammation and tissue damage, potentially revolutionizing the way we monitor and manage VCA patients.

The sensor fabrication was performed on in-house fabricated porous laser-engraved graphene (PLEG)-electrode, utilizing the laser-induced carbonization (LIC) technique on a thin (12.5 µm) polyimide (PI) surface at optimized laser parameters (laser power-22%, speed-5.2%, and gas flow-50%). Compared to conventional screen-printed platforms, the PLEG electrode provides higher surface area, receptor loading, electrical conductivity, ease of surface modification, and improved sensitivity with an average resistance of 32 ± 3 Ω/cm. Subsequently, the connection pad and reference electrodes (RE) were coated with silver/silver chloride (Ag/AgCl) conductive paste for improved connection. The RE was stabilized by coating it with polyvinyl butyrate (PVB) and sodium chloride polymeric cocktail. Three working electrodes (WE) were designated as WE-1 (for IL6), WE-2 (for lactate), and WE-3 (for pH). The sensor construction was initiated with surface activation WEs in 0.50 M H_2SO_4 containing 0.10 M KCl as a supporting electrolyte by sweeping potential between 1.0 and -1.2 V vs. Ag/AgCl reference electrode. IL-6 and lactate sensors were fabricated by electrodeposition of prussian blue (PB) and gold nanoparticles (AuNPs) on preactivated WEs, crosslinked with 11-mercaptoundecanoic acid (11-MUA). Subsequently, IL-6 monoclonal antibodies or lactate oxidase were immobilized through EDC: NHS activation and passivated with bovine serum albumin. For pH sensing, a composite PVB/Ag/AgCl electrode was utilized as the RE to determine the open-circuit potential of a nafion/PANI/PLEG electrode. Functionalization of the PLEG electrode was characterized using Raman, FTIR, XRD, and SEM techniques. Gracilis myocutaneous (GMC) flap VCA were performed across fully SLA-mismatched swine donor-recipient pairs and followed to Banff Grade III-IV clinical AR or postoperative day (POD) 6.

Post characterization, the sensor's electrochemical measurements to detect IL6, lactate, and pH were performed in buffer, artificial interstitial fluid, porcine blood, and serum samples with a portable potentiostat for a practical demonstration. Under optimal experimental conditions, the devised sensor showed a sensitivity of 2.59 µA/(log10IL6), 0.021 µA/mM, and ~49.39 ± 2 mV in spiked serum for IL6, lactate, and pH. Subsequently, serum samples of porcine VCA recipients were collected on postoperative days (POD) 0, 2, and 6 and tested using the IL-6, lactate, and pH sensors, respectively. The sensors can successfully track the change in the levels of IL6 (increasing) and lactate (increasing) and the change in pH post-surgery and align with clinical observations of inflammation and ischemia post-allograft on POD6. The sensor results were also validated using commercial IL-6 ELISA and lactate kits using the same samples. They obtained a high correlation (r) of r = 0.9885 (n=3, for IL6) and r

= 0.9896 (n=3, for lactate). These results validate the effectiveness of the developed miniaturized platform, instilling confidence in its potential for real-time monitoring of biomarkers in VCA models.

Ternary Inverter Circuits Based on Carbon Nanotubes and MoS_2 Heterojunctions with Asymmetric Electrodes

Hye Young Lee[1], Jinhyeok Pyo[2], SeungNam Cha[3], Sangyeon Pak[2] and Bongjun Kim[1]; [1]Sookmyung Women's University, Korea (the Republic of); [2]Hongik University, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Multi-valued logic (MVL) circuits, which can process much more data with fewer devices than conventional binary logic circuits, are considered one of the possible solutions to the challenges of further scaling. A key component for the implementation of MVL circuits is a negative transconductance (NTC) field-effect transistor (FET) whose channel is composed of pn junctions. A monolayer of MoS2 is a representative two-dimensional n-type semiconductor; however, reliable and repeatable formation of pn junctions is challenging due to the relatively small flake size and irregular shape of MoS2. To form reliable pn heterojunctions with n-type monolayer MoS2, a random network of single-walled carbon nanotubes (SWCNTs) can be a good option for a p-type semiconductor channel.

In our devices, SWCNTs are inkjet printed to completely cover the channel area between the source and drain electrodes of the NTC FET, while the underlying MoS2 is connected to the drain electrode only where the MoS2 partially covers the channel. This hybrid channel can be roughly modeled as variable resistors composed of an ambipolar channel and a p-channel connected in series, resulting in the region where the current decreases with increasing voltage (called NTC) after a local current peak. The width of the NTC region plays an important role in the operation of the ternary inverters because the mid-logic state occurs when the currents of two FETs forming ternary inverter circuits overlap in the NTC region.

In this presentation, we will show that the width of the NTC region can be tuned by using asymmetric electrode design. By increasing the width of the source electrode while keeping the width of the drain electrode small, the p-channel I-V characteristic is shifted to the positive voltage direction, resulting in an expanded NTC region. This enables the clear representation of the mid-logic state when the MoS2/SWCNT heterojunction-based NTC FET is connected to another n-type MoS2 FET. The ternary inverter exhibits three distinct logic states at full swing.

Enormous Temperature Coefficient of Resistance in Carbon Nanotube/Oxide Ceramic Composites

Akinobu Shibuya[1,2], Tomo Tanaka[1,2], Noriyuki Tonouchi[1,2], Takashi Miyazaki[1,2], Toshie Miyamoto[1,2] and Ryota Yuge[1,2]; [1]NEC Corporation, Japan; [2]AIST, Japan

Bolometer-type infrared sensors, which can detect and visualize infrared without cooling, are utilized in various fields such as human thermography, inspection equipment for structures and food, night vision to support car driving at night, and security cameras. Our research group is engaged in the research and development of an infrared imaging sensor using semiconducting single-walled carbon nanotubes (SWCNTs) as the bolometer material [1-2]. Using the semiconducting SWCNT extracted by the "electric-field inducing layer formation (ELF)" method [3], and by controlling the manufacturing condition of the SWCNT network, we achieved a temperature coefficient of resistance (TCR) of about -6%/K [1], which was three times larger than the conventional bolometer material, VO_x[4].

In this study, we developed SWCNT/oxide ceramics composites and evaluated the magnitude of TCR for potential

confirmation as a bolometer material. As a result, in an elementary evaluation, a TCR of about -15%/K was obtained.
The manufacturing method of the composite is as follows. After producing an oxide ceramic particle aqueous suspension, we drop-casted the suspension onto a p-type Si substrate with a thermal oxide film with Au electrodes, and dried and solidified it to form an oxide ceramic porous film. Then, we formed a silane coupling self-organizing monomolecular film (SAM) on the surface of the oxide ceramic particles of the porous film, and dripped a SWCNT dispersion liquid onto the film, and formed a SWCNT network on the surface of the oxide particles and the substrate. Then, we dropped a polymethylmethacrylate (PMMA) solution, baked it to fix the SWCNT/ceramic oxide composite, and removed the ceramic oxide film and SWCNTs where PMMA was not formed. For comparison, simple SWCNT network elements were also fabricated in a similar process.
From the microstructure observation by scanning electron microscope (SEM) and transmission electron microscope (TEM), we confirmed that the developed composite material forms a three-dimensional network of SWCNTs based on a 2-3 μm thick oxide ceramic porous film. The oxide ceramic particles used had an average particle size of about 1μm, and the SWCNTs were present on the particles and the substrate surface and also existed in a form bridging the voids between the particles.
The substrate used for the TCR evaluation had electrodes on the backside as gate electrode, and the drain and source electrodes on the top surface. Thin-film transistor (TFT) devices were fabricated by forming materials such as the SWCNT/oxide ceramic composites and simple SWCNT networks on the surface as channels between the drain and source electrodes. We evaluated the output and transfer characteristics of the TFTs. These measurements were performed at 25°C and 30°C for the TCR calculation. As a result, it was confirmed that the best performance was achieved when $Zn_{1-x}Mg_xP_2O_7$ *was used as the oxide ceramic. In the composite, a TCR of about 15%/K was achieved, although the issue of hysteresis presented in the transport characteristics of the evaluated TFT.*
In conclusion, by compositing SWCNT and oxide ceramic, we realized enormous TCR, and demonstrated the potential for further improving the performance of SWCNT bolometers.

Advancing Boron Neutron Capture Therapy—Novel Insights from Boron-Based Nanomaterials *Manjot Kaur*[1] *and Akshay Kumar*[2]*;* [1]*Chandigarh University, India;* [2]*Sardar Patel University, India*

According to the World Health Organization (WHO), cancer is a leading cause of death globally. Binary radiation therapies have gained significant research attention for treating challenging tumors, with boron neutron capture therapy (BNCT) emerging as a promising targeted chemo-radiotherapeutic technique. This study presents an innovative investigation into the synthesis and characterization of boron-based materials to advance BNCT. We synthesized highly water-dispersible ^{10}BN *nanoparticles using a solvothermal method at a relatively low temperature. Structural and morphological analyses reveal the unique properties of* ^{10}BN*. Cytotoxicity assays on normal (HEK-293) and cancer (HeLa, MCF-7) cells demonstrate the low toxicity of* ^{10}BN*. Importantly, BNCT studies show a remarkable antitumor effect in* ^{10}BN*-treated HeLa cells exposed to a thermal neutron fluence of approximately* $6.3 \times 10^{12}/cm^2$*, achieving nearly 50% cell killing. Expanding our research, we introduce boron*

carbide quantum dots (B_4C QDs) synthesized via a straightforward solvothermal approach at a relatively low temperature. These quantum dots, averaging around 7 nm in size, exhibit enhanced fluorescence intensity in tumor cells compared to normal cell lines, due to defect states. Cytotoxicity analysis and BNCT studies further highlight the potential of B_4C QDs as a promising alternative to traditional boron agents like L-BPA. B_4C QDs show promise as both detectors and treatments for tumor cells.
Additionally, we explore the synthesis of boron carbon nitride (BCN) as a prospective boron compound for BNCT, using a simple solvothermal method. BCN is highly soluble with a hexagonal structure containing defect states. Morphological analysis confirms the formation of a layered structure with a highly porous network. Optical property characterization reveals a calculated band gap of approximately 3.85 eV. Cytotoxicity analysis positions BCN as a viable candidate for BNCT applications, and observed anti-tumor effects on HeLa and U-87MG cell lines showcase its potential compared to L-BPA. BCN demonstrates more effective performance compared to previous studies on BN and B_4C. In summary, our research provides novel insights into the successful synthesis and characterization of ^{10}BN, B_4C QDs, and BCN for their potential applications in BNCT. These materials exhibit promising properties, including low toxicity and significant antitumor effects, making them effective tools for tumor cell treatment, thereby advancing the field of BNCT.

Converting Fluorinated Graphite to Nitridated Graphene for Room-Temperature Magnetic Applications

Madhuparna Chakraborty, David C. Ingram and Wojciech Jadwisienczak; Ohio University, United States

The development of magnetic inks based on graphene holds the potential for fully printed flexible electronic devices with magnetic functionalities. By manipulating graphene's electronic, optical, and magnetic properties through precise control over its lateral size, doping levels, we can tailor its characteristics for specific applications. Nitrogen doped graphene (N-doped graphene) has gained attention due to its atomic size, which is comparable to that of carbon. This doping introduces additional electrons and localized states within the graphene lattice, significantly altering its electronic structure and enhancing magnetic interactions [1]. Our research aims to establish a synthesis route for converting fluorinated graphite to nitrogen-doped graphene that achieves room-temperature magnetism.

In this study N-doped graphene was synthesized via top-down approach by thermal exfoliation of fluorinated graphite. The process employed a two-stage annealing technique to achieve controlled nitrogen doping. The fluorinated graphite was initially annealed in an ammonia atmosphere at 400°C. This step facilitates the incorporation of nitrogen atoms into the graphene lattice. The material was subsequently treated in an argon atmosphere at 650°C. This step helps to further exfoliate the graphene sheets and stabilize the nitrogen doping. This method is chosen for its efficiency in producing high-quality graphene with controlled doping.

The N-doped graphene samples were subjected to various characterizations to validate the success of the graphite exfoliation, doping level and the resulting magnetic properties. The presence of the D and G peaks around 1350 cm^{-1} and 1580 cm^{-1} in the Raman spectra provided an understanding of graphene's formation and quality. X-ray Photoelectron Spectroscopy (XPS) analysis was conducted to assess the nitrogen doping level and nature of specific nitrogen configuration within carbon lattice. The XPS results reveal a 5.26% incorporation of nitrogen into the graphene lattice, with distinct peaks corresponding to pyrolytic, pyridinic and graphitic nitrogen bonding configurations. This confirms the effectiveness of our doping process and provides insights into the types of nitrogen bonds present, which are crucial for understanding the material's magnetic properties. The magnetic characterization was conducted using a vibrating sample magnetometer (VSM). Our results, depicted by the moment versus magnetic field curve, demonstrate the desired ferromagnetic trait with magnetic saturation of 0.2emu/g.

Our study successfully demonstrates the formation of nitrogen-doped graphene with room-temperature ferromagnetic properties, achieved through a controlled top-down thermal exfoliation method. The integration of nitrogen atoms into the graphene lattice has been verified by both XPS and Raman spectroscopy, and the magnetic measurements confirm the desired ferromagnetic behavior. This development opens the door for the use of nitrogen-doped graphene inks in flexible and printable electronic devices, where magnetic functionality is a key requirement, for instance in magnetic sensors.

Electrochemical Synthesis and Modification of Carbon-Based Materials *Sun Hwa Lee[1], Won Kyung Seong[1] and Rodney S. Ruoff[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)*

Electrochemistry is a growing method for green and mild reactions. Driving chemical reactions using electrochemistry offers advantages for basic studies, including precise control of the potential, current, and cell configuration as well as quantitative analysis techniques, such as cyclic voltammetry, chronoamperometry, and electrochemical impedance spectroscopy. It is a versatile method for energy storage, sensing, conversion technologies, surface science, pollutant removal, and real-time analysis/screening. Here, we utilized electrochemistry to synthesize and modify carbon-based materials such as polymers, structured carbon materials, and graphene. The mechanisms of electrochemical polymerization are challenging to understand fully. We focus on understanding the reaction mechanisms during the electrochemical polymerization of polyhydrocarbons using electrochemical methods combined with spectroscopy. Well-ordered carbon nanowalls were synthesized with the help of electrochemical reactions in molten salt electrolytes and single-crystal metal substrates. Also, we present the covalent functionalization of single-crystal monolayer graphene without destroying its lattice and how functionalization depends on the detailed electrochemical parameters and the substrate that the graphene resides on.

NM01.11.02

Engineered Nanocomposites Through Embedding of Smaller "Organic Inorganic" Nanoparticles in Thermoplastic Poly(2-Vinylpyridine) Polymer Matrix *Sanju Gupta; The Pennsylvania State University, United States*

Polymer nanocomposites (PNCs) are significant for modern and future applications owing to their multifunctionality promoted by morphology and tailored interfaces between the constituents. However, 'forward' *engineered polymer (host) composites with smaller size nanoparticles (guest) providing desired properties remain challenging as they depend upon nanoparticle aggregation, size, shape, and loading (volume or weight) fraction. This study strategically designs and develops PNCs comprising thermoplastic poly(2-vinyl pyridine) (P2VP) polymer matrix impregnated with spherical polyhedral oligomeric silsesquioxane (N-POSS) nanoparticles (diameter ~2-5 nm) and anisotropic planar nitrogenated graphene nanoribbons (GNR, strip width ~5-10 nm) commensurate with polymer chain radius of gyration,* R_g*, (or segment length ~1.5 nm) and comparable energy scales of electrostatic interaction and attractive hydrogen bonding. We investigated the static and dynamic structure and thermophysical properties to correlate with interfacial regions and the results are compared with larger graphene oxide (GO, lateral dimension ~100-200 nm) nanosheets and silica (*SiO_2*, ~25-50 nm) particles. While electron microscopy revealed nanoparticle distribution, the lattice bonding, conjugation length, and mechanical properties were determined from micro-Raman spectroscopy and atomic force microscopy, respectively. The differential scanning calorimetry provided a measure of the glass transition temperature,* T_g*, with a positive shift of ~10-18* ^oC *with nanoparticles loading indicating the strength of structural relaxation/chain rigidity behavior and thermogravimetric analysis displayed increased thermal stability and conductivity (decreased interfacial resistance). We also measured temperature-dependent dc electrical conductivity and dielectric relaxation spectroscopy gaining insights into percolation and dynamic interfacial layer. This study signified an understanding of interactions and interfacial regions, key elements to demystify the microscopic structure-property relationships.*

NM01.11.03

Dielectric and Small Angle Neutron Scattering Analysis of Molded and 3D Printed Polypropylene-Graphene Nanocomposites *Radha Perumal Ramasamy[1], Vinod K. Aswal[2], Yu-Chung Lin[3] and Miriam Rafailovich[3]; [1]Anna University, India; [2]Bhabha Atomic Research Centre, India; [3]Stony Brook University, The State University of New York, United States*

Graphene is an important 2D material and has several beneficial characteristics [1-2]. 3D printing is a very useful technique for making polymeric materials of desired shapes. Dielectric characteristics are important physical properties of materials. Recently, we observed negative dielectric constant values in polyethylene – graphene nanocomposites [3]. It was observed that the composite became negative dielectric constant material when the concentration of graphene increased to 20%. In this research the variation in dielectric characteristics was studied for both molded and 3D printed polypropylene graphene nanocomposites. In this work polypropylene (PP) and graphene were mixed using plastic order (brabender) to have polypropylene with 0, 10 and 20% graphene. This average size of the graphene used is 5 micron length, 15 nm thickness and typical surface area is 60-80 $m^2 g^{-1}$ *. Graphene nano platelets – grade H5 were obtained from XG sciences, USA. Small angle neutron scattering (SANS) is a useful technique to understand the microstructure of the nanocomposites. Using SANS it was observed that fractal structures were observed in graphene containing molded and the 3D printed samples. As the graphene concentration increased the scattering increased. The scattering intensity for molded samples was greater than the scattering intensity for the 3D printed samples. Broadband dielectric relaxation spectroscopy (BDS) is a useful technique to study the polymer dynamics and conductivity in polymer composites. Using BDS it was observed that between at higher frequencies (10 3 -10 6 Hz) the dielectric constant for molded and 3D printed polypropylene is nearly the same (2.9 and 3.1) respectively. However the dielectric constant at higher frequencies for 90%PP-10%graphene molded samples is ~ 40.5±12.4 and for 3D printed samples it is ~12.1± 0.4. Similarly the dielectric constant for 80%PP-20%graphene at high frequencies for molded samples is ~102.4 ± 46.0 and for 3D printed samples it is ~52.3 ± 24.8 . Hence the dielectric constant at higher frequencies for molded samples is greater than that of 3D printed samples. Interestingly, negative dielectric constant was also observed at lower frequencies. It was observed that the dielectric constant for molded samples became more negative when compared to the 3D printed samples. other parameters such as dielectric loss, loss tangent, electric modulus were also measured and* *it was observed that their values were different for 3D printed samples from that of samples prepared by molding process. hence the dielectric properties can be tailored using 3D printing technique. This research could benefit using graphene in batteries.*

Effect of Low Energy Helium Ion Irradiation on Polystyrene—Graphene Nanocomposites *Radha Perumal Ramasamy[1], Amirthapandian Sankarakumar[2], Vinod K. Aswal[3] and Miriam Rafailovich[4]; [1]Anna University, India; [2]Indira Gandhi Centre for Atomic Research, India; [3]Bhabha Atomic Research Centre, India; [4]Stony Brook University, The State University of New York, United States*

Recently, magnetism has been observed in graphene and has been attributed to structural defects namely dislocations, vacancies, adatoms and impurity atoms [1-6]. In this work, polystyrene [PS] and graphene were mixed using plasti-corder (brabender) to have 88% PS and 12 % graphene. The samples were then hot pressed between brass electrodes. The samples were made in the shape of disc of 1 mm thickness and 2 cm diameter. The samples were irradiated with 100keV He $^{+}$ ions with the ion fluences 1×10 ^{14}, 1×10 ^{15} and 1×10 ^{16} ions/cm ^{2} . The SEM analysis showed that (a) the surface has clear distinct light and dark regions in all the samples, (b) some fragments were observed to be present on the surface and (c) There are also more crater like structures in the ion irradiated samples. The ratio I_D/I_G where I_D and I_G are the Raman peak intensities of D band (1350 cm $^{-1}$) and G band (1582 cm $^{-1}$) is used to characterize the level of disorder in graphene. As disorder in graphene increases, I_D/I_G will increase. It was observed for un-irradiated samples that the G band was very prominent, when it is compared to the D band. For the ion fluences of 0, 1×10 ^{14}, 1×10 ^{15} and 1×10 ^{16} ions/cm ^{2}, the ratio of I_D/I_G became ~ 0.07, 0.2, 0.5 and 0.9. This indicates that the disorder in graphene increases with increase in ion fluence. Small angle neutron scattering (SANS) is a useful technique to understand the microstructure of the nanocomposites. Using SANS it was observed that fractal structures were present in the ion irradiated and un-irradiated polystyrene graphene nanocomposites. The polymer dynamics and conductivity was studied using broadband dielectric relaxation spectroscopy (BDS). BDS analysis showed that the dielctric properties such as dielectric constant, dielectric loss, loss tangent, electric modulus were significantly affected by the presence of graphene in the nanocomposites. This research could benefit using graphene in batteries.

Design of Nanostructured Polyaniline Sensors for Advanced Hydrogen Detection *Perizat Askar, Dana*

Kanzhigitova, Aigerim Ospanova, Aslan Tapkharov, Sagydat Duisenbekov, Munziya Abutalip, Baktiyar Soltabayev, Amanzhol Turlybekuly, Salimgerey Adilov and Nurxat Nuraje; Nazarbayev University, Kazakhstan

The growing hydrogen (H_2) energy industry has highlighted the need for effective hydrogen detection due to its high flammability and severe safety risks. This study investigates a novel kind of gas sensor using conducting polymer.This study explores a novel conductive polymer gas sensor, which offers enhanced responsiveness and faster detection of H_2 within a nitrogen environment. Drawing inspiration from the unique characteristics of carbon nanotubes (CNTs) and graphene, we synthesized polyaniline (PANI) hollow nanotubes and PANI films to examine the correlation between structure and properties. The PANI hollow nanotube sensor developed in this research is capable of detecting hydrogen at 1 ppm concentration at room temperature, demonstrating high sensitive response (29%) and rapid response time (15 seconds) and recovery times (17 seconds). This finding suggests that conducting polymers, particularly PANI, could be effective for the rapid detection of H_2 leakage across various industrial contexts.

NM01.11.06

Sub-ppm Hydrogen Sensing with Functionalized Carbon Nanotubes at Room Temperature

Rahul Pandey; SRI International, United States

Hydrogen is a clean and efficient energy carrier with the potential to significantly reduce greenhouse gas emissions and facilitate the transition from fossil fuels. However, the environmental impact of increased hydrogen emissions in a future hydrogen economy remains poorly understood. Monitoring hydrogen levels in the atmosphere, especially at sub-ppm concentrations, is essential for evaluating its effects on safety, climate change, and the environment. In this work, we employ a novel approach to chemically functionalize single-walled carbon nanotubes with platinum nanoparticles to create ultra-sensitive chemiresistive sensors capable of detecting hydrogen concentrations as low as 100 ppb and responding to ppb-level changes at room temperature. Our results demonstrate that these sensors can reliably detect hydrogen across a wide range, from 100 ppb to 0.5%. Additionally, the sensors exhibit robust performance across varying temperatures and humidity levels and maintain high stability, showing a robust response to 100 ppm of hydrogen gas for over 90 days in ambient conditions. The low-cost of sensor fabrication, robust design and high sensitivity makes our sensors ideal for large-area hydrogen monitoring.

NM01.11.07

Novel Hydrocarbon-Derived Graphene Nanoparticles and Their Morphology, Properties and Applications

Yufan Zhang[1], Anubhav Sarmah[1], Ramu Banavath[1], Kailash Arole[1], Sayyam Deshpande[1], Huaixuan Cao[1], Smita Dasari[1], Dylan Cook[2], Richard Parliman[2], Stephnie Peat[2], Joseph Kosmoski[2], Evan Johnson[2] and Micah Green[1]; [1]Texas A&M University, United States; [2]Nabors Energy Transition Solutions LLC, United States

Over the past two decades, there has been a significant increase in the industrial production of carbon nanomaterials. Many high-quality nanomaterials require the use of metal-based catalysts, which in turn raise production costs, require post-processing, and limit scaleup. Here, we analyze two new industrial nanomaterials, graphene nanoparticles-A (GNP-A) and GNP-B, that are derived from hydrocarbon streams via a scalable catalyst-free process in a proprietary reactor. The resulting carbon nanomaterials exhibit a unique morphology, featuring nanoscale building blocks in micro-scale networks. The nanomaterials display exceptional performance in several applications due to their pre-networked structure, yet each formulation has their own unique capabilities. These carbon nanomaterials are promising as conductive additives for supercapacitor and zinc ion batteries electrodes, thermoset and thermoplastic composite reinforcement.

NM01.11.08

Enhanced Electronic Transport Properties of High Quality Te-Roll Like Nanostructures

Emilson R. Viana[1], Nestor Cifuentes[2] and Juan C. González[2]; [1]Universidade Federal do Paraná, Brazil; [2]Universidade Federal de Minas Gerais, Brazil

In this work, the electronic transport properties of Te roll-like nanostructures were investigated in a broad temperature range by fabricating single-nanostructure back-gated field-effect-transistors via photolithography. These one-dimensional nanostructures, with a unique roll-like morphology, were produced by a facile synthesis and extensively studied by scanning and transmission electron microscopy. The nanostructures are made of pure and crystalline Tellurium with trigonal structure (t-Te), and exhibit p-type conductivity with enhanced field-effect hole mobility between 273 cm^2/Vs at 320 K and 881 cm^2/Vs at 5 K. The thermal ionization of shallow acceptors, with small ionization energy between 2 and 4 meV, leads to free-hole conduction at high temperatures. The free-hole mobility follows a negative power-law temperature behavior, with an exponent between −1.28 and −1.42, indicating strong phonon scattering in this temperature range. At lower temperatures, the electronic conduction is dominated by nearest-neighbor hopping (NNH) conduction in the acceptor band, with a small activation energy $E_{NNH} \approx 0.6$ meV and an acceptor concentration of $N_A \approx 1\times10^{16}$ cm^{-3}. These results demonstrate the enhanced electrical properties of these nanostructures, with a small disorder, and superior quality for nanodevice applications.

Time Responses of Casimir Forces Induced on a Flake in a Liquid Controlled by a Tunable Graphene Layer

Haruko Toyama, Taro Ikeda and Hideo Iizuka; Toyota Central R&D Laboratories, Inc., Japan

Casimir forces arise between two bodies nearby due to electromagnetic quantum fluctuations. In thermal equilibrium, Casimir forces are attractive in vacuum except for forces on nonreciprocal materials. On the other hand, repulsive Casimir forces can be generated in a liquid environment, which enhances the controllability of Casimir forces and expands their potential for applications. One attractive example of such applications is the stable levitation of a nanoflake in a liquid. Recently, it has been experimentally demonstrated that a gold nanoflake in ethanol can stay at a distance away from the substrate by manipulating the Casimir force with a proper choice of materials. For further development of this technique, the dynamic control of the levitation by Casimir forces is expected.

In this research, we focus on graphene due to its tunable optical response by adjusting the chemical potential. By numerical calculations, we show that the floating position of a nanoflake in a liquid can be dynamically modulated by tuning the chemical potential of graphene inserted in the substrate. For instance, the zero-force position of a graphene nanoflake in ethanol can be varied from 38.6 to 43.0 nm above the Teflon/graphene/SiO$_2$ substrate when the chemical potential is adjusted from 1 to 0 eV. The stable levitation by zero Casimir forces is induced by the mechanism as follows: The total Casimir force on the nanoflake can be decomposed into attractive and repulsive force components, and the magnitude of each component increases as the distance between two bodies decreases. The nanoflake stably levitates above the substrate where attractive and repulsive force components are balanced. By increasing (decreasing) the chemical potential of graphene in the substrate, the attractive force component becomes larger (smaller), and the stable zero-force position of the nanoflake approaches (departs from) the substrate.

The dynamical behavior of the floating nanoflake is investigated by calculating the equation of motion considering the Casimir force, gravity, and buoyancy. By assuming that the Casimir force is proportional to the distance variation around the zero-force position, we develop a harmonic oscillator model for the system. The validity of this analytical model is confirmed by showing that the time constant based on the harmonic oscillator model is in good agreement with that obtained by the numerical calculation results. This allows us to discuss the tractability of the

levitated nanoflake by the spring constant which indicates how strong the Casimir force is, and by the fluid resistance coefficient. As a result, we find that the thickness of the topmost film of the substrate can largely change the zero-force position and the time constant.
In addition, proper choice of materials allows high tunability of the zero-force position and the tractability in our control scheme. For example, the time constant in the dynamics for a graphene nanoflake is 3 to 6 times longer than that for a gold nanoflake. Furthermore, the upper limit of the zero-force position of the nanoflake is discussed. Our scheme significantly broadens the degrees of freedom for dynamic control of nanoflakes in a liquid.
Our system, based on tunable levitation by the zero Casimir force, is applicable to various applications. One such application is a new concept of a graphene chemical sensor device. Since the Casimir force can be modulated by altering the chemical potential of graphene, the absorption of chemical materials on the surface of graphene results in the position shift of the nanoflake in a liquid.

NM01.11.10

Controlled Growth of Vertical Graphene Nanosheets on Perforated Cu Foil via Laser Patterning

Mohammed Bahabri[1], Majed Alrefae[2], Yahya Kara[1], Gilles Lubineau[1], Jordan Figueiredo[1] and Deanna Lacoste[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Yanbu Industrial College, Saudi Arabia

Vertical graphene nanosheets are graphitic nanostructures with graphene layers oriented vertically from the substrate surface. These structures are synthesized mainly using plasma-enhanced chemical vapor deposition systems with different morphology and density depending on plasma conditions, such as gas precursors, temperature, and pressure. Vertical graphene nanosheets show potential in many applications that includes biomedical, energy, and sensing applications. However, there are many challenges facing this material upscaling to an industrial level including control of the grown structures and high yield. To that end, previous work shows the potential of vertical graphene growth on perforated substrates like metallic meshes for upscaling the VG growth to the wafer scale.
Due to the design of the system in this study, the electric field points away from the plasma cloud, leading to the growth to occur on the surfaces shielded from the plasma. This leads to the deposition of vertical graphene to be limited to the edges of classical substrates like copper foil, while perforated substrates like copper mesh allow the growth to cover the substrate fully. Scanning electron microscopy (SEM) shows that the VG growth on copper foil leads to a higher density of nanosheets compared to copper mesh. However, VG grown on the mesh has longer nanosheets (along the xy plane). Under the same pressure, gas composition, and plasma power, optical emission spectroscopy results show similar spectra between the two processes, indicating that these differences emanate from the substrate geometry. Moreover, our previous work shows that by varying the opening area of copper meshes from 0.31 – 0.83 the thickness of the growth (along the z-axis) increased from 230 nm – 610 nm. These findings suggest that increasing opening area, the shielding of the plasma decreased, allowing for more active radicals to flow to the growth zone, increasing the growth rate. However, as the opening area of the mesh is a function coupling both the wire diameter and the distance between the wires, the effect of each geometrical parameter on the VG structure was not clear.
The primary objective of this study is to investigate how the geometry of perforated substrates, specifically the substrate thickness and the opening area, influences the growth of vertical graphene. The substrates were fabricated using laser lithography on copper foils with varying thicknesses. The initial findings suggest that increasing the opening area enhances the growth rate, while the growth rate decreases with increasing substrate thickness. This technique allows the deposition of VG with controlled height and density on perforated substrates. This work will expand the understanding of VG growth on perforated substrates, especially how the different parameters affect the growth on the nanoscale. This will pave the way to varying the structures allowing for precise control of the VG growth to be tailored to different application.

NM01.11.11

Strengthening Effect in Aluminum-Graphene Nanolayered Composites via Interface Engineering *Dae ho Kim and Seung Min J. Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Two-dimensional (2D) graphene, renowned for its outstanding mechanical properties, has been extensively studied as an interlayer in metal or metallic glass composites to enhance their performance. Graphene's high in-plane intrinsic strength (130 GPa) and modulus (1 TPa) enables it to effectively block dislocations despite being a single atomic layer in thickness, thereby increasing the strength of the composite. For Al-graphene nanolayered composite, the presence of a native oxide layer that forms during breaking of vacuum for graphene layer transfer prevents the formation of a direct bonding between the metal and graphene. There is a lack of understanding of the effect of the presence of the oxide layer and the focus of this study is to examine the deformation mechanisms by studying Al-graphene nanolayered composite with different interfacial bonding and structure. In this study, we evaluated the mechanical properties of Al-graphene nanolayered composite with the presence of thin native oxide of 5 nm (Al/Al_2O_3/graphene) and compared the results to that of Al layer passivated with a thin epitaxial layer of Ag (5 nm), that is alternated with graphene, i.e. Al/Ag/graphene nanolayered composite. The Ag inhibits the formation of oxide in the Al layer and hence was chosen as an interlayer to study the effect of interfacial properties. High-resolution transmission electron microscopy (HRTEM) was used to determine the dislocation interaction at the two different interface types of Al/Al_2O_3/graphene and Al/Ag/graphene. The presence of Ag passivation layer that suppressed the formation of the alumina allowed for direct bonding between aluminum and graphene as evidenced by XPS analysis. Therefore, such strong interfacial bonding allowed for a notable enhancement in strength of the composite. The outcomes of this study revealed that interfacial engineering of metal-graphene nanolayered composite can contribute to different interaction of dislocations at the interfaces thereby is critically affecting the overall mechanical properties.

NM01.11.12

Interfacial Properties of Composites Based on h-BN and c-BN in Function of Temperature–A Molecular Dynamics Study *Pedro A. Parra and Eliezer F. Oliveira; University of São Paulo State–UNESP, Brazil*

Boron Nitride (BN) is a material with potential for use in various technological applications and this is due to its unprecedented structural, chemical, thermal, mechanical, optical and electrical properties [1]. Among its various polymorphs, those that have a two-dimensional hexagonal (h-BN) and three-dimensional cubic (c-BN) crystal structure have been the most studied [1-3]. Under normal pressure and temperature conditions, h-BN is more stable than c-BN, however it is possible to cause a c-BN→h-BN phase transition over a wide temperature range, depending on the degree of impurity, grain size and defects in c-BN [4,5]. Recent research has demonstrated that mixing c-BN and h-BN could produce new composites with desirable properties for optoelectronics and thermal energy management applications [6,7]. However, there is still a need for a better understanding of the interfacial interaction between the cubic and hexagonal phases, which can influence the mechanical, thermal and electrical properties of the resulting composite [7]. In this work, using molecular dynamics simulations and the ReaxFF force field, we study the c-BN/h-BN composites under different temperatures in order to evaluate the interfacial interaction between the composite constituents and the possibility of c-BN→h-BN phase transition. Our results demonstrate that the surface termination of the c-BN (whether B or N terminated) is a crucial factor for a phase transition in function of the subjected temperature. The B terminated c-BN surface presents lower energy than the N-terminated one. However, in comparison with h-BN energy, the B terminated c-BN surface presents a lower and N-terminated c-BN surface presents a higher energy than the h-BN. Then, increasing the temperature, the energy of the B terminated c-BN surface becomes closer and closer to the h-BN ones which results in a detachment of it between 500-700K, becoming a h-BN layer. Keeping increasing the temperature, more h-BN layers will be detached from the newly formed B terminated c-BN surface. Then, temperature variations that the c-BN/h-BN *composite can suffer in certain applications can impact the proportion between the different phases in relation to the initial one, changing the properties of the composite.*

Macroscale Superlubricity Enabled by Graphene Nanocomposite Films on Metallic Surfaces

Tabiri Asumadu[1], Winston W. Soboyejo[1], Nima Rahbar[2], Desmond Klenam[3], Mobin Vandadi[2], Samuel Kwofie[4], Emmanuel Gikunoo[4] and Kwadwo Mensah-Darkwa[4]; [1]State University of New York Polytechnic Institute, United States; [2]Worcester Polytechnic Institute, United States; [3]University of the Witwatersrand, Johannesburg, South Africa; [4]Kwame Nkrumah University of Science and Technology, Ghana

Globally, ~100 million terajoule of energy is required to reduce friction, accounting to a fifth of energy generated annually. About 1 – 4% of the Gross Domestic Product (GDP) of industrialized economies is spent on friction and wear phenomena. Ultra-low friction at micron and nano scales have been achieved by application of graphene and its variants, due to their excellent lubrication properties. However, depositing these carbon-based coatings on substrates at the macroscale is challenging and expensive. The mechanisms of superlubricity is also not fully understood. In this work, graphene-like coatings with multiwalled graphene signatures were deposited on Ni, Ti, Ti-6Al-4V and AISI 1045 steel. The method used for the deposition process was a novel low-cost high temperature biowaste treatment at 900°C. Wear behaviour using ball-on-disk configuration on the bulk coated metallic substrates were investigated. Microstructural features and Raman scattering of the as received and worn surfaces were characterized. The results showed sustained ultra-low friction and wear on the bulk metallic surfaces with the lowest coefficient of friction value of 0.003. This was attributed to the coated carbon nano crystals deforming to graphene nano composite films, providing the needed incommensurability and multiple micropoints interactions for frictionless conditions. The wear rates of the treated substrates were drastically reduced. The underlying tribo-oxidation and stress induced tribo-transformation controlled interactions and mechanisms were elucidated, before exploring the implications of the current results for the design of robust and next generation 2D and 3D carbon-based coatings with frictionless property at the macroscale.

Synthesis and Characterization of 2D Mo_2C and Its Graphene Heterostructures via Chemical Vapor Deposition

Zehra Z. Guler[1], Elif Okay[1], Omer R. Caylan[2], Eren Atli[1], Aziz K. Sancar[1] and Goknur Cambaz Buke[1,1]; [1]TOBB University of Economics and Technology, Turkey; [2]Massachusetts Institute of Technology, United States

Transition metal carbides (TMCs) are highly valued for their exceptional mechanical and electrical properties, which make them ideal candidates for advanced nanoelectronics including sensors, electron emitters, and catalytic systems such as those used in hydrogen evolution reactions. Despite their potential, synthesizing these nanomaterials with large area, high quality, reproducibility, and homogeneity through scalable processes, remains challenging. Among various synthesis methods, chemical vapor deposition (CVD) stands out for its scalability and precise control over the microstructure. This study aims to explore the impact of various parameters for precise control and optimization over obtaining high-quality, large area and ultra-thin Mo_2C crystals via CVD. Catalyst

thickness, temperature, duration, gas flow rates/ratios, and pressure were changed systematically to investigate variations in the morphology and growth kinetics of the crystals. By elucidating the relationship between these parameters and Mo_2C crystals and comprehending the fundamental development, application-specific morphology design and crystal fabrication are made feasible for numerous cutting-edge technologies.

NM01.11.15

Development of "Moisture-Enabled Electric Generating Paper" Based on Carbon-Nanotube-Composite Paper

Hiyu Mitsumaki[1], Koya Arai[2] and Takahide Oya[1,3]; [1]Yokohama National University, Japan; [2]Mitsubishi Materials Corporation, Japan; [3]IMS, Yokohama National University, Japan

We propose a unique moisture-enabled electric generation device using carbon-nanotube (CNT)-composite paper named "moisture-enabled electric generating paper."

Energy harvesting that is attracting attention as one candidate for solving global energy problems utilizes energy normally waisted in the environment, such as heat, light, and vibration, to generate electricity. Although the scale of power generation is not large, it is expected to be applied to IoT devices and other devices that operate at low power and for which frequent battery replacement is difficult. Recently, we discovered the behavior of electric power generation by moisture vapor on our CNT-composite paper by chance in the course of various experiments. The CNT-composite paper that is a composite material composed of CNTs and paper, can be made easily using the modified Japanese washi paper making method. It is known that it has many useful properties based on CNT and a paper. Therefore, we aim to develop a new power generating device that utilizes the high electrical conductivity of CNT and the energy of moisture vapor in this work. However, in previous study, the principle of power generation by moisture on CNT-composite paper has been unclear. In our recent work, we are finding that the moisture-enabled electric power generating paper is feasible, and furthermore, the dispersants used in the preparation of CNT-composite paper may have an influence on moisture-enabled electric generation.

To prepare our CNT-composite paper, first, a CNT dispersion that contains single-walled CNT (SG101) and a dispersant is prepared by ultrasonication in pure water. At the same time, a pulp dispersion contains pulp, the raw material of the paper, dispersed in pure water. After that, two dispersions are mixed. Next, water is removed from this mixed dispersion with a fine mesh. It is then dried, molded, and completed. In order to examine the effects of dispersants, we chose sodium dodecyl sulfate (SDS) as an anionic surfactant, Distearyl-dimethyl-ammoniumchloride (DODMAC) as a cationic surfactant, Brij as a non-ionic surfactant, Catechin which disperses CNTs in water by creating π-π interactions, and cellulose nanofiber (CNF) which disperses CNTs in water because the hydroxyl group and fibers enter between the CNTs.

In the experimental procedure, CNT-composite paper is firstly attached to the antistatic film with carbon tape to reduce the effects of Faraday current and static electricity, and then fixed with a clip to prevent the tape from coming off. The CNT-composite paper in this state is exposed with moisture vapor along the top from the bottom for 10 minutes. The generated electromotive force (E.M.F.) is measured every 5 seconds using a digital multimeter, and this is done 5 times for each sample. It was confirmed that all CNT-composite papers reacted to moisture vapor and generated E.M.F. Furthermore, samples with SDS and DODMAC, which are ionic surfactants, showed outputs with opposite E.M.F. And they showed greater output compared to samples with Brij, catechin, and CNF. This may be due to the ionic surfactants reacting with moisture vapor and ionizing it, thereby increasing their ability to provide charge over nonionic surfactants.

As the next step in this research, we aim to further improve the output by changing the type of pulp and CNT. Since the moisture-enabled power generating paper obtained in this study can generate electricity anywhere in an environment where steam is generated, we believe that in the near future it can be used as an environmental power generator in hot spring areas, areas where fog, or clouds.

NM01.11.16

Synthesis of Vertically-Aligned Fractal Mo_2C Nanorods via CVD *Eren Atli, Elif Okay, Erhan Gurpinar, Ikra Ucar, Ali D. Kirdok, Oyku S. Uluturhan and Goknur Cambaz Buke; TOBB University of Economics and Technology, Turkey*

Transition metal carbides (TMCs) are known for their superior properties, including catalytic behavior, electrical conductivity, and mechanical strength making them highly appealing for advanced applications. Among TMCs, Mo_2C is a promising candidate for advanced applications such as HER, Field Emission, sensors, and optoelectronic applications with properties such as Pt-like electronic structure, and thermal and chemical stability. Particularly for catalytic applications, nanostructures with high surface area are crucial, hence one-dimensional (1D) nanostructures like nanorods and nanowires are essential components for these systems. Therefore, the controlled synthesis of 1D nanomaterials is vital for improving the performance of these systems. Existing methods for synthesizing 1D Mo_2C nanostructures by chemical vapor deposition (CVD) are mostly based on the carburization of 1D molybdenum oxide templates. This approach involves complex and lengthy processes with limited control. To address these challenges we present a novel CVD approach. By heating the gallium-molybdenum stack at 1000°C under an inert atmosphere and introducing a hydrocarbon precursor (CH_4), we promote the synthesis of vertically aligned fractal molybdenum carbide nanorods. In this process, gallium is an effective catalyst facilitating the solubility of carbon and molybdenum in gallium which is crucial for the formation of molybdenum carbide nanostructures. After removing gallium by hydrofluoric acid etching vertically aligned molybdenum carbide nanorods with high surface area are successfully produced. Characterization of resulting 1D molybdenum carbide structures was achieved through scanning electron microscope and Raman Spectroscopy providing insights into their morphology. This innovative synthesis method not only eliminates the reliance on the template materials but also offers a pathway for the scalable production of self-aligned 1D molybdenum carbide nanostructures for various applications including hydrogen evolution reaction, field emission, and sensors. (This study is supported by the Air Force Office of Scientific Research, grant number FA9550-18-1-7048.)

NM01.11.17

Elastic Polymer Sheets with Carbon Nanotubes Electrically Aligned in Out-of-Plane Direction *Soichiro Ichiki, Yoshihiko Kubota, Naoki Tanaka, Masafumi Inaba, Michihiko Nakano and Junya Suehiro; Kyushu University, Japan*

Carbon nanotubes (CNTs) are nanomaterials with excellent properties such as high current density tolerance, high thermal conductivity, and high specific surface area. We are investigating the fabrication of anisotropic conductive sheets with oriented CNTs with electrical alignment. In this study, we report on the fabrication of elastic polymer sheets with CNT bundles oriented in out-of-plane direction bridging the sheet and periodically located in in-plane direction, which are not intersecting each other.

To uniformly disperse single-wall CNTs (SWCNTs), SWCNTs were dispersed in chloroform. This mixture was added to an elastic polymer of poly dimethyl siloxane (PDMS), stirred, and left overnight to remove the chloroform to make a SWCNTs suspension. The SWCNTs suspended PDMS was poured into a mold and the mold was sandwiched between parallel plate electrodes. AC high voltage was applied while rotating the electrodes to suppress the effect of filler sedimentation due to gravity. During this process, the resin was simultaneously polymerized and cured by a heater to obtain sheet samples [1].

The dispersion and alignment of SWCNTs in the PDMS were observed from the cross-sectional optical images. In the case of no voltage application, SWCNTs kept dispersed during polymerization and no apparent aggregation of SWCNTs were observed. When high voltage was applied, it was shown that columnar structures that cross-linked perpendicular to the sheets were periodically formed in in-plane direction. The distance between the columnar structures of SWCNTs was approximately 100 µm. We consider that this periodic alignment stems from the interactive between SWCNTs during the electrical alignment. First, in the electrical alignment, SWCNTs are polarized and oriented along with the direction of electric field. This polarization causes the oriented SWCNTs to attract nearby SWCNTs and form a bundle. Next, the bundle attracts SWCNTs from their respective neighbors. The *bundles formed columnar structures along the sheet thickness direction. The columnar structures were uniformly distributed, and the distance between them was approximately 100 µm. It suggested that the occurrence of phenomena causing the alignment of the SWCNT pillars. We are measuring the electrical conductivity of the columnar structures and details will be presented at the site.*

Nanomechanical Characterization of Boron Nitride Nanotube—Metal Interfaces *Zihan Liu, Yingchun Jiang and Changhong Ke; Binghamton University, The State University of New York, United States*

Boron nitride nanotubes (BNNTs) are promising reinforcing fillers for cutting-edge metal-matrix nanocomposite (MMNC) technology due to their ultrahigh strength, large surface-to-volume ratios, exceptional thermal stability, and low density. The reinforcing mechanism in BNNT-reinforced MMNCs critically depends on efficient load transfer at the nanotube-metal interface. However, the understanding of interfacial load transfer on BNNT-metal interfaces remains elusive, posing a major scientific challenge in the development of BNNT-reinforced MMNC technology. In this study, we investigate the mechanical strengths of interfaces formed by individual BNNTs with aluminum or titanium matrices using in situ scanning electron microscopy nanomechanical single-nanotube pull-out techniques. By pulling out individual nanotubes from metal matrices with atomic force microscopy force sensors inside a high-resolution scanning electron microscope, the pull-out force and the embedded tube length were measured with resolutions of a few nano-Newtons and nanometers, respectively. The load transfer at the nanotube-metal interface is found to follow a shear lag behavior, and the nanotube-metal interfacial strength is significantly affected by metal oxidation. These research findings are crucial for better understanding load transfer at the nanotube-metal interface and the reinforcing mechanism of nanotube-reinforced metal nanocomposites.

NM01.11.19

Graphene Enhances the Optical Bandgap Measurements in $Ca_xSr_{1-x}RuO_3$, x= 0.00- 1.00 Perovskite Composites *Elizabeth Chavira[1], Patricia Eugenia Altuzar[1], Samantha Janeth Morales Tejeda[1], Manuela Calixto Rodríguez[1], Jonathan Javier Sayago Hoyos[1], María Elena Nicho Díaz[2], Salvador Escobar Guerrero[1] and Adolfo Quiroz[3]; [1]Universidad Nacional Autónoma de México, Mexico; [2]Universidad Nacional Autónoma del Estado de Morelos, Mexico; [3]Universidad Tecnológica de Xicotepec de Juárez, Mexico*

The optical energy bandgap, Eg, is a fundamental property of the inorganic semiconductor in a photoelectrochemical cell for solar fuels generation. It dictates the amount of photon energy absorbed by the from the excitation source, and thence the ultimate photon-to-fuel conversion efficiency that can be achieved. Optical bandgaps are directly measured on compact powder surfaces using two methods: One method using UV-vis spectrophotometric measurements by diffuse reflectance mode and the other method include luminescence emission measurements. The $Ca_xSr_{1-x}RuO_3$, x= 0.00- 1.00 perovskite system first was prepared by solid-state reaction method. At last with graphene, the $Ca_xSr_{1-x}RuO_3$@GO composites perovskites type were synthesized by a simple sonochemical method. The obtained composite was characterized by powder X-ray diffraction, XRD, Infrared spectroscopy, UV-vis diffuse reflectance, scanning electron microscopy and photoluminescence spectroscopy at room temperature. By Infrared spectroscopy was found, that chemical bonds between perovskite and graphene were formed. The chemical bonding between perovskite and graphene minimizes the interface defects, reducing the recombination of the photo-generated electron-hole pairs. The average crystal size by XRD of the $Ca_xSr_{1-x}RuO_3$, x= 0.00- 1.00 system, was around 100 nm while the average crystals size of the $Ca_xSr_{1-x}RuO_3$@GO, x= 0.00- 1.00 system, was 50 nm. The sensitization of the perovskite by graphene enhances the visible light absorption property. Furthermore, the graphene enhances the measured optical bandgap values from 2.3 in *perovskites to 2.38 eV in composites perovskites. This effect enhances electrons transport by providing low resistance conduction pathways, leading to improved photo-conversion efficiency. It could corroborate this fact, by the measure of the conductivity was bigger in the $Ca_xSr_{1-x}RuO_3$@GO than in $Ca_xSr_{1-x}RuO_3$, x= 0.00- 1.00 system. In conclusion, the graphene opens up a new way of obtaining photoactive Graphene-perovskites composites for hydrogen production under visible light.*

NM01.11.20

Electrical Properties of Solution-Processed Zinc-Tin Oxide/Carbon Nanotube Composite Transistors with Stacked Nano Structure Active Layer

Kim Yong-Jae, Young Jik Lee and Woon-Seop Choi; Hoseo University, Korea (the Republic of)

Thin film transistors (TFTs) are being applied to complementary metal-oxide-semiconductor (CMOS) devices and organic light emitting diodes (OLEDs) due to their excellent carrier mobility and high optical transparency. Among them, zinc-tin oxide (ZTO), indium-zinc oxide (IZO), and indium-gallium-zinc oxide (a-IGZO) have been studied as active layers for oxide thin-film transistors [1-2]. However, the instability of oxide materials limits the performance of devices, and their low mobility is still not sufficient to meet the demands for future high-performance display applications.

On the other hand, single-walled carbon nanotubes (SWNTs) have been researched for flexible and high-performance electronic applications due to their high carrier mobility, high current density, excellent mechanical flexibility/stretchability, and compatibility with printing processes [3]. Up to now, devices made by mixing SWNTs with oxide materials such as indium zinc oxide (IZO) and amorphous indium gallium zinc oxide (a-IGZO) have been reported in previous studies [4-5]. However, the manufacture of these active layers is facing increasingly serious challenges due to the growing scarcity of indium and the typically expensive equipments processes required. Therefore, it is necessary to find conductive materials that are affordable and can be easily integrated with flexible platforms.

To enhance the electrical performance of solution-processed TFTs, a mixture of zinc-tin oxide/single-walled carbon nanotubes (ZTO/SWNT) is used as the channel layer material. Unlike the previously mentioned oxide materials, ZTO is an oxide semiconductor that does not require indium and can be used as the active layer in TFTs. In particular, the solution process is regarded as a key trend in TFT manufacturing due to its relatively simple production process and the ability to reduce costs. However, there are no reports on the impact of active channels made from a ZTO/SWNT nanocomposite, prepared by solution process for TFTs.

Therefore, in this study, a solution process was utilized to develop ZTO/SWNTs nanocomposites, leveraging the ease of large-scale fabrication of ZTO and the high conductivity of the nanomaterial SWNTs. SWNTs were dispersed using an efficient dispersion method, and UV chemical treatment along with multiple annealing processes were applied in the active channel of the selective layer to reduce defects in the substrate and enhance adhesion.

In conclusion, the mobility is approximately 15 cm^2/Vs, the Ion/Ioff current ratio is roughly 10^8, the subthreshold swing is about 1.02 V/decade, and the threshold voltage (Vth) is less than 1.1 V. The electrical properties of this multi-layered ZTO/SWNTs TFTs, utilizing a multi-stacked structure with multi-layer stacks, were superior to those of the simple ZTO/SWNTs composite TFT and the single-layer ZTO TFT, with enhanced stability as well.

Antiferromagnetic Single Crystalline VTe_2 with Double Zigzag Chain-Like Modulation *Sunghun Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

Recently, two-dimensional (2D) ferromagnetic materials have rapidly garnered much interest for the future spintronic and quantum computing devices, where they may serve the implementation of spin-transfer torque memory. In addition, the multiple polymorphic phases in a single material can lead to the exotic physical properties, stimulating to investigate discovery of new materials or modification of well-known materials. Here, we demonstrate that highly single crystalline VTe_2 with double zigzag chain structure has antiferromagnetic ordering, verified by temperature dependent Raman spectra and theoretical calculations. The lattice parameters estimated by in-depth diffraction patterns analyses reveal monoclinic structure unlike previous reported hexagonal structure. Interestingly, the Raman peaks related to phonon vibration modes of VTe_2 are saturated, while two Raman peaks newly emerge at very low temperatures, originating from antiferromagnetic ordering. By the bulk density functional theory calculation, we find that distorted zigzag structure is the most stable structure in considered VTe_2 atomic configuration and stronger in-plane magnetic interaction than that across the van der Waals gap. Our findings not only provide insight into further 2D vanadium-based chalcogenides, but also pave the way toward practical incorporation of 2D ferromagnetic materials.

NM01.11.22

Development of High-Efficiency Charge Transfer Materials and Bio-Compatible Devices for Advanced Healthcare Systems *JinKyeom Kim[1,2], Jeong Min Baik[1] and Xudong Wang[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]University of Wisconsin–Madison, United States*

TENG (triboelectric nanogenerator), it occurs when two materials with different polarity based on triboelectric series are brought into contact and transfers tribo-charges on two material's surfaces called as triboelectrification. A method of driving by increasing the amount of surface charge transfer, followed by the generation of electric potentials between them. Here, for maximize the performance of TENG, research in which positively charged and bio-medical application. The important point is that the positively charged material layered composites synthesized MoS_2/SiO_2 core-shell (MSCS). Synthesizing core-shell structures with silica for charge trapping and MoS_2 for high charge transfer efficiency maximizes each characteristic, creating high-efficiency charge transfer materials. MSCS can maximize the efficiency of TENG by trapping charge to make a lot of electrons flow on the circuit. The positively charged charge made of core-shell accumulates charge between the interfaces. The negatively charged material was PFA (perfluoroalkoxy polymer). The continuous average open-circuit voltage 739 V, short-circuit current 42.9 μA and charge density 429 $\mu C/m^2$ at a two-layer device (size 2 x 2 cm^2). That results reveal that 50nm thickness, high frequency and larger pressure can improve the maximum power density. High charge retention is maintained approximately over 80% within 25 hour. At relatively high humidity, stably induced the high surface charge density. MSCS is maintained amount of charge between the interfaces regardless of humidity. Miniaturizing and optimizing bio-devices by combining them with bio-compatible materials allows for long-term, high-efficiency, and stable operation inside or outside the heart and other human organs.
Utilizing current patches and self-powered pacemakers to create an advanced medical system, we aim to detect and transmit data on bodily changes by applying these devices to in-vitro, ex-vivo, and in-vivo models. This will

implement a bio-interface platform for patches and heart pacemakers, addressing the need for new healthcare system technologies due to the high global incidence of cardiovascular diseases. Effective diagnosis and treatment are challenging with conventional methods, necessitating these new technologies. Specifically, we need technologies that provide electrical stimulation to the sinoatrial node in the right atrium to aid blood circulation and monitor biomechanical changes in real-time and over long periods. As the aging population grows, the need for atrial fibrillation treatment and vascular interventions increases. Current pacemakers, battery-operated with a lifespan of about five years, are bulky and require periodic check-ups. Ensuring a stable energy supply for regular atrial contractions and developing IoT platforms to communicate biological anomalies are crucial. However, technical challenges impede the practical implementation of medical devices that can be implanted in gastrointestinal organs due to wet and highly flexible surfaces of the heart and muscles, dynamic environments of continuous contraction and relaxation for efficient blood supply, difficulty in stable long-term attachment and fixation of medical devices, and technical limitations in attaching and removing devices from target organs. Addressing these challenges necessitates the development of high-efficiency, high-output devices capable of data transmission and reception, and platforms for semi-permanent use within the body.

NM01.11.23

Boron Nitride Nanotubes Toughen Silica Ceramics *Nasim Anjum, Dingli Wang, Feilin Gau and Changhong Ke; Binghamton University, The State University of New York, United States*

Ceramics are renowned for their exceptional mechanical stiffness, strength, chemical inertness, and thermal stability. However, their intrinsic brittleness significantly limits their engineering applications. Enhancing the bulk mechanical properties of ceramics with fillers presents a viable solution. Boron nitride nanotubes (BNNTs) are promising reinforcing fillers for ceramics due to their extraordinary structural and mechanical properties, as well as their thermal stability. While improvements in bulk mechanical properties have been reported, the underlying reinforcing mechanism remains unclear. This ambiguity is partly due to the difficulty in directly and quantitatively evaluating the interfacial load transfer, which is critical for mechanical reinforcement, from bulk mechanical measurements and microscopic imaging. In this study, we investigate how BNNTs reinforce silica nanocomposites by quantifying their bulk and interfacial mechanical properties using in situ Raman micromechanical characterization techniques and microstructural analysis. Additionally, we employ the digital image correlation (DIC) technique in conjunction with finite element method (FEM) simulations to directly quantify the local deformation of the matrix and correlate the data with Raman analysis. Silica is chosen for its technological relevance to devices and composites and its widespread industrial usage. The incorporation of even small amounts of BNNTs can result in substantial microstructural changes in the ceramic matrix (such as crystallinity, grain size, porosity, etc.), thereby influencing the overall bulk mechanical properties of the ceramic nanocomposite. Our studies reveal that incorporating small amounts of BNNTs (0.1 to 0.5 wt.%) significantly increases the flexural strength (~51% to ~153%) and fracture toughness (~44% to ~167%) of silica. The effective interfacial shear stress in the bulk BNNT-silica nanocomposite follows a shear-lag model, reaching a maximum value of ~92 MPa. Microstructural analysis shows that incorporating BNNTs in silica prominently influences its crystallization, increasing porosity and decreasing crystal size and lattice strain. These collective microstructural changes substantially contribute to the bulk mechanical properties of the BNNT-silica nanocomposite. Our findings provide valuable insights into the reinforcement mechanism of BNNTs in ceramics and contribute to the optimal design of light, strong, tough, and durable ceramic materials.

NM01.11.24

Investigating Thermal Resistance of Carbon Nanotube Forests as Thermal Interface Materials *Yamato Watanabe, Takayuki Nakano and Yoku Inoue; Shizuoka University, Japan*

Thermal interface materials (TIMs) are becoming increasingly crucial for enhancing heat dissipation efficiency in electronic devices. Among these materials, carbon nanotubes (CNTs) stand out for their exceptional thermal conductivity and mechanical flexibility. However, the effective utilization of CNTs as TIMs demands a deep understanding of their intrinsic thermal conductivity and their interfacial thermal resistance, a key focus of our study.

In this study, we systematically investigated the thermal properties of CNT forests and their interfacial thermal resistance using transient thermal response measurements. $Fe/Al_2O_3/SiO_2$ *layers were sputter-deposited onto a silicon substrate, followed by the growth of high-density CNT forests with varying lengths (100-1000 µm) via chemical vapor deposition (CVD). These CNT forests were subsequently detached and subjected to transient cooling experiments. The resulting transient cooling curves were numerically converted into thermal structure functions, allowing for a detailed analysis of thermal resistance.*

Our results indicate a significant increase in thermal resistance with longer CNT forests, suggesting a decrease in macroscopic thermal conductivity as forest length increases. This behavior is attributed to the reduced density at the roots of longer CNT forests. The interfacial thermal resistance was estimated to be approximately 0.5–1 cm2K/W, while the thermal resistance of a 100 µm long CNT forest was found to be 0.1 cm2K/W.

These findings underscore the predominance of interfacial thermal resistance over the intrinsic thermal resistance of CNTs, highlighting a critical area for future research. Addressing and mitigating interfacial thermal resistance is essential for optimizing the performance of CNT-based TIMs in advanced electronic applications.

NM01.11.25

Fabrication and Evaluation of CNT Forest-Based Thermal Interface Materials for High-Performance Integrated Circuits *Tomoki Okumura, Takayuki Nakano and Yoku Inoue; Shizuoka University, Japan*

The escalating demand for thermal interface materials (TIMs) in high-performance integrated circuits necessitates innovative solutions for effective heat dissipation in devices with substantial power consumption. Traditional thermal greases, due to their liquid state, are unsuitable for high-temperature applications. In contrast, carbon nanotube (CNT) forests exhibit promising characteristics as TIMs owing to their softness, elasticity, and exceptional thermal conductivity.

In this study, we present the fabrication and thermal performance evaluation of a novel sheet-type TIM composed of CNT forests. High-density CNT forests, with a height of 120 µm and mass density of 140 mg/cm^3*, were synthesized via chemical vapor deposition (CVD). This high density was achieved through a rapid nucleation process, characterized by a temperature ramping rate of 110 °C/min and early feedstock supply.*

The CNT-based TIM (CNT-TIM) was constructed by sandwiching a polyvinylidene chloride (PVDC) film (10 µm) between two CNT forest layers, followed by hot-pressing at elevated temperatures and moderate pressures to ensure fusion. Thermal resistance was quantitatively assessed using thermal transient response measurements and subsequently analyzed with Siemens T3Ster Master software. The thermal resistance of the CNT-TIM was determined to be 0.3 cm2 K/W.

Cross-sectional scanning electron microscopy (SEM) revealed a closely connected interface between CNT forests and the PVDC film, with minimal PVDC infiltration into the CNT structure. This robust binding method preserves the high thermal conductivity of the CNT forests while enhancing the mechanical integrity and handling of the TIM.

Our findings demonstrate that integrating CNT forests with thin polymer films is a viable approach for developing high-performance TIMs, which offer substantial improvements in thermal management for next-generation electronic devices.

NM01.11.26

Thermal Transport in a 2D Amorphous Material *Yuxi Wang, Nianjie Liang, Wujuan Yan, Haiyu He and Bai Song;*

Peking University, China

Amorphous materials such as glass have captured human imagination for thousands of years and continue to be of immense value for diverse technologies including advanced manufacturing, high-performance electronics, and thermal barrier coatings, in light of their intriguing structures and fascinating properties. In particular, recent years have witnessed substantial progress in terms of fabrication, characterization, and simulation. For example, the atomic structures of glassy solids (e.g., silica and high-entropy alloy) have finally been directly observed ever since the continuous-random-network (CRN) model was developed in 1932. Two-dimensional (2D) crystals proved revolutionary soon after graphene was discovered in 2004, however, 2D amorphous materials only became accessible in 2020 and remain largely unexplored. In particular, the thermophysical properties of amorphous materials are of great interest upon transition from 3D to 2D.

In this work, by systematically measuring and simulating thermal transport in 2D amorphous carbon, we attempt to address one important scientific question: how would thermal transport in amorphous materials vary upon transition from 3D to 2D? First, multiple monolayers were assembled into a set of vdW stacks for cross-plane thermal measurement using the laser pump-probe technique of frequency-domain thermoreflectance. Subsequently, for in-plane transport, the microbridge method was employed with the monolayer amorphous carbon samples suspended across pairs of custom-fabricated heating and sensing micro-islands. We observed a cross-plane down to 0.079 ± 0.012 $Wm^{-1}K^{-1}$ at room temperature which is one of the lowest values reported to date, and a remarkable high in-plane up to 5.47 ± 0.32 $Wm^{-1}K^{-1}$ which is a few times larger than what is predicted by conventional wisdom for 3D amorphous carbon with similar sp^2 fraction.

In order to understand these unusual observations, we then performed systematic molecular dynamics simulations which highlighted the role of disorder and dimensionality in both directions. The ultralow cross-plane thermal conductivity originates from the synergistic interplay between the cross-plane structural disorder and the weak interlayer vdW interaction characteristic of 2D materials. For the unusual high in-plane thermal conductivity, the crucial role of the low-frequency propagating modes in MAC is corroborated by their notably higher vibrational density of states and participation ratio. These distinct characteristics can be traced back to the 2D nature of MAC which significantly promotes out-of-plane vibrations. Amorphous materials at the 2D limit open up new avenues for understanding and manipulating heat at the atomic scale. We expect the unusual thermal properties of 2D MAC combined with its chemical stability, mechanical strength, and electrical tunability to be uniquely beneficial to various thermal management and energy harvesting applications.

NM01.11.27

Electrochemical Device Fabricated with Carbon Nanostructured Materials Based on Graphene and Nanodiamond Applied on Environmental and Biological Analysis *Fernando C. Moraes, Anderson M. Santos, Ademar Wong and Maria H. Feitosa; Universidade Federal de São Carlos, Brazil*

Carbon nanostructured materials have been used in electrochemical analysis due to their chemical, physical, and mechanical properties, which are found to boost electrocatalytic activity in different redox systems. In special, composite material based on graphene and nanodiamonds can exhibit high surface area, fast electronic transfer, excellent conductivity. All these characteristics become interesting for the fabrication of electrochemical devices. In this scenario, the present work reports the development and application of a new carbon paste electrode modified with graphene and nanodiamond for the determination of nimesulide in biological and environmental samples. The morphology and electrochemical properties of the carbon nanostructures were characterized by scanning electron microscopy, cyclic voltammetry and electrochemical impedance spectroscopy. The application of the proposed electrochemical sensor led to a significant improvement in the analytical signal and nimesulide oxidation was found to occur at a potential of +0.97 V (vs. Ag/AgCl (KCl 3.0 mol L^{-1}). The determination of nimesulide was performed based on the application of differential pulse voltammetry, and the results obtained *showed a linear concentration range of 0.50 to 9.0 µmol L^{-1} (r=0.999) with limit of detection of 15 nmol L^{-1}. The proposed analytical method was successfully applied for the determination of nimesulide in spiked river water, serum and synthetic urine samples, where recoveries close to 100% were obtained.*

NM01.11.28

1D Carbon Nanotube@Perovskite Core-Shell van der Waals Heterostructures *Mengjia Zhu, Kailun Xia and Yingying Zhang; Tsinghua University, China*

Perovskite is an emerging material with immense potential in the field of optoelectronics. One-dimensional (1D) perovskite nanowires are crucial building blocks for the development of optoelectronic devices. However, producing perovskite nanowires with high quality and controlled alignment is challenging. In this study, we present a novel approach for the direct epitaxial growth of perovskite on oriented carbon nanotube (CNT) templates through a chemical vapor deposition method. The strategy involves three steps, growth of ultra-long CNT templates, deposition of inorganic precursor lead iodide (PbI_2), and deposition of organic precursor methylammonium iodide (MAI). Our research delved into the deposition processes of PbI_2 and MAI, and proposed a layer plus island growth mechanism to interpret the experimental observations. Leveraging the aligned long CNTs as 1D templates, we successfully grew CNT@perovskite core-shell heterostructure with a high aspect ratio (>10^4) to withstand large deformation. Furthermore, the obtained 1D heterostructure can be precisely manipulated and transferred, facilitating the preparation of microscale flexible devices. For proof of concept, we fabricated a photodetector based on an individual CNT@methylammonium lead iodide heterostructure, whose highest photoresponsivity is up to 173.9 A W^{-1} under 532 nm laser irradiation. This work provides a new approach to constructing 1D hetero-nanostructure and may inspire the design of novel flexible nanophotodetectors.

NM01.11.29

Flexible and Highly Conductive Polyester-Graphene Nanocomposites *Kathryn Shaw and Albert Dato; Harvey Mudd College, United States*

Electrically conductive nanocomposites composed of polymers and graphene have a broad range of impactful applications, such as flexible conductors, printable electronics, and energy storage devices. New knowledge on the relationships between the processing, structure, and electrical properties of polyester-matrix nanocomposites (PNCs) loaded with graphene nanoplatelets (GNP) will be reported in this presentation. We will discuss the process of fabricating flexible GNP-filled PNCs and present the remarkable electrical properties of polyester resins containing GNP. Our results reveal how GNP flake dimensions can alter the resistivities and percolation thresholds of PNCs. Furthermore, we will show that the curing characteristics and loading limits of PNCs are influenced by the aspect ratios of graphitic flakes such as GNP, graphite, and reduced graphene oxide (RGO). We will also demonstrate that nanocomposites consisting of polyester and GNP exhibit electrical conductivities that cannot be attained in PNCs containing graphite, RGO, and Ketjen black. Therefore, this presentation will (1) advance our understanding of the processing-structure-property spectrum of graphene-filled thermosetting polymers and (2) illustrate feasible approaches for the manufacturing of applications for flexible and highly conductive polyester-GNP nanocomposites.

This study was supported by the U.S. National Science Foundation under Grant No. 1943599.

NM01.11.30

Development of "Paper Tribo-Electrio Nano-Generator" Based on Carbon-Nanotube-Composite Papers *Kazuki Okochi[1] and Takahide Oya[1,2]; [1]Yokohama National University, Japan; [2]IMS, Yokohama Nat'l Univ., Japan*

We propose unique tribo-electric nano-generator (TENG) based on CNT-composite papers. The CNT-composite paper we developed that is a composite material composed of CNTs and paper, can be made easily using the modified Japanese washi paper making method. It is known that it has many useful properties based on CNT and a paper. On the other hand, TENG consists of a combination of different materials, which are repeatedly touched and separated by vibration to generate electric power. Conventional TENGs may not be able to collect all of the generated power. For this, we focus on CNT-composite paper, because a paper is one of suitable materials for TENG, and a three-dimensional CNT network in the composite paper is expected to collect all of the generated power efficiently. Therefore, we develop "paper TENG" based on our CNT composite paper and further improve the power generation.

To prepare our CNT-composite paper, a CNT dispersion that contains CNT and a dispersant is firstly prepared by ultrasonication in pure water. At the same time, a pulp dispersion contains pulp, the raw material of the paper, dispersed in pure water. After that, two dispersions are mixed. Next, water is removed from this mixed dispersion with a fine mesh. It is then dried, molded, and completed. After that it is cut out into 3 cm squares. The cut composite paper is attached to an aluminum plate using conductive tape. It acts as an electrode in the paper TENG. The output voltage of it depends on the speed at which the different materials contact and separate repeatedly.

In this study, the influence of contained CNTs was investigated. The CNT dispersion to make the composite paper was prepared with 15 mg of CNTs (we choose one from SG101, chirality (6,5), (7,6), NC7000), 100 mg of surfactant (SDS) and 20 ml of pure water when making the composite paper. Pulps were also prepared with 100 mg each of eucalyptus. As a results, we found tribo-electricity generation from CNT-composite paper. Tribo-electricity was also observed for both SG101, (6,5), and (7,6) CNTs with semiconducting properties and NC7000 carbon nanotubes with metallic properties. Therefore, carbon nanotubes do not work to increase power output in triboelectricity generation using this carbon nanotube composite paper, and they are thought to work as a conductive material to assist charge transfer within the composite paper, regardless of their metallic or semiconducting properties.

We investigated the influence of changing the amount of contained CNTs on the power output. In concrete, the composite paper was prepared with 5, 15, and 30 mg of CNTs (SG101), 20 ml of pure water, and 200 mg of eucalyptus pulp material. Changing the amount of CNTs did not result in loss of tribo-electric performance, on the other hand did make a difference in output intensity. There was no significant difference in power output when the amount of CNTs was 5 mg and 30 mg, and about 3.7 times more power output was obtained when 15 mg was used than when 5 mg and 30 mg were used. This suggests that there is an optimal amount of CNTs. This is because CNTs are not fully dispersed in the composite paper when the amount of CNTs is small, and when the amount of CNTs is large, the area where CNTs and aluminum electrode are in direct contact becomes large, which is thought to lower the output.

From the above, feasibility of the paper TENG based on CNT-composite paper was confirmed in this study, and CNTs are thought to play a role in this tribo-electricity generation by efficiently transferring the electric charge generated by the pulp and electrodes to the electrodes.

NM01.11.31

Reduced Graphene Oxide Based Thermally Insulative Membranes for Membrane Dehumidification

Md Ashiqur Rahman, Lily A. Waterman, Setareh Heidari, Saba Z. Shahvari and David M. Warsinger; Purdue University, United States

Conventional vapor compression dehumidification is an energy extensive process as it operates below the dew point temperature to condense moisture, whereas membrane-based dehumidification saves energy using a selective membrane to avoid the phase change. Passive membrane dehumidification (PMD) is one the most promising technologies that uses water vapor pressure differential between feed and permeate stream to remove *the moisture. However, current passive systems cannot efficiently reject humidity without losing heat, due to their poor membrane thermal insulation. In this work, we fabricated a highly thermally insulating support layer of polyvinylidene difluoride (PVDF) and reduced graphene oxide (RGO), and a hydrophilic selective layer (or, active layer) of PEBAX 1657 and graphene oxide (GO) using casting and phase inversion method. Dimethylformamide (DMF) with 10% PVDF was mixed with DMF-RGO (0%, 0.5%, 1%, and 1.5% of RGO relative to PVDF) solution (80°C and 600 rpm for 45 minutes) and then cast using a casting knife on a glass plate. The support layer was then subjected to a DI water bath for 24 hours and dried for another 24 hours inside a controlled oven (25°C and RH = 35%). For active layer, 1.5 g of PEBAX 1657 pellets in 50 mL water/ethanol solution (30/70 by volume) was prepared (80°C and 800 rpm for 2.5 hours) and then mixed with 10 mL of GO solution (0.4% by weight in water) in a container. The active layer solution was then cast on a side of the PVDF/RGO support layer (from herein, the membrane can be referred to as PVDF/RGO/PEBAX/GO/(RGO %)). The thermal conductivity of the membrane support layer was found to be 0.041 W/m-K and 0.084 W/m-K for the PVDF/RGO/0.5 and PVDF/RGO/1.0 samples, respectively. In comparison, the PVDF without any RGO has a higher thermal conductivity of 0.114 W/m-K that matches the value mentioned in other literatures. For dehumidification performance analysis, water vapor permeance was measured using ASTM E96 Standard – Wet Cup Method, and air permeance was measured following ISO 15101-1:2007 standard. The reported water vapor permeance for the fabricated membranes varied in a range of 2100 – 5000 GPU while polyvinyl alcohol (PVA) based active layer membrane reached water vapor up to 1050 GPU . As the amount of RGO in the support layer increased, the pores became smaller and thus showed a lower water vapor permeance. The air permeance for the membrane was almost constant and thus, the selectivity (ratio of water vapor permeance/air permeance, range of 480 – 1000) decreased in the order of water vapor permeance. Scanning electron microscopy (SEM) and capillary flow porometry (CFM) were also used to measure the pore size and porosity of the fabricated membrane. Due to its high water vapor permeance and selectivity, this thermally insulated membrane can be used in PMD/SMD systems to improve efficiency. In the future, we will investigate the energy performance of these thermally insulated membrane modules in the proposed system under different operating conditions.*

NM01.11.32

Performance Improvement of "Thread Transistor" Using Carbon Nanotube Composite Thread by Using New Dispersant for Its Making Process

Hiroki Kodaira; *Yokohama National University, Japan*

In the development of IoT digital tools, wearable devices are being developed as terminals that connect things and people. And in the development of the devices, high-performance flexible devices that solve the challenges of flexibility and drapeability are attracting attention. These devices are called "smart textile." We believe our CNTCTs has possible applications as the smart textile.

It is known that the CNTs have many excellent properties such as highly electrical conductivity, highly chemical stability, electrical properties that can be metallic or semiconducting depending on their structure. Because of these properties, CNTs are expected to have a wide variety of applications. However, since the CNTs exist on a nanoscale, it is difficult to handle them on their own. For this reason, many approaches such as combining with other materials have been proposed. In previous work, we succeeded in developing CNTCTs by combining CNT and cotton threads. Cotton threads were chosen because it is light weight, highly flexible, inexpensive, and a familiar material of our daily life. Furthermore, we also succeeded in developing "thread transistor" by using CNTCTs. However, several problems have remained, including highly off-state current. So, the purpose of this research is to improve the performance of the thread transistor.

In this study, we are aiming to reduce off-state current by using N,N-dimethylformamide (DMF) as new dispersants for CNTs. We have already found that dispersants contained in semiconducting CNTCTs cause highly off-state *current. So, in previous study, we have used Brij®100 which is known as a strong surfactant as dispersants of semiconducting CNTs and succeeded in reducing off-current. Based on these results, we choose DMF in this study as a next dispersant because it is a solvent capable of dispersing CNTs and can be removed by heat treatment at relatively low temperatures (boiling point = 154°C). By this, we expected our thread transistor used new dispersant can more reduce off-state current.*

Our thread transistor is fabricated by combining a metallic CNTCT, a semiconducting CNTCT, and Ionic gel. The production method of our CNTCTs is based on the traditional dyeing method for threads. It is so simple method of dipping a thread in the CNT dispersion and drying in oven. The method of preparing CNT dispersion was a typical one. Multi-walled CNT (NC7000) were chosen to produce metallic CNTCTs and (6,5)-chirality CNT were chosen to produce semiconducting CNTCTs were chosen to use. Ionic gels are prepared by combing ionic liquids (EMI-TFSI), polymers (PVDF-HFP), and solvents (acetone). The solution is agitated until homogeneous. Ionic gels have high mechanical toughness, and by using the ionic gel for the gate dielectric material can operate as an Electric Double Layer (EDL) transistor. So, it can acquire its large capacitance and low operating voltage. Our thread transistor can be manufactured by dropping the ionic gel onto the semiconducting CNTCTs, then inserting the metallic CNTCTs into the ionic gel. By combining the semiconducting CNTCT as a channel and the metallic CNTCT as a gate electrode, the thread transistor can be easily constructed. Here, a drop of the ionic gel inserted between both CNTCTs to construct our EDL transistor.

As results of measurements, output characteristics of the thread transistor were p-type, realized highly gate controllability, and low operation voltage. Furthermore, we succeeded in reducing off-state current by 67% compared to that of one in our previous studies. Although the problem of new fabrication method still remains, this approach is effective for performance improvement of our thread transistor.

By further developing this approach, we believe that our CNT composite thread will be used as transistor in the near future.

Theoretical Study of Functionalized Carbon-Based Nanomaterials Including Defects and Dopants Rodion Belosludov[1] and Victor Nemykin[2]; [1]Tohoku University, Japan; [2]The University of Tennessee, Knoxville, United States

The carbon-based materials recently take a lot of scientific interest as the state-of-the-art of carbon-based adsorbent that may apply for effective, clean and low energy requirement storage/separation process [1]. The strategies that may improve the adsorption properties of these materials are N-doping, surface functionalization and extra-framework ions. Therefore, it is important to control the nitrogen concentration as well as nitrogen effect on the long-term stability of microporous carbons. The realization of the uniform nanomaterials based on thermally and chemically robust structures containing nitrogen and extra-framework ions is one of the possible solutions for controlling the doping concentration and its thermal stability. Porphyrins may consider as interesting building blocks. These thermally and chemically robust molecules found a variety of applications ranging from traditional dyes and pigments to more contemporary cancer therapies, environmental and biochemical sensors. We have presented a conceptual design for functional 3D porphyrin-based nanostructures, which would bridge the gap between the well-known fullerenes and nanotubes and a new class of the functional nanomaterials. We have explored three major motifs for functional nanostructures which vary by three- or four-fold topology, porosity, degree of conjugation, and electronic structures [2]. The stability of proposed nanocages, nanobarrels and nanotubes generated by conversion from nanobarrels was revealed on the basis of density functional (DFT) and molecular dynamics (MD) calculations, whereas their optical properties were assessed using a time-dependent density functional (TDDFT) approach.

In comparison with pure nanocarbon structures the walls in the proposed structures contain ordered holes (defect) owing to the specific geometry of the corresponding building blocks. This peculiarity opens the possibility of adsorbing small molecules not only inside and outside nanostructures but also in the intermediate spaces. Thus, the ability to store large quantities of methane (106–216 cm^3(STP)/cm^3) was observed in all cases with several compounds being close to or exceeding the DOE target of 180 cm^3(STP)/cm^3. TDDFT calculations demonstrate that by varying the degree of conjugation we can easily adjust the low-energy transitions between 417 and 751 nm, thus covering the majority of the solar spectrum.

Recently, the accurate prediction of the excited states in a series of fully conjugated triple-linked porphyrin oligomers were done in the gas phase and solution [3]. These oligomers have three optical windows such as the lowest energy near-infrared or infrared transition region (I), the low energy visible range transition region (II) and transition region (III) located on the edge of the ultraviolet zone. It was confirmed that with increasing size of the porphyrin tape, there is an increase in intramolecular charge transfer transitions between spectral regions II and I. The spectral region III is dominated by a single transition state that originates almost exclusively from a HOMO to LUMO excitation. It was also demonstrated, at least for the shorter tapes (2−4), that spectral region I is dominated by the y-polarized Soret-type transition. Moreover, our calculations agree well with available experimental MCD data reported previously for systems [4].

Characterization and Optimization of Reduced Graphene Oxide for Industrial Applications—Insights from Raman Spectroscopy and Correlated Spectroscopy

Tae G. Lee[1], Jaekak Yoo[1,2] and Mun Seok Jeong[2]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Reduced graphene oxide (rGO) and graphene oxide (GO) are key 2D materials with significant potential for a wide range of industrial applications, although their precise evaluation and hybrid electrical properties pose notable challenges. In this study, we synthesize findings from two comprehensive investigations to address these issues, focusing on the characterization and application of carbon nanostructures. First, we investigate the degree of reduction of rGO using Raman spectroscopy. We propose the intensity ratio of D to G band as a novel indicator of rGO quality. Through systematic thermal treatment of GO (100-900 °C) and subsequent spectral analysis, we establish a robust correlation between the D*/G intensity ratio and the C/O atomic ratio. This relationship, elucidated by density functional perturbation theory calculations, provides a reliable metric for assessing rGO quality and understanding its atomic vibrational properties. Second, we investigate the hybrid electrical properties of GO by correlating infrared and ultraviolet-visible absorption spectroscopy using advanced imaging techniques. We identify C-H and C-O rich regions by infrared imaging and analyze their electronic behavior by ultraviolet-visible absorption spectra. Our results show that C-H and C-O rich regions absorb distinctively at 280 nm (4.43 eV) and 380 nm (3.26 eV), respectively. These correlations are validated by several GO flakes and supported by density functional theory calculations. Together, these studies provide a comprehensive approach to evaluate and optimize rGO and GO for diverse applications such as electronic devices, energy storage, and chemical sensors. Our findings contribute to a broader understanding of carbon nanostructures, paving the way for advanced applications and emerging technologies.*

Conductive Carbon-Ceramic Foam Filters Modified by Nanofillers as Electrode Materials for Electrolysis/Photoelectrolysis

Iwona Kaczmarzyk, Zofia Jeleniewska, Marta Przesniak-Welenc, Jacek Ryl and Robert Bogdanowicz; Gdansk University of Technology, Poland

Carbon-ceramic foam filters modified with photoactive fillers have been developed as cost-effective, efficient, and environmentally friendly electrode materials for photoelectrochemical processes. The manufacturing process involves mixing α-Al203 ceramic powder with crushed sintering coal, crushed organic coal binder, aqueous silicic acid sol, and sodium lignosulfonate. Additionally, 5% wt. of potassium hexavanadate and titanium oxide are added to induce high activity for electrooxidation. The resulting mass is coated with polymer foams and baked at high temperatures in an oxygen-free atmosphere.

The resulting carbon-ceramic foam filter has a developed surface that improves surface oxidation and generates turbulence in the open pores structure. This leads to a significant increase in the mass transfer coefficient, resulting in greater current efficiencies and lower energy consumption. The anodes exhibit high repeatability, reproducibility, and corrosion stability. SEM images and Raman spectroscopy analysis show that the photoactive fillers are well-dispersed and uniformly distributed in the composite matrix.

The developed carbon-ceramic foam filters modified with TiO_2 and KVO were tested as anode materials for electrolysis supported by photodegradation in Xe arc lamp to simulate sunlight. The oxidation of caffeine was promoted by hydroxyl radicals generated via the oxidation of water on the anode surface. The efficiency of the degradation of caffeine was analyzed via UV-Vis spectroscopy. The repeatability, durability, and ability of modified carbon-ceramic foam were also evaluated. Overall, the mechanical and chemical stability of these composites make them ideal for electrochemical applications as highly developed surface anode materials for wastewater treatment. The use of carbon-ceramic foam filters modified with photoactive fillers offers a promising alternative to traditional electrode materials.

Molecular Imprinted Polymer Based on Carbon Quantum Dot for Instrument-Free Distance-Based Microfluidic Paper-Based Devices for IFN- γ/IL-4 Analysis

Jooa Lee[1], Jaewon Yoon[2], Eunsoo Oh[3], Ignasia Handipta Mahardika[4], Sarath Kin[4] and Jutiporn Yukird[4]; [1]Lexington High School, United States; [2]Salisbury School, United States; [3]St. Mark's School, United States; [4]Sogang University, Korea (the Republic of)

The analysis of IFN- γ and IL-4 level is critical for understanding immune response in various clinical conditions. In this study, we developed an innovative, instrument-free, distance-based microfluidic paper-based device (μPAD) that allows for the detection of IFN-γ and IL-4 without the need for specialized equipment. The sensing mechanism is based on fluorescence "turn-on" and "turn-off" behavior of carbon quantum dots (C-dots) in response to the presence of IFN-γ and IL-4. By integrating a molecularly imprinted polymer (MIP) layer within the μPAD, the device can selectively capture and detect these target analytes. Upon binding to the MIP layer, the interaction between the analytes (IFN-γ/IL-4) and the carbon dots results in a fluorescence quenching effect, where the intensity of fluorescence is inversely proportional to the concentration of the analytes present. The fluorescence quenching effect is visually measurable by the distance of fluorescence reduction along the μPAD, allowing for a naked-eye

readout of the biomarker levels. The μPAD demonstrates excellent sensitivity, providing a linear detection range for IFN-γ from 5 to 100 ng/mL. Furthermore, the device's selectivity, portability, and cost-effectiveness make it an attractive alternative to conventional diagnostic methods.

Nanomaterial-Mediated Origami Paper-Based Sensor for Pancreatic Cancer Screening *Jaewon Yoon[1], Eunsoo Oh[2], Jooa Lee[3], Sarath Kin[4], Jutiporn Yukird[4] and Ignasia Handipta Mahardika[4]; [1]Salisbury School, United States; [2]St. Mark's School, United States; [3]Lexington High School, United States; [4]Sogang University, Korea (the Republic of)*

Pancreatic cancer is among the five deadliest cancers, with bile duct obstruction occurring in 60-70% of cases, causing jaundice. Therefore, as a jaundice biomarker, bilirubin has a potential for early pancreatic cancer screening. In this study, dual detection of high and low bilirubin concentration in origami paper-based (oPAD) sensor has been developed. A high concentration of bilirubin is detected through gold nanoparticles (AuNPs) formation as colorimetric detection. Bilirubin reduces gold ions to form AuNPs, turning the solution from yellow to red, with the color intensity corresponding to bilirubin concentration. Additionally, microwave-assisted synthesized carbon dots (CDs) is employed to detect low concentrations of bilirubin by fluorescence detection under UV light (365 nm). The interaction between bilirubin and CDs forms a complex, resulting in quenching effect, reducing the fluorescence intensity of the CDs. Integrated into the oPAD sensor, the detection method effectively identifies high bilirubin concentrations (0.2 – 1 g/L) through colorimetric detection and low concentrations (0.01 – 0.1 g/L) via fluorescence detection. This technology offers a portable, cost-effective diagnostic tool for early pancreatic cancer detection without needing laboratory facilities, making it ideal for rapid diagnostic tools, especially in resource-limited settings.

Electrochemical Biosensor Based on Nitrogen and Sulfur Co-Doped Graphene Quantum Dot Decorated Gold Nanostars for Breast Cancer Diagnosis—From Academic Research to Clinical Translation *Thi Kim Anh Nguyen and Jason Chia-Hsun Hsieh; Chang Gung Memorial Hospital, Taiwan*

In this study, we leveraged the synergistic effect of nitrogen and sulfur co-doped graphene quantum dots (NSGQDs) and three-dimensional gold nanostars (AuNS) in the hybrid material of AuNS@NSGQDs as a superior material for constructing a label-free electrochemical biosensor. Consequently, the as-prepared AuNS@NSGQDs nanocomposite was simply drop-casting onto the screen-printed platinum electrode (SE), followed by conjugating with phytohemagglutinin-L (PHAL) to form the SE=AuNS@NSGQDs/PHAL sensor probe. This SE=AuNS@NSGQDs/PHAL sensor probe was then employed for the detection of MCF-7 breast cancer cells, illustrating the remarkable sensitivity and selectivity through linear sweep voltammetry (LSV) and electrochemical impedance spectrometry (EIS). Intriguingly, the sensing system exhibits enhanced electrochemical performance with excellent conductivity owing to AuNS@NSGQDs, while PHAL serves as an effective anchor for the MCF-7 breast cancer cells, which provides outstanding background for electrochemically ultrasensitive and selective detection. In fact, the developed novel AuNS@NSGQDs/PHAL biosensor depicts an outstanding performance in detecting MCF-7 with an impressively low limit of detection (LOD) of 3 cancer cells mL^{-1} in a wide linear range of 10 - 10^{5} cells mL^{-1}, showcasing a great potential in clinical and cancer diagnostic applications. Furthermore, the SE=AuNS@NSGQDs/PHAL reveals a remarkable selectivity over different co-existing cell lines, highlighting its specificity for MCF-7 cells. The sensor also displayed remarkable stability and reproducibility, maintaining performance over a storage period of 100 days and sustaining functionality over 30 consecutive cycles of reuse. The low toxicity of AuNS@NSGQDs nanocomposite was observed at high concentrations, indicating a trivial effect on the MCF-7 cell line, underscoring its safety for biosensor applications. This achievement paves the way for the development of an electrochemical sensing probe as a robust platform for simple, rapid detection of MCF-7 with *high accuracy and specialty, facilitating early diagnosis and therapy of diseases, particularly in the context of breast cancer.*

Ozonated Monolayer Graphene for Extended Performance and Durability in Hydrogen Fuel Cell Electric Vehicles

Shanmukh Kutagulla, Matthew J. Coupin, Devi Mutyala, Christopher Favela, Nicholas D. Ignacio, Nam H. Le, Isabel T. Caldino Bohn, Jamie Warner, Narayana Aluru, Brian A. Korgel and Deji Akinwande; The University of Texas at Austin, United States

Hydrogen fuel cells have the potential to revolutionize the heavy-duty transportation sector, but their widespread adoption has been impeded by the limitations of current proton exchange membranes (PEMs). Hydrogen crossover remains a critical challenge, leading to reduced efficiency and accelerated membrane degradation. While previous attempts to incorporate 2D materials into PEMs have shown promise in mitigating crossover, they have unilaterally resulted in compromised proton conductivity and overall performance, caused by mitigation of water permeation through the membrane. [1,2,3]

This work presents a novel and scalable approach to extend both PEM lifetime and performance using UV-ozone treated monolayer graphene as a selective barrier layer without any degradation in performance.

This work utilizes a UV-ozone treatment approach allowing for precise control over the size and density of angstrom and nanometer scale defects in the graphene lattice. By tuning the ozone exposure time, we create a defect distribution that maximizes hydrogen/proton selectivity while minimizing the impact on proton conductivity by facilitating the transport of water. Our results demonstrate a 27% increase in selectivity over state-of-the-art Gore Select membranes, a 24% decrease in hydrogen crossover, and up to a 19% enhancement in current density at 0.7 V. Moreover, our ozonated graphene PEMs exhibit an impressive 39% improvement in durability, displaying no performance loss after a 100-hour accelerated stress test.

The significance of our approach lies in its simplicity and scalability to integrate size selective graphene with traditional PFSA membranes. The UV-ozone treatment is a straightforward post-processing step that can be readily applied to commercially available graphene materials and seamlessly integrated into existing PEM manufacturing processes. This makes our technology a practical solution with immense potential for real-world implementation. This work sets the stage for further advancements in PEM design and opens new avenues for the development of high-performance, ultra-durable fuel cell systems.

Advanced Mechanical Characterization of CNT-Polymer Composites—Influence of Volume Fraction and Aspect Ratio

Manish Dhawan; Lovely Professional University, India

This study presents a comprehensive investigation into the mechanical properties of natural rubber (NR) composites reinforced with single-walled carbon nanotubes (SWCNTs), exploring the effects of varying volume fractions, aspect ratios, and chirality configurations. The intrinsic mechanical properties of the NR matrix were initially characterized, providing a baseline for subsequent simulations. Molecular Dynamics (MD) simulations were employed to model the interfacial interactions between SWCNTs and the NR matrix at the atomic scale, *enabling precise predictions of the composites' mechanical responses under diverse conditions. The study systematically evaluates the impact of SWCNT aspect ratios—ranging from 5 to 25—on the stiffness and overall mechanical performance of CNT/NR composites. Comparative analyses with Mori-Tanaka theoretical predictions, implemented via MATLAB, offer a robust evaluation of the reinforcement mechanisms, revealing how aspect ratio influences the mechanical enhancement of the composites. Our findings provide critical insights into the optimization of SWCNT aspect ratios, demonstrating their pivotal role in tailoring the mechanical properties of polymer composites. This research advances the understanding of nanoscale reinforcement mechanisms, contributing valuable knowledge to the design of high-performance materials in the field of advanced composites. The outcomes suggest strategic pathways for the development of next-generation polymer composites with superior mechanical characteristics, highlighting the potential of SWCNTs to revolutionize material performance in engineering applications.*

NM01.11.41

Surface Modifications of $Ti_3C_2T_x$ MXene and Their Impact on Its Physiochemical Properties

Leopoldo E. Posada Escobar[1], Shreyasi Sengupta[1], Caroline Anastasia[2], Howard Fairbrother[2] and Zeev Rosenzweig[1]; [1]University of Maryland, Baltimore County, United States; [2]Johns Hopkins University, United States

MXenes, a recently discovered family of two-dimensional transition metal carbide/nitride nanomaterials, have garnered considerable attention from researchers due to demonstrating many advantageous properties such as high electrical conductivity, mechanical sturdiness and flexibility, and colloidal stability in water. As a result, they have found applications in many fields, such as energy storage, smart textiles, flexible electronics, optoelectronics, catalysis, filtration devices, and sensors. Due to the success MXenes have had in these and many other fields, there has been a recent shift towards using these nanomaterials in biomedical and environmental applications. However, it has been recently discovered that when solutions of MXenes are made in more complex media (e.g., buffers), which are ubiquitously used in these fields, they tend to have adverse effects on the physiochemical properties of MXenes. Therefore, this project aims to develop a molecular level understanding of the complex interactions that occur at the MXene surface when suspended in complex media while simultaneously developing a strategy to modify the MXene surface to reduce these detrimental effects by using a combined computational and experimental approach.

NM01.11.42

Redox Dye Mediated Fluorescence Energy Transfer of Carbon Nanotube Based Nanosensors

Shoichi Nishitani and Markita Landry; University of California, Berkeley, United States

Single-walled carbon nanotubes (SWCNTs) are attractive materials for biochemical sensing and imaging, due to their stable photoluminescence in the tissue-transparent, near-infrared (NIR) region. Certain single-stranded DNA (ssDNA) biopolymers have been known to effectively quench the fluorescence of SWCNTs, a process made reversible by the introduction of biomolecules such as catecholamines. These nanosensors have enabled visualization of dopaminergic neuromodulation, yet with limitations in 1- selectivity of dopamine over other catecholamines, and 2- the necessity to screen for molecular recognition. These limitations motivated us to devise nanosensors with the capability to detect a broader spectrum of biomolecules based on an engineered quenching phenomenon.

Apart from ssDNA, certain redox dyes can quench SWCNT fluorescence via surface binding. Excitingly, we find that catecholamines do not reverse redox dye-based quenching, instead, fluorescence de-quenching can be selectively reversed upon removal of the dye molecules from the SWCNT surface. Motivated by this finding, we sought to design and develop rationally-designed, reversible dye-quenching mediated nanosensors capable of *selectively detecting target biomolecules[1].*

As a proof-of-concept, we designed the SWCNT corona where DNA hybridization is linked to the dynamic movement of methylene blue (MB), a representative dye molecule used in this study, on the SWCNT surface; thus, selectively modulating SWCNT fluorescence emission. In particular, $(GT)_{15}T_{20}$-wrapped SWCNTs were designed as a model to hybridize with the target sequence, A_{20}. To show that the movement of MB on the surface modulates SWCNT fluorescence, we designed multiple variations, where MB was conjugated either to the 3'-end or between $(GT)_{15}$ and T_{20} of $(GT)_{15}T_{20}$, or to the 5'-end or 3'-end of A_{20}. All ssDNA-wrapped SWCNTs were prepared by general sonication-based dispersion. Importantly, we prepared these nanosensors under conditions where ssDNA does not quench the fluorescence; thus, eliminating any contribution from non-specific turn-on responses.

When MB was conjugated to $(GT)_{15}T_{20}$, fluorescence intensity specifically increased upon incubation with A_{20}. As expected, the increment was significantly stronger when MB was conjugated to the 3'-end of the sequence than between $(GT)_{15}$ and T_{20}, because the hybridization does not affect the position of MB in the latter case. For the other design where MB was conjugated to A_{20}, A_{20}-MB (MB conjugated to 3'-end) more effectively quenched the fluorescence of $(GT)_{15}T_{20}$-SWCNT than MB-A_{20}, which was also expected from the unidirectional nature of DNA hybridization. Overall, these results strongly suggest that the movement of MB away from the SWCNT surface modulates SWCNT fluorescence intensity. Notably, the normalized change in fluorescence intensity reached 100% upon optimization for $(GT)_{15}T_{20}$-MB-SWCNT. These nanosensors' high turn-on ratio can be beneficial in developing NIR fluorescence nanosensors for DNA and RNA detection, and possibly in the future for other biomolecules. Correspondingly, we used our design to develop nanosensors capable of detecting viral RNA fragments in plants, using tobacco mosaic virus as a model pathogen. Thus, our results demonstrate the potential of using redox-dye movement relative to the SWCNT surface as a fluorescence mediator to develop rationally-designed, selective nanosensors for the detection and imaging of a broad range of biomolecules.

DNA-Guided Single-Molecule Modifications of Carbon Nanotubes by Magnetic Beads-Assisted Purification

Shoichi Nishitani, Zirun Liang and Markita Landry; University of California, Berkeley, United States

Single-walled carbon nanotubes (SWCNTs) offer significant potential for probing molecular interactions at single-molecule resolution, owing to their unique optical/electronic properties and their one-dimensional structure. However, achieving precise SWCNT surface modifications has been challenging, primarily due to the difficulty in manipulating chemical reactions at the single-molecule scale. In this study, we propose a facile, magnetic beads-assisted sorting strategy to achieve single-molecule modifications of SWCNTs.

Our methodology encompasses a two-step process: 1- Synthesizing SWCNT dispersion with a mixture of unmodified ssDNA and biotin conjugated ssDNA (ssDNA-Bt). With a sufficiently low ssDNA-Bt/ssDNA ratio in the starting material, we predict SWCNTs that have ssDNA-Bt, will only have one ssDNA-Bt at a distinct probability; thus, a single biotinylation on a SWCNT. 2- These singly-biotinylated SWCNTs are selectively isolated using streptavidin-coated magnetic beads. To overcome the strong biotin-streptavidin binding during recovery, we employ desthiobiotin (dtBt), a biotin analogue with reduced affinity for streptavidin, facilitating the release of SWCNTs through an affinity-based exchange. Finally, a single biomolecule can be conjugated selectively to a SWCNT through the ssDNA-dtBt bond either by using a streptavidin-assisted conjugation or by including conjugation chemistry on a ssDNA-dtBt strand.

As a proof-of-concept, we prepared $(GT)_{15}$-dtBt/$(GT)_{15}$-SWCNT with a starting mixing ratio of as low as 1/1000. The synthesized SWCNT sample was then incubated with streptavidin-coated magnetic beads for 1 h, followed by the addition of biotin to recover the captured biotinylated SWCNTs. The recovery of SWCNT was characterized by near-infrared (NIR) fluorescence microscopy. Accordingly, 80% of the dtBt-functionalized SWCNTs were selectively recovered. Notably, recovery from the control samples [$(GT)_{15}$-Bt/$(GT)_{15}$-SWCNT or $(GT)_{15}$-SWCNT] was negligible, highlighting the ability of our strategy to enable single molecule SWCNT functionalization with high efficiency. We further quantified the functionalization sites by atomic force microscopy and an enzymatic activity assay. Thus, we herein developed a facile strategy of single-molecule functionalization of SWCNTs, a method which may be generalized for broader applications in SWCNT based sensing and sorting, including chiral separations and single-defect engineering.

NM01.11.44

Laser Engraved Graphene-Based Ink-Modified Flexible Electrochemical L-Lactate Sensor *G M Mehedi Hossain[1], Jazmin Garza[1], Pritu Parna Sarkar[1], Ali Ashraf[2], Ahmed Hasnain Jalal[1], Nazmul Islam[1] and Fahmida Alam[1]; [1]The University of Texas at Rio Grande Valley, United States; [2]The University of South Florida, United States*

Lactate serves as a critical metabolic marker, with its concentrations in sweat and blood providing valuable information on physiological conditions, including metabolic stress, muscle fatigue, and various medical disorders. This research presents the development of flexible, disposable laser-engraved Kapton (LEK) electrodes modified with graphene-conductive polyaniline (G-PANI) ink for enhanced lactate sensing applications. The novel LEK/G-PANI electrodes offer a promising solution, demonstrating high reproducibility, sensitivity, and stability, making them suitable for wearable and flexible bioelectronics applications. Kapton, a polyimide material, was laser-engraved to create a flexible electrode substrate. The laser-induced graphene (LIG) was directly patterned on the Kapton surface through a CO_2 laser process, offering a simplified fabrication method without complex substrate-transfer techniques. This method resulted in the formation of a conductive graphene network. The electrode's working area was subsequently modified using a conductive G-PANI ink, which was prepared by combining graphene nanoflakes with polyaniline in an acidic medium. The ink provided improved conductivity and biocompatibility, enhancing the electrode's performance in physiological environments. The sensor was optimized by introducing immobilized lactate oxidase (LOx) onto the electrode surface, followed by N-(3-Dimethylaminopropyl)-N'-ethylcarbodiimide hydrochloride (EDC) and N-Hydroxysuccinimide (NHS). The modified electrodes were characterized using cyclic voltammetry (CV) to detect varying lactic acid concentrations. Results demonstrated a highly sensitive and stable response across this wide range of lactic acid concentrations. The minimum detection limit was 100pM, and the coefficient of determination was 96.30%, which is significantly linear. The G-PANI modification significantly enhanced sensor performance compared to unmodified LIG electrodes. Additionally, the LEK/G-PANI electrodes exhibited mechanical stability, maintaining their performance even after multiple bending cycles, which is essential for integration into flexible and wearable biosensing devices. The results revealed that the LEK/G-PANI electrodes can detect lactate levels within the physiological range of sweat and blood. The enhanced conductivity provided by the G-PANI ink, coupled with the electrode's flexibility and disposability, makes the LEK/G-PANI sensors highly attractive for real-time lactate monitoring in athletic and clinical settings. The LEK/G-PANI sensor exhibited excellent repeatability and reproducibility, critical for reliable biosensing applications. This consistency demonstrates the sensor's ability to deliver stable and repeatable results under identical conditions. Furthermore, the reproducibility of the sensor was confirmed through the fabrication of multiple LEK/G-PANI electrodes, all of which provided similar lactate detection performance with high sensitivity. Furthermore, the fabrication process offers scalability and cost-effectiveness, providing an efficient and practical solution for mass production and real-world applications. These attributes position the sensor as a strong candidate for advanced wearable bioelectronics, offering a promising alternative to *commercially available lactate sensors. Further optimization and testing in real-world conditions will be essential to fully validate the sensor's potential in practical applications, including integration into smart textiles and health monitoring devices. This study contributes to the growing field of flexible biosensors and highlights the potential of graphene-modified electrodes for point-of-care applications.*

NM01.11.45

Graphene Oxide and Carbon Nanotubes in Lipid-Enzyme Langmuir-Blodgett Films—Hybrid Nanomaterials for Sensing and Energy Storage Applications *Gabriel Nerath[1], Felipe M. Marinho[1], Rebeca d. Rodrigues[1], Laura O. Péres[1], Danilo Alves Oliveira[2], Jose Roberto Siqueira Junior[2] and Luciano Caseli[1]; [1]Universidade Federal de São Paulo, Brazil; [2]Universidade Federal do Triângulo Mineiro, Brazil*

Incorporating carbon nanotubes and graphene oxide into Langmuir-Blodgett (LB) films of enzymes confined in lipids significantly enhances their catalytic performance, making them highly suitable for bioelectronics applications such as robust biosensors and supercapacitors for energy storage. Enzyme catalysis using nanomaterials improves performance, efficiency, and stability by facilitating precise charge transfer, while the nanostructure provides a high surface area and enhanced conductivity. This synergy results in eco-friendly, high-performance energy storage solutions crucial for various applications, from portable electronics to renewable energy systems. In this study, we harnessed the versatility of Langmuir-Blodgett films to create meticulously organized thin films with specific enzyme properties, coupled with graphene oxide and carbon nanotubes, to develop biosupercapacitors. Langmuir monolayers, the precursors of LB films, were constructed with stearic acid or 1,2-dimyristoyl-sn-glycero-3-phosphate (sodium salt), carbon nanotubes, and either galactose oxidase or laccase. The lipids were dissolved in organic solvents and spread on the air-water interface, forming floating monolayers. Enzyme solutions of enzymes and single-walled carbon nanotubes (CNTs) functionalized with poly(aminobenzenesulfonic) dispersions or graphene oxide (GOs) were inserted into the aqueous subphase of the stearic acid monolayers. Comprehensive characterization using tensiometric, rheological, morphological, and spectroscopic techniques was conducted before transferring the monolayers to solid supports, yielding Langmuir-Blodgett films. We observed that both the enzymes and GOs/CNTs adsorbed onto the lipid monolayers and incorporated into the lipid interstices, interacting with both the hydrophobic and hydrophilic moieties of the lipid. Infrared spectroscopy evidenced the maintenance of the enzyme's secondary structure. After transferring the floating monolayers from the air-water interface to the air-solid interface using the LB technique, the films were characterized, confirming the co-transfer of all components and preserving the enzyme structure. Enzyme activity and interaction with the enzymatic substrate were measured using electrochemical and electrical measurements. These hybrid films, containing lipids, enzymes, and carbonaceous materials, exhibited superior performance, with persistent enzyme activity higher than films without these materials. However, increasing film thickness did not enhance enzymatic activity, indicating a surface-driven process. We further explored the electrochemical properties of the films, revealing stability compatible with supercapacitor applications. The introduction of carbon nanotubes demonstrated higher capacitance, indicating the potential viability of the films for energy storage applications. As a result, the enzyme accommodated in these LB films preserved its catalytic activity, while carbon nanotubes helped maintain these properties over extended storage periods. This method enhances catalytic activity and explains why specific film architectures exhibit improved performance. Acknowledgments: FAPESP (2022/03736-7) and CNPQ

Exploration of Complex Hybrids in Lithium Salt Under UV Exposure *Moin A. Siddiqui[1], Shahzad Ahmed[1,2], Arshiya Ansari[1], Pranay Ranjan[1] and Devendra S. Negi[1]; [1]Indian Institute of Technology Jodhpur, India; [2]The State University of New York at Buffalo, United States*

A simple approach was employed to fabricate hybrid titanium dioxide (TiO$_2$) nanoparticles and poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) embedded with lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) and carbon quantum dots (CQDs) on a p-type of silicon (p-Si) substrate by utilizing the drop-casting method. The structural analysis was conducted using Raman spectroscopy. A UV radiation source with a wavelength of 365 nm and an intensity of 200 mW cm^{-2} was utilized to observe the alteration in conductivity under both illuminated and non-illuminated conditions. The device consisting of TiO$_2$/PEDOT:PSS/LiTFSI demonstrated a responsivity of 25.3%, and the response/recovery times were obtained to be 467/577 seconds, respectively. The responsivity of the CQDs:TiO$_2$/PEDOT:SS/LiTFSI device was measured to be 22.2%, and the response/recovery times were found to be 300/393 seconds, respectively. The design methodology employed in our approach holds promise for application in the fabrication of different sensors capable of detecting harmful UV rays, which is known to contribute to premature aging, sunburn, cataracts, skin cancer, and a range of other UV-related dermatological conditions.

NM01.11.47

Direct Synthesis of Carbon Nanotubes on Alumina Powder by Rotary CVD for Improved Thermal Management Performance *Jong-Hwan Lee, Hyun-Ho Han and Goo-Hwan Jeong; Kangwon National University, Korea (the Republic of)*

The increasing demand for high performance electronic devices and the rapid growth of the electric vehicle market have highlighted the importance of efficient thermal management. Effective heat dissipation is critical to ensure the safety, longevity, and reliability of semiconductor devices and batteries. To address these challenges, polymer-based composites with thermally conductive fillers have emerged as a cost-effective solution. In this study, we developed nanocomposites composed of carbon nanotubes (CNTs) grown directly on the surface of alumina (Al$_2$O$_3$) particles with the aim of producing high-performance thermal fillers for polymer composites. A rotary chemical vapor deposition (RCVD) system, which incorporates a rotating reactor in conventional horizontal CVD, was used to improve the uniformity and mass production of the CNT/Al$_2$O$_3$ nanocomposites. This approach provides efficient dispersion of the CNTs within the polymer matrix, which enhances the reliable thermal performance of the produced composites.

Key process parameters for CNT synthesis, such as reaction temperature, time, and reactor rotation speed, were optimized to maximize CNT yield. Structural characterization of the composites was characterized using scanning electron microscopy and transmission electron microscopy. In addition, Raman spectroscopy was used to evaluate the structural integrity of the CNTs. Thermogravimetric analysis was also used to quantify the CNT growth yield. Additionally, the incorporation of blades on the inner wall of the quartz reactor significantly increased the uniform and enhanced exposure of the Al$_2$O$_3$ particles to the hydrocarbon feedstock to improved CNT yield and crystallinity in the nanocomposites compared to the case without blades. The reactor configuration ensures efficient and uniform dispersion of CNTs within the polymer matrix, ultimately improving the thermal performance of the composites.

To confirm the performance of the synthesized CNT/Al$_2$O$_3$ nanocomposites as fillers for enhanced thermal conductivity, the CNT/Al$_2$O$_3$ powders were dispersed into epoxy resin to fabricate polymer composite sheets. Thermal conductivity was measured using a laser flash analysis, with the results were directly compared to polymer composites made of either pure Al$_2$O$_3$ or commercial CNT/Al$_2$O$_3$ mixtures. The superior thermal properties obtained from the composites produced by direct growth of CNT confirm the effectiveness of this scalable synthesis for thermal management applications.

NM01.11.48

Parallel-Aligned SWNTs—Controlled Synthesis on Quartz and Characterization After Transfer to Slit-Structured Substrates *Jong-Hwan Lee, Hyun-Ho Han and Goo-Hwan Jeong; Kangwon National University, Korea*

(the Republic of)

The outstanding properties of single-walled carbon nanotubes (SWNTs) are attributed to several factors, including their unique one-dimensional structure, peculiar electronic structure, high electron mobility and thermal conductivity. Based on these extraordinary properties, SWNTs are being widely explored in various fields, including electronics such as field effect transistors, transparent conductive films, light emitting devices and nanoscale sensors.

Due to the direct relationship between the chirality of SWNTs and electron-related physical properties, growth parameters such as growth temperature, catalyst composition, catalytic particle size, flow rate and type of feedstock should be adjusted during growth to obtain SWNTs with pre-designed chirality.

In order to realize the parallel growth of SWNTs with single chirality, we report here our preliminary results on the parallel growth of single SWNTs on quartz substrate using conventional horizontal chemical vapor deposition (CVD) and successive transfer from quartz wafer to slit substrate for precise characterization of the chirality or diameter of SWNTs using Raman spectroscopy, photoluminescence, atomic force microscopy and transmission electron microscopy.

To facilitate the lattice-guided growth of SWNTs, we used single crystal quartz wafers and optimized the annealing conditions to achieve a high degree of horizontal alignment. We investigated the effects of growth temperature, growth time, and catalyst particle size on the parallel alignment and density of SWNTs, recognizing that improved alignment can enhance performance in nanoelectronics and sensors. Since suspended SWNTs produce significantly enhanced signals in optical spectroscopy, we also fabricated slit-structured substrates to obtain obvious results from parallel-aligned SWNTs after transfer to these substrates. We have optimized cleanroom processes for the fabrication of the slit substrates. Finally, we will present the successful growth of parallel-aligned SWNTs, their transfer to slit-structured substrates, and characterization results of the transferred SWNTs.

NM01.11.49

Conveyor CVD to High-Quality and Productivity of Large-Area Pristine and n-Doped Graphene and Its Sensing Response

Dong Yun Lee[1], Jungtae Nam[1], Gil Yong Lee[1], Junyoung Jung[2], A-Rang Jang[2] and Keun Soo Kim[1]; [1]Sejong University, Korea (the Republic of); [2]Kongju National University, Korea (the Republic of)

The mass production of high-quality graphene is required for industrial application as a future electronic material. However, the chemical vapor deposition (CVD) systems previously studied for graphene production face bottlenecks in terms of quality, speed, and reproducibility. Herein, we report a novel conveyor CVD system that enables rapid graphene synthesis using liquid precursors.[1] Pristine and nitrogen-doped graphene samples of a size comparable to a smartphone (15 cm × 5 cm) are successfully synthesized at temperatures of 900, 950, and 1000 °C using butane and pyridine, respectively. Raman spectroscopy allows optimization of the rapid-synthesis conditions to achieve uniformity and high quality. By conducting compositional analysis via X-ray photoelectron spectroscopy as well as electrical characterization, it is confirmed that graphene synthesis and nitrogen doping degree can be adjusted by varying the synthesis conditions.[2] Testing the corresponding graphene samples as gas sensor channels for NH_3 and NO_2 and evaluating their response characteristics show that the gas sensors exhibit polar characteristics in terms of gas adsorption and desorption depending on the type of gas, with contrasting characteristics depending on the presence or absence of nitrogen doping; nitrogen-doped graphene exhibits superior gas-sensing sensitivity and response speed compared with pristine graphene.

Flexible and Thermoformable Printed Capacitive Sensors for Automotive Applications Using Exfoliated Graphene

Djibril Ndiack Faye[1], Ricardo Campos[1], Cláudia Buga[1,2], Catarina Ribeiro[2], Júlio Viana[1,2] and Paulo Pedrosa[1]; [1]DTx Colab, Portugal; [2]Universidade do Minho, Portugal

Over the last two decades, flexible printed electronics (PE) has garnered significant interest and is seen as a promising trend in material science, especially in the development of lightweight functional systems for automotive applications. In this work, we evaluated the potential of screen-printing technology combined with 2D graphene-based materials to produce functional circuits and sensors for automotive interiors. These circuits were designed to be processed through in-mold electronics (IME) – i) screen printing, ii) thermoforming, and iii) overmoulding. Graphene was obtained using a proprietary liquid-phase exfoliation process and used for developing water-based and solvent-based inks. Then, combined with polycarbonate and PET substrates, we screen printed flexible and in-molded functional circuits and capacitive sensors using a SD 56/36 (280mesh) stainless steel screen.

A detailed characterization study was carried out to evaluate the electromechanical, morphological and electrical properties of the screen-printed materials. It was shown that the morphological characteristics are affected by the surface energy of the substrates but also by the used solvent. Successful printing was obtained for wider lines (0.3mm) and for specific substrates, although screen clogging issues were encountered for narrower lines. The electrical properties were improved with prints showing a sheet resistance up to around 100 ohm/square by using ethyl cellulose and terpineol as solvent and PET as substrate. The printed circuits showed good electromechanical properties with conductive tracks still functional after over strains Ds~10%. We demonstrated successful feasibility of flexible and thermoformable circuits and capacitive sensors. Thermoformed samples reveal that the best overall performance can be observed with specific combinations of substrate and ink. The proof-of-concept for electrical functionality, demonstrated through the integration of sensors into a PCB with SMD LEDs is discussed, alongside inductance characterization.

This study underscores the importance of defining adequate product specifications to optimize graphene ink properties for automotive applications.

Machine Learning-Driven Prediction Model for Zero TCR Polymer Composites Incorporating Carbon Black and Carbon Nanotubes

DongKwan Lee, Kunwoo Nam, Won-Jin Kim and Sung-Hoon Park; Soongsil University, Korea (the Republic of)

Polymer composites using carbon fillers are lightweight, flexible, and exhibit excellent electrical and thermal properties, making them widely applicable in various electronic devices, wearable sensors, automotive heaters, and more. However, these composites may experience resistance changes due to temperature fluctuations, which can compromise the stability of electronic devices or increase the risk of device damage due to overcurrent. The overcurrent issue, in particular, is a significant safety concern in electronic devices, necessitating research to address it. Carbon filler polymer composites undergo a temperature coefficient of resistance (TCR) change when heated by resistive heating. Among these fillers, carbon black, a zero-dimensional filler, exhibits a positive temperature coefficient (PTC) behavior, where electrical resistance increases due to an expansion in the distance between particles caused by thermal expansion during resistive heating. On the other hand, carbon nanotubes, a one-dimensional filler, display a negative temperature coefficient (NTC) behavior, where electrical resistance decreases as the number of contact points increases due to the rearrangement of the nanotube strands during

thermal expansion. When both fillers are uniformly dispersed in the polymer matrix, the PTC and NTC effects can complement each other, achieving a zero-temperature coefficient of resistance (zTCR) with minimal resistance changes. In this study, a composite material with negligible resistance change during heating was fabricated by mixing conductive fillers, carbon black and carbon nanotubes, into polydimethylsiloxane (PDMS). Furthermore, this research aims to present a mathematical model capable of predicting the temperature at which zTCR occurs based on the mixing ratio of the two carbon fillers. Accordingly, zTCR was observed at specific temperatures, with resistance variations within 0.5%, depending on the composition ratio of the two carbon fillers. Based on the experimental results, a machine learning model was developed to predict the temperature at which zTCR occurs, and its prediction accuracy was thoroughly verified using experimental data from composites with various compositions. This study successfully developed composites with negligible resistance changes during heating by utilizing zero-dimensional and one-dimensional carbon nanomaterials. The zTCR properties of the composites were systematically analyzed through experiments, and a mathematical predictive model using machine learning was proposed to guide the design of composites that maintain electrical properties under various temperature conditions.

Graphite Evolution by Metal Induced Crystallization of Amorphous Carbon e on SiN_x/Si Substrate with 8 Inch Scale *Hye-Young Kim[1,2], Seul-Gi Kim[1], YongKyung Kim[1,3], Kihun Seong[1,2], Hyun-Mi Kim[1], Hyeongkeun Kim[1] and Ji-Beom Yoo[2]; [1]Korea Electronics Technology Institute, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Hanyang University, Korea (the Republic of)*

Graphite is an attractive candidate for next-generation EUV pellicles due to its high emissivity (>0.3) and robust mechanical properties, such as a Young's modulus of 4.1 GPa, which ensures excellent thermal and mechanical stability. A pivotal necessity for EUV pellicles is the attainment of high EUV transmission, which demands the utilization of ultra-thin films with a thickness of approximately tens of nanometers, while simultaneously ensuring uniformity across extensive areas. The most common method for synthesizing graphite is chemical vapor deposition (CVD) on thick metal catalysts, but this approach has several drawbacks, including difficulties in controlling thickness uniformity and potential damage during wet-transfer processes. To address these challenges, we propose a direct synthesis of graphite films (thickness < 30 nm) on insulating substrates at a relatively low temperature of around 500°C. This process starts from amorphous carbon (a-C) deposited on a thin metal catalyst layer and is referred to as graphite-metal induced crystallization of a-C (G-MICA). Previous studies have shown that when metal and a-C layers of equal thickness are sequentially deposited and subjected to heat treatment, the a-C diffuses through the metal, forming graphite between the insulating substrate and the metal layer. Using this method, graphite can be directly grown on insulating substrates. In our study, we employed Ni as the metal catalyst, achieving uniform graphite layers with a thickness of 30 nm on 8-inch SiN_x/Si substrates.
To investigate the growth kinetics of graphite from a-C through the Ni catalyst, leading to a uniform G-MICA layer, we carefully monitored the microstructural evolution of the graphite with the increasing the annealing temperatures from 400 to 800°C using X-ray diffraction, Raman spectroscopy, scanning electron microscopy (SEM), and double Cs-corrected transmission electron microscopy (TEM). The a-C (30 nm)/Ni (30 nm)/a-C (1 nm) layers were RF sputtered without vacuum interruption onto a 150 nm SiN_x/Si substrate. We observed that at 400°C, graphite nucleation begins at both the interface between a-C and Ni, as well as between Ni and the SiNx substrate, and all nucleation occurs in Ni layer. This agrees well with thermodynamic calculations regarding interface energies under nucleation conditions. However, further growth beyond 500°C suggests that the dominant nucleation site is the interface between a-C and Ni. The vertical growth of graphite nuclei at this interface is constrained by the thickness of the Ni layer. Interestingly, we found that the graphite thickness remained around 30 nm across all temperatures above 500°C. Furthermore, in samples with varying Ni thicknesses (10, 30, and 50 nm) while maintaining a constant a-C thickness (100 nm), and in samples with varying a-C thicknesses (30, 50, and

80 nm) with a constant Ni thickness (30 nm), the graphite thickness matched the Ni thickness in all cases. The interstitial in-diffusion of carbon into Ni is governed by the substitutional out-diffusion of Ni into a-C. Thus, it appears that the completion of Ni out-diffusion is dependent not on the thickness of the a-C layer but rather on the matching amounts of carbon and Ni. Additionally, at temperatures above 600°C, Ni begins to diffuse into the SiN_x *layer, and Si and N are detected within the Ni layer. Therefore, we determined that the optimal annealing temperature should remain below 600°C to prevent unwanted diffusion. Ultimately, we demonstrate the successful formation of a uniform graphite layer, less than 30 nm thick, on an 8-inch* SiN_x*/Si wafer after annealing at 500°C for 1 hour.*

In this presentation, we will describe the detailed temperature-dependent the microstructure evolution of graphite from a-C through Ni thin film and the thickness control mechanism along the corresponding kinetic pathways.

Novel Devices Based on Quantum Carbon Dots Exhibiting Non-Linear Current-Voltage Characteristic *Scott Copeland[1], David Sanchez[2], Sungguen Ryu[2], Nick Krasko[3], Kazunari Imai[3], Zhixiang Lu[3] and Paul Czubarow[1]; [1]eM-TECH, United States; [2]Universitat de les Illes Balears, Spain; [3]NAMICS North America R&D Center, United States*

As the field of semiconductor technology rapidly evolves, the need for advanced 3D integration solutions becomes increasingly critical. Traditional two-dimensional designs are reaching their physical limits as devices continue to shrink, making it essential to explore new approaches to hardware design. One area of interest in 3D integration is surge suppression using alternative materials and designs. In this work, we introduce a novel composite surge arrestor device constructed by crudely depositing an epoxy paste filled with carbon quantum dots (CQDs) on to a interdigitated electrodes geometry. When subjected to electrical bias of 5V, 2mA at room temperature, this device displays a variety of nonlinear current-voltage (IV) characteristics, including behaviors typical of a varistor, Schottky diodes, tunneling diodes, and Coulomb blockade phenomena. This variety of nonlinear responses is influenced by several factors, including the design of the interdigitated electrodes, the molecular additives in the epoxy matrix, and the CQDs. The inclusion of nano metal oxide and chemical dopants and CQDs within the epoxy matrix enables electrochemical interactions with the interdigitated electrodes, modifying electron trapping behavior. In addition to our experimental results, we present theoretical models that not only validate observations but also explain electron traps to quantum dot interactions which help create observed nonlinear behaviors. Initial testing of the samples consistently yields nonlinearity factors (α-values) between 6 and 8, with the highest recorded value reaching 15. However, after two or more tests on any one sample, the sample will exhibit more monotonic behavior trending towards an α-value of 1 - 2, suggesting a shift in their electrical properties. Under bias, these electron traps open and close, generating the nonlinear IV curves seen during initial tests. However, further testing beyond test 2 on any one sample shows that this nonlinear behavior diminishes, indicating that the electron traps in the epoxy matrix permanently close in a way that results in a stabilized monotonic response. The precise mechanism behind the so far irreversible change in the sample could be a form of equilibrium in electron traps being occupied between the epoxy side and electrode side of the samples. Furthermore, the nonlinear behaviors observed do not appear on more traditionally made components in conjunction with our epoxy CQD matrix indicating that the electrode architecture plays a significant role in producing nonlinear IV curves. The presence of various nonlinear IV curves further increase the utility of the electrode with deposited epoxy matrix as this opens the door for replacing not only varistors but types of diodes as well. Additionally, the observation of the Coulomb blockade phenomenon in some samples poses an opportunity to potentially obtain higher α-values where the IV curve displays a staircase effect acting as short cut, rather than curving in the traditional sense of a varistor and diode. This innovative solution presents one way a more compact and efficient 3D integrated varistor component could replace bulkier constructs utilized now, further enabling streamlined and densely packed hardware architectures.

Study on the Selective and Tailered Functionalization of Large-Area Graphene Using DUV *Dong Yun Lee[1], Jungtae Nam[1], Gil Yong Lee[1], Junyoung Jung[2], A-Rang Jang[2] and Keun Soo Kim[1]; [1]Sejong University, Korea (the Republic of); [2]Kongju National University, Korea (the Republic of)*

Controlling the properties of graphene as desired is important for expanding graphene research into applications and further studies. In particular, it is very important to selectively obtain desired properties at specific locations. We synthesized large-area CVD graphene[1], created a window with a desired pattern, and exposed only local locations to DUV for a certain period of time. Graphene is oxidized on the exposed surface by ozone (O_3) generated by DUV.

We studied how the exposure time of graphene to DUV changes its electrical and optical properties. Graphene exposed to DUV exhibited increased optical transmittance[2], significant p-type characteristics, and decreased charge mobility. Based on the results, only a portion of the graphene channel was exposed to DUV to partially functionalize it. Graphene channels, which have junction without boundaries, have various properties depending on their ratio without creating an increase in resistance at the interface. The functionalized graphene was characterized by Raman spectroscopy, spectrometry, and electrical properties.

High Efficiency Upconversion Photoluminescence Properties of Nitrogen Doped Graphene Quantum Dots for Biomedical Applications *Muhammad Shehzad Sultan[1], Angela Luis Matos[1], Wojciech Jadwisienczak[2], Bianca S Umpierre Ramos[3], Daniela D Negron Negron[3], Luis O. Ramos Alers[3], Brad R. Weiner[3] and Gerardo Morell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]Ohio University, United States; [3]University of Puerto Rico - Río Piedras, United States*

The graphene quantum dots (GQDs), a zero-dimensional graphene quantum structure, have triggered intense research worldwide. GQDs possess unique optical, chemical and physical properties as compared to conventional quantum dots (QDs), such as low toxicity, biocompatibility, optical stability, chemical inertness, high photostability and good water-solubility and therefore hold great application potential in biomedical, optoelectronics and energy storage devices. The doping of GQDs with heteroatoms is one of the most effective ways to tune their photoluminescence emission and to increase quantum yield. In this study, we developed a novel approach to synthesize high-quality Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. To observe optical properties of as synthesized N-GQDs, the UV-vis and Photoluminescence measurements were carried out. The as-synthesized NGQDs exhibit high quality crystalline structure of graphene with an average size of about 3.7 nm. A high quantum yield was exhibited by the obtained N-GQDs as compare to the pristine GQDs. The obtained N-GQDs with oxygen-rich functional groups exhibit a strong emission and excellent upconversion PL properties. These outcomes result in an ample opportunity for the biomedical and optoelectronic applications.

Emerging Applications of Boron Nitride Nanostructures for Advanced Electronics and Biomedicine *Yoke Khin Yap; Michigan Technological University, United States*

The electrically insulating and optically transparent hexagonal boron nitride (h-BN) nanostructures are not applicable as the transport channel of electronic and energy devices. Recent advancements in controlled synthesis of high-purity boron nitride nanotubes (BNNTs) [1-3] and h-BN nanosheets have enabled unique applications in advanced electronics and bio-imaging. For example, we reported using BNNTs as the one-dimensional templates for room-temperature single-electron transistors (SETs)[4], and two-dimensional gold quantum dots with tunable optical bandgap[5]. We also reported field-effect transistors (FETs) by van der Waals Tellurium (Te) atomic chains encapsulated inside BNNTs [6]. Last but not least, we have demonstrated high-brightness fluorophores for immunophenotyping of antigens by flow cytometry.[7] In my talk, I will discuss these emerging applications,[8, 9], and the latest use of h-BN nanostructures as high-brightness probes (HBPs) for gene and troponin protein detection.

One-Step Synthesis of Hierarchical Boron Nitride Porous Nanomaterials *Ping-Yuan Lee[1], Barbara M. Maciejewska[1], Mathew Cross[2], George T. Tebbutt[1], Marcel Swart[3,4], Andrew S. Weller[2] and Nicole Grobert[1,5]; [1]University of Oxford, United Kingdom; [2]University of York, United Kingdom; [3]Universitat de Girona, Spain; [4]ICREA, Pg. Lluís Companys, Spain; [5]WAE Technologies Ltd, United Kingdom*

Porous boron nitride (BN) has shown great promise in the field of molecule separations, particularly for gas *sorption applications such as CO_2 capture or H_2 storage. Herein, we report the straightforward synthesis and detailed characterization of high purity, porous, three-dimensional solid constructed from hybrid one-dimensional hexagonal BN (h-BN) nanofibers and two-dimensional h-BN nanosheets. The structure is synthesized through a one-step, template-free, substrate-free polymer-derived ceramic thermolysis of linear B–N backbone polymer*[1] *in a reduction environment, resulting in porous and mechanically stable interconnected h-BN hierarchical structure. The thermal dehydrogenation, so-called "chemical blowing",*[2] *of the polymeric precursor plays a pivotal role in the synthesis process. Comprehensive characterizations, including high-resolution transmission electron microscopy, X-ray diffraction, X-ray photoelectron spectroscopy, and Raman spectroscopy, all confirm the high purity and crystallinity of the resultant BN phase. A theoretical model based on density functional theory (DFT) calculations combined with reactive force field (ReaxFF)*[3] *molecular dynamics simulations is proposed for the formation of this novel hybrid h-BN architecture. To our knowledge, the method presented here represents the first instance of reliable, controllable, and scalable production of h-BN hierarchical structure of its kind. Overall, this approach offers a straightforward route to porous BN production potentially valuable for gas sorption applications in extreme environments.*

Fast Crystallographic Texture Mapping of Atomically-Thin hBN Films on Ni(111) Using Secondary Electron Contrast *Vitaly Babenko, Se Hun Joo, Christopher Pickard and Stephan Hofmann; University of Cambridge, United Kingdom*

High-throughput characterisation and rapid quality feedback play pivotal roles in accelerating advanced materials development and expand their horizon of applications. This is particularly pertinent for the chemical vapor deposition (CVD) driven industrialisation of ultra-thin device materials, like hBN, where complex texture at atomic layer level remains hard to characterise and thus feedback loops and workflow remain slow.[1] Scanning electron microscopy (SEM) is a well-established technique particularly for facile characterization of emerging 2D materials, where secondary electron (SE) contrast allows rapid and non-destructive mapping of monolayer domains and films on a wide range of substrates. Here, we show that SE contrast generated by surface-sensitive in-lens detectors can be used to fingerprint monolayer hBN domains alignment to the Ni(111) surface, thus opening fast crystallographic texture mapping capabilities with conventional SEM.[2] This is supported by density functional theory (DFT) computations indicating a work function difference of 50 meV between the two anti-parallel epitaxial hBN orientations, and of around 600 meV between epitaxial and non-epitaxial (rotated) hBN orientations, where we also account for realistic vicinal Ni surfaces. We demonstrate how this enables the effective and systematic analysis of the large-area structure of hBN CVD films and gives insight in their evolution, including the nature of resulting domain boundaries [3] and bilayer regions.

Salt-Assisted Growth of Transition Metal Dichalcogenide Nanotubes—Mechanisms from Molecular Dynamics *Daniel S. Vadseth[1], Shigeo Maruyama[2] and Alister Page[1]; [1]The University of Newcastle, Australia; [2]The University of Tokyo, Japan*

The use of inorganic salts to increase the yield and quality of 2D transition metal dichalcogenide (TMD) monolayers during CVD has become well established in recent years[1-2]. While 2D van der Waals (vdW) heterostructures have been extensively studied since the late 2000's, their 1D counterpart, the 1D nanotube vdW heterostructure, was first reported in 2020.[3] Salt assisted growth has become a strategy for synthesising 1D heterostructures as well, highlighting the importance of a better understanding of these salts in the synthesis of TMD nanomaterials. Proposed mechanisms for this type of salt assisted growth feature lower melting temperature salts (compared to for example MoO_3/WO_3) such as Na_2WO_4 and $NaMoO_3$, which provide a steady flux of TMD metal to the substrate, thereby increasing yield and quality.[2,4] Similarly, Na_2MoO_4 has been proposed to form a eutectic with the chalcogen, before monolayer TMDs are precipitated.[3]The formation of transition metal oxychlorides as intermediates that more readily reduces has also been investigated as an explanation of these effects.[4] However, the precise atomistic mechanism by which the salt acts to make these improvements remains unclear.

Here we present quantum chemical molecular dynamics (MD) simulations using the GFN1-xTB[5] method to explore the role of NaCl in the formation of MoS_2. MoO_3, S_2 and varying amounts of NaCl were modelled in the gas phase to better understand the intermediates that form and the individual role of Na and Cl on the formation of these intermediates. We show that adding NaCl doubles the rate of oxidation/reduction of Mo and O, with gas-phase Na^+ cations being the main facilitator of this change. Our results show new insights highlighting the role of Na, which has so-far been neglected in attempting to understand salt assisted growth, as a key reduction agent and catalyst driving bond rearrangement between Mo, O and S.

Investigation of the Structural Evolution of Thermal Treated Imogolite Nanotubes *Yifan Pan[1], Pascale Launois[1], Delphine Vantelon[2], Valérie Magnin[3], Stéphan Rouzière[1], Nicolas Trcera[2] and Erwan Paineau[1]; [1]Université Paris-Saclay, France; [2]Synchrotron SOLEIL, France; [3]Institut des Sciences de la Terre, France*

Thermal treatment is one of the most commonly applied process to modify the structure, porosity, and surface reactivity properties of clay minerals. Among them, imogolite nanotubes, $(OH)_3Al_2O_3(Si,Ge)OH$, have a unique structure consisting of a curved octahedral $[O_3Al(OH)_3]$ outer layer on which isolated $[Si(Ge)O_3(OH)]$ tetrahedron units are bonded on the inner surface by sharing three mutual oxygen atoms [1]. A recent study by Monet et al. [2] has shown that three different intermediate stages occur during the thermal annealing of hydrophilic aluminogermanate imogolite nanotubes, until re-crystallization into a Ge-mullite compound beyond 950 °C.

Interestingly, after dehydroxylation, a metaimogolite structure is formed with both six-fold and five-fold coordinated Al atoms, which further reorganizes into Al(VI) and Al(IV) at temperature higher than 600 °C. The family of imogolite nanotubes also includes methylated imogolite nanotubes, where inner hydroxyl groups are replaced by methyl units. In particular, it has been demonstrated that the rolling mode of methylated and hydroxylated nanotubes are different [3], which may result in different structural evolutions as a function of temperature.
Here, we investigated the thermal transformation of methyl-modified germanium-based nanotubes $(OH)_3Al_2O_3GeCH_3$*. Dehydration and dehydroxylation and demethylation have been observed with ex-situ Infrared spectroscopy up to 500 °C. Complex structural transformations and atomic re-organization occur at higher temperature, which are studied thanks to time-resolved in-situ X-ray Absorption Near Edge Spectroscopy (XANES) and X-ray scattering (XRS) experiments, , up to ~1000 °C. XRS diagrams give information on the evolution of the shape and organization of the nanotubes. Furthermore, Pair Distribution Function investigations have been performed to examine the transformation from long to short range order when heating, in the metastable states formed above 500 °C. Moreover, XANES spectra at Al K-edge coupled with the Multivariate Curve Resolution with Alternating Least Squares chemometrics quantitative analysis give the evolution of Al environments during heating, except for Al(V), which is usually elusive by XANES [2]. The Al coordination shows an evolution from an Al(VI) octahedral environment to a combination of two different Al coordination sites. Only octahedral Al(VI) and tetrahedral Al(IV) environments were evidence by XANES for hydroxylated aluminogermanate nanotubes [2] Interestingly, a very peculiar intermediate signature of Al is thus revealed for its methylated counterpart, whose metaphases appear to be different [2].*
Finally, the thermal treatment allows one to modify the physico-chemical properties of clays nanotubes. As hydrogen storage is an environmental issue of importance, we will illustrate the effect of thermal treatment of imogolite nanotubes on hydrogen storage capacities.

Boron Nitride Nanotube Coatings for Improved Thermal Management and Mechanical Durability of Flexible Printed Conductors

Kaitlin Wagner[1,2], Arnold Kell[2], Yadienka Martinez-Rubi[2], Xiangyang Liu[2], Chantal Paquet[2] and Benoit Lessard[1]; [1]University of Ottawa, Canada; [2]National Research Council Canada, Canada

Large-scale production of flexible conductors hinges on developing economically viable printable materials that can be formed under rapid processing. To decompose and convert the ink to its metallic state, sintering techniques with high irradiative and thermal requirements, such as photonic sintering, can be used to form conductive traces on a millisecond timescale. However, utilizing intense processing techniques with low-temperature substrates like polyethylene terephthalate (PET) or polylactic acid (PLA) can lead to warping of the substrate and subsequently poor trace morphology due to the uneven heat accumulation at the interface between the substrate and the printed trace. To combat this issue, incorporating an electrically insulating film interposed between the substrate and the printed feature can aid in spreading heat laterally away from the substrate-feature interface without sacrificing conductive performance or flexibility of the plastic substrate. Boron nitride nanotubes (BNNTs) exhibit high thermal conductivity and impressive mechanical robustness, and therefore present a *promising platform to minimize thermal and mechanical degradation of the printed feature and the substrate over time.*

We present the use of modified boron nitride nanotubes (BNNTs) as a heat dissipating layer to mitigate deformation and thermal damage to PET and PLA substrates upon curing of silver molecular inks through IPL and UV sintering. Conductive traces were printed onto BNNT-coated substrates of varying surface concentrations and exposed to a wide range of sintering energies to fully investigate the effects of increasing thermal heat generation across varying trace designs. The inclusion of the BNNT thin-film at the substrate-trace interface resulted in reduced warpage of the substrate, as well as improved trace morphology and subsequent conductivity at increasing BNNT surface concentrations, confirmed through scanning electron microscopy (SEM), 2D scan profilometry, and energy-dispersive x-ray spectroscopy (EDS). Thermal infrared imaging observed a decrease in average peak temperature of the features at high BNNT surface concentrations, owing to the lateral heat diffusive properties of the BNNT network. Furthermore, incorporating the BNNT interlayer into thermoformed structures assists in normalizing the conductivity at elongated stress points due to the mechanical durability of the underlying BNNT network. The BNNT interfacial film as a thermal management tool successfully maintains the structural integrity of conductive traces upon rapid processing techniques, and holds promise for integration into wearable electronics platforms to extend operational lifetime.

Porosity-Controlled Conductivity in Nanosheet Networks Facilitates Chemiresistive Sensing *Hannah J. Wood[1,2], Sean P. Ogilvie[1], Aline Amorim Graf[1], Peter Lynch[1], Conghang Qu[2], Gothamie Ratnayake[2], Jeremy Thorpe[1], Matthew Large[1], Izabela Jurewicz[3], Mauricio Terrones[2,2,2] and Alan Dalton[1]; [1]University of Sussex, United Kingdom; [2]The Pennsylvania State University, United States; [3]University of Surrey, United Kingdom*

Transition metal dichalcogenides such as molybdenum disulfide (MoS_2) are layered materials of great interest due to their unique thickness-dependent properties and potential for a range of printed electronic devices. Networks of MoS_2 nanosheets are exfoliated in a surfactant-assisted liquid phase; often water-based systems are ideal for cost effective production of inks on the larger scale. The non-covalent relationship between surfactant and nanosheet allows for the effective isolation of polydisperse nanomaterials [1]. This work looks at the subsequent size selection and deposition of MoS_2 sheets used to assemble chemiresistive devices capable of sensing ammonia (NH_3) and nitrogen dioxide (NO_2) down to levels of 10 ppb and 50 ppb. An enhancement of the nanosheet network conductivity by two orders of magnitude from 10^{-5} S m^{-1} to 10^{-3} S m^{-1} can be interpreted in terms of the nanosheet size and network distribution [2,3]. The optimisation of the porosity and nanosheet size comprising these networks results in the sensitive response to chemical analytes. The built devices show to be sensitive to 10 ppb NH_3 and exhibit a current response over multiple cycles highlighting the potential for MoS_2 devices for chemical sensing.

Polypropylene-Derived Luminescent Carbon Dots *Yongqi Yang[1], Sneha Sreekumar[1], Robert Chimenti[2] and*

Deirdre O'Carroll[1]; [1]Rutgers, The State University of New Jersey, United States; [2]Rowan University, United States

Carbon dots (CDs), as an emerging material class, have been actively investigated for applications in biomedical fields, supercapacitors, and optoelectronic devices. Recently, consumer plastics have been shown to be promising starting materials for the preparation of CDs due to the high carbon percentage in their chemical composition. This also offers an upcycling pathway for waste consumer plastics that otherwise cause a significant waste management issue. Our research aims to develop a generalizable approach to upcycling plastic to carbon dots. Among all plastics, we chose to start with polypropylene as it is one of the most challenging consumer plastics to recycle or upcycle due to its excellent chemical and thermal stability. We developed an effective two-step synthesis for the preparation of carbon dots from polypropylene [1]. In the first step, bulk polypropylene is converted to nanoparticles with diameters of 310±178 nm using a dissolution/reprecipitation process. In the second step, the polypropylene nanoparticles (PP-NPs) are carbonized by hydrothermal treatment with sulfuric acid. The resulting product is polypropylene-derived carbon dots (PP-CDs) with diameters ranging from 1.8 nm to 108 nm depending on hydrothermal treatment temperature.

The structure and photonic properties of the PP-CDs also vary significantly with hydrothermal treatment temperature. At a lower temperature (120 °C), the PP-CDs are large in size (~70 nm), have low photoluminescence quantum yield, and broad emission spectra, and they exhibit a small variety of surface functional groups. At higher temperatures, the product is free from unconverted polypropylene due to the combination of the high surface-to-volume ratio of the PP-NPs formed during the first step and the effective carbonization in the second step. The size of the PP-CDs formed at higher temperatures (150 °C and 180 °C) reduces significantly to ~3 nm in diameter, the quantum yield increases to 10.3 %, the emission is narrower, and the chemical composition is more heterogeneous. Powder X-ray diffraction and scanning electron microscopy also indicate the crystallinity of the post-processed CDs from 150 °C and 180 °C is high, with a graphitic-like structure. This work demonstrates an effective two-step method to fully convert polypropylene to carbon dots and shows a high degree of tunability in the size, structure, and photonic properties of the carbon dot product.

Production of Magnetic Arsenic–Phosphorus Alloy Nanoribbons with Small Band Gaps and High Hole Conductivities

Fengfei Zhang[1], Eva Aw[1], Alexander Eaton[2], Oliver Payton[3], Loren Picco[3], Christopher Howard[1] and Adam Clancy[1]; [1]University College London, United Kingdom; [2]University of Cambridge, United Kingdom; [3]Bristol Nanodynamics Ltd., United Kingdom

By cutting 2D nanomaterials into 1D nanoribbons, their properties may be tuned by width-dependent quantum confinement. Phosphorene is one of the most studied 2D materials, and our group recently developed a route the bulk synthesizing its nanoribbon analogue [1], which are predicted to exhibit exotic properties, including the Seebeck effect, tunable layer-dependent electronic, optical and ionic transport properties. Recent experiments have demonstrated room-temperature magnetism [2] in PNRs and their ability to enhance hole mobility in solar cells [3]. By combining the flexibility and unidirectional properties of nanoribbons with the high surface area and anisotropic properties of 2D phosphorene sheets, PNRs are expected to exhibit high conductivity due to the 2D confinement of electronic movements and edge effects.

An important approach to modifying layered materials is via alloying, as is well established for transition metal dichalcogendides. This approach may be accomplished for bP via alloying phosphorus with its group 15 neighbour, arsenic (As). By partial substitution of phosphorus with arsenic precursors in typical black phosphorus (bP) *syntheses, so-called black AsP (bAsP) is formed with the orthorhombic puckered honeycomb lattice structure of bP, but with a fraction of the P atoms replaced by As atoms over a continuum of As:P ratios.*

Here, we expand nanoribbon formation to bAsP, creating the first every alloyed 1D nanoribbons. By ionically etching the layered crystal black arsenic−phosphorus using lithium electride followed by dissolution in amidic solvents, solutions of AsPNRs are formed. The ribbons are typically fewlayered, several micrometers long with widths tens of nanometers across, and both highly flexible and crystalline. The AsPNRs are highly electrically conducting above 130 K due to their small bandgap (ca. 0.035 eV) [4], paramagnetic in nature, and have high hole mobilities, as measured with the first generation of AsP devices, directly highlighting their properties and utility in electronic devices such as near-infrared detectors, quantum computing, and charge carrier layers in solar cells.

The AsPNRs are synthesised using a two-step method. Firstly, bAsP is intercalated with alkali metal ions, followed by exfoliation to form stable liquid dispersions of AsPNRs [5]. This scalable approach allows us to isolate high quality individual AsPNRs from bulk bAsP. By comparing different fractions of As in the initial bAsP, we can probe the mechanism of formation and tune our materials. Interestingly, the intermediate intercalation compound has been shown to be superconducting, a property we are currently investigating alongside Cambridge Cavendish Laboratory.

High-Brightness Fluorophores (HBFs) for Rare Antigen Detection Nazmiye Yapici[1,2], Estelle Chiari[2], Xiuling Liu[1,2], Catherine Pilon[2], Daniel Gibbs[2], Rodney Oakley[2], Dongyan Zhang[1] and Yoke Khin Yap[1]; [1]Michigan Technological University, United States; [2]Stabilux Biosciences, United States

Cancer immunotherapy has revolutionized in recent years thanks to cutting-edge tools that have empowered researchers to understand adaptive immune systems better. Flow cytometry, for example, has become indispensable for immunological research and has evolved from a single to 50-color parameters. This multiplexing capability in flow cytometry is decisive for understanding complex tumor samples. However, there is a delicate balance between the quality and quantity of data. Spillover and auto-fluorescence have continued to limit multi-color measurement. Brighter dyes or fluorophores with high resolution are essential to ensure high-quality data. Introducing a breakthrough in our field, we present a new series of high-brightness fluorophores (HBFs) that promise to revolutionize rare antigen detection. Our NovoLux646, for instance, when conjugated with anti-human CD127, delivers a staining index (SI) of 107, a staggering 20X higher than that from Anti-CD 127-APC. NovoLux646 also outshines AlexaFluor647 in brightness. We also evaluated our violet NovoLux420 for CD 127 detection, achieving an SI as high as 222 from Anti-CD 127- NovoLux420, 16X brighter than cFluor420. These results hint at the potential of our HBFs to enable the detection of many more rare antigens, sparking a new era in immunological research. Details of our findings will be discussed at the conference.

Chirality Magic from Magic-Sized Clusters *Richard Robinson[1,2]; [1]Cornell University, United States; [2]Kavli Institute at Cornell for Nanoscale Science, United States*

Magic-sized clusters (MSC) are identical CdS inorganic cores that maintain a closed-shell stability, inhibiting conventional growth processes. Because MSCs are smaller than nanoparticles, they can mimic molecular-level processes, and because of their small size and high organic-ligand/core ratio, MSCs have “softer” inter-particle interactions, with access to a richer phase diagram beyond the classical close packed structures seen with larger particles. In this talk I will highlight some remarkable behavior we have recently found in their ability to isomerize and their ability to self-organize into hierarchical assemblies with optical activity. These MSCs display a surprising ability to self-organize into films with hierarchical assembly that spans over seven orders of magnitude in length scale. Meniscus-guided evaporative assembly of these nanoclusters results in large-scale homochiral domains with anisotropy values (g-factors) near 0.15 – among the highest reported for all semiconductor particles – and domains surpassing 6 mm^2. Through Mueller matrix polarimetry spatial mapping we unravel the mechanism behind the formation of the self-organized chiral domains. Our hypothesis is that the fibrous nanocluster hybrid materials undergo pinning and twisting under fluid flow, leading to helical assemblies. Beyond optical properties, the multiscale self-organization behavior of these MSCs displays similarities to biosystems, providing a new platform for the design and study of materials.

Roles of Metal-Ligand Complexes for the Controlled Synthesis of Thiolate-Protected Metal Nanoclusters *Ji Soo Kim[1,2], Taeghwan Hyeon[1,2] and Jungwon Park[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)*

Synthesis of atomically uniform nanoparticles is crucial in various fields due to their strong structure-property relationship. In this perspective, metal nanoclusters (NCs) have garnered significant interests as they are potential candidates to be synthesized with perfect uniformity. Metal NCs comprise metal atoms and ligands with a precise number from less than ten to a few hundred, endowing them with size less than 2~3 nm. Previous studies have predicted that such ultrasmall metal NCs can be synthesized with negligible heterogeneity in their number of metal atoms. However, it still remains elusive how the metal NCs can actually acquire high monodispersity in atomic level. It is because the formation mechanism of metal NCs, especially in terms of precursor chemistry, has been less understood. Herein, we investigate the synthetic principle of thiolate-protected metal NCs by controlling the formation of metal-thiolate complexes, actual precursors to metal NCs. Firstly, we reveal that the reaction between Au salts and thiol ligands governs the amount and coordination chemistry of Au-thiolate complexes, which alters their reduction kinetics and the uniformity of the finally produced Au NCs. Secondly, we show that such relationship between complex formation and monodispersity of NCs can be widely applied to the controlled synthesis of various metal NCs composed of Ag, Pt, Pd, or Rh. Finally, we discover that the structure of thiol ligands determines the stability of Au-thiolate complexes, which results in the different amount of $NaBH_4$ required for the controlled synthesis of $Au_{25}(SR)_{18}$ NCs. Our findings offer a molecular-level insight into the understanding of synthetic mechanism of metal NCs and general principles for their controlled synthesis.

Atomistic Self-Assembly of Nanostructure *Nicola Gaston; The MacDiarmid Institute for Advanced Materials and Nanotechnology, New Zealand*

The manipulation of interatomic interactions for structural self-assembly is a seductive promise of nanotechnology, most tantalisingly made evident by biological examples in nature. Much of the promise of sustainability in materials science comes from the idea of such structural control being able to be achieved at low energetic cost.
At the risk of anthropomorphising atoms, this talk will present some examples of how, by developing an understanding of how particular atoms want to behave, we can manipulate structure by proxy. Not through forcible manipulation of atoms, but through understanding their environmental preferences, and how these change through many-body interactions as they assemble.
The use of low-temperature liquid metals, such as gallium, as media for the dilution of other metals has led to an increasing variety of examples of how temperature- and concentration-dependent interactions can be used to direct the self-assembly of nanostructure, with astonishing precision, resulting in novel pattern formation [1]. This talk will introduce the use of ab initio molecular dynamics for the elucidation of the mechanisms of structural

formation, whether via the differential mobility of dopant metal atoms [2], or due to the formation of structure at the surface of the liquid metal [3]. The concentration-dependence of the alloy behaviour will also be discussed [4]. Finally, the mechanism of nanocrystal formation within liquid metals will be discussed, based on ab initio calculations [5], giving insight into the atomistic self-assembly process.

Computational Insights and Predictions into Atomic Substitutions of Keggin-Type Nanoclusters

Sara E. Mason; Brookhaven National Laboratory, United States

This talk will present our computational approach to understanding and predicting the formation, structure, and reactivity of these complex nanoclusters, which are pivotal in applications such as water purification and contaminant transport.
Our research has focused on the use of density functional theory (DFT) and thermodynamic analysis to explore the substitution reactions of heteroatoms in MAl12 Keggin nanoclusters, where M can be Al, Ga, Ge, among others. By analyzing the energetics and geometric properties of these substitutions, we have developed predictive models that guide experimental efforts to isolate new nanocluster species. For instance, our DFT calculations reveal that single-atom Ge substitution in the ε-isomer facilitates the formation of the largest Keggin-type cluster, Ge4Al48, by activating deprotonation at key surface sites, crucial for the self-condensation process.
Additionally, our computational studies have provided insights into the reactivity trends of these nanoclusters, particularly in relation to anion adsorption. We have correlated bond length changes and adsorption energy values with experimentally observed oxygen-isotope exchange rates, demonstrating that Ga, Al, and Ge substitutions lead to significant differences in reactivity. Our findings suggest that the pKa of anions interacting with these nanoclusters plays a critical role in their crystallization and stability.
Moreover, we have successfully predicted and confirmed the formation of novel mixed Al/Cr Keggin-type nanoclusters, where Cr^{3+} substitution occurs preferentially at octahedral sites. This substitution pattern alters the surface reactivity and may influence the binding of external cations, as evidenced by the unique placement of Na+ in Cr3+-substituted structures.
The talk will also cover the synthesis and structural characterization of new Ga-substituted polyaluminum species, δ-$GaAl_{12}$ and $Ga_{2.5}Al_{28.5}$, which were crystallized from partially hydrolyzed solutions. Our DFT studies corroborate the experimental findings, showing a preference for Ga^{3+} substitution in tetrahedral sites and the role of rotated trimers in driving cluster formation.
These computational insights enhance our understanding of the fundamental chemistry behind Keggin-type nanoclusters and provide a robust framework for the design and synthesis of novel materials with tailored

properties for specific applications.

Precision Synthesis of Semiconductor Nanoclusters—Merging Material and Molecular Chemistry *Chenjie Zeng; University of Florida, United States*

Colloidal semiconductor nanocrystals are complex materials, with packing of atoms in the core and bonding of molecules on the surface. Thus, atomic-level control of nanocrystals calls for the merging of material and molecular chemistry at the nanoscale. Here, I will present our recent progress in combining coordination, cluster, and colloidal chemistry to achieve the precision synthesis of atomically defined semiconductor nanoclusters. The development of precise nanoscale reactions allows us to answer some important questions in semiconductor nanochemistry, including (i) how the surface of nanocrystals is collaboratively passivated by different types of ligands, (ii) the origin of chirality and polarity in semiconductor nanostructures, (iii) the precise correlation between the optical properties and electronic structures, and (iv) the atomic level insights into the intricate nanoscale reaction mechanisms. We expect that precision nanosynthesis will provide a designable approach to access a library of atomically precise semiconductor nanocrystals with tailored properties, thus enhancing their existing applications or enabling emergent ones.

3:45 PM *NM02.03.02
Co-Crystals of Atomically Precise Nanoclusters with Organic Macrocycles *Jarad A. Mason, Yingwei Li, Grant Stec, Hong Ki Kim, Surendra Thapa, Shao-Liang Zhen and Arthur McClelland; Harvard University, United States*

Atomically precise nanoclusters combine the unique, size-depended properties of nanoparticles with the structural and chemical uniformity of molecules, making them powerful building blocks for the synthesis of functional nanomaterials. Here, we discuss a strategy to assemble nanoclusters into solid-state materials with tunable structures and properties by leveraging supramolecular interactions mediated by charged organic macrocycles. The high level of structural control afforded by the resulting nanocluster-organic ionic cocrystals allows cluster packing and the orientation of cluster surface ligands to be controlled through the judicious design of macrocycles with specifically tailored size, symmetry, and ionic charge. When the organic macrocycle is appropriately matched to the nanocluster, for example, this enables chirogenesis—the emergence of chirality from an achiral organic molecule and an achiral inorganic nanocluster—and leads to large solid-state chiroptical effects. Broadly, we will describe how our approach could provide access to a new phase space of highly tunable atomically precise nanomaterials with unique properties and functions.

4:15 PM NM02.03.03
Insights of the Efficient Hydrogen Evolution Reaction Performance in Bimetallic Au_4Cu_2 Nanoclusters *Aarti Devi[1], Harpriya Minhas[2], Lipipuspa Sahoo[1], Biswarup Pathak[2] and Amitava Patra[1,3]; [1]Institute of Nano Science and*

Technology, India; [2]Indian Institute of Technology Indore, India; [3]Indian Association for the Cultivation of Science, India

The design of efficient electrocatalysts for improving hydrogen evolution reaction (HER) performance using atomically precise metal nanoclusters is an emerging area of research. Traditional nanoparticles lack atomic-level precision in size and alloy composition, making it challenging to correlate structure and properties accurately. Ligand-protected metal nanoclusters (NCs) with atomic-level precision, ultrasmall sizes of approximately 2 nm, and unique properties, have garnered considerable attention for catalytic applications. However, bimetallic nanoclusters could potentially offer improved catalytic activity and selectivity compared to their monometallic NCs due to the synergistic effects of heteroatoms. Here, we highlight the superior efficiency in catalyzing the HER of bimetallic Au_4Cu_2 NCs compared to monometallic Au_6 NCs and Cu_6 NCs. Bimetallic Au_4Cu_2/MoS_2 composite exhibits excellent HER catalytic activity with an overpotential (η_{10}) 155 mV vs reversible hydrogen electrode observed at 10 mA/cm^2 current density. The improved HER performance in Au_4Cu_2 NCs is due to the increased electrochemically active surface area (ECSA) and the Au_4Cu_2 NCs exhibit better stability than Cu_6 and Au_6 systems and bare MoS_2. This augmentation offers a greater number of active sites for the favorable adsorption of reaction intermediates. Furthermore, by employing XPS and Raman analysis, the kinetics of HER in Au_4Cu_2/MoS_2 composite were elucidated, attributing the favorable performance due to the better electronic interactions occurring at the interface between Au_4Cu_2 NCs and MoS_2 substrate. Theoretical analysis reveals that the inherent catalytic enhancement in Au_4Cu_2/MoS_2 is due to favorable H atom adsorption over it and the smallest Gibbs Free Energy change value. The downshift in the d-band of the Au_4Cu_2/MoS_2 composite influences the binding energy of intermediate catalytic species. This new catalyst sheds light on the structure-property relationship for improving electrocatalytic performance at the atomic level.

SESSION NM02.04: Atom Precise Two-Dimensional Materials
Session Chairs: Andre Clayborne and Matthew Jones
Tuesday Morning, December 3, 2024
Hynes, Level 1, Room 105

9:15 AM *NM02.04.01
***Two-Dimensional Superatomic Semiconductors** Xavier Roy; Columbia University, United States*

Over the past 20 years, two-dimensional (2D) materials have garnered significant attention due to their exceptional physical, mechanical, and chemical properties, as well as our ability to seamlessly incorporate them into various devices. This presentation presents our recent advancements in the development of the next generation of 2D materials. We discuss our efforts to assemble atomically defined clusters of atoms, which we refer to as "superatoms", into hierarchical 2D structures. These superatoms mimic the role of atoms in conventional 2D "atomic" solids, resulting in remarkable material properties. We introduce the new carbon allotrope graphullerene and the superatomic semiconductor $Re_6Se_8Cl_2$. We highlight recent synthetic breakthroughs and explore the distinctive transport behaviors that emerge due to the atomic precision of the 2D lattice and the specific interactions between these superatomic building blocks.

9:45 AM NM02.04.02
***Generation of Ordered Atomic Gold Nanowires Via Tip-Enhanced Terahertz Field** Sheng Hung Lee[1], Woei-Wu Pai[2] and Tyler Cocker[1]; [1]Michigan State University, United States; [2]National Taiwan University, Taiwan*

We report an innovative way of generating gold single-atom-wide nanowires through a purely optical method, using tip-enhanced terahertz (THz) radiation in a scanning tunneling microscope. Our finding highlights ordered nanostructures could be fabricated by ultrafast THz pulses. The nature of the single-atom gold nanowires is verified by scanning tunneling spectroscopy from the dispersion of 1D confined states. Furthermore, we observe a previously unknown surface (2x2) superlattice on Au(111), which is overlaid on the herringbone reconstruction, accompanying the nanowires. The formation mechanism is not yet fully understood but plausible scenarios will be discussed.

10:00 AM BREAK

SESSION NM02.05: Advanced Characterization and Structure Determination

10:30 AM NM02.05.01

Dual-Emissive DNA-Templated Silver Nanoclusters with Emission in the Second Near-Infrared Window *Anna Gonzalez Rosell[1], Vanessa Rück[2], Mikkel B. Liisberg[2], Cecilia Cerretani[2], Tom Vosch[2] and Stacy Copp[1]; [1]University of California, Irvine, United States; [2]University of Copenhagen, Denmark*

Deep tissue biological imaging is currently hindered by the lack of small, bright, biocompatible fluorophores that emit in the second near-infrared window (NIR-II; 1,000-1,400 nm), where tissues are transparent up to a few centimeters in depth. DNA-stabilized silver nanoclusters (Ag_N-DNAs) hold significant potential for overcoming this challenge. Ag_N-DNAs are composed of a 10-30 Ag atom silver core that is stabilized by 1-3 DNA oligomers, whose DNA sequence selects the size and shape of the Ag_N core. Thus, Ag_N-DNAs have sequence-defined photophysical properties, including bright visible to NIR-I (700-1,000 nm) emission colors. Ag_N-DNAs with visible emission are well-studied, and correlations of nanocluster size and charge to fluorescence wavelengths have been established.[1] More recently, Ag_N-DNAs with dual green and red/NIR-I emission have been reported.[2,3] The structure-property relationships of these emitters are not yet well-understood.
This study reports the photophysical properties of the first known dual-emissive Ag_N-DNAs with NIR-II emission and provides insights to guide conjugation to biomolecules for targeted staining that will enable deep tissue imaging technologies. Using high throughput experiments, we discovered two Ag_N-DNAs that have the same peak emission wavelength and are templated by DNA oligomers that differ by only one base. Using high performance liquid chromatography and high-resolution electrospray mass spectrometry, we determine the molecular formulae of these nanoclusters to be $(DNA)_2[Ag_{17}]^{11+}$. Ultrafast spectroscopy reveals that the $(DNA)_2[Ag_{17}]^{11+}$ exhibit two distinct emission pathways resulting in nanosecond-lived NIR-I fluorescence and microsecond-lived NIR-II photoluminescence. Both nanoclusters resisted crystallization, preventing X-ray diffraction to solve their crystal structures. Instead, we examined how variations in nucleobase sequence alter peak emission wavelengths. We find that adding a single adenosine or thymidine at the 5' end of the DNA oligomer maintains the composition and photophysical properties of the Ag_N-DNA, suggesting a potential site for nanocluster conjugation in future biomedical applications.

STM Imaging of Gold Atoms Growth into 1D, 2D and 3D Islands on a TiO2(110)-1x1 Surface at Elevated Temperature *Xiao Tong; Brookhaven National Laboratory, United States*

The lack of knowledge about the kinetics and dynamics of nano metal cluster growth or sintering on oxide surfaces at the atomic level hinders the control of cluster properties and the improvement of industrial catalytic performance. In this work, we used ultra-high vacuum scanning tunneling microscopy to determine and characterize the thermal growth of Au atoms into 1D structures, 2D sheets, and 3D islands on a TiO2 (110)-1x1 surface at elevated temperatures. The dynamics of structural evolution, migration, and coalescence for 1D and 2D structures were also observed in real time.

3D Electron Microscopy Characterization of Nanoscale Materials for Catalysis and Optoelectronics Under Realistic Conditions *Sara Bals, Kellie Jenkinson, Irina Skvortsova, Tom Stoops, Nadine Schrenker, Deema Balata, Annick De Backer and Sandra Van Aert; University of Antwerp, Belgium*

Electron tomography is a powerful tool to explore the morphology, 3D structure, and composition of a broad range of (nano)materials. Although these experiments are already at the state-of-the-art, several open questions remain. These questions are often related to the fact that 3D characterization by TEM is typically performed using the conventional conditions of a TEM: ultrahigh vacuum and room temperature. Since it is known that the morphology and consequently, the activity of nanomaterials will transform at higher temperatures or pressures, this poses a fundamental limitation. It is therefore not surprising that much effort has been devoted to monitoring nanoparticle transformations upon application of external stimuli by TEM.

In situ TEM characterization can be performed either using a dedicated environmental TEM or through a wide variety of holders based on MEMS devices. In this manner, we were able to characterize strong metal support interaction for catalytic Ni nanoparticles on TiO_2 supports under operando conditions [1]. However, understanding the complex changes for anisotropic nanosystems in 3D rather than in 2D remains very challenging and conventional electron tomography techniques are no longer applicable. By combining aberration corrected electron microscopy with a quantitative interpretation and modelling approaches [2], we can perform quantitative measurements of the coordination numbers of the surface atoms of catalytic nanoparticles at high temperatures and in gaseous environments.

An additional challenge is related to the beam sensitivity of specific nanostructured materials. For example, metal halide nanocrystals are extremely sensitive to the electron beam. In order to distinguish degradation effects caused by the electron beam from those related with external triggers, new low-dose electron microscopy techniques need to be applied. One such technique exploits the use of four-dimensional scanning transmission electron microscopy, a technique during which for every scan position a diffraction pattern is collected. In this manner, we were able to investigate $FAPbBr_3$ nanocrystals and reveal an elongation of the projected Br atomic *columns. This is caused by an anisotropic displacement of the Br anions perpendicular to the Pb-Br-Pb bonds, leading to local distortions in an on-average cubic crystal structure. Finally, we also used low-dose in situ electron microscopy to understand the role of defects in the stabilization processes of doped metal halide perovskites.*

Real-Time Quantum Dynamics in Plasmonic Nanoparticle Arrays *Bryan M. Wong; University of California, Riverside, United States*

In this talk, I will present a unique analysis of electronic couplings that mediate excitation energy transfer (EET) in plasmonic nanoparticle arrays using large-scale quantum dynamical calculations. To capture the intricate electronic interactions in these large systems, real-time, time-dependent, density functional tight binding (RT-TDDFTB)[1-3] is used to characterize the quantum-mechanical efficiency of EET in plasmonic nanoparticle chains with subnanometer interparticle spacings. In contrast to classical electrodynamics methods, our quantum dynamical calculations give qualitatively different results for EET when the interparticle spacing between the nanoparticles of the nanoantenna is decreased. Most notably, we show a sudden drop in EET efficiencies as the interparticle distance decreases, which we attribute to the onset of quantum charge tunneling between the nanoparticles.[1,2] We further characterize this abrupt change in EET efficiency through visualizations of both the spatial and time-dependent charge distributions within the nanoantenna, which provide an intuitive classification of the various types of electronic excitations in these plasmonic systems. Finally, while the use of classical electrodynamics methods has long been used to characterize complex plasmonic systems, our findings demonstrate that quantum-mechanical effects can result in qualitatively different (and sometimes completely opposite) results that are essential for accurately calculating EET mechanisms and efficiencies in these nanoparticle systems.

Atomistic Modeling of Iron Oxide Nanoparticle/Nanocluster Interaction with Shewanella Oneidensis Cytochromes and Electron Transfer Kinetics *Pranab Sarker, Jiahuiyu Fang, Shuting Zhang and Tao Wei; University of South Carolina, United States*

Shewanella oneidensis is a metal-reducing bacteria that is capable of reducing dissimilatory metal oxides by *transferring electrons through transmembrane cytochromes. Electron transfer (ET) occurs from the interior of the cell to the exterior through the network formed by the hemes in the proteins. In this work, we use an iron oxide nanoparticle/nanocluster to represent the extracellular mineral and study its interaction with the proteins as well as the outer membrane of S. oneidensis. This work investigates the interaction of iron oxide nanoparticles/nanoclusters (NP/NC) with MtrF, an extracellular decaheme cytochrome, and the MtrCAB complex, a transmembrane protein with three subunits and 20 hemes, using a combination of all-atom molecular dynamics simulations and kinetic Monte Carlo simulations. The protein corona formation in bulk water and the corresponding ET kinetic behavior are studied. The effect of the size and curvature of NPs/NCs on protein adsorption and ET behaviors of proteins is examined. Additionally, the interaction of NP/NC with the outer membrane, composed of a lipid bilayer and multiheme cytochrome proteins, is investigated. The stability of the protein complex and ET behavior are also analyzed. This work has important applications in biotechnology.*

Understanding Coherent and Spin-Polarized Dynamics in Metal Nanoclusters *Kenneth L. Knappenberger, Nathanael Smith, Juniper Foxley and Daniel Heintzelman; The Pennsylvania State University, United States*

The influence of atomic- and molecular-level structure on chiroptical excitation, spin, and electron dynamics in monolayer-protected clusters (MPCs) will be described. Gold nanoclusters spanning from sub-to-two nanometer –diameters show a diverse range of magneto-chiral excitation behaviors. The visible magnetic circular dichroism (MCD) spectrum of $Au_{144}(SC_8H_9)_{60}$ *includes nineteen distinct peaks. Among these, signatures of paramagnetic, diamagnetic, and mixed charge transfer excitations are all resolved. The results indicate that structurally well-defined gold clusters near the onset of metallicity present many opportunities for understanding and tailoring spin properties at metal-ligand interfaces. Of particular interest, the influence of metal-ligand vibrations on the persistence of spin-polarized excitation has been examined. Signatures of strong vibronic coupling between metal electrons and ligand vibrations were detected for paramagnetic excitation in gold MPCs. Using ultrafast multi-dimensional spectroscopy, the influence of vibrational coupling on coherence lifetimes was resolved with both state and mode specificity. The results demonstrate the capability of advanced spectroscopic methods for determining structure-property correlations in metal nanoparticles.*

Analysis of Nano-Bio Interfaces with Multi-Scale Molecular Simulations *Qiang Cui; Boston University, United States*

I'll discuss our recent analyses of nano-bio interfaces with multi-scale molecular simulations. In particular, we will discuss the integration of coarse-gained and atomistic molecular dynamics simulations to analyze how nano-sized plastic particles (nanoplastics), which originate from the breakdown of microplastics, drive changes in the membrane structure and dynamics. Using uncrosslinked polystyrene nanoparticles as a model for nanoplastic *particles, Laurdan fluorescence spectroscopy experiments have observed a concentration dependent blue shift that would typically be interpreted as a fluid to gel membrane phase transition for traditional nano-bio interactions. Our molecular simulations suggested instead that the flexible, hydrophobic nature, of polystyrene nanoparticles allows them to penetrate and dissolve into the membrane interior leading to a dehydration of Laurdan probe molecules that confounds traditional interpretation of Laurdan fluorescence. We then discuss the use of non-linear spectroscopies to further probe the mechanism at the molecular scale. Some of the computational approaches we develop might be applicable to the mechanistic analysis of nanoparticle assembly as well.*

Computational Tuning of Gold Nanoclusters for Targeted Cancer Therapy *María Francisca Matus and Hannu Häkkinen; University of Jyväskylä, Finland*

Ligand-protected gold nanoclusters (AuNCs) are ideal candidates for developing new targeted drug delivery nanosystems with a unique control on their surface functionalities, which can help achieve enhanced delivery performance.

We designed and characterized a set of twenty-eight targeted Au144 nanoclusters through extensive classical molecular dynamics (MD) simulations to be potentially employed as combination therapy in gastric cancer treatment. The proposed AuNCs are functionalized with (i) anti-cancer drugs and (ii) Arginine-Glycine-Aspartic acid (RGD) peptides as targeting ligands, and we studied the role of ligand ratio in their optimal structural conformation using atomistic models. The most promising AuNCs were then ranked based on their binding free energy using umbrella sampling simulations to obtain the optimal formulations.

The results show that the peptide:drug ratio is a crucial factor influencing the potential targeting ability of the AuNCs. In most cases, they exhibit a higher affinity for the cell receptor when they contain more drugs than targeting peptides on the surface, but they must be assessed on a case-by-case basis.

This work demonstrates the broad applicability of MD simulation tools for studying the functionalization of these nanomaterials and provides essential information at the atomic level for ligand tuning and improved targeting, which can serve as a valuable guide in the experimental phase. The findings of this study could potentially pave the way for the development of more effective and targeted drug delivery systems.

Ligand Dynamics on Gold Nanoclusters *Christopher J. Ackerson; Colorado State University, United States*

Gold nanoclusters comprised of ~10 to ~500 inorganic atoms are often stabilized with a ligand shell. The ligand shell (organothiols, phosphines, acetylides, NHCs) both protects the gold cluster cores from sintering and provides chemical identity to the surface of the cluster. Ligands on such clusters are surprisingly dynamic, participating in facile ligand exchange reactions with mechanisms that incldue associative exchange, inter-cluster exchange, intra-cluster exchange and sometimes dissociative exchange. This talk will summarize our recent findings on topics such as mechanism and kinetics of acetylide for thiol exchange, the role of ligand rotational conformations in exchange, and practical methods for suppressing ligand exchange, which may be important in *biological applications of gold clusters, where thiols such as glutathione are ubiquitous.*

11:00 AM ^NM02.08.02

Photochemical Synthesis and Light-Activated Purification and Characterization of Nanoclusters *Kevin Stamplecoskie; Queen's University, Canada*

Many synthesis methods for isolating monolayer protected gold (and other metal) clusters provides distributions of sizes with various number of metal atoms and ligands. This is especially the case with aqueous metal clusters. Further, most biomedical studies investigate the properties/effects of mixtures of clusters, making it difficult to attribute specific optical, electronic, or reactivity properties of MPCs to specific clusters of interest.
In this talk, photochemical methods for preparation of MPC will be discussed. The light activated synthesis of Au clusters followed by an accelerated size-focusing step using a sequence of peptides as a ligand will be presented. Numerous methods have been reported for size focussing. Herein, the mechanism of photo-induced purification (size-focusing) will be discussed and some of the merits of this approach in relation to other size-focusing techniques.
The use of fluorescence excitation-emission matrix (EEM) spectroscopy and PARAFAC analysis to assess optical purity will also be presented.[1,2]

Automatic Atomic Structure Determination Through X-Ray Absorption Spectroscopy (EXAFS) *Yanna Chen[1,2] and Shelly Kelly[1]; [1]Advanced Photon Source, United States; [2]Canadian Light Source, Canada*

Extended x-ray absorption fine structure (EXAFS) has become a widely used technique for atomic structure determination. Fourier transformation connects EXAFS in k-space and R-space. However, determining the appropriate k range for the transformation can be challenging. In this study, we present an automatic method to determine the k range using the Larch package and a Python program. The first step is to evaluate the maximum value in the k range (k_{max}) by estimating noise for different k_{max} values. The k_{max} is determined by applying an empirical noise threshold of the second derivative of the noise, which is the point the noise level changes dramatically. Using the obtained k_{max} value, the first shell is then modeled to determine E_0 and to estimate the minimum value for the k range (k_{min}) through the R-factor of the fit. The k_{min} value is identified as the point where the R-factor is minimized. Our method was tested on various typical data sets and resulted in suitable k ranges for Fourier transformation and accurate first-shell fitting. This approach helps to avoid unreliable and irreproducible data analysis, especially for noisy data from the diluted samples.

Intelligent Tumor Microenvironment Responsive Nanoclusters Assembled from Heteroatom-Doped-Carbon Dot and Mn^{2+} for Imaging and Cooperative Cancer Therapy *Wubshet M. Girma[1,2]; [1]Donghua University, China; [2]Wollo University, Ethiopia*

For effective brain glioma tumor diagnosis and cooperative therapy, development of innovative nanomedicine formulation is urgently needed. Due to the existence of blood-brain barrier (BBB), therapeutic drugs or contrasting agents entering into the intracranial tumor sites remain very limited, significantly hampering its theranostic efficacy. Herein we report tumor microenvironment (TME) activated all-in-one approach for diagnosis and therapeutic applications of brain glioma tumor. A multifunctional macrophage membrane (MAs) coated nanocluster (NCs) assembled from heteroatom-doped carbon dots (h-CDs) and Mn^{2+}, as a novel nanoplatform is proposed. h-CDs offered straightforward to enhance its magneto-fluorescence properties, depletion of glutathione (GSH) in the tumor area, for chemodynamic therapy (CDT) via $Mn^{/2+}$-mediated Fenton-like reactions. The reactive oxygen species (ROS)/acidic pH in TME activated the release of Mn^{2+}. The macrophage membrane coating renders the h-CDs/Mn^{2+} NCs with prolonged blood circulation time, and enhanced tumor accumulation due to the homing properties endowed by MAs, to boost BBB permeation and glioma targeting for specific theranostics. The redox-responsive dissociation of NCs to single CDs enabled the dynamic “fluorescent turn-on” imaging and Mn^{2+} mediated MR imaging. MAs membrane-coated h-CD/Mn@MAs clusters, rendered them with BBB crossing ability, allowing for cooperative theranostics of orthotopic brain glioma. The developed TME-responsive NCs theranostic platform will display immense potential to be eventually translated for clinical applications.

NM02.09.02

Analysis of the Crystallization Process of Pt Single Atoms on Graphene *Kenji Yamazaki, Makoto Moriya and Ikeda Yunoske; Hokkaido University, Japan*

Crystallization is a widely observed phenomenon in daily life, within biological systems, and in industrial processes, but its detailed mechanism at the atomic level remains a topic of ongoing discussion. We have achieved single Pt atoms adsorbed on graphene by plasma sputtering. Graphene films were synthesized by a CVD method on a copper substrate (Alfa Aesar, 99.8%, thickness: 25 μm). After the etching of Cu substrate by 100 mM ammonium peroxodisulfate solution, the specimen was rinsed thoroughly with distilled water. Next, it was transferred on a carbon-supported Cu TEM grid. We deposited dispersed Pt single atom on graphene by magnetron spattering. We use a pure Pt thin film (t = 0.1mm) for the spatter. The chamber was evacuated to 4.5 Pa in air. The metal Pt atoms were spattered by strong magnetic and electric fields between a Pt target and the TEM grid. We deposited single-atom Pt dispersion by short-pulsed spattering. In order to observe the translational motion of Pt single atoms on graphene, this study conducted continuous imaging using aberration-corrected STEM. We have shown that Pt atoms are dominantly adsorbed near the step edges of nanoscale graphene stacked on monolayer pristine graphene, which is called nanographene, and hardly adsorbed on the terraces. In addition, we found that the Pt 5dxy-orbital forms a bond to the step edge. However, Pt atoms may cause aggregation from single atoms into 2D clusters or 3D nanoparticles at high concentrations. Single Pt atoms on graphene moved across the surface under electron beam irradiation and also gradually aggregated. We found that graphene supporting Pt single atoms becomes damaged and its structure changes under electron beam irradiation, leading to increased mobility of the Pt single atoms. On the other hand, when the structure of the graphene remains stable, the movement distance of many Pt single atoms between images is smaller than the nearest-neighbor distance of carbon atoms in graphene (1.4 Å). Furthermore, the motion of Pt single atoms was suppressed when nitrogen was doped in graphene. By measuring the number of Pt single atoms before aggregation, we were able to analyze how *many atoms are required to form Pt nanoparticles with a three-dimensional structure. Nanoparticles with a three-dimensional structure incorporated additional Pt single atoms and crystallized on graphene. We were able to directly observe the entire process from assembly of single atoms to crystallization. On the day of the presentation, we also plan to report on the analysis results regarding nucleation and the critical nucleus.*

NM02.09.03

Hierarchical Zeolite-Based Catalysts for Tandem One-Step Renewable Diesel Production via Fischer-Tropsch Synthesis

Binchao Zhao[1], Chunxiang Zhu[1,2], Fangyuan Liu[1] and Puxian Gao[1]; [1]University of Connecticut, United States; [2]3D Array Technology LLC, United States

The demand for low carbon biofuels such as renewable diesel (RD) and sustainable aviation fuel (SAF) is increasing drastically worldwide as driven by the shift towards cleaner energy and the imperative need to reduce carbon footprint while maintain the balance of transportational energy landscape toward the decarbonization goal 2050. Fischer-Tropsch synthesis (FTS), converting biomass-derived syngas into long-chain hydrocarbons, is a promising route for sustainable RD and SAF production. However, the liquid hydrocarbons obtained from FTS usually require additional refinements and upgrade treatments, such as hydro-processing, distillation, and fractionation, prior to further application. Here, through rational materials design and manipulation, we have formulated a multi-layer hierarchical monolithic catalyst which can integrate the syngas-to-wax hydrocarbons and wax hydrocarbons-to-diesel fuel conversions in a tandem one-step catalysis process for sustainable drop-in RD production via FTS. The multi-layer hierarchical catalyst comprises of a bottom layer of cobalt oxide (Co_3O_4) dispersed on γ-alumina (γ-Al_2O_3) support, covered by a top zeolite layer. The influence of zeolite type (ZSM-5 and Zeolite Y), ion-exchange cations (H, Na, K, La, and Ce), and reaction parameters on FTS performance have been investigated. Results show that multilayer catalysts exhibit high diesel selectivity under 220 °C at 20 bar conditions. The produced RD possesses high cetane number and low aromatic content with drop-in fuel potential. For the catalyst formulation, the ion-exchange cations and their dispersion extent play an important role in product selectivity and carbon number distribution. This work provides an energy efficient and cost-effective strategy for sustainable drop-in diesel fuel production with easy catalyst scalability and high market demand.

NM02.09.04

Homogeneous Bimetallic AuPd Nanocatalysts Decorated TiO_2 Nanohelices for Selective Toluene Gas Sensor

Hyeonwoong Hwang, Hanseo Bae, Eunji Ahn, Bongwon Kim, Hyeonho Cho, Donghwa Lee, Sei Kwang Hahn and Jong Kyu Kim; Pohang University of Science and Technology, Korea (the Republic of)

Functionalizing metal oxide (MOX)-based gas sensors with nanocatalysts (NCs) can significantly enhance gas sensitivity and reduce operating temperatures. Especially, bimetallic NCs decorated on MOX have garnered great attention due to their unique catalytic properties controlled by tailoring the composition, atomic ordering, and size. However, it is hard to control the atomic ratio of bimetals with typical synthesis methods, leading to the mixture phase of monometallic and bimetallic NCs with random compositions. This heterogeneity obscures the understanding of the catalytic kinetics with well-controlled atomic compositions of bimetals, acting as the bottleneck of designing highly selective and sensitive MOX-based gas sensors decorated with bimetallic NCs. Herein, we propose a rational strategy to synthesize and decorate bimetallic NCs with homogeneous composition and size on MOX-based gas sensors. AuPd bimetallic NCs were synthesized homogeneously using the Turkevich method, and the NCs were isolated in micelle form through polyethylene glycol (PEG)-conjugation to ensure uniform dispersion. Subsequently, PEG-conjugated AuPd NCs were coated onto vertically aligned TiO_2 nanohelices (NHs) prepared by the oblique angle deposition (OAD) method, followed by rapid calcination for removing the PEG and anchoring the AuPd NCs to the TiO_2 NHs. Owing to the benefits of homogeneous AuPd NCs, the d-band position of the sensing materials was precisely controlled by tailoring the composition ratio of Au and

Pd. For $Au_{55}Pd_{45}$ NCs with a d-band center value of -2.8 eV from the Fermi level (E_F), the adsorption of oxygen (O_{ads}) on AuPd NCs-decorated TiO_2 NHs was maximized, achieving a significant response value ($R_g/R_a \sim 10^6$ at 100 ppm) and a low limit of detection (LoD= 32 ppb) for toluene gas at 200 °C. Further density functional theory calculations confirmed both the selectivity for toluene gas and d-band shift with different composition ratios of Au and Pd. With our homogeneous bimetal NCs decoration method, we believe that sensors with outstanding selectivity and sensitivity can be designed and realized by exploring optimum catalytic combinations, far surpassing traditional gas sensors.

NM02.09.05

Kelvin by Kelvin Controlled Diffusion, Nucleation, Growth and Coarsening Within and Across Different Compartments of an On-Surface Supramolecular Network

Aisha Ahsan[1,2], S.Fatemeh Mousavi[1], Thomas Nijs[1], Sylwia Nowakowska[1], Olha Popova[1], Aneliia Wackerlin[1], Jonas Bjork[3], Lutz Gade[4] and Thomas Jung[2]; [1]Universität Basel, Switzerland; [2]Paul Scherrer Institute, Switzerland; [3]IFM, Sweden; [4]Universität Heidelberg, Germany

Noble gases, with their close-shell structure and their predominantly physisorptive interaction with metals serve as models to understand adsorption, diffusive mass transport and nanocluster nucleation and growth. Our present work roots in stepping up the complexity of the adsorbent surface while keeping noble gas atoms as 'probes' for the on-surface assembly and dynamics of nucleates. Atomically precise on-surface architectures in the form of 2D coordination networks of a N-substituted perylene linked by Cu adatoms have been assembled on Cu(111) single crystal surfaces. By the step-wise increase of the sample temperature in our Ultra High Vacuum (UHV) Low Temperature (LT) Scanning Tunneling Microscope, we gained insight into the unexpected complexity of the adsorption physics and the thermodynamic equilibration between higher binding energy and lower binding energy adsoption sites. As we increase the thermal energy, kT, we clearly observe Xe diffusion between energetically different adsorption sites. Interestingly, the nodes of the network are occupied with higher probability after dosing of Xe into the system, BUT nevertheless 'fall' into the pores of the networks as we increase the thermal energy. This apparent paradox can be attributed to the presence of a high electron confined surface state which effectively repels individual Xe atoms impinging from the source and directs them to the energetically less favourable node sites. With increasing ambient temperature, the system equilibrates and surprisingly allows for Xe atoms in the less-energetically favoured positions to migrate to minimum energy sites where they nucleate. In our studies we have in particular observed that Xe nucleates of small (n<7 Xe atoms) 'evaporate' and fill up those pockets which already host more than 7 Xe atoms. This leads to a 'perfect' coarsening transition in the form that the pores are either completely full (n=12) or remain completely empty. Thereby the added complexity of an on-surface coordination network modifies the surface energy landscape significantly and we can trace the complex re-distribution/re-nucleation and coarsening/growth phenomena.

Within individual pores of the network we show that adsorbates and clusters can be evaporated/re-captured into/from 'gas phases' or 'lattice gas phases'. The participation of different thermodynamic reservoirs to host diffusing Xe is observed to be changing in many steps between 5K to 40K. While only very few Xe atoms are already mobile at 5K after surface adsorption hopping motion between different confinements (0D) and then also along the boundaries of the network (1D) and across the whole network backbone (2D) becomes thermally activated. This gradual activation of different reservoirs for thermodynamically activated diffusion also leads to gradual re-equilibration of Xe atoms which are originally confined in more Energy minimal states of the complex surface potential. After heating to ~40K and cooling back to 5K the Xe atoms are almost exclusively found in the thermally minimal state of 12 Xe atoms filling one pore, a process which we assign to the analogous of Ostwald ripening and coarsening transition which is in the case of these nanometers confined porous network clearly limited in size. By the capability to design on-surface architectures complex functions may be realizable, far beyond the demonstrated capability to adsorb 12 Xe atoms per pore. It may be envisioned that the specific environment of a pore containing specific electronic states is not only a capable absorber, but also a very specific catalytic reaction *environment that can be loaded/unloaded via the diffusion mechanisms, in the specific case for trapping atoms or molecules. Low Temperature Scanning Tunneling Microscopy (LT-STM) studies enriched our knowledge how rare gases behave at atomic level.*

NM02.09.06

Highly Luminescent Indium Phosphide Magic-Sized Clusters via Kinetically Controlled Surface Fluorination

Changhyun Joo, Seongbeom Yeon, Junhui Lee, Yong-Hoon Cho and Himchan Cho; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

InP Quantum Dots (QDs) are promising materials with significant potential as environmentally benign alternatives to toxic Cd-based QDs. However, the high oxophilicity, strong covalent-bonding nature, and steep size-band gap relationship of InP hinder their complete replacement of Cd-based QDs. To address these challenges, post-treatment methods such as HF treatment are commonly employed. Despite these approaches, the complexity of QD surfaces makes it difficult to correlate observed optoelectronic changes to actual surface phenomena. To overcome this issue, a precise atomic-level understanding of surface chemistry is necessary.

Fortunately, InP QDs are known for their nonclassical nucleation, often forming unique intermediates called Magic-Sized Clusters (MSCs) during synthesis. MSCs are atomically precise intermediates with sizes typically between 1-2 nm, exhibiting higher thermodynamic and kinetic stability compared to nanocrystals of the same size. Understanding these intermediates is essential for comprehending the overall behavior of QDs, and the near-monodispersity of MSCs can provide a platform to address the complexity of QDs.

We developed a novel recipe using zinc chloride and benzoyl fluoride to generate HF via a Friedel–Crafts acylation reaction. This approach avoids the harsh conditions of previous methods by kinetically controlling the HF generation rate to prevent MSC degradation. With this novel recipe, we achieved unprecedented luminescence in InP MSCs and confirmed the mechanism through various analyses. Additionally, we demonstrated that the optoelectronic properties of InP MSCs change while their crystal structure remains stable.

We conducted an in-depth analysis of the surface modifications induced by our novel treatment, revealing the mechanisms behind the observed improvements. Our findings highlight the potential for controlling surface defects at the atomic level, suggesting that this approach can achieve superior optoelectronic performance in InP QDs.

NM02.09.07

Synthesis, Characterization and Antibiofilm Activity Against Pseudomonas Aeruginosa of ZnO-Ag Nanocomposite

Fatima S. Alhosani[1], Deema K. Islayem[1], Shamma A. Almansoori[1], Laith Nayfeh[2], Awais Zaka[1], Anna-Maria Pappa[1], Ahmed Yousef[1] and Ammar Nayfeh[1]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]Dunecrest American School, United Arab Emirates

The rise of antimicrobial resistance poses a significant challenge to public health worldwide, necessitating the development of novel materials with potent antimicrobial properties. Two of the most prominent antibacterial nanoparticles (NPs) are silver (Ag) and zinc oxide (ZnO). Silver is commonly used in dentistry, where it damages bacteria by releasing silver ions, generating reactive oxygen species (ROS). ZnO NPs, under UV light, enhance ROS generation due to their photocatalytic activity, amplifying their antibacterial activity. Some nano ZnO materials with sharp edges can disrupt the cell membrane. In this work, we synthesized a ZnO-Ag nanocomposite using a calcination-impregnation method adopted from [1]. We analyzed its properties and composition using TEM-EDS, SEM, AFM, FTIR, and XRD. We then tested its antibacterial and antibiofilm activity against Pseudomonas aeruginosa (P. aeruginosa), a versatile gram-negative bacterium frequently found in soil, water, and hospital environments. This bacterial strain is known to form biofilm, a cluster of bacteria attached to a surface and/or each other and embedded in a self-produced matrix, being more resistant to antibiotics.

The ZnO-Ag material was synthesized using a simple calcination-impregnation method by initially dissolving Zinc Acetate Dihydrate and Silver Nitrate in deionized water at a 2:1 ratio. The mixed solution was stirred thoroughly to ensure homogeneity and then sonicated, producing a solid precursor. This precursor was then placed in a muffle furnace and calcined at 400°C for 1 hour. During the calcination process, the zinc acetate decomposed to form zinc oxide (ZnO), whereas the silver nitrate decomposed to produce silver nanoparticles (Ag), which enabled them to impregnate the ZnO surface, ensuring a high degree of interaction between ZnO and Ag. The resultant ZnO-Ag composite was allowed to cool to room temperature to be further used. TEM-EDX was performed to check the material's chemical composition and gain precise images. Furthermore, XRD was performed to analyze the crystal structure and orientation of the nanomaterial. The material's surface morphology and thickness were analyzed using air topography AFM; the nanocomposite was deposited on a 1cm x 1cm glass slide by spin coating a suspended solution (ZnO-Ag in DI water) and then heating it for 30 minutes. The nanomaterial's thickness was 41 nm, and the surface contained sharp peaks, indicating the nano-composite's potential to penetrate the bacteria using its sharp edges. Further analysis of the material's photocatalytic behavior and an FTIR analysis will be performed.

To verify the material's potential as an anti-bacterial agent, it was first tested against P. aeruginosa using inhibition zone assay. LB agar plate was inoculated with P. aeruginosa, then a small amount of the material solution was dispersed on the agar. After incubating the agar plate at 37 C for 24 hours, it was found that the nanocomposite inhibited the growth of the bacteria in the area where the material is dispersed compared to the control sample where DI water was used. Regarding the material's antibiofilm activity, 1 by 1 cm glass slides were spin coated by 500uL of the suspended nanocomposite, at a concentration of 50 mg/mL . Then, P. aeruginosa was grown on the coated glass slide for 3 days at 27 C. After that, the samples were prepared for SEM by fixation with 2% glutaraldehyde followed by graded ethanol dehydration. Notably, the SEM images showed that the sample coated with nanocomposite inhibited the biofilm growth compared to control sample, which was not coated with nanocomposite. This highlights ZnO-Ag nanocomposite potential use as an anti-biofilm agent.

Tailoring Magnetic Nanocluster Dimensions to Bacteria Separation Applications *Alicia M. Chandler, Jingge Chen and Vicki L. Colvin; Brown University, United States*

Drinking water treatment systems, food industries, and biotechnological applications require bacteria separation methods beyond existing commercial techniques; magnetic nanoparticles offer a promising solution. We applied porous iron oxide nanoclusters with superparamagnetic properties to separate bacteria from aqueous mediums. These core materials were surface-functionalized with a cationic polymer, polyethyleneimine (PEI), via crosslinking with glutaraldehyde to facilitate an electrostatic attraction with negatively charged bacteria membranes. Functionalized nanoclusters spontaneously adhered to bacteria, forming aggregates that could be removed from aqueous mediums with an external magnetic field. We synthesized iron oxide nanoclusters with dimensions from 50 to 420 nm and evaluated variations in bacteria separation performance throughout this range. We compared capture efficiencies, adsorption capacities, and separation kinetics for different initial concentrations of gram-negative E. coli and gram-positive S. aureus. Results indicate that smaller nanomaterials have higher adsorption capacities and faster separation kinetics due to their larger surface to volume ratios. However, larger nanomaterials provide better capture efficiencies for cases with low initial concentrations of bacteria. We hypothesize that the smaller magnetic moments of smaller nanoclusters limit aggregate formation in low bacteria concentrations, leading to less effective bacteria capture. These findings offer important insights for *customizing magnetic nanomaterial dimensions to diverse bacteria separation applications.*

NM02.09.09

Deciphering Concurrent Seed Growth and Cation Exchange Kinetics in the Transformation of $Cu_{2-x}S$ Nanocrystals to $CuGaS_2$ Nanorods *Yunpei Duan and Moonsub Shim; University of Illinois at Urbana-Champaign, United States*

Cation exchange offers a novel approach for synthesizing complex-structured nanocrystals. This process typically involves using easily synthesized and controllable nanoparticles as seed templates, with the subsequent partial or complete exchange of cations regulated by factors such as ligands, temperature, and time. Nanocrystals prepared through cation exchange can flexibly control crystal phase, stoichiometry, and morphology. Beyond cation exchange without altering shape and size, achieving anisotropic heterostructured nanorods through concurrent epitaxial growth has garnered significant attention. Here, we quantify the kinetics of the transformation from low-chalcocite $Cu_{2-x}S$ to wurtzite $CuGaS_2$ nanorods through concurrent epitaxial growth, cation exchange, and interfacial diffusion. We investigate the effects of growth temperature and seed size on the reaction kinetics and the resulting morphology. By precisely controlling temperature and time, a series of Janus particles with varying elemental ratios up to fully substituted $CuGaS_2$ nanorods can be obtained. This provides a practical approach for the precise regulation of the competition between cation exchange process and solution epitaxial growth.

Insights into the Optical Properties of the $Au_{25}Tre_{18}$ Nanocluster—A Joint Experimental-Computational Study
Kithma Sajini Dileka Gampala Liyanapathiranage, Mohammad Bodiuzzaman, Harini Perera, Dang Truong, Jia Tu, William Ndugire, Wendy Gavin, Mingdi Yan and Jerome Delhommelle; University of Massachusetts Lowell, United States

Metal nanoclusters play a major role in nanotechnology. Atomically precise metal nanoclusters are a specific type of nanocluster stabilized by layers of ligands. These clusters can vary in size from a few metal atoms to hundreds of atoms. The metal core can be made of various metals such as gold, silver, and copper and it is enveloped by the ligand layer, typically composed of organic ligands such as thiolates, phosphines, alkynyls, or carbenes. Between the metal core and the ligand layer lies a metal-ligand interface, usually consisting of sulfur or phosphorous, which connects the two layers physically. These metal nanoclusters find application in various fields due to their unique properties. In medicine, they are utilized for targeted drug delivery and imaging due to their small size and ability to interact with biological molecules.[1] In catalysis, they serve as highly efficient catalysts, accelerating chemical reactions while minimizing waste, owing to their large surface area-to-volume ratio. Additionally, they act as excellent photocatalysts, generating electron-hole pairs upon photon absorption, which participate in redox reactions on the catalyst surface. In electronics, their conductivity and optical properties make them essential components in sensors, displays, and energy devices. They also play a role in environmental remediation, catalyzing degradation reactions and facilitating pollutant degradation and wastewater treatment.[2–5]In particular, gold nanoclusters capped with carbohydrates, have various applications in targeted drug delivery, biosensing, and beyond the drug delivery, in therapeutics. The focus of this project lies on a specific nanocluster $Au_{25}Tre_{18}$, which has 25 gold atoms capped with 18 trehalose ligands. We have successfully synthesized $Au_{25}Tre_{18}$ and characterized it using high-resolution mass spectrometry (HRMS), ultraviolet-visible (UV-Vis), circular dichroism (CD), and nuclear magnetic resonance (NMR) spectroscopy. However, interpreting the CD spectrum has proven challenging due to fluctuations and complexity in the experimental data. To address this, we perform quantum (TD-DFT) calculations and predict the CD and UV-Vis spectra of $Au_{25}Tre_{18}$, thus providing theoretical support to the experimental findings. This work represents the first computational modeling of the CD spectrum for trehalose-capped Au_{25} nanoclusters, providing crucial insights into their chiroptical properties. By comparing the theoretical *spectra with the experimental spectra, we offer a comprehensive understanding of the observed spectral fluctuations, thereby supporting the experimental characterization of $Au_{25}Tre_{18}$.*

Keywords: *Au nanocluster, density functional theory, computational chemistry, optical properties.*

Effects of Crystal Orientation on the Corrosion Behavior of Copper in Sodium Hydroxide Solution—Combined Experimental and Computational Density Functional Theory

Jun Yang[1,2], Yong Fang[1,2], Pak Yan Moh[3] and Hanyang Zuo[1,2]; [1]Sichuan University, China; [2]Sichuan University of Science and Engineering, China; [3]Universiti Malaysia Sabah, Malaysia

During the material growth process, nanoscale clusters typically form first. Clusters can continuously adjust their internal atomic arrangement and ultimately evolving into crystal structure. The crystal structure exhibits different crystal orientations, which can lead to changes in the chemical activity and electronic structure of the metal surface, thereby influencing the interaction between metal and corrosive medium. This article thoroughly investigates the impact of crystal orientation on copper corrosion. It provides a foundation for understanding the role of nanoclusters in corrosion processes. The effects of crystal orientation on the corrosion behavior and mechanism of a single crystal copper in a 0.1 M NaOH solution were systematically investigated by conducting experiments and calculations on density functional theory (DFT). Both the electrochemical and calculation results showed that the crystal orientation had a significant effect on the corrosion resistance of Cu. In this study, a single crystal of copper with an exposed surface configuration of (100), (110), and (111) was taken as the research object. Electrochemical methods (potentiodynamic polarization and electrochemical impedance spectroscopy) were employed to investigate the corrosion behavior in a 0.1 M NaOH solution. Both impedance and corrosion current density values were in the following order: Cu(110) > Cu(100) > Cu(111), indicating that the corrosion resistance was in the same order. The density of state, surface energy, work function, and Mulliken charge were calculated through first-principles calculations with DFT to reveal the corrosion mechanism. The calculation results showed that the Mulliken charge distribution was closely related to the corrosion resistance. A higher value of Mulliken charge led to a greater number of electrons participating in the electrochemical reaction, which resulted in a poorer corrosion resistance. The sequence of Mulliken charge values on the first atom was (110) < (100) < (111), and in turn the corrosion resistance sequence was Cu(110) > Cu(100) > Cu(111). Employing simulation calculations in combination with experimental observations to interpret results and explore the corrosion

mechanism is an effective research method. Once calculation models are established, they could be used to predict the corrosion behavior under different environmental conditions. Furthermore, it offers new directions for enhancing corrosion resistance by optimizing crystal orientation through studying the properties and behavior of nanoclusters.

Synthesis of Highly Dispersed Metal Nanoparticle-Based Heterogeneous Catalysts Via Spray Pyrolysis and Their Application to Dry Reforming of Methane Reaction *Bonjun Ku, DongHyun Kim and Kyubock Lee; Chungnam National University, Korea (the Republic of)*

Nanosized metal and metal oxide particles in heterogeneous catalysts offer notable benefits in energy and material sciences due to their superior catalytic activity and ease of use. Traditional preparation methods, however, often face challenges in achieving uniform metal dispersion and maintaining structural durability. This study introduces spray pyrolysis as an alternative method for fabricating Ni-based catalysts with enhanced metal dispersion. Spray pyrolysis, an aerosol processing technique, converts precursor solutions into fine droplets that are rapidly heated, forming an inorganic network through fast polycondensation reactions. Metal species are trapped within the inorganic network, which limits their growth. This method is a key effect known as "kinetic quenching" to achieve better metal dispersion. Nickel catalysts supported on silica were produced using spray pyrolysis and evaluated for their performance in the dry reforming of methane, which requires uniform metal nanoparticle dispersion and stability. The spray pyrolysis method resulted in Ni nanoparticles with sizes ranging from 3 to 4 nm, significantly improving catalytic activity and resistance to carbon deposition compared to catalysts prepared via sol-gel and impregnation methods. Analysis through TEM, XRD, and Hydrogen-pulse chemisorption confirmed these improvements, while TPO-MS techniques validated the role of the kinetic quenching effect in enhancing dispersion. This work highlights the potential of spray pyrolysis to advance catalyst preparation by offering superior dispersion and stability, thereby enhancing catalytic performance.

NM02.09.13

Precision Synthesis of Cadmium Selenide Semiconductor Nanoclusters Via Cation Exchange *Fuyan Ma, Khalil Abboud and Chenjie Zeng; University of Florida, United States*

Precision synthesis at the nanoscale with well-defined precursors, pathways, and products is important for atomic-level engineering of nanomaterials. Despite the importance, the progress in synthesizing atomically precise semiconductor clusters has been a daunting task due to their complex structures and entangled reaction kinetics. Cation exchange reactions have been widely used to access novel colloidal nanocrystals. In this presentation, we will discuss the “precisionalization” of cation exchange reactions to synthesize atomically defined CdSe nanoclusters. Specifically, the reaction of a $Cu_{26}Se_{13}(PEt_2Ph)_{14}$ template cluster with a $CdI_2(PPr_3)_2$ cation complex afforded a $Cd_{26}Se_{17}I_{18}(PPr_3)_{10}$ cluster with near-unity conversion yield. X-ray crystallography shows that the Se_{13} anion framework in the template cluster is preserved and further enlarged in the product cluster. The surface ligands of the CdSe cluster are fully dictated by the complex precursor. The atomic structures of $Cd_{26}Se_{17}$ clusters further unveil the origin of charity and polarity of semiconductor nanoclusters. Atomic insights into transformation pathways can be derived based on the in situ absorption spectra and the comparison of the crystal structures. In addition, by changing the ligands in the cadmium complex, a carboxylate-protected CdSe cluster can be produced with a slower transformation rate due to the lower reactivity of Cd(II)-carboxylate precursors. The realization of atomic precision in cation exchange reactions is expected to expand the library of atomically precise semiconductor nanomaterials and further understand their structure-property relationships.

2D Indium Chalcogenides—Progress on Growth and Electronic Devices *Deep M. Jariwala; University of Pennsylvania, United States*

Silicon has been the dominant material for electronic computing for decades and very likely will stay dominant for the foreseeable future. However, it is well-known that Moore's law that propelled Silicon into this dominant position is long dead. Therefore, a fervent search for (i) new semiconductors that could directly replace silicon or (ii) new architectures with novel materials/devices added onto silicon or (iii) new physics/state-variables or a combination of above has been the subject of much of the electronic materials and devices research of the past 2 decades. Therefore, there is a pressing need for complementing and supplementing Silicon to operate with greater efficiency, speed and handle greater amounts of data since modern computing has become more data centric with the emergence of artificial intelligence.
The above is however not possible without fundamental innovation in new electronic materials and devices. Therefore, in this talk, I will try to make the case of how novel layered two-dimensional (2D) Indium chalcogenide materials might present interesting avenues to overcome some of the limitations being faced by Silicon hardware. I will start by presenting our ongoing and recent work on integration of 2D In chalcogenide semiconductors with

silicon[1, 2] to realize low-power tunnelling field effect transistors. In particular I will focus on In-Se based 2D semiconductors[1] for this application and extend discussion on them to phase-pure, epitaxial thin-film growth over wafer scales,[3] via Metal Organic Chemical Vapor Deposition (MOCVD) at temperatures low-enough to be compatible with back end of line (BEOL) processing in Silicon fabs. In addition, I will show that by careful precursor injection control, one can selective achieve phase-pure growth of InSe vs In_2Se_3. Finally, I will present ongoing work on In2Se3 electrical characterization including in and out of plane ferroelectricity. I will end the talk with opportunities to extend applications of InSe and In_2Se_3 materials and devices.

Gas-Phase Alloying of Sulfur-Selenium Dielectrics with High Ionic Mobility for Next-Generation Electronics

Pradyumna Kumar Chand[1,2,1], Radha Raman[2,3], Zhi-Long Yan[2], Ian D. Santos[1], Wei-Ssu Liao[1], Ya-Ping Hsieh[2] and Mario Hofmann[1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan; [3]National Central University, Taiwan

The increasing demands of future electronics necessitate the development of innovative dielectric materials that can meet the diverse requirements of advanced electronic applications. Enhanced electrostatic control in ultrascaled transistors requires dielectrics with higher dielectric constants, while improved power efficiency can be achieved through effective dielectric polarization control. Additionally, the development of wearable and implantable devices necessitates flexible dielectrics for use as substrates and gates. In-memory computing also relies on the emergent memristive properties of dielectrics. To address these diverse requirements, we investigate sulfur-selenium (S-Se) alloy as a dielectric material for advanced electronic applications. By employing an innovative chemical vapor deposition (CVD) technique, we produce ultrathin, crystalline S-Se alloy films with uniform large-scale morphology. Experimental diffraction analysis and materials modeling reveal a modified lattice structure in the alloy, which enhances ionic mobility. This characteristic is confirmed through electrochemical impedance spectroscopy and utilized to fabricate memristive devices with outstanding performance. Our results highlight the potential of gas-phase alloying to develop dielectrics with multifaceted functionality, robust mechanical stability, and precise morphology control, thereby paving the way for the integration of these materials in next-generation electronic devices.

11:15 AM NM03.01.03

Temperature-Dependent Carrier Transport and Persistent Photoconductivity in WSe_2 Based Nanocomposite Thin Films *Akshay Kumar[1] and Manjot Kaur[2]; [1]Sardar Patel University, India; [2]Chandigarh University, India*

This study investigates the complex relationship between temperature-dependent electrical transport and persistent photoconductivity in WSe_2/MoS_2 nanocomposite thin films. Using thermal evaporation, we fabricated n-type semiconductor films approximately 150 nm thick with a carrier concentration of 10^{23} cm^{-3}. Field Emission Scanning Electron Microscopy (FESEM) confirmed film uniformity and thickness, while X-ray Photoelectron Spectroscopy (XPS) verified the presence of WSe_2 and MoS_2, indicated by the +4 oxidation state of W and Mo and

the -2 oxidation state of S and Se. Raman spectroscopy, specifically the E^1_{2g} *mode, further confirmed interlayer coupling in the films. Our analysis revealed a photoluminescence emission peak at 1.59 eV, associated with excitons bound to defects, introducing mid-bandgap states. The films showed a significant presence of trap/defect states and high disorder levels, providing new insights into carrier transport in these materials.*
Examining carrier transport from 150 to 350 K, we found that trap states from chalcogenide vacancies in WSe_2/MoS_2 *play crucial roles. These states contribute to the formation of localized states. From 150 to 250 K, the electrical conductivity aligns with Mott's variable range-hopping model due to these localized states. At higher temperatures, electrical transport is driven by nearest-neighbor hopping and thermally activated conduction. We also explored the impact of defect/trap states and local potential fluctuations on persistent photoconductivity. The entrapment of carriers in trap states causes delayed recombination. Notably, the introduction of oxygen into sulfur vacancies, forming acceptor states, increases photocurrent when the films are exposed to air versus vacuum. These results offer deep insights into the conduction mechanisms of multifunctional transition-metal dichalcogenide-based nanocomposites, advancing potential applications.*

11:30 AM *NM03.01.04
Engineering the Photodetection, Strain and Neuromorphic Performance of 2D-TMD Transistors *Saurabh V. Lodha; Indian Institute of Technology Bombay, India*

In recent years, researchers have leveraged the unique physical properties of layered two-dimensional (2D) van der Waals (vdW) materials, such as a wide range of thickness-dependent bandgaps and facile fabrication of heterostructures with defect-free heterointerfaces, for several electronic and optoelectronic applications. At the same time, their optical and electrical properties can be controlled using strain tuning of band structure parameters because of their high tensile strength, as well as via electrostatic gating-based tuning of carrier concentrations because of their ultra-thin nature.

The first part of the presentation will cover results on engineering photo-detection of transistors based on 2D vdW transition metal dichalcogenide (TMD) semiconductors and their heterostructures. Photoresponsivity and speed of few-layer TMD photodetectors are fundamentally traded-off with each other by modulation of the effective trap concentration, as shown through electrostatically gated supported and suspended ReS_2 *photodetectors.[1] This trade-off can be attenuated by nearly 2× using an electrostatically tunable in-plane p-n homojunction integrated laterally with a* WSe_2 *phototransistor, enabling enhanced photoresponsivity (>100 A/W), and high detectivity (*$>10^{12}$ *Jones) along with switching speed in the ms range at the same time.[2] Beyond single-TMD photodetection, TMD/TMD heterostructures offer the possibilities of interlayer interface engineering for improving photodetection parameters. For instance, engineering the band alignment from type-II to type-III in a* $WSe_2/SnSe_2$ *p-n heterodiode helps realize a high negative responsivity of* 2×10^4 *A/W with a fast response time of ~1 ms due to a tunneling photocurrent.[3]*

The next part will describe the strain-modulated performance of 2D-TMD transistors, wherein an electrically actuated piezo-stack is employed to fine-tune optical and electrical parameters of MoS_2 *field-effect transistors with tensile as well as compressive strain, offering improved control and integration possibilities over existing mechanical methods.[4] Finally, we will describe the use of independent electrostatic gating of contact and channel barriers in 2D TMD transistors towards realizing neuronal spiking behaviour, closely mimicking biological neurons with functionalities such as spike-frequency adaptation and post-inhibitory rebound, at a low energy consumption of 3.5 pJ/spike.[5]*

Non-Local Transport from Magnetic Topological Superconductivity in 2D Fe-Chalcogenides *Kenneth Burch; Boston College, United States*

Magneto-Chiral topological superconductivity is a rare phase long pursued for error-free quantum computation. Its 1D chiral modes possess topologically protected long-range coherence well beyond that of the cooper pairs, which could be fruitful for quantum transduction and low-temperature spin transport. While evidence for such modes is mounting, unambiguous signatures, such as non-local transport via co-tunneling, remain elusive. I will describe our realization of 1D chiral hinge modes mediating the direct tunneling of electrons from source to drain in FeTe0.55Se0.45. Specifically, I will discuss our evidence that the non-local tunneling signatures are decoherence-free and emerge from this material's combination of surface magnetism, bulk topology, and superconductivity. Time remaining, I will discuss how these advances can be used for Majorana Circuits and future efforts in cryogenic spintronics.

2:00 PM *NM03.02.02
Interface-Engineered Chalcogenide Topological Quantum Matter *Seongshik Oh; Rutgers, The State University of New Jersey, United States*

Topology has emerged as a new paradigm of classifying electronic materials over the past decade, and a series of topological materials including topological insulators (TIs) and topological semimetals (TSMs), many of which belong to the chalcogenide family, have been predicted and subsequently identified experimentally. Nonetheless, soon after the discovery of TIs and their topological surface states (TSS), it became evident that their transport properties are far from theoretically expected, with the bulk states conducting instead of insulating due to unintended native defects. While many researchers focused on solving this problem by mixing multiple elements to compensate for the residual bulk carriers [SciPost Phys. Lect. Notes 58 (2022)], we showed that in the thin regime, it is the interfacial, rather than bulk, defects, that dominate the transport properties of TIs [PRL 109, 116804 (2012),], and subsequently, demonstrated that by introducing defect-minimizing interfacial layers, one can achieve fully bulk insulating TI in Bi_2Se_3 thin films [PRL 113, 026801 (2014), Nano Lett. 15, 8245 (2015)], which still hold the highest surface state mobility among TIs to this day. Then, we discovered quantum Hall effect as well as the long-awaited quantized Faraday and Kerr rotations [Science 354, 1124 (2016)], which have been considered the hall mark of TSS in the quantum regime. Subsequently, by introducing similar interface engineering schemes, we discovered the first quantum Hall effect in Sb_2Te_3 films [Adv. Mat. 31, 1901091 (2019)] and record-high-temperature quantum anomalous Hall effect through magnetic proximity effect in heterostructures of

$(Cr,Bi,Sb)_2Te_3$[Nano Lett. 23, 5673 (2023)].
While the above works are achieved on known topological materials such as Bi_2Se_3, Sb_2Te_3, and $(Cr,Bi,Sb)_2Te_3$, we also introduced a new material system, $(Bi_{1-x}In_x)_2Se_3$, as the first topologically tunable thin film platform [PRL 109, 186403 (2012)]: bulk crystals of this material were made available only a few years later. $(Bi_{1-x}In_x)_2Se_3$ thin films have since been utilized as the most successful platform to test the role of TSS [Nat. Phy. 9, 410 (2013), Nat. Photon. 16, 620 (2022)].
In addition to the topological materials discussed above, we recently discovered a new platform of Fe(Te,Se)-based topological hybrids structures can be created utilizing another interface engineering scheme, as detailed below. To any epitaxial thin film expert, it is well known that choice of the substrate is critical for the quality of the films. So, the first thing to consider when growing any film is the lattice matching with the underlying layer. Although lattice mismatch is itself a useful tuning parameter to control the film properties, we do not expect to achieve epitaxial (high quality) compound thin films on a substrate with different in-plane symmetry. Nonetheless, we showed that it is possible to grow epitaxial, superconducting four-fold Fe(Te,Se) films on three-fold chalcogenide materials such as topological insulator, Bi_2Te_3 and antiferromagnetic MnTe, with atomically sharp interfaces [Nano Lett. 21, 6518 (2021), Nano Lett. 22, 18, 7522 (2022), Adv. Mat. 35, 2210940 (2023)]. We found that this unique growth mode, which we named as "hybrid symmetry epitaxy", is possible due to accidental uniaxial lattice match. With these discoveries, Fe(Te,Se)-based hybrid structures are emerging as a new platform combining superconductivity, topology and magnetism, particularly merging the two families of chalcogenides, topological materials and iron-based superconductors, both of which emerged separately in late 2000s as two new families of quantum materials.

Van der Waals Ferroelectrics—From Materials Characterization to Device Application *Lin Wang, Han Chen, Yinfeng Long and Mingfeng Chen; Shanghai Jiao Tong University, China*

Ferroelectric properties, traditionally studied in bulk materials, feature spontaneous electrical polarizations that are controllable via external electric field, thus holding enormous potential for non-volatile electronic devices application with high-density, high-speed, high energy-efficiency. Yet, the promise of conventional ferroelectrics has yet to materialize, primarily due to lattice mismatch and interfacial issues, resulting in deficient compatibility with silicon complementary metal-oxide-semiconductor (CMOS) technology and/or insufficient device reliability. Van der Waals (vdW) ferroelectrics, owing to their unique advantages including atomic thicknesses, dangling-bond-free surfaces, and weak interlayer couplings enabling construction of artificial structures, have recently triggered extensive research interests owing to their potential in addressing the challenges confronting their traditional counterparts, providing an unprecedented platform for implementing ultrathin ferroelectric devices as key hardware components in the post-von Neumann computing era. In this talk, I will introduce the state of the art in vdW ferroelectrics with a focus on their exploration in non-volatile ferroelectronics. A few directions that are worthy of research endeavors to fully unleash their potential will be discussed. Particularly, I will present our latest *research on α-In_2Se_3, a representative vdW ferroelectric semiconductor, including the use of advanced electrical mode atomic force microscopy (AFM) techniques for investigating its intriguing physical properties combining ferroelectricity and semiconductivity on the material, MOS structure, and device levels towards non-volatile device application. As a typical example, I will introduce the application of scanning microwave impedance microscopy (SMIM) in visualizing α-In_2Se_3 flakes of varying thicknesses and in probing the change in its resistance state in ferroelectric semiconductor field effect transistors (FeSFETs) subject to gate voltage stimuli. The capacitive SMIM signal dependence on α-In_2Se_3 flake thickness is in consistency with finite element simulation, and the in-situ SMIM characterization results correlate well with electrical transport properties of α-In_2Se_3 FeSFET, manifesting the feasibility of SMIM as a convenient complementary technique in studying vdW ferroelectric materials and devices.*

Atomic Layer Deposited 2D SnS Thin Film and Its Ferroelectric Properties *Dowook Lee[1], Jangho Bae[1], Heejun Yoon[1], Dukhwan Kim[2], Junmo Kim[2], Hyungtak Seo[2,2] and Hyeongtag Jeon[1,1]; [1]Hanyang University, Korea (the Republic of); [2]Ajou University, Korea (the Republic of)*

Various properties that two-dimension (2D) thin film materials possess but have not been turned out are continually being revealed through recent research results. Based on the novel properties that have recently been revealed, further research is being conducted worldwide to apply 2D materials to various fields such as sensors, catalysts, batteries, and solar cells. Among these, transition metal di-chalcogenide (TMDC) materials such as MoS_2 and WS_2 are currently one of the most actively researched materials due to their excellent electrical and physical properties. However, transition metals in TMDC are generally embedded in rare amounts on earth, which cause budget issues during process development. Also transition metals are toxic. So achieve environmentally friendly research is impossible. In addition, they have a higher melting temperature than other metals. Therefore, it is difficult to deposit materials onto flexible substrates used to fabricate flexible, wearable devices. Research for new materials that can overcome this disadvantages is necessary. Therefore, we conducted research about tin sulfide materials that could replace TMDC. Tin sulfide is a material that exhibits a 2D structure. Also tin is abundant on earth, non-toxic, and has a low melting point, making it possible to process it at low temperatures. Among tin sulfides, tin mono-sulfide (SnS) has a structure that exhibits low symmetry, so that ferroelectric property based on the polarization easily appears inside the thin film when an external force or electric field is applied. This makes it possible to fabricate a highly sensitive sensor using SnS. Furthermore, since SnS exhibits ferroelectric property predominantly in the in-plane direction, it is hardly affected by the upper and lower electrodes that may occur when the device thickness is reduced. A variety of processes are used to deposit SnS thin film, including atomic layer deposition (ALD), chemical vapor deposition (CVD), physical vapor deposition (PVD), and mechanical exfoliation. To confirm whether the ferroelectric property changes with the SnS thin film characteristics, we deposited and evaluated SnS thin film using ALD, a process based on a self-limiting reaction mechanism.
In this study, ALD process was proceeded at 150°C using $Sn(acac)_2$ precursor and H_2S reactant to deposit SnS thin film. Annealing was performed to improve the crystallinity of the SnS thin film after deposition. Annealing was performed in an Ar atmosphere at a temperature of 350°C. X-ray reflectance (XRR) analysis was performed to confirm the thickness and growth rate of the SnS. Growth rate of $Sn(acac)_2$ SnS thin film was 0.34Å/cycle. X-ray diffraction (XRD) and Raman were utilized to compare the crystallinity and phase of SnS thin film. After annealing, SnS thin film showed higher crystallinity compare with as-deposited SnS thin film. Also single orthorhombic phase was achieved at post annealed SnS thin film. Transmission electron microscope (TEM) was used to confirm the 2D layered structure. Clearly 2D layered structure was showed by annealed SnS thin film. In addition, x-ray photoelectron spectroscopy (XPS) analysis was performed to check the bonding state of SnS thin film. The Sn 3d and S 2p spectra binding energy was similar with other SnS thin film research papers. Finally, positive up negative down (PUND) and piezoresponse force microscopy (PFM) were performed to evaluate the ferroelectric properties.

Results of PUND and PFM analysis confirmed that SnS thin film deposited using ALD exhibited ferroelectric property.

3:45 PM NM03.03.03

Bulk Photovoltaic Effect in Single Domain Ferroelectric SnS *Ryo Nanae[1], Satsuki Kitamura[1], Yih-Ren Chang[2], Kaito Kanahashi[1], Tomonori Nishimura[1], Redhwan A. Moqbel[3], Kung-Hsuan Lin[3], Mina Maruyama[4], Yanlin Gao[4], Susumu Okada[4], Kai Qi[1], Jui-Han Fu[1], Vincent Tung[1], Takashi Taniguchi[5], Kenji Watanabe[5] and Kosuke Nagashio[1]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan; [3]Academia Sinica, Taiwan; [4]University of Tsukuba, Japan; [5]National Institute for Materials Science, Japan*

Ferroelectrics are a group of materials in which spontaneous polarization reversal is possible in crystals with non-centrosymmetry, and ferroelectric domains have been subject to control in many electrical/mechanical conversion devices. On the other hand, oxide ferroelectrics exhibit the photovoltaic phenomenon known as the bulk photovoltaic effect (BPVE). BPVE is classified into two types: shift current, arising from non-centrosymmetric crystals, and the domain wall photovoltaic effect (DW-PVE), originating at the ferroelectric domain interface. BPVE is attracting attention as a next-generation photovoltaic mechanism capable of achieving the photovoltage above the band gap using a single material unlike pn junctions.
Recently studies have intensively explored BPVE in 2D materials. However, there has been limited discussion on DW-PVE in 2D materials because research on ferroelectric 2D is limited. In this study, we have successfully grown sizable crystals of 2D ferroelectric SnS, facilitating comprehensive yet intricate examination of domain configurations utilizing polarized optical microscopy, second harmonic generation microscopy and piezoresponse force microscopy. By properly selecting the large ferroelectric single domain within SnS crystals, uniform intrinsic BPVE across the domain was conclusively demonstrated. Furthermore, to further enhance intrinsic BPVE, manipulation of strain poling increased photocurrent, suggesting that locally distributed polarizations due to imperfection introduced in SnS crystals are aligned by strain. These findings pave the way for a more profound understanding of DW-PVE in 2D ferroelectrics.

Complementary Effects of External Strain and Functionalization Towards Enhanced HER Activity on $FePS_3$ Basal Plane *Tisita Das; Harish-Chandra Research Institute, India*

In the quest for inexpensive photo- or electro-catalytic materials, layered transition metal tri-chalcogenides (TMTC) have recently emerged as one of the most promising candidates for electrocatalytic Hydrogen Evolution Reaction (HER). Earlier experiments showed that among a wide range of investigated MPX_3 compounds, $FePS_3$, $CoPS_3$, $NiPS_3$, $FePSe_3$ and $MnPSe_3$ can exhibit excellent HER activity for electrocatalytic water splitting in both acidic and alkaline medium. However, most of the exciting results involved investigations of the activity on their bulk or few-layer forms where the activity enhancement is mainly attained through quantum confinement either by reducing the layer numbers or using substrate effect. In a couple of recent works through first principles simulations we discovered that the basal plane of these TMTC monolayers are not at all active, it is the chalcogen or P edge sites that facilitates the HER process. While this microscopic knowledge of catalytically active sites is a definite progress, the particular knowledge that the active sites are at the edges is only partly positive. It would be more beneficial to have a material with active sites on the basal planes because in a layered material, there will be larger number of basal plane sites than edge sites. Hence in this current work, we have tried to envisage if any of these TMTC materials can be engineered to have active sites on their basal planes. And as a test material we selected $FePS_3$ monolayer where a three-fold strategy has been considered to tune the HER activity on the basal plane. We investigate how functionalization and vacancy induced defect in pristine $FePS_3$ monolayer can influence its electrochemical activity. Our results suggest that N substitution for S creates catalytically active sites that are *not present in the pristine material. On the other hand, although C- and P-substitution induces a significant improvement in the activity but it is not as good as the nitrogen case. Therefore a further strain engineering has been implemented in these two systems which results in very promising HER activity. In addition, to explore the hydrogen coverage dependency, we have determined the activity in both low and high H^+ concentration condition. To the best of our knowledge, this is the first work employing detailed first principles calculations showing how a synergy between functionalization through doping and strain engineering can enhance HER catalytic activity on the basal planes of $FePS_3$. We strongly believe that this work will be an interesting addition to the body of work on this important class of materials*

4:15 PM *NM03.03.05

Controlling Phase and Functionality of Ultra-Thin Chalcogenide Films Through Heteroepitaxy *Rafael Jaramillo; Massachusetts Institute of Technology, United States*

Low-dimensional crystal structures and polymorphism feature prominently in the science and applications of chalcogenide semiconductors. These can present processing challenges, as it can be difficult to prepare uniform thin films over large areas. However, with great challenges come great opportunities for controlling phase and functionality through epitaxy. A diversity of crystal phases and optoelectronic properties can be accessed through slight changes in thermodynamic boundary conditions. Opportunities abound for fundamental studies. Opportunities also abound for applications, but only if the processing outcomes can be well controlled. I will present several examples wherein we control the phase and properties of ultra-thin chalcogenide films through molecular beam epitaxy, focusing on heteroepitaxial growth on oxide substrates.

The layered material SnSe has pronounced in-plane structural and optical anisotropy, which may be useful for integrated photonics and ferroelectric field-effect devices, but only if the anisotropy can be controlled. By choosing to grow SnSe on oxide substrates with square or rectangular symmetry, we control the distribution of ferroelastic domains, and the optical properties. This is a relatively straightforward example that can be understood by considering the mismatch between substrate and film in-plane lattice constants.

A more complicated example is the growth of the perovskite $BaZr(S,Se)_3$ on $LaAlO_3$. In this case, Nature deviates widely from what we expect based on straightforward considerations of lattice mismatch. Instead, we observe a process of surface passivation and the self-assembly of a nm-thick buffer layer that supports epitaxial growth of fully-relaxed films with cube-on-cube orientation, despite a lattice mismatch exceeding 30%. This ultra-thin, self-assembled chalcogenide layer has a rock-salt-like structure, and fully accommodates the heteroepitaxial misfit strain without misfit dislocations. This illustrates how complex, multicomponent interface chemistry can produce surprises – that, in this case, are enabling for growth and characterization of strain-free and epitaxial chalcogenide perovskite thin films.

As a third example, I will present control of polymorphism and domain epitaxy in $BaZrSe_3$ thin films. We have previously shown that high-Se-content $BaZr(S,Se)_3$ perovskite alloys can be made by direct co-deposition of Ba, Zr, S, and Se, or by post-growth selenization of $BaZrS_3$. However, $BaZrSe_3$ is thermodynamically most stable in a hexagonal, face-sharing structure (i.e., not a perovskite). The orthorhombic perovskite phase (orth-$BaZrSe_3$) features a direct band gap near 1.4 eV and may be of interest for photovoltaics. The hexagonal phase (h-$BaZrS_3$) is theoretically predicted to have a band gap in the mid-infrared (MIR), is expected to have exceptionally strong birefringence, and may be of interest for infrared photonics. We find that sufficiently-aggressive selenization of $BaZrS_3$ converts the film from the perovskite to the hexagonal phase. orth-$BaZrSe_3$ and h-$BaZrS_3$ both crystallize on oxide substrates, but the choice of substrate affects the relative stability. On hexagonal substrates, the perovskite-to-hexagonal transformation occurs more readily. On square planar substrates, the perovskite phase is more *stable; when h-$BaZrSe_3$ does form, it does so with the optic axis in-plane, with domain degeneracy that renders it challenging to measure the film birefringence. However, on substrates with rectangular symmetry, h-$BaZrSe_3$ films form with the optic axis in a single orientation across the substrate. As result, we are able to demonstrate wave-plate functionality for infrared light. This illustrates how relatively subtle changes in thermodynamic boundary conditions can produce functionally diverse outcomes, spanning from a candidate solar cell absorber material, to a highly-birefringent optical coating for infrared photonics.*

SESSION NM03.04: Advanced Synthesis I

Cl_2-Based Selective Etching of Transition Metal Dichalcogenides *Nicholas Trainor[1,1,2], Pawan Kumar[2], Benjamin Groven[2], Dries Vranckx[2], Henry Medina Silva[2], Annelies Delabie[3], Pierre Morin[2] and Joan M. Redwing[1,1]; [1]The Pennsylvania State University, United States; [2]imec, Belgium; [3]KU Leuven, Belgium*

Two-dimensional semiconducting transition metal dichalcogenides (TMDs) are highly promising candidates for advanced electronic and optoelectronic devices. However, current stage-of-the-art deposition approaches for growing TMD monolayers suffer from undesired nucleation and growth of additional layers. Such bilayer islands negatively impact electrostatic control in device structures, resulting in increased variability in key parameters of interest, such as threshold voltage and subthreshold swing [1]. One possible solution is to selectively remove such bilayer islands after growth using a selective etch. Prior work has demonstrated that chlorine gas (Cl_2) can selectively etch and remove bilayer islands from monolayer MoS_2, resulting in improved device performance and reduced variability. However, the effect of different process parameters was not investigated and the impact on the remaining monolayer was not studied extensively [2].

Here we present a Cl_2-based etch process to selectively etch superficial bilayer MoS_2 islands on a continuous MoS_2 monolayer on sapphire. Prior to the etch process, single-crystalline MoS_2 was grown by metal-organic chemical vapor epitaxy from molybdenum hexacarbonyl and hydrogen sulfide precursors on c-plane sapphire substrates using an industry-standard 200 mm horizontal and hot-wall CVD reactor. The etch process was conducted on a similar 300 mm reactor. When exposed to Cl_2 at temperatures between 400°C and 550°C, the bilayer islands are selectively removed without noticeable etching of the underlying monolayer as observed with scanning electron microscopy (SEM) and atomic force microscopy (AFM). Complete bilayer removal was achieved within 10 minutes of exposure at 500°C. When the temperature is increased to 600°C and above, the Cl_2 reacts with the MoS_2 monolayer, with complete etching and removal occurring within 10 minutes at 750°C.

The selectivity of the etch can be additionally tuned by co-injecting S-containing species. Preliminary thermodynamic calculations suggest that H_2S and Cl_2 can react to form sulfur chlorides. Such reactions may have the dual effect of depleting Cl_2 and generating etching products, which should shift the thermodynamic equilibrium to disfavor etching. Indeed, the inclusion of H_2S suppresses bilayer etching, with bilayer islands being present even after treatment at 700°C. In contrast, co-injection of H_2 has a more limited impact, which thermodynamic calculations suggest is due to gas phase reactions between the H_2 and Cl_2 to produce less reactive HCl. Furthermore, thermodynamic calculations suggest that it is more favorable to etch WS_2 compared to MoS_2, which may enable preferential etching of specific transition metals within heterostructures.

In addition to morphological changes, the Cl_2 etching caused changes in the Raman and photoluminescence (PL) *response. The MoS_2 Raman modes narrowed after Cl_2 exposure; however, this effect was reduced with the co-injection of H_2S and is likely in part due to the removal of scattering sites along the edge of bilayer islands. The room temperature photoluminescence response strongly increases with treatment, while the cryogenic spectra suggest that Cl_2 exposure causes n-type doping of the MoS_2. Electronic device statistics will be presented as well.*

9:00 AM *NM03.04.02

***Direct Heterogeneous Integration of Transition Metal Dichalcogenides** Zakaria Al Balushi; University of California, Berkeley, United States*

*In this talk, I will discuss our recent developments centered on a process to produce fully soluble solutions from a unique molecular chemistry to enable the creation of wafer-scale monolayer 2D semiconductors, like MoS2 and WS2, for logic and memory device applications. These molecules can be dissolved in common solvents and coated onto various substrates, including crystalline substrates, printed electrodes, and polymers. It can also be integrated into superlattice heterostructures like the gate-all-around (GAA) transistor architecture as well as for fabricating atomically thin memresistors for neuromorphic devices. Our method of rapidly synthesizing large-area 2D semiconductor films, particularly in monolayer form *via* spin-coating, represents a novelty, as it hasn't been demonstrated previously with a single-source chemistry.*

***Writing Multi-Compositional Heterostructure in 2D Materials** Hossein Taghinejad[1,2], James Analytis[1,2] and Ali Adibi[3]; [1]University of California, Berkeley, United States; [2]Kavli Energy NanoScience Institute, United States; [3]Georgia Institute of Technology, United States*

***Abstract.** Spatial confinement drives most quantum effects in semiconductors. In two-dimensional (2D) materials, the gifted confinement along the out-of-plane direction enables a plethora of quantum effects and unprecedented properties. Extra degrees of confinement within the plane of 2D materials requires the development of advanced material synthesis methods combined with state-of-the-art nanofabrication techniques. Towards this goal, the formation of lateral junctions between heterogeneous 2D materials has been intensely pursed. However, the degree of spatial confinements offered by available techniques is far from dimensions at which quantum effects start to emerge. Here, we present a technique that enables the synthesis of lateral heterostructures with dimensions as small as a few tens of nanometers, with any desired geometries, in isolated or periodic fashions, in predefined locations, and with tunable material compositions. The prospect of our technique for applications including photovoltaics and optoelectronics will be discussed.*

9:45 AM NM03.04.04

***Improving Monolayer MoS_2 Optical Properties Through Thermal Treatments** Antonino Madonia[1], Emanuele Sangiorgi[1], Francesca Migliore[1], Gianmarco Laurella[1], Salvatore E. Panasci[2], Emanuela Schilirò[2], Filippo Giannazzo[2], Fiorenza Esposito[2,3], Luca Seravalli[2], Gianpiero Buscarino[1], Franco M. Gelardi[1], Marco Cannas[1] and Simone Agnello[1,1]; [1]Università degli Studi di Palermo, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]Università degli Studi di Parma, Italy*

The research on two dimensional (2D) materials has recently witnessed rapid advancements towards industrial applications. In particular, several efforts have been poured into the development of optoelectronic devices based on heterostructures composed of several stacked 2D layers having complementary features.[1] Van der Waals materials such as semiconducting transition metal dichalcogenides (TMDs) are considered particularly useful for their atomic-scale thickness, direct bandgap, and good electronic and mechanical properties.[2] Among these, monolayer molybdenum disulphide (1L-MoS_2) has been widely studied so that nowadays several different production routes which can be easily scaled up and allow to obtain flakes of large size and high quality are available. The intense photoemission at 1.8eV displayed by 1L-MoS_2 flakes excited in the visible light range, originating from an excitonic recombination, is strongly coupled to properties of the material such as strain and doping.[3] Consequently, defects introduced in the monolayer structure during the synthesis can significantly affect the optical performances of this material.[4] Nonetheless, it is possible to exploit the high sensitivity of 1L-MoS_2 to the external environment in order to enhance its photoluminescence by modifying its structural properties following its production.

We have explored how performing thermal treatments conducted under a controlled atmosphere allows to predictably alter the properties of this 2D semiconductor, affecting its strain and doping while at the same time tuning the shape and intensity of its emission. We have compared several 1L-MoS_2 flakes obtained using different preparation methods and studied their properties before and after each thermal treatment. Additionally, in order to better understand the underlying mechanism, the effect of different atmospheres used to perform the treatments has been compared while observing at the same time how the physical properties of conducting, insulating or semiconducting substrates can have a role in the overall results. In general we were able to observe an enhancement of the optical properties of the studied 1L-MoS_2, indicating the effectiveness of the post-synthesis procedure towards reducing the defects introduced by some preparation methods. As such, we believe that our results allow to make use of the most advantageous production routes by solving their drawbacks through an additional treatment step. From a fundamental perspective, the performed comparison enables us to further understand the role of the several factors influencing the optical properties of 1L-MoS_2 and to attempt to harness them. Finally, we aim to control the light-emitting capabilities of the studied 2D material towards its usage in the field of optoelectronics, exploiting the developed post-synthesis treatments versatility for the realization of heterostructure-based devices incorporating 1L-MoS_2 flakes.

2D Quantum Materials Pipelines for Automated Production of 2D Heterostructures at the MonArk NSF Quantum Foundry *Nicholas J. Borys; Montana State University, United States*

Layered two-dimensional (2D) materials enable seemingly endless opportunities to engineer 2D heterostructures by assembling stacks of atomically thin 2D sheets with distinct structural, optical, electronic, and magnetic properties. With interlayer van der Waals bonding, the interfaces between the layers can be pristine, and the selection of the atomic sheets to be integrated as well as their assembly do not need to account for chemical and structural compatibility between the individual layers. Untethered from such limitations and equipped with a vast library of 2D materials, the design and fabrication of novel 2D heterostructures to explore new emergent phenomena or precisely tailor functionalities for technological applications can be intensely pursued with unprecedented freedom. However, the current procedures for fabricating 2D heterostructures are manual, heavily relying on humans to perform the critical processes of mechanically exfoliating bulk crystals, identifying single layers, and stacking individual layers on top of one another. The reliance on manual processes makes 2D heterostructure fabrication tedious, plagues it with low yields, and limits the rate at which results can be reproduced and confirmed. In this talk, I will provide an overview of the 2D Quantum Materials Pipelines (2D-QMaPs) of the MonArk NSF Quantum Foundry that aim to overcome these challenges by automating the assembly of 2D heterostructures with robotic devices for mechanical exfoliation, optical identification of single layers, and stacking of layers into an assembled heterostructures. By leveraging industrial automation technologies and implementing machine learning and artificial intelligence, the 2D-QMaPs significantly accelerate the rate at which these key steps are performed. Select use cases demonstrate how substantially improved reliability and repeatability facilitate faster and higher-quality production of 2D heterostructures as well as more rapid exploration of new 2D material systems. I will discuss how the 2D-QMaPs are integrated with nanofabrication capabilities to realize an end-to-end assembly line for 2D quantum devices that is ultimately intended to provide samples and devices to the overall community of 2D materials researchers.

11:00 AM NM03.05.02

Defect Engineering in MoS2—Thermal Transport in Superlattice Structures *Riccardo Dettori, Francesco Siddi, Claudio Melis and Luciano Colombo; Università degli Studi di Cagliari, Italy*

The study of thermal transport in TMDC and MoS2 monolayers, particularly with a focus on defect engineering, is a crucial area of research in material science due to its potential applications in thermoelectrics and nanoelectronics. In this work, we investigate the role that defects (identified in this case as sulfur vacancies) play in the system thermal conductivity. While random distributions of vacancies are detrimental to thermal transport due to the increased phonon scattering, our results suggest that when defects are arranged periodically, the thermal conductivity behavior is more complex: non-equilibrium molecular dynamics simulations and lattice dynamics calculations indicate that there is no simple monotonic relationship between the defect spacing and thermal conductivity. This can be attributed to interference phenomena and the formation of mini-bands or localized phonon modes that can either enhance or suppress phonon transport depending on the specific periodicity and arrangement of the defects. Understanding the relationship between defect distribution and heat transport can lead to the design of MoS2-based materials with tailored thermal properties, optimizing them for thermoelectric applications.

11:15 AM NM03.05.03

Luminescence Enhancement and Raman Characterization of Vanadium-Doped WSe2 Monolayers *André d. Barbosa[1], Shuai Zhang[1], Anna Safonova[2], Zhuohang Yu[3], Nicola Daldosso[2], Mauricio Terrones[3] and Fernando Lazaro Freire Junior[1]; [1]Pontifícia Universidade Católica do Rio de Janeiro, Brazil; [2]Università degli Studi di Verona, Italy; [3]The Pennsylvania State University, United States*

Monolayer Tungsten diselenide (WSe_2) is a direct band gap semiconductor that has good luminescence properties which are of great interest for optoelectronics applications. In this study, the effect of vanadium (V) incorporation in WSe_2 monolayers grown by chemical vapor deposition (CVD) was ivestigated by a multi-technique approach. Our results indicates that lightly V-doped WSe_2 exhibits an enhanced photoluminescence (PL) response when compared to pristine WSe_2 (up to 250%) and strongly quenched PL signal for highly doped samples. Resonance Raman spectroscopy measurements were performed to study the disorder effects due to the presence of V in the lattice. It was possible to observe the activation of the defect-related LA(M) mode and the evolution of the 2LA(M) and A(M) modes as a function of V concentration. Further, complementary, X-ray photoelectron spectroscopy (XPS) and high-resolution scanning transmission electron microscopy (HR-STEM) measurements were performed to investigate the strucutral and chamical changes in the samples.

11:30 AM *NM03.05.04

Using Spectroscopic Ellipsometry as an In Situ Technique to Control the Growth of Chalcogenide Films *Frank C. Peiris; Kenyon College, United States*

While there are several ex-situ experimental tools to characterize chalcogenide thin films, it is imperative to use in-situ techniques, ideally operated in-operando during growth, to obtain immediate feed-back to control the quality, thickness and alloy concentration of films. Spectroscopic ellipsometry (SE) is a non-destructive optical method that can be employed to determine the dielectric function and thickness of films. The dielectric function obtained from SE can be further analyzed to extract fundamental band gap as well as the higher order electronic transitions, providing insights into the band structure of the material under study. More importantly, the dielectric function obtained from SE can be correlated with other results, such as X-ray diffraction and Raman experiments, to deduce its functionality on thickness, alloy concentration and quality of the chalcogenide film in question. Consequently, having access to such calibrated dielectric functions will enable the incorporation of SE as an in-situ technique to provide immediate-information on thickness, alloy concentration and quality of the chalcogenide film being grown.

In this presentation, we will discuss in-situ SE results on several molecular beam epitaxy-grown chalcogenide films including, Bi_2Se_3, In_2Se_3, $(Bi_{1-x}In_x)_2Se_3$ and $PtSe_2$. SE spectra of both single-layer films and multi-layer heterostructures were analyzed at each step of the growth cycle, including the spectra of the substrate prior to the growth of the film. The dielectric function found for each film via SE is modelled as a collection of oscillators, each of which is associated with an electronic transition in the material. This procedure allows us to infer the quality of films via the broadening parameter of oscillators. Specifically, we find that the Bi_2Se_3 films grown on a buffer layer of $(Bi_{0.7}In_{0.3})_2Se_3$ have a higher quality compared to Bi_2Se_3 grown directly on sapphire. Besides gathering information on the quality of films, in-situ SE predicts the thickness variance of a sample as growth proceeds. Extensive work performed on Bi_2Se_3 films show that in-situ SE can detect unintentional desorption of layers as thin as a quintuple layer of Bi_2Se_3 during a temperature ramp-up, and subsequent cool-down back to the growth temperature. With regard to the multilayer structures, the optical models developed for these structures can decipher minute perturbations in layers as the growth progresses. For instance, our models show that a ~7 nm Bi_2Se_3 layer grown next to a sapphire substrate seems to disappear as the structure is annealed at 600 °C. In addition to the quality and thickness, in-situ SE can determine the alloy concentration of chalcogenide ternary compounds. We are able to predict the alloy concentration of $(Bi_{1-x}In_x)_2Se_3$ at the initial stages of its growth by analyzing in-situ SE spectra. In addition, by examining SE spectra obtained every 15 seconds during the growth, we can monitor if the alloy concentration fluctuates during the growth of the structure. Finally, we will discuss our results on the growth of ultra-thin MoS_2, and show how in-situ SE can be used to control the deposition of monolayers and bilayers of this material.

SESSION NM03.06: Ferromagnetism & Bio Applications

How to Use Defects in 2D Materials to Probe the Bio-World *Yu Lei, Cong Wang, Menghan Wu, Linxuan Sun, Yichao Bai, Haoqi He, Mingchuang Zhao, Jianxiang Gao, Wenbo Li and Mauricio Terrones; Tsinghua University, China*

Extensive research efforts have been dedicated to the field of two-dimensional (2D) materials in a short period of time. From semi-metallic graphene, to semiconducting MoS_2, to insulating hexagonal boron nitride (hBN), 2D materials provide a wide range of physicochemical properties that can be engineered for diverse applications. Recently, defect engineering has emerged as a primary approach to tailor the physiochemical properties and further extend the functionalities of 2D materials. Comprehensive understanding between the atomic-scale defects and the effects on the physio-chemical properties is challenging and essential for the materials community to design multi-functional 2D materials. It is also equally important to develop scalable approaches to control and tailor the defect types and concentration. With the urgency, I have dedicated in defect engineering in 2D materials: 1) Developed universal approaches to introduce defects in 2D materials; 2) Utilized the atomic-scale defects to activate the basal plane reactivities of 2D materials, and proposed a multi-scale strategy to understand the correlation between the reactivities and the atomic-scale defects; 3) Explored the application of defects in 2D materials for single molecule sensing and DNA cleavage. Overall, the work aims to provide a comprehensive understanding of the synthesis, characterization, properties, and application of 2D materials' defects in the context of bio-applications.

Above Room Temperature Ferromagnetism in Epitaxial Thin Films of the Layered Ternary Chalcogenides Fe_5GeTe_2 and Fe_3GaTe_2 *Joao Marcelo J. Lopes; Paul-Drude-Instit für Festkörperelektronik, Germany*

Layered magnetic materials are promising building blocks for the realization of ultra-compact spintronic devices. Moreover, combining them with other layered crystals to form the so-called van der Waals (vdW) heterostructures is a very attractive route to realize hybrid systems exhibiting integrated electronic, optical, and magnetic functionalities. So far, most of the experimental research on layered magnets and related vdW heterostructures has been conducted utilizing micrometer-sized flakes exfoliated from bulk single crystals. However, the implementation of these materials in various technologies depends strongly on the development of bottom-up, scalable synthesis approaches allowing to realize highly uniform films with well-defined interfaces. It also requires that each material component of the heterostructure remains functional, which ideally includes magnetic order above room temperature for the magnetic materials. Among different candidates, the ternary transition metal chalcogenides $Fe_{5-x}GeTe_2$ (FGeT, $x \sim 0$) and Fe_3GaTe_2 (FGaT) show a great potential due to their relatively high Curie temperature and highly tunable properties. Both materials possess a layered vdW structure with each single layer being formed of Fe and Ge (Ga) slabs encapsulated by layers of Te.
In this talk, I will report on our results on epitaxial growth of FGeT and FGaT thin films on substrates such as single crystalline graphene (on SiC) and WSe_2 (on Al_2O_3) via molecular beam epitaxy. Structural characterization using

different methods reveals the formation of high-quality crystalline films with sharp interfaces to the underlying templates. Importantly, magneto-transport and magnetometry measurements reveal ferromagnetic order persisting above 350 K with a predominant out-of-plane anisotropy for both FGeT and FGaT films. I will discuss the correlation between structure and magnetism, in particular the effect of thickness and Fe composition tuning on the magneto-transport properties of the films. These results represent an important advance beyond non-scalable flake exfoliation from bulk crystals, thus marking a crucial step towards the implementation of ferromagnetic chalcogenides in practical applications.

Advanced Insights into Multilayered TMDC Growth Dynamics *Nadire Nayir*[1,2]*; *[1]*Istanbul Technical University, Turkey; *[2]*The Pennsylvania State University, United States*

High-quality transition metal dichalcogenides (TMDCs) are pivotal for driving innovation and creating new opportunities across various industries. The advancement and sustainable development of TMDCs are intricately linked to our ability to manipulate matter across different length scales, requiring a comprehensive theoretical understanding of nucleation and growth dynamics. This presentation will delve into the critical thermodynamic and kinetic factors governing TMD materials' intricate multilayer growth processes. It will explore the current and published findings [1-3], addressing compelling experimental challenges such as (i) the orchestration of surface chemistry and substrate crystallographic structure to elevate the van der Waals epitaxy, (ii) the intricate interplay of operational conditions influencing multilayer growth dynamics, and (iii) the seamless integration of nuclei into crystalline films.

Mathematical Optimization of Large-Area Thickness and Homogeneity of Atomic-Layer Deposited Ultrathin ZnO *Axel A. Ortiz Atondo*[1,2]*, Jonathan Montalvo Urquizo*[3]*, Dalia A. Mazón Montijo*[4,2]*, Ana L. Martínez García*[1,2]*, María I. Mendivil Palma*[1]*, Obed Y. Ramírez Esquivel*[4,2] *and Zeuz Montiel González*[4,2]*; *[1]*Centro de Investigación en Materiales Avanzados S.C., Subsede Monterrey, Mexico; *[2]*Laboratorio de Diseño y Optimización de Recubrimientos Avanzados (DORA-Lab) CIMAV-Mty/TECNL-CIIT Parque de Investigación e Innovación Tecnológica, Mexico; *[3]*Tecnológico de Monterrey, Mexico; *[4]*Consejo Nacional de Humanidades, Ciencias y Tecnologías, Mexico*

Motivated by numerous applications in energy-related technologies such as solar cells, photocatalysts, and smart windows, the study of semiconductor thin films has emerged as an important research area. The production of thin films calls for efficient processes to successfully deposit semiconductor films on expansive substrates such as windows, panels, pipes, and containers. Thin films make photoactive components suitable for diverse large-scale applications including buildings, industries, and vehicles. However, scalability remains a significant challenge across various deposition methodologies, whether vapor- or liquid-phase based. In this contribution, we report the use of experimental measurements combined with mathematical optimization based on metamodels to improve and optimize the process parameters for the atomic layer deposition (ALD) of zinc oxide (ZnO) ultrathin films (~10 nm), a versatile photoactive material in energy research. The optimization process aimed to ensure uniform thickness and homogeneity across 8-inch diameter Si wafers. By considering ALD parameters crucial for film quality and properties, a specific set of inputs, including zinc precursor dose, purge duration, and inner and outer carrier gas flows, were determined based on literature review, expertise, costs, and reactor design considerations. The metamodel focused on optimizing the average thickness and homogeneity of the films. Through iterative calculation and experimentation, a set of ALD parameters was identified, resulting in a ZnO ultrathin film with an average thickness of 11.38 nm, achieving a deposition rate of 1.9 Å/cycle—representing a significant advancement close to the highest reported value for ZnO by ALD. The final thickness variation over the entire 8-inch wafer reached values under 2.61 nm, indicating exceptionally smooth thickness distribution across the whole deposited area. These findings offer promise in transitioning from laboratory-scale synthesis to large-scale production of thin-film-based optoelectronic devices. The results directly point towards finding efficient process parameters for correctly scaling ALD technology, opening new insights that might also work for other deposition methodologies based on thermal ALD, previously inaccessible for mass production.

3:45 PM NM03.07.03

Quantum and Classical Supervised Learning Assessment of Transition Metal Dichalcogenide Monolayer Coverage *Andrew S. Messecar[1], Chen Chen[2], Isaiah A. Moses[2], Wesley Reinhart[2], Joan M. Redwing[2], Steven M. Durbin[3] and Robert A. Makin[1]; [1]Western Michigan University, United States; [2]The Pennsylvania State University, United States; [3]University of Hawaii at Mānoa, United States*

The potential for machine learning models to accurately recognize patterns in data has made them a top strategy for optimizing the simulation, synthesis, characterization, and processing of a broad range of thin film material systems. Learning algorithms have previously been shown to enhance both experimental and theoretical studies of few and single layer materials, including transition metal dichalcogenides (TMDs). For example, supervised learning has previously been implemented to optimize the chemical vapor deposition (CVD) of WTe_2 nanoribbons, and multiple investigations have been conducted to apply active learning, supervised classification and regression, as well as unsupervised learning to study the CVD of MoS_2 from solid state S and MoO_3 precursors. Building upon these efforts, we have applied quantum as well as conventional supervised learning algorithms to study the metal–organic chemical vapor deposition (MOCVD) of TMD thin films – including MoS_2, WS_2, and WSe_2 – as grown with dihydrogen chalcogenide gas and transition metal hexacarbonyl precursors.

Several hundred discrete records of MOCVD–grown TMD thin films synthesized in a single laboratory have been organized into material–specific data sets. For each deposition experiment, Raman spectra characterizing the resulting sample have been utilized to assess monolayer coverage in the resulting thin film. The distance between the A_{1g} and E_{2g} Raman mode peaks in each spectrum was measured and associated with the respective growth record as an output variable in the data set. The MOCVD synthesis parameter data was subsequently mapped to the measured A_{1g} and E_{2g} Raman mode peak distance using supervised learning. A combination of p–value calculations, Pearson's correlation coefficients, and regression tree splitting rules were used to investigate the statistical importance of each MOCVD operating parameter for influencing the expected value of the distance *between the A_{1g} and E_{2g} Raman mode peaks. For MoS_2, agreement between the primary and secondary splitting rules of the regression tree as well as the magnitudes of the correlation coefficients indicate that two of the most influential synthesis parameters are the flow rate of the $Mo(CO)_6$ injector hydrogen gas during the growth step of the deposition process, as well as the flow of $Mo(CO)_6$ during the reaction temperature ramp up step.*

Various quantum as well as classical supervised machine learning algorithms – including k–nearest neighbors, tree–based algorithms, and quantum support vector regressors, were trained on the data and compared for generalization performance. The hyperparameters of each regression model were optimized for the data. The generalization performance of each optimized and trained algorithm was evaluated by calculating the mean squared error (MSE) of the values predicted by the model for a subset of the data that was withheld for testing. The algorithm demonstrating the lowest MSE on the testing data set was selected to forecast the distance between the A_{1g} and E_{2g} Raman mode peaks beyond the experimental data available for training. In the case of MoS_2, this generalization indicates that maximizing both the $Mo(CO)_6$ injector hydrogen gas flow during the growth step and the value of the $Mo(CO)_6$ flow during the reaction temperature ramp up step is forecasted to result in a minimization of the A_{1g} and E_{2g} Raman mode peak distance. This predicted reduction of the peak distance between the A_{1g} and E_{2g} vibrational modes in Raman spectra acquired of MoS_2 thin films corresponds with improved monolayer coverage. The methodology demonstrated in this supervised learning investigation of synthesis–structure relationships can be applied to additional features of interest within Raman spectra, as well as to other TMDs, such as WS_2 and WSe_2.

Defect-Related Properties and Growth Kinetics in 2D Layered Systems—Dopant-Dopant Interactions, Defect Electron-Phonon Coupling and Defect Spin Dynamics *Yuanxi Wang; University of North Texas, United States*

Many functional properties and growth complications of chalcogenide films originate from their 2D form. In this talk we highlight defect-related properties and growth kinetics unique to 2D layered systems – some discovered in chalcogenide films, others anticipated. Specifically, we focus on dopant-dopant interactions, defect electron-phonon coupling, and defect spin dynamics in 2D films.

For dopant-dopant interaction, we show that rhenium doping of MoS2 is complicated by a strong dopant-dopant affinity at ~0.5 eV that could result in dopant clustering and deactivation. For example, a rhenium dopant pair deviates strongly from the classical hydrogen molecule analog by introducing deep levels through a pseudo Jahn-Teller distortion, leading to a strong affinity. The strong dopant-dopant affinity suggests that MoS2 may have an upper doping limit below that of conventional semiconductors, where donor deactivation kicks in at < 1% dopant concentrations.

For electron-phonon coupling, we demonstrate the potential of finding defects with small Huang-Rhys (HR) factors in 2D systems. For example, the small HR factor of hBN boron vacancies of 0.54 (c.f. HR factor = 3.7 for diamond NV– triplet transition) is enabled by the availability of two types of antibonding orbitals, π and σ, only present in sp2 bonded solids. A small HR factor is a key performance metric for defect applications as single-photon emitters (SPE), directly related the degree of photon indistinguishability achievable. This discovery is enabled by a general SPE design principle we have developed from first principles, involving the degree of bonding-character similarity between excited and ground states.

For spin dynamics, we show that spin-orbit coupling matrix elements (SOCME) in 2D materials defects – a central ingredient in calculating intersystem crossing rates – can be much larger than those in conventional defects such as diamond NV– due to the availability of perpendicular orbitals. This finding is based on our recent plane-wave implementation of calculating SOCMEs at the density functional theory level, where efficient descriptors are also constructed based on easily computable Kohn-Sham orbital projections. We further show that our implementation avoids common inconveniences in model construction, cluster size convergence tests, edge passivation strategies (especially for chalcogenide systems), and calculating spin-vibration coupling.

Interface Growth and Engineering of 2D Semiconductors *Kibum Kang and Seunghwan Seo; Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

In this presentation, I will focus on the critical role of interface engineering in the growth and integration of materials in contact with 2D semiconductors. Given the potential of 2D semiconductors as next-generation logic channels and for Monolithic 3D integration, understanding and optimizing these interfaces is paramount. Achieving high-quality interfaces on 2D semiconductors without the use of plasma or seed layers presents significant challenges. The interface between the 2D semiconductor and the deposited thin films often acts as a trap, significantly affecting the performance of the semiconductor. Additionally, conventional plasma or high-temperature processes tend to damage the delicate mono or bilayer structures of 2D materials.
Firstly, I will discuss our breakthroughs in selective area ALD (AS-ALD) processes, particularly on laterally heterogeneous 2D semiconductor surfaces. Our findings highlight the importance of the physisorption of ALD precursors, which is essential for achieving selective deposition patterns, thereby expanding the applicability of AS-ALD beyond traditional limits and potentially forming high-quality interfaces between ALD materials and 2D semiconductors.
Secondly, the presentation will explore the vertical, hetero, and epitaxial growth of 2D and 3D materials, with a particular emphasis on the 2D/3D interface within van der Waals epitaxial growth. This research underscores the potential and understanding of utilizing van der Waals epitaxy for forming interfaces between 2D and 3D materials, paving the way for more reliable and efficient integration of 2D semiconductors in advanced electronic applications.
Lastly, I will briefly introduce the recent advancements in low-temperature MOCVD growth and device processing in my group, including new 2D semiconductor materials beyond TMDs.

11:00 AM NM03.08.02
Phases Control of Epitaxial MnTe Through Buffer Layers *Yuxing Ren and Kang Wang; University of California, Los Angeles, United States*

MnTe is one of the 3D semiconductors that can exhibit anomalous Hall effect. The potential edge states correlated with the alter-magnet properties in the α-phase MnTe is also under study these days. The epitaxial growth becomes one method to tune the electronic structure. In this work we have grown both α-phase and β-phase MnTe *by Molecular Beam Epitaxy on GaAs (111) and sapphire (0001) substrates with different buffer layers.*

While in bulk crystal MnTe α-phase is the most stable state at room temperature, in the epitaxial structure β-phase MnTe can also be achieved in the as-grown thin films without post-growth annealing. On GaAs (111) substrates α-phase MnTe are naturally favored without any buffer layer. When using Bi_2Te_3 series TI (topological insulators) the buffer layers on sapphire (0001) substrates, we found out that β-phase MnTe are favored over pure Bi_2Se_3 buffer due to the smaller lattice mismatch. However, when we add some alloy effect to the buffer layer, though the lattice mismatch is still smaller in β-phase, α-phase is actually grown. This shows the role of the entropy effect and the changed in the surface potential. The nanorods structure in MnTe α-phase can also be controlled by buffer layer control and a $CrSe_x$ layer under it.

11:15 AM NM03.08.03

P-Type Doping of Tungsten Diselenide (WSe_2) Thin Films Using Nitric Oxide (NO) *Andrew R. Graves[1], Chung-Yu Cheng[1], Jeremy Guevara[2], Chen Chen[1], Muhtasim Ul Karim Sadaf[1], Sakib Najam[1], Saptarshi Das[1] and Joan M. Redwing[1]; [1]The Pennsylvania State University, United States; [2]Florida International University, United States*

WSe_2 has garnered interest for use in complementary metal–oxide–semiconductor (CMOS) applications because it is one of the few transition metal dichalcogenides (TMDs) with inherent p-type conductivity. However, Fermi level pinning near the mid-gap prevents the full realization of high-performance WSe_2 devices. Additionally, the relatively low intrinsic carrier concentration limits the film's conductivity. P-type doping, however, can address both challenges. Doping the material at the metal contact to the degenerate limit can de-pin the Fermi level, and lightly doping the channel region can improve device on-currents.

Previously it has been reported that p-type doping of WSe_2 can be accomplished by substituting the metal site with acceptors such as V, Rh, and Ta. Although this results in stable incorporation due to the six-fold bonding coordination, such substitution must be done during film growth when reactive metal sites are accessible, and the energetics are favorable. Alternatively, others have shown that atomic substitution at the chalcogen site can be accomplished with the pnictogens (N, As, etc.) after film growth due to the accessibility of the chalcogen sites at the crystal surface and the availability of native vacancies. Nitrogen-based plasmas can be used to provide the energy and generate highly reactive species for this chalcogen substitution, but this approach can lead to excessive film damage. Among all the pnictogens, nitrogen is an ideal candidate because it has the lowest formation energy for chalcogen substitution. Others have shown that thermal treatment of processed WSe_2 field-effect transistors under an atmosphere of NO results in substantial improvements in on-state currents. However, the mechanism of p-type doping of WSe_2 by NO and its impact on contact resistance are not yet fully understood.

In this work, we report on a low temperature post-growth annealing process to substitute NO at Se sites and induce p-type doping in WSe_2. MOCVD was used to grow high quality few-layer epitaxial films of WSe_2 at the 2-inch wafer scale on c-plane sapphire. Using a hot walled tube furnace setup, these films were then exposed to NO at temperatures ranging between 60 - 300 °C for durations from 2 - 120 minutes. Complementary studies were conducted under air and ultra-high purity argon. These results help elucidate the chemical action of NO as a doping agent versus air induced oxidation and deconvolute purely thermally derived effects.

The films were characterized by scanning electron and atomic force microscopy (SEM and AFM) techniques as well as Raman, photoluminescence (PL) and x-ray spectroscopy (XPS). XPS results indicate substitution beginning at temperatures as low as 100 °C and a complete conversion to a suboxide of tungsten oxynitride (WN_xO_{1-x}) above 250 °C. Further, the doping amount can be incrementally tuned by modulation of the annealing temperature and time. AFM results show a 2D morphology is still maintained after complete conversion from tungsten diselenide (WSe_2) to a suboxide of tungsten oxynitride (WN_xO_{1-x}).

Treated films were transferred to SiO_2 substrates where back gated field effect transistor (FET) arrays were fabricated and tested. FET arrays fabricated from untreated WSe_2 were also annealed under NO across the same *range of temperatures and durations. FET characteristics were extracted, and preliminary results show a clear improvement in FET device performance with I_{on} values improving by at least three orders of magnitude. Additionaly, doping to the degenerate limit was also achieved. These results are of interest because they indicate a viable path towards the realization of high-performance nanoscale WSe_2-based CMOS devices.*

11:30 AM *NM03.08.04

Diffraction-Based Characterization of Polycrystalline Two-Dimensional Materials—A WSe_2 Case Study

Michael T. Pettes; Los Alamos National Laboratory, United States

Application relevant materials are usually polycrystalline, and one of the major challenges in structural analysis resides in accurately identifying the grain boundary orientation and size distribution over a wide field of view with enough spatial resolution to capture tens-of-nanometer sized domains. Four-dimensional scanning transmission electron microscopy (4D-STEM) now enables the fast collection of nano-beam electron diffraction patterns on a two-dimensional array of spatial positions in which various computational analyses can reveal structural variations on a pixel-by-pixel basis over different scales while reducing knock-on damage in samples which have been traditionally very challenging to characterize. In this presentation, I will showcase our advancements in the field of transmission electron microscopy and nanoscience with an emphasis on understanding effects of strain and defects in low-dimensional materials including transmission electron microscopy-based automated orientation mapping, which has significant follow-on impact for electron scattering based nanoscale structure characterization in application relevant 2D materials such as WSe_2.

Epitaxial Growth and In Situ Studies of Ultra-Thin Chalcogenides Coupled to Graphene

Amalia Patane; University of Nottingham, United Kingdom

Two-dimensional semiconductors can drive advances in fundamental science and advanced technologies. However, they should be free of any contamination; also, the crystallographic ordering and coupling of adjacent layers, and their electronic properties should be well-controlled, tuneable and scalable. Here, these challenges are addressed by a new approach, which combines molecular beam epitaxy and in-situ band engineering in ultra-high vacuum of semiconducting gallium selenide (GaSe) on graphene to form a heterostructure referred to as 2semgraphene. In-situ studies by electron diffraction, scanning probe microscopy and angle-resolved photoelectron spectroscopy reveal that atomically-thin layers of GaSe align in the layer plane with the underlying lattice of graphene. The GaSe/graphene heterostructure features a centrosymmetric polymorph of GaSe, a band structure tuneable by the layer thickness, and a charge dipole at the GaSe/graphene interface. Both as-grown and defective GaSe layers are remarkably resilient to oxidation in a pure O_2 environment at room temperature, and chemisorption of O_2 molecules on the surface can effectively electronically neutralise the doping in the layer. Also, a high-temperature annealing of the grown layers in an O_2-rich environment can promote the chemical transformation and full conversion of GaSe into the crystalline oxide Ga_2O_3. These features are scalable, as demonstrated experimentally and modelled by density functional theory. The newly-developed 2semgraphene is *used to demonstrate ultrathin optical sensors that exploit the photoactive GaSe and the sensitivity of its interface with the graphene channel to photogenerated carriers. Versatile functionalities are demonstrated in GaSe- and Ga_2O_3-based photon sensors, ranging from electrical insulation to unfiltered deep ultraviolet optoelectronics, unlocking the technological potential of GaSe and its crystalline oxide.*

2:00 PM *NM03.09.02
***MOCVD Growth of Wafer-Scale Two-Dimensional Semiconductors** Yufeng Hao; Nanjing University, China*

Two-dimensional semiconductor thin film materials are typically represented by a type of transition metal chalcogenide compounds. Its unit structure is a layer of transition metal M (such as molybdenum or tungsten) atoms sandwiched between two layers of chalcogen element X (such as sulfur or selenium) atoms. The MX2 structure is less than 1nm thick. This type of three-atomic-layer-thick film is a semiconductor with a band gap between 1.5-2 eV and a typical carrier mobility greater than 1cm2V-1S-1. It has important application prospects in the field of next-generation electronics and optoelectronics. This presentation will first introduce our research progress in designing, building, and improving MOCVD equipment for the growth of two-dimensional semiconductor films; I will also introduce typical two-dimensional semiconductor films, such as MoS2, WS2, MoSe2, WSe2, and other film basic growth parameters. We will focus on the progress in the growth dynamics of two-dimensional thin film materials on sapphire substrates, including nucleation, epitaxial growth, crystal domain merging, continuous film formation and other processes at the micro scale, and point out the impact of these microscopic processes on wafer-sized two-dimensional thin films. Finally, we will propose the current problems faced by MOCVD growth of two-dimensional semiconductor thin films and the directions of efforts.

3:30 PM *NM03.10.01
***Atomic-Scale Investigation of 2D Films and Flakes** Danielle Reifsnyder Hickey; The Pennsylvania State University, United States*

Ever since the discovery of graphene, two-dimensional (2D) materials have captivated the scientific community. Their unique properties stem from their unusual combination of covalent and van der Waals bonding, as well as the fact that they can be as thin as a single atom and can be integrated into heterostructures or devices. Numerous properties of 2D materials have been demonstrated to depend on thickness, and because they are so thin, atomic-scale defects can play a very important role. This presentation will feature atomic-scale characterization of ultrathin 2D films grown via metal–organic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE), as well as bulk crystals that have been thinned via mechanical exfoliation. We will explore how grains in films have merged, drawing connections between how films are grown and the defects and defect arrays that result. We will also show examples of how features such as thickness and point defects can be readily identified using machine learning and discuss how key information can be extracted by multiple methods. We will focus on tungsten-based chalcogenides (e.g., WS_2, WTe_2) and then extend the discussion to other systems, including *heterostructures.*

4:00 PM NM03.10.02

Thickness Dependencies and Angstrom Scale Reductive Nanopatterning of Chalcogenide Films *Adanma Akoma, K.M. Abu Hurayra Lizu, Karla Del Cid-Ledezma, William Huey, Will Linthicum and Bryan D. Huey; University of Connecticut, United States*

Layered chalcogenides can exhibit a wide range of relevant and tunable electronic, optical, magnetic, and coupled properties—even when vanishingly thin. The many property mapping variations of Atomic Force Microscopy are ideal for investigating these effects, particularly to map ferroelectric or magnetic domains, conductivity, or photovoltaic responses. Leveraging advances in precision reductive nanopatterning, achieved with custom feedback in an Atomic Force Microscope, we extend such studies into the thickness dimension. Both by preparing thickness gradients from 100nm down to an underlying substrate, and by implementing Tomographic AFM for full 3D nanoscale mapping, we uniquely investigate chalcogenide specimens as a function of thickness. For example, domain pinning is observed for $CuInP_2S_6$ supported on a back electrode when less than 10 nm thick. Examples of truly Angstrom scale depth patterning are also presented, enabling distinct layer exposure as well as the preparation of pilot dimensions of metamaterial devices.

4:15 PM NM03.10.03

Chalcogen-Dependent Efficiency of Synthesizing Janus Monolayer Transition Metal Dichalcogenides by Atomic-Layer Substitution *Tianyi Zhang[1], Kaichen Xie[2], Zhuohang Yu[3], Ji-Hoon Park[1], Ang-Yu Lu[1], Kunyan Zhang[4], Wenjing Wu[4], Shengxi Huang[4], Mauricio Terrones[3], Yunfan Guo[5], Ting Cao[2] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Washington, United States; [3]The Pennsylvania State University, United States; [4]Rice University, United States; [5]Zhejiang University, China*

Janus monolayer transition metal dichalcogenides (TMDs) are a unique category of two-dimensional (2D) materials with intriguing properties arising from their out-of-plane asymmetry and inherent electric dipole. Room-temperature (RT) synthesis and patterning of Janus TMDs have recently been realized through an atomic-layer substitution (ALS) approach that steers the reaction pathway in a diverse energy landscape compared to the high-temperature process. In principle, the RT-ALS synthesis of MSSe-type Janus TMDs (M = Mo, W, etc.) can start from either MS_2 or MSe_2, but the associated energy landscapes of these pathways may vary, influencing the reaction efficiency. Herein, we investigate the conversion of Janus MSSe monolayers from MS_2 and MSe_2 prepared by different methods, and our experimental results indicate that the RT-ALS process is more efficient and has a broader reaction window for converting MSe_2 to MSeS than starting the conversion from MS_2. Density functional theory calculations reveal that the reaction energy barrier and overall reaction energy are considerably lower when MSe_2 is employed as the starting material, agreeing with experimental findings. These results improve our understanding of the RT-ALS process, and provide useful guidance for the future design of optimum reaction pathways for various Janus materials with high yield, enhanced uniformity, and controlled dipole orientations.

4:30 PM NM03.10.04

Mechanical Modulation of Two-Dimensional WS_2 *Yarden M. Jahn[1], Guy Alboteanu[1], Dan Mordehai[2] and Assaf Yaakobovitz[1]; [1]Ben-Gurion University of the Negev, Israel; [2]Technion–Israel Institute of Technology, Israel*

Tuning the physical properties of two-dimensional (2D) materials is crucial for their successful integration into flexible electronic devices. It was recently reported that strain engineering is an efficient means to modulate the electrical and optical properties of 2D materials. We show here that it is also a powerful tool for tuning their mechanical properties.

In this work, we applied compressive strain through the buckling metrology to 2D tungsten disulfide (WS_2). In this method, a controlled uniaxial strain is transferred from a compliant substrate to a thin film, and the deformed (wrinkled) shape of the latter is used to extract its elastic properties. We clamped polydimethylsiloxane (PDMS) substrate to movable stages and stretched the PDMS by bringing the stages apart. Then, we mechanically transferred a thin WS_2 flake via scotch tape exfoliation from a solid crystal to the substrate of the stretched PDMS. Lastly, we transferred the strain from the PDMS to the WS_2 by bringing the stages closer, thus compressing it and creating wrinkles due to buckling, with compressive strain ranging between 0.3% and 4%. We demonstrated mechanical softening manifested by the reduction of the effective Young's modulus of WS_2

In addition, we performed in-situ Raman spectra experiments, in which we acquired the Raman spectra of strained WS_2 samples (compressive strain ranged from 0% to 2%). Due to compression, all peak positions (A_1^{-}, $E_{2g}^{'+}$, and $E_{2g}^{'}$-modes) redshifted with the increasing strain, indicating vibrational modes softening in the WS2. Importantly, this observation agrees with the mechanical softening observed in our buckling experiment. In addition, we calculated Grüneisen parameter (γ_{E2g})=0.29) and its shear deformation potential (β_{E2g})=0.56) – both are similar to the values of other 2D materials. In parallel, we conducted an atomistic molecular dynamic (MD) simulation that confirmed the validity of continuum mechanics modeling in the nanoscale and revealed that due to sequential atomic-scale buckling events in compressed WS_2, it shows a mechanical softening.

Previous theoretical studies indicated that the interatomic distance decreases under compression, which results in the dominance of repelling forces in the interatomic interactions. As a result, compressed WS_2 is expected to be more resistant to an external load, namely, it predicts stiffening. However, our buckling experiments demonstrated a clear softening of the WS_2. Our MD simulations show that atomic scale buckling events occur under compressive strain, which results in a significant shape change of the WS_2 to the buckled shape, and thus, also a reduction of its capability to resist external loads. This was further backed by Raman measurements that demonstrated the softening of vibrational modes. Therefore, by tuning the mechanical properties of WS_2 we shed light on its fundamental physics, thus making it an attractive candidate material for high-end flexible electronic and optoelectronic devices.

Harnessing Crystalline Membranes Based on Non-Centrosymmetric Materials for Computing and Energy Transformation *Jian Shi; Rensselaer Polytechnic Institute, United States*

The successful development of various methods for creating crystalline freestanding membranes in functional materials creates the possibility for designing and developing novel computing and energy devices. In this talk, I will present our recent progress in developing freestanding crystalline nanomembranes based on non-centrosymmetric materials for energy and computing applications. By editing the mechanical boundary conditions, electron-phonon coupling, and symmetry of nanomembranes, I will demonstrate the experimental and theoretical observation of effective tuning of their polar, spin, and topological properties. These observations highlight the uniqueness of using nanomembranes as promising building blocks for designing future computing devices such as spin logic or topological devices.

11:00 AM NM04.01.02
Custom-Shaped Freestanding Conducting Oxide Membranes on Demand *Andrea D'Alessio, Katja I. Wurster, Charline K. Kirchert, Carlos Nunez, Thomas S. Jespersen, Nini Pryds and Felix Trier; Technical University of Denmark, Denmark*

Creating freestanding oxide membranes with shape control opens the possibility to study a highly desirable range of feature sizes for future experiments and devices. One of the main challenges in patterning freestanding membranes is the tedious process required to synthesize the films, release and transfer them, and then shape them into a desired design. The question is whether we can achieve the desired shape in a single step, thereby eliminating numerous intermediate fabrication stages and allow the study of devices where the twist angle with respect to the new substrate can be varied systematically. Here, we present a simple and straightforward procedure to produce patterned freestanding membranes, which requires minimal laborious and time-consuming fabrication steps. Deposition of thin films is carried through shadow masks, which are placed between the material source (in this case, a PLD target) and the sacrificial layer on which the material is deposited. By doing this, a thin layer of material is deposited and structured simultaneously. The patterned structure is then transferred on a substrate of choice, in this case on SiO2. The resolution of a shadow mask depends on two key parameters: the size of its features and the thickness of its mask. The relationship between these parameters is called the aspect ratio. The highest resolution is achieved when the aspect ratio is one. At this ratio, the influence of the mask's sidewalls on the dimensions of the deposited material is minimized, allowing for more precise patterning. In the current work we have used STO-based conducting oxide as an example. The membranes were grown in a Hall-bar shape and then transferred. Transport measurements were performed to study both the electric and magnetic properties.

11:15 AM NM04.01.03
Phonon Mean Free Path Spectra of Single Crystalline Silicon Thin Film *Taehoon Kim and Jae Hun Seol; Gwangju Institute of Science and Technology, Korea (the Republic of)*

Fourier’s law, which is applied for heat conduction in bulk materials, becomes unsuitable for thermal transport at *the nanoscale. Especially, when phonon mean free path (MFP) is longer than the characteristic length of a system, phonons in the system tends to be scattered significantly at the boundary, leading to the reduction of thermal conductivity. Therefore, nanostructuring is one of attractive ways to manipulate the thermal conductivity of material in some applications such as thermoelectric devices and thermal insulators. To predict the extent of thermal conductivity reduction via nanostructuring, it is significantly crucial to figure out the contribution of each MFP to thermal conductivity, which is phonon MFP spectrum. Thus, there have been numerous theoretical and experimental studies up to date. The 1st principle calculation has been successful to predict the MFP spectrum for simple atomic structures such as Si, Ge, and etc. Among experimental approaches, the time-domain thermoreflectance and thermal grating method are representative for this research but have some limitations. The former adopts a metal transducer, which makes the analysis complicated, and the latter is limited in decreasing the size of grating, i.e., the characteristic length, due to the diffraction limit of light. Also, most of previous works have studied only about bulk-scale materials, even though modern micro- or nanoelectronic devices are often based on thin film structures. In this work, nanoslots with various widths, which were patterned on a suspended silicon film using a focused ion beam system, provided different ballistic thermal resistances. Undesired damages such as amorphization and redeposition were minimized by employing sacrificial Al layers. The effective thermal conductivities of films including nanoslots were measured in a temperature range of 40–300 K using suspended devices, which were individually fabricated from silicon-on-insulator (SOI) wafer. From the measurement results, the phonon MFP spectrum was extracted by a convex optimization, using suppression function obtained by solving freqeuency-independent Boltzmann transport equation. Additionally, to better understand the measurement results, discrete ordinate method was used with inputs by first principle calculation. This study offers, for the first time, the phonon MFP spectrum for thin films using a non-optical experimental approach.*

11:30 AM *NM04.01.04
Probing Electronic States at Endotaxial 2D Heterostructures *Rachel S. Goldman; University of Michigan, United States*

Endotaxial 2D heterostructures have recently emerged as promising candidates for the achievement of novel quantum states for classical and quantum computing. Of particular interest is the achievement of ultra-clean defect-free 2D materials within a bulk. Examples include chemically-homogeneous sandwiches of octahedral polytypes within the prismatic polytypes of TaS2 and MoSe2 ("polytype heterostructures"), as well as in van der Waals superlattices in which single or multiple 2D Bi2Te3 or Sb2Te3 layers are protected by Bi- or Sb-layers. In this talk, we present scanning tunneling spectroscopy and quasi-particle interference mapping of both endotaxial polytype heterostructures and van der Waals superlattices, emphasize the role of point defects on nucleation and propagation of endotaxial layers as well as the possibility of hosting topologically protected states along certain line defects in the van der Waals superlattices.
This work is supported in part by the Air Force Office of Scientific Research through the Multidisciplinary University Research Initiative, Award No. FA9550-23-1-0334 and the National Science Foundation through the Materials Research Science and Engineering Center at the University of Michigan, Award No. DMR-2309029.

SESSION NM04.02: Application of Freestanding Membranes
Session Chairs: Sanghoon Bae and Jeongkeun Song

1:30 PM *NM04.02.01

Silicon Nanomembranes in Bioresorbable Electronics *John A. Rogers; Northwestern University, United States*

Monocrystalline semiconductor nanomembranes represent versatile classes of materials that enable a broad range of unconventional electronic and optoelectronic technologies – due to their mechanical flexibility, their chemical characteristics and surface properties, their capacity for heterogeneous integration and/or their unusual transport properties. This talk describes recent progress in the use of silicon nanomembranes as bioresorbable active elements of electronics for temporary implants, uniquely enabled by their ability to naturally dissolve in biofluids to biocompatible end products. The focus includes silicon nanomembranes in bipolar junction transistors as light-activated electronic switching elements for self-powered cardiac pacemakers, for diaphragm pacers and for phrenic nerve stimulators.

2:00 PM NM04.02.02

Dipole Behavior Modulation Through Interface Relaxation in Artificially Designed 2D/3D Heterostructure

Sangmoon Han[1], Justin Kim[1,1], Eugene Park[2], Sunok Kim[1], Yuan Meng[1], Zhihao Xu[1,1], Bo-In Park[2], Yunseok Choi[1], Frances M. Ross[2] and Sanghoon Bae[1,1]; [1]Washington University in St. Louis, United States; [2]Massachusetts Institute of Technology, United States

Dipoles, as elements that allow control of dielectric materials, play a crucial role in implementing logic, memory, energy storage, micro-electromechanical systems, and wireless communication. These dipoles can be modulated by designing heterostructures, enabling the control of properties such as poling direction and poling speed. However, lattice mismatch and differences in thermal expansion coefficients hinder the creation of single-crystalline heterostructures, deteriorating dipole controllability as well as insulating performance. Freestanding nanomembranes can be exfoliated from the host substrate, enabling single-crystalline artificial heterostructures by adopting 2D layers, thereby overcoming the limitation. By stacking these materials, tailored heterostructures with novel functionalities are engineered. Nevertheless, since the behavior at these interfaces differs from that of covalent bonds, a more comprehensive fundamental study of their interfaces is necessary for effective dipole engineering.

In this talk, we discuss the relaxation at the 2D/3D van der Waals (vdW) interface and its impact on artificial 2D/3D heterostructures using single-crystalline and freestanding $BaTiO_3$ nanomembranes (SBTO). Due to the differences in dielectric constant and conductivity between SBTO and 2D layers, charge accumulation at the vdW interface was induced because of Maxwell-Wagner (MW) relaxation. To evaluate the effect of the relaxation at the interface according to the supporting layer, we chose 2D conducting (graphene), 2D semiconductor (MoS_2), and 2D insulator (h-BN). The h-BN/SBTO heterostructure induced stronger charge accumulation because of the low conductivity and high dielectric constant of h-BN, acting as a screener for dielectric polarization in the crystal. However, the large amount of charge accumulation suppressed the maximum polarization. In contrast, the MoS_2/SBTO heterostructure provided higher maximum polarization and relatively low remnant polarization, enabling giant energy storage performance. Such charge accumulation at discontinuous gaps can offer new physical phenomena based on fundamental physics of the dipoles, providing new insights for various multifunctional platforms.

2:15 PM NM04.02.03

Free-Standing 2D Ferro-Ionic Memristor via Nanoscale Flexoelectric Engineering *Jinhyoung Lee[1,2], Gunhoo Woo[1], Jinill Cho[1], Sihoon Son[1], Hyelim Shin[1], Hyunho Seok[1], Ziyang Wang[1] and Taesung Kim[1,1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)*

2D van der Waals ferroelectric materials, which have non-volatile switching with switchable polarization, have emerged as significant platforms for next-generation functional devices. Among these 2D ferroelectric materials, *ferro-ionic $CuInP_2S_6$ has received considerable attention due to its phase tunability. Depending on the interlayer Cu^+ ion dynamics, $CuInP_2S_6$ offers the versatile advances for neuromorphic computing via ferro-ionic characteristics. While the $CuInP_2S_6$ exhibits ferroelectric phase with insulating properties at the room temperature, external temperature or electric field are required to facilitate the ferro-ionic conduction. However, the external conditions inevitably cause the stochastic conductive filament formation, which completely limits the practical application of the memristor devices. Herein, we present the programmable flexoelectric engineering for nano-confined conductive filaments in free-standing 2D ferro-ionic memristor. To spatially modulate the Cu^+ ion, an ultra-high vertical shear strain was site-selectively facilitated in the free-standing area to activate the flexoelectric energy conversion, which allowed local positioning of the $CuInP_2S_6$ phase transition. Moreover, we experimentally demonstrated the concept of a free-standing 2D ferro-ionic memristor with nanoscale shear strain engineering. As the local flexoelectric engineering results in a fully reversible paraelectric V_{th} shift, a 6.25×10^2-fold increased $I_{max, with strain}$ / $I_{max, without strain}$ ratio was experimentally observed owing to the vertical shear strain 720 nN, which is theoretically supported by the 3D flexoelectric simulation. Additionally, a topographical Cu^+ ion extraction was locally confined within 232.42 nm width and 58.98 nm height, while the upward polarized bottom In_2Se_3 suppresses the undesirable ionic conduction in the suspended junction area. In conclusion, we envision that our free-standing 2D ferro-ionic memristor provides the extendable geometric solution for ultra-high strain gradient and reliable neuromorphic computing systems.*

Thin Film Air-Bridge Thermal Photovoltaic Cells—Approaching the Efficiency Limit *Stephen R. Forrest, Jihun Lim, Bosun Roy-Layinde and Andrej Lenert; University of Michigan, United States*

The combination of non-destructive epitaxial liftoff and cold weld bonding of III-V materials developed in our laboratory has opened the way to realizing a variety of thin film inorganic semiconductor devices that can serve applications that have heretofore not been accessible to conventional semiconductors.[1] For example, we have demonstrated devices as diverse as cylindrical and hemispherical imagers, the latter of which that undergo a topological transformation during fabrication,[2] and more recently, extremely high efficiency InGaAsP and InGaAs thermal photovoltaics that employ exceptionally long air-bridges where the very thin active semiconductor is suspended between gold pillars.[3, 4] These cells result in almost perfect photon utilization given the very high reflectivity of the air bridge construction. In this talk we will discuss advances and state of the art in both single junction and tandem thin film air bridge thermal photovoltaic cells and their potential use in widespread thermal energy storage.

Ferroelectric Switching in Two-dimensional β-Ga2O3 Down to Sub-Nanometer *Tong Jiang, Han Chen, Yubo Yuan, Xiang Xu, Huaze Zhu, Wenbin Li and Wei Kong; Westlake University, China*

Ferroelectric materials engineered into atomically thin films hold significant promise for nanoscale sensors and actuators, as well as high-density integrated logic and memory devices. Maintaining ferroelectric properties at these reduced dimensions is crucial for advancing next-generation electronics, particularly in applications requiring device miniaturization without compromising, and potentially enhancing, functionality. However, the size effect in ferroelectricity, especially the depolarization phenomenon at ultrathin regimes, presents significant challenges. This depolarization diminishes the performance and stability of ferroelectric materials, limiting their practical potential. Additionally, pronounced interface and surface effects at these scales further complicate the material's behavior, making optimal functionality difficult to achieve. Therefore, designing suitable low-dimensional films to overcome these challenges is imperative.

In this study, we demonstrate ferroelectricity in two-dimensional β-Ga_2O_3 crystalline thin films down to an unprecedented sub-nanometer thickness. Similar to the van der Waals surfaces of two-dimensional (2D) materials, the β-Ga_2O_3 (100) surface exhibits weak surface interactions, with surface free energy comparable to that of graphene. These properties facilitate the easy exfoliation of β-Ga_2O_3 epitaxial layers along the (100) surface.[1,2] We have successfully exfoliated epitaxial β-Ga_2O_3 films down to a half-unit cell and transferred it to arbitrary substrates, akin to two-dimensional materials.[3,4] We find that ultrathin epitaxial β-Ga_2O_3 undergoes a non-ferroelectric to ferroelectric phase transition under biaxial strain at reduced thickness, as predicted by theoretical calculations. Ferroelectricity in Ga2O3 is preserved down to 0.6 nm, corresponding to half-unit-cell thickness. Utilizing ferroelectric Ga_2O_3, we further demonstrate ferroelectric tunnel junction (FTJ) devices that operate at room temperature with a large on/off ratio. This work opens new avenues for exploring ferroelectric materials at the sub-nanometer scale, facilitating the development of low-power applications that can be hetero-integrated with silicon technology via the back end of line (BEOL) process.

Improvements in SiC Remote Epitaxy for Stackable Electronics *Rachael Myers-Ward[1], Daniel Pennachio[1], Jenifer Hajzus[1], Andrew Lang[1] and Rhonda Stroud[2]; [1]U.S. Naval Research Laboratory, United States; [2]Arizona State University, United States*

Remote epitaxy (RE) is a growth process performed on a graphene-covered substrate where the adatom registry is guided by the electrostatic fields penetrating through the graphene from the underlying substrate rather than interactions with the graphene lattice. The RE-grown material is easily exfoliated from the substrate due to weak van der Waals bonding of the graphene at the interface, enabling transfer to desired substrates and thus enabling heterostructures that typically cannot be created with current methods. This technique has the possibility of impacting several research areas including SiC and GaN SMART power, heterogeneous integration of opto- and electronic devices, improving HEMT performance by transferring to higher thermal conductivity substrates, flexible

electronics and quantum sciences.
In this work, we focus on the RE of SiC grown on epitaxial graphene on SiC (0001) using a hot-wall chemical vapor deposition reactor. To maintain the graphene during SiC remote epitaxy, a study was conducted comparing the carrier gas during SiC remote epitaxial growth in an Ar/H_2 *to an all-Ar growth process. The graphene thickness was varied between 1-5 monolayers by using SiC substrates with different offcuts to see the effect of different layer counts on SiC RE. Single crystalline material was achieved for both the on- and off-axis substrates when a low C/Si ratio was used in both an Ar/*H_2 *and all Ar carrier gas flow. Films were characterized using Nomarski microscopy, atomic force microscopy, x-ray diffraction, scanning electron microscopy, transmission electron microscopy and electron backscatter diffraction. While SiC was grown in these experiments, continuous graphene did not remain. Using a high C/Si ratio during the initiation of growth increased the amount of graphitic carbon present at the interface after SiC RE. We will present these results along with studies of using a silane precursor 2% diluted in Ar instead of* H_2 *to reduce etching effects of graphene during the initiation of SiC RE.*

Remote Epitaxy Application for SiC Wafer Cost Reduction *Takuji Maekawa; ROHM Co., Ltd., Japan*

Professor Jeehwan Kim reported epitaxial growth on 2D material-coated substrates and exfoliation of the remote epitaxial film from the graphene-GaAs substrate in 2017 [1]. Furthermore, SiC production wafers are fabricated by physical vapor transport (PVT) at a temperature over 2200 degree C in inert gas environment. This seeded sublimation growth needs extremely time-consuming. If the wafer production time and costs can be significantly reduced, SiC power devices will be more widely used and greatly contribute to solving environmental issue.
In the present study, we introduce the application of remote epitaxy technology through graphene to SiC alternative substrates with epitaxial membranes. Epitaxial graphene is formed by a graphitization process, where the top layer of silicon (Si) atoms on the (0001) surface of 4H-SiC wafer is sublimated at high temperature and epitaxial growth of 4H-SiC is obtained on graphene-coated SiC substrates with the same crystal orientation direction as the SiC substrates used. Then, the epitaxial membrane is exfoliated with using stressor films and the polycrystalline SiC substrate is formed on the peeled epitaxial film. This remote epitaxy method allows the reuse the SiC substrates for fabrication of SiC epitaxial layer and significantly reduces the cost of crystal growth and material loss for SiC wafer production compared to existing methods.

4:45 PM *NM04.02.08
Large Scale Heterointegration of 2D Hexagonal Boron Nitride and GaN-based Materials for Future Opto-electronic Devices *Abdallah Ougazzaden[1,2], Suresh Sundaram[1,2,3], Phuong Vuong[1,2,3], Vishnu Ottapilakkal[2], Andre Perepeliuc[2], Rajat Gujrati[2], May Tran Thi[4], Ashuthosh Srivastava[1,2,3], Tarik Moudakir[4], Simon Gautier[4], Paul L. Voss[1,2] and Jean Paul Salvestrini[1,2,3]; [1]Georgia Institute of Technology-Laurraine, France; [2]Georgia Tech-CNRS IRL 2958, France; [3]GT Europe, France; [4]Institut Lafayette, France*

Hexagonal boron nitride (h-BN) is a futuristic wide bandgap 2D nitride semiconductor material. Wafer-scale growth of high quality two dimensional (2D) materials such as h-BN by MOVPE with possible hetero-integration with existing III-nitrides and other conventional device structures have recently attracted lots of interest [1, 2]. Especially, heterointegration of III-nitrides with h-BN has several advantages, one of them is h-BN growth is compatibible with III-nitride MOVPE growth. It can be grown in the same MOVPE reactor as other IIInitrides, leading *to facile integration avoiding contamination and reproduciblity issues. Here we report, exploration of MOVPE van der Waals eptaxial growth of h-BN and successful demonstration of its integration with other III-nitride devices. These material growth by MOVPE has been successfully scaled up to 6" diameter [3]. Further, we present the characteristics of the light emitting diodes grown on h-BN/sapphire which can be lifted off from the sapphire susbtrates, preserving the phyical properties and transfered to any arbitrary templates. Controllable growth of this 2D materials on dielectric patterned substrates leading to selective area growth of III-nitride based device arrays has been employed for realizing transferrable micro-LEDs with smooth side walls [4]. In addition, these BN in bulk form can be can be employed effectively as a hole injection layer in active UV-LED structures. We demonstrate electrically stimulated emission from the p-hBN/AlGaN MQWs/n-AlGaN structure around 290 nm. These growth experiments on scaling up and heterointegration gives a very important insight on the possible commercialization of use of 2D materials integration in novel device structures, especially h-BN which will be discussed as a path forward to solve the critical issues in free standing/indivually addressable, thin flexible LEDs and other novel device structures.*

Large Area van der Waals Epitaxy and Lift-Off for Integration of GaN High Electron Mobility Transistors

Michael Snure; Air Force Research Laboratory, United States

Integration of electronic materials and devices on to arbitrary substrates is of great interest to produce more compact and capable electronics systems. In particular, integration of GaN devices, like the high electron mobility transistor (HEMT), are of interest due to their high frequency and power handling capabilities, which far surpass Si and III-V based electronics. So far integration at the chiplet level has proven successful, improving power, and performance, while reducing area, design time and fabrication costs. By integrating just the thin active layers and bonding them to a common substrate, even closer integration can be achieved further improving the size, weight, and power (SWAP). Unlike Si and III-Vs, which have well established commercial epitaxial lift-off (ELO) methods, lift-off of GaN layers and devices from the growth substrate is particularly challenging. Of the ELO technologies for GaN, van der Waals (vdW) based lift-off offers great promise but is still in the early stages of development and has yet to demonstrate the scale and yield of other ELO technologies. vdW lift-off involves growth of GaN on a vdW buffer layer, BN on sapphire is used in this work, followed by mechanical separation of the GaN films from the substrate. We will highlight the potential of this process for integration of GaN films and HEMTs at scale. Both tape/stamp based mechanical lift-off and Ni spalling based lift-off will be compared. The effects of the BN vdW template and GaN epitaxy on transfer yield, area, and damage will be covered with the goal of achieving high quality films that can be easily lifted off and transferred. Finally, the impact of this transfer method on GaN HEMT *performance will be discussed.*

9:30 AM NM04.03.02

Quasi-van der Waals Epitaxial of Single Crystal β-Ga_2O_3 on (100) Surface *Tong Jiang[1], Hao Wang[1], Junwei Cao[1], Xiaoqing Huo[2], Shengnan Zhang[2], Junshuai Li[1], Huaze Zhu[1] and Wei Kong[1]; [1]Westlake University, China; [2]China Electronics Technology Group Corporation, China*

Gallium oxide (β-Ga_2O_3), an emerging wide bandgap semiconductor, shows significant promise for power devices due to its high breakdown voltage and low on-resistance. β-Ga_2O_3 is one of the most thermodynamically stable polymorphs of Ga_2O_3, with the (100) surface being more readily obtainable in melt-based bulk crystal growth, offering the potential for producing high-quality, large-area single crystal substrates.

However, similar to the van der Waals surfaces of two-dimensional (2D) materials, the Ga_2O_3 (100) surface exhibits weak surface interactions, with a surface energy of 0.49 J/m^2, comparable to that of graphene.[1] The homoepitaxy of Ga_2O_3 on the (100) surface, akin to quasi-van der Waals epitaxy on 2D materials, is prone to lack of nucleation with epitaxial orientation.[2] Twinning of 180 degrees in-plane rotation formation occurs due to its small twin energy difference. Twins tend to grow in a three-dimensional island and prevent proper film coalescence, resulting in a large number of grain boundaries.[3] Twinning reduces breakdown voltage and decreases carrier mobility, severely impairing device quality. Achieving epitaxial films without twin structures on this surface has been challenging, significantly limiting the application potential of the (100) substrate.

In this study, we achieved quasi-van der Waals epitaxial growth of single-crystal Ga_2O_3 on (100) substrates by introducing excess indium as a catalytic metal during growth. The excess indium facilitates the surface diffusion of gallium adatoms on the substrate. The increased mobility helps gallium adatoms find energetically favorable sites, promoting the formation of a well-ordered crystalline structure.[4] By increasing the growth temperature to ensure indium evaporation and maintaining a high Group III-VI ratio, we shifted the growth mode from 3D island to 2D layer, and achieved β-Ga_2O_3 epitaxial growth on the (100) surface approaching thermal equilibrium conditions. This approach eliminates twin nucleation sites due to their unstable energy state near thermal equilibrium. Additionally, these conditions ensured a layer-by-layer growth mode, with single-crystal nucleation sites expanding into a film. Therefore, we achieved the epitaxial growth of twin-free single-crystal thin films with atomically flat surfaces on Ga_2O_3 (100) substrates. This advancement significantly improves the material quality of β-Ga_2O_3 epitaxially grown on (100) substrates and greatly expands the substrate choices for Ga_2O_3-based power semiconductor devices. With the recent successful development of 6-inch or even larger (100) β-Ga_2O_3 substrates, the pathway for developing high-performance, cost-effective Ga_2O_3-based power devices is now feasible.

CVD Growth of SiC/Graphene/SiC(0001) Heterostructures for Thin Film Transfer *Daniel J. Pennachio, Jenifer Hajzus and Rachael Myers-Ward; U.S. Naval Research Laboratory, United States*

Remote epitaxy (RE) is a thin film growth technique where epitaxial alignment is directed by interactions with a substrate despite it being covered by a top layer of material.[1] This top layer must be inert and atomically thin for the underlying substrate's potential field to dominate the epitaxial alignment. Since the intermediate layer is inert, the epitaxial thin film is weakly bonded to the substrate and can be removed as a freestanding membrane and the substrate can be reused, without the damage associated with other transfer techniques such as controlled cleaving or ion implantation. Transferred 2D two-dimensional (2D) material, such as graphene, is commonly used for a layer, but the transfer can degrade the film and increase process complexity. To avoid this, we aim to grow in situ graphene in the same chemical vapor deposition (CVD) RE growth as SiC. RE SiC is advantageous since the high cost of SiC makes substrate reuse appealing and isolated SiC membranes are excellent for quantum photonics. Despite these benefits, SiC's high-temperature hydrogen-containing CVD environment can easily damage graphene, making RE difficult.

This study established growth windows for in situ graphene via propane-based hot wall CVD followed by subsequent SiC deposition. Growing at 1620 °C in 20 slm H_2 with 20 sccm propane flow produced predominantly monolayer (ML) graphene films on on-axis 6H-SiC(0001) substrates with minimal defects found in Raman spectral maps. The films grown on 4° off-axis 4H-SiC(0001) substrates appear to be thicker multilayer graphene despite experiencing the same conditions as the on-axis substrates. These films exhibited increased uniformity over graphene grown via Si sublimation from the SiC substrate, as determined by atomic force microscopy (AFM) and Raman spectral maps. This optimal graphene growth condition was used for subsequent RE attempts to study the effect of SiC growth temperature, precursor C/Si ratio, and growth rate on epilayer crystallinity and graphene barrier damage. Nomarski microscopy, scanning electron microscopy (SEM), and AFM found SiC grown at 1620°C with a C/Si ratio of 1.55 to have the smoothest surface morphology and fewest polytype inclusions. SiC crystalline quality appeared correlated to growth rate, with lower growth rates producing smoother films with fewer polytype inclusions. Single-crystalline, polytype-pure SiC epilayers was achieved on 4° off-axis CVD graphene/4H-SiC(0001). Cross-sectional transmission electron microscopy (TEM) of some growth interfaces in this study exhibited non-uniform multilayer graphitic carbon, motivating further study of this growth system to improve boundary uniformity and SiC epilayer quality.

Nucleation and Growth of GaAs on a Carbon Release Layer by Halide Vapor Phase Epitaxy *Dennice M. Roberts[1], Hyunseok Kim[2], Kuangye Lu[2], Kevin Schulte[1], Aaron Ptak[1], Jeehwan Kim[2] and John Simon[1]; [1]National Renewable Energy Laboratory, United States; [2]Massachusetts Institute of Technology, United States*

We couple halide vapor phase epitaxy (HVPE) growth of III-V As-P materials with liftoff from an ultrathin carbon release layer to address two significant cost components in III-V devices – epitaxial growth and substrate cost. HVPE is a potentially lower-cost high-throughput manufacturing technique of III-V devices, and the use of carbon layer has been shown to enable substrate reusability to mitigate the large cost of the single crystal wafers. We investigate nucleation and growth of GaAs layers by HVPE on a thin, amorphous carbon layers that can be mechanically exfoliated, enabling recovery of the substrate for re-use. The carbon layers were grown in an organo-

metallic vapor phase epitaxy (OMVPE) reactor with a capability to grow III-V epitaxial layers in situ. This setup allows for the growth of both the carbon layers and GaAs buffers in the same reactor to avoid surface oxidation before deposition of the carbon layer on the GaAs substrates. Samples were then transferred to an HVPE reactor, through air, to demonstrate compatibility with a potentially low-cost and high throughput deposition method of III-V material. Degradation of the carbon release layer was observed with prolonged air exposure during sample transfer between OMVPE and HVPE reactors. The nature of the degradation still requires further study, but is reproducibly demonstrated by increased roughness of GaAs films grown on carbon release layers with more exposure to air before HVPE growth. As a result, air exposure was kept to a minimum during transfer before conducting any HVPE growth studies. Growth was performed under a nitrogen environment to eliminate any degradation of the carbon layer via reaction with high temperature hydrogen present in typical HVPE growth. We studied HVPE nucleation as a function of carbon layer thickness and growth rate and found island-like nucleation during the initial stages of HVPE growth. The island nucleation density during HVPE growth decreases with increasing carbon layer thickness. We then studied various GaAs growth conditions including V/III ratio, growth temperature, and growth rate to minimize film roughness. Lower III/V ratios and thicker films during HVPE growth led to drastically smoother surfaces with reduced threading dislocation density. Finally, we grew an initial GaAs photovoltaic device on a carbon release layer that has an efficiency of 7.2%. A GaAs cap layer was added on top of the carbon layer before removing it from the OMVPE reactor to avoid air exposure of the carbon layer, since air exposure could still be affecting material quality despite efforts to minimize it. This resulted in improved solar cell efficiency up to 12.3%. Device efficiency remains limited by the large dislocation density of the initial GaAs buffer layer due to island growth on top of the carbon release layer.

In Situ Nucleation and Growth Mechanisms of Chiral Tellurium on 2D Materials *Kate Reidy[1,2], Noya R. Itzhak[3], Chen Wei[4], Lothar Houben[3], Paul Miller[1], Federico Panciera[4], Ernesto Joselevich[3] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Miller Institute for Basic Research in Science, University of California, Berkeley, United States; [3]Weizmann Institute of Science, Israel; [4]Université Paris-Saclay, France*

The nucleation and growth mechanisms of chiral crystals have been a topic of open discussion since their initial investigation by Pasteur in 1848. Chiral materials exhibit great potential for integration into emerging nanoscale devices including polarization detectors, chiral catalysts, non-linear photonics and drug testing. However, integration of chiral nanomaterials in devices relies on the ability to selectively synthesize chiral nanostructures with high crystallinity and enantiomeric selectivity. Understanding fundamental nucleation and growth mechanisms has the potential to unlock new regimes of reproducible solid-state chiral nanostructure synthesis, compatible with large-scale manufacturing.

Here, we utilize a unique in situ environmental transmission electron microscope (ETEM) equipped with molecular beam epitaxy (MBE) deposition sources to observe and analyze the epitaxial growth mechanism of chiral Te nanoribbons on 2D materials. Growth on freestanding membranes enables atomic resolution observation. Previous studies of growth on van der Waals (vdW) materials have been conducted primarily on three-fold symmetric materials such as transition metal dichalcogenides (TMDs), where the epitaxial orientation and structure of nanoislands are strongly dependent on the three-fold symmetric surface structure, chemical identity, and defect density. Compared to three-fold symmetric TMDs, growth on more asymmetric 2D material surfaces results in facetted rods or ribbons with a single growth orientation. In situ observation of nucleation and growth allows us to determine step flow mechanisms and distinguish between nucleation-driven and growth-driven models of chiral nanostructures. We elucidate the effect of substrate symmetry, temperature, and flux rate on the resulting interface, and determine kinetic limiting factors such as diffusion distance, morphology, and activation barriers. Our results aid us in determining routes towards enhancing the enantiomeric excess, and expanding the *materials toolbox in which chiral vdW epitaxy occurs.*

Emerging Phase Transitions and Phenomena in Complex Oxide Membranes *Ruijuan Xu; North Carolina State University, United States*

Complex oxides are fascinating materials that exhibit a diverse range of electrical, magnetic, optical, and thermal properties. The advent of freestanding oxide membranes offers exciting opportunities to explore emerging properties in these materials through strain and other external stimuli. In this talk, I will highlight the enormous potential of this new materials platform for enabling and probing emerging phase transitions and phenomena in complex oxides. This includes size-induced ferroelectric transitions in lead-free antiferroelectric membranes and highly confined surface phonon polaritons in strontium titanate membranes.

3D Islands on 2D Materials as Individual Reactors for Measuring Nanoscale Growth Processes and Phase Transformations *Frances M. Ross; Massachusetts Institute of Technology, United States*

When metals such as Au, Ag, Hf or Ti are deposited on a van der Waals material, the result is not a thin film but instead an array of nanoscale islands, a consequence of the difficulty of nucleation and the fast adatom diffusion on the clean and inert surface. These spontaneously formed, crystalline islands can be aligned with the substrate through the process of quasi-van der Waals epitaxy and can show regular shapes and surface facets. The resulting 2D/3D hybrid structures are of interest for their applications in catalysis or in electronic or plasmonic devices. In this presentation, however, we emphasize a different aspect of these structures: the exciting opportunities they offer to probe fundamental questions in crystal growth and transformations in nanoscale volumes.

Our experiments take place in an ultrahigh vacuum electron microscope equipped with gas delivery and evaporation capabilities. The samples consist of flakes of graphene, boron nitride or a transition metal dichalcogenide suspended over holes in a thick silicon nitride membrane on Si. After a cleaning step, the island array is grown at low flux and with the substrate at a temperature of up to several hundred degrees. The islands are then covered by a second metal that is deposited while maintaining vacuum, or exposed to reactive gases such as disilane, digermane or oxygen, and imaged in situ or post-growth. We find that individual islands on the weakly interacting substrate act as essentially isolated systems in which growth phenomena or phase transformations can be resolved. With an entire island within the field of view during an experiment, nucleation sites, defects and the spatial extent of phase transformations can not hide from the view of the microscopist. Analysis of the ensemble of islands with their range of sizes helps determine nucleation statistics, mechanisms and rate-limiting steps. We will illustrate such measurements with several examples. These include strain relaxation through island curvature or through formation of a dislocation array in specific regions of the islands; stability of strained bimetallic islands; lateral growth to form core-shell structures; nucleation of Ge at island corners; silicide formation, and transformations between strain-related crystal structures. Phase transitions in nanoscale volumes *are not constrained to follow the rules of the bulk phase diagram by virtue of the surface and interface energy terms and the kinetic hindrance arising from scarce nucleation sites. Microscopy shows the ways in which nanoscale systems behave differently from larger ones, and opens an intriguing window into materials reactions.*

2:00 PM NM04.04.02

The Integration of Freestanding Perovskite Ferroelectrics with Two-Dimensional Materials for Low-Power Ferroelectric Field Effect Transistors *Tianqing Wan, Yiping Xiao, Sijie Ma and Yang Chai; The Hong Kong Polytechnic University, Hong Kong*

Perovskite ferroelectrics with low coercive field and high crystal quality consume low write energy, which are promising for low-power memory and data-intensive applications. Ferroelectric field effect transistors (FeFETs) demonstrate remarkable energy efficiency due to the non-volatile retention and non-destructive read operation. However, the growth of high-quality perovskite ferroelectrics requires lattice-match substrates, high temperature, and oxygen atmosphere, which restricts their integration with semiconductor and insulator. Here we epitaxially deposit the $BiFeO_3$ *on the sacrificial* $Sr_3Al_2O_6$ *layer, then transfer freestanding* $BiFeO_3$ *films and integrate with two-dimensional materials for metal-ferroelectric-metal-insulator-semiconductor (MFMIS) FeFETs. The freestanding* $BiFeO_3$ *films exhibit low coercive field (30 kV/cm) and low current leakage* (10^{-6} A/cm^2)*. The van der Waals integration with two-dimensional (2D) materials realizes low interfacial trap density* (D_{it}~10^{11} cm^{-2}eV^{-1})*, which contributes to efficient gate control and low write voltage. The resulting ferroelectric transistors show low write energy of* 10^{-20} *J. This work establishes a promising route by integrating high-quality perovskite ferroelectrics for various high-performance electronic devices and physical science.*

2:15 PM NM04.04.03

Intercalation in 2D TMDs and Membranes Fabrication for Water Purification *Zhiyuan Zeng; City University of Hong Kong, Hong Kong*

We developed a lithium ion battery intercalation & exfoliation method with detailed experimental procedures for the mass production of 11 two dimensional TMDs and inorganic nanosheets, such as MoS_2, WS_2, TiS_2, TaS_2, ZrS_2, *graphene, h-BN,* $NbSe_2$, WSe_2, Sb_2Se_3 *and* Bi_2Te_3*, among them 3 TMDs achieved mono- or double layer yield > 90%. Then, a one-step covalent functionalization of* MoS_2 *nanosheets for membrane fabrication is reported, which is accomplished by simultaneous exfoliating and grafting the lithium-ion-intercalated* MoS_2 *in organic iodide water solution. The lithium intercalation amount in* MoS_2 *is optimized so that the quality of the produced 2D nanosheets is improved with homogeneous size distribution. The lamellar* MoS_2 *membranes are tested in reverse osmosis (RO), and the functionalized* MoS_2 *membrane exhibits rejection rates of >90% and >80% for various dyes (Rhodamine B, Crystal Violet, Acid Fuchsin, Methyl Orange, and Evans Blue) and NaCl, respectively. Furthermore, we proposed a S vacancy functionalization strategy for fabricating high performance nanolaminate membranes by grafting three kinds of functional groups on* MoS_2 *nanosheets, in which one functionalized* MoS_2 *membrane exhibited best salt rejection (99.3%) and water/salt selectivity (800 bar*$^{-1}$*) in forward osmosis (draw solution: sucrose solution). We found the capillary width increased from 0.2 Å in pristine* MoS_2 *to around 5 Å in this functionalized* MoS_2 *membranes. Numerical simulations suggest that nanofluidic properties of the functionalized membranes are governed by the fundamental interaction between water and the corresponding functional group, and the interlayer distance. For capacitive deionization, we reported a high-density semi-metallic molybdenum disulfide (1T'-*MoS_2*) electrode with compact architecture obtained by restacking of exfoliated nanosheets, which achieved high capacitance up to ~277.5 F cm*$^{-3}$ *under an ultrahigh scan rate of 1000 mV s*$^{-1}$ *with a lower charge-transfer resistance and nearly ten-fold higher electrochemical active surface area than the 2H-*MoS_2 *electrode, the 1T'-*MoS_2 *electrode demonstrates exceptional volumetric desalination capacity of 65.1* mg_{NaCl} *cm*$^{-3}$ *in CDI experiments, which provides a new method to design compact two-dimensional layered nanolaminates with high* *volumetric performance for CDI desalination.*

Exploring Graphene/Oxide Hybrid Heterostructures *Woo Seok Choi; Sungkyunkwan University, Korea (the Republic of)*

Hybrid heterostructures, composed of 2D layered materials and perovskite oxides, showcase unexpected physical and chemical properties arising from functionally synergistic interfaces [1]. Specifically, the interfacial interaction between the strongly correlated nature of complex oxides and quantized electronic states of graphene allows for facile modulation of the electromagnetic characteristics that would not have been achievable otherwise.
First, we show that the quantum Hall effect of graphene can be employed as a quantum sensor of the electrochemical state of perovskite oxide. The substantial voltage scaling in the quantum Hall states of graphene [2] can be utilized to monitor the oxygen vacancy concentration in the $SrTiO_3$ thin film within the graphene/$SrTiO_3$ hybrid heterostructures [3].
Second, we reveal that the interfacial interaction with a ferromagnetic $LaCoO_3$ epitaxial thin film effectively lifts the spin degeneracy in graphene [4]. The presentation highlights a substantial spin exchange splitting in graphene, up to several hundreds of meV, which can be adjusted by the gate electric field. The substantial and tunable exchange splitting is attributed to interfacial charge transfer, as the conventional magnetic proximity effect fails to explain the magnitude and adjustability of the observed exchange splitting.
Hybrid heterostructures used as a platform hold the potential to open avenues for unexpected electromagnetic functionalities.

2D Materials-Assisted Epitaxy and Assembly of Compound Semiconductors for Micro-LED Technology
Hyunseok Kim; University of Illinois at Urbana-Champaign, United States

Heterogeneous integration of functional materials offers exciting new opportunities for advanced device platforms and functional systems. In this talk, I will introduce the integration of III-V and III-N compound semiconductors with 2D materials as a pathway for novel micro-LED platforms.
I will first introduce three epitaxy techniques for synthesizing thin films on 2D materials; remote epitaxy, quasi-van

der Waals epitaxy, and selective-area epitaxy [1,2]. I will discuss the challenges and prospects of each approach, in terms of the availability of materials, the quality of as-grown thin films, and the compatibility with various transfer and integration processes.

Second, the application of such techniques for heterogeneous integration will be discussed, with a focus on micro-LED technology. By transferring III-V and III-N LED layers from their host substrates, a vertically stacked RGB structure becomes feasible. The stacked structure can be applied for two distinct applications; small-sized displays with extremely high pixel densities for AR/VR [3], and large-sized micro-LED displays with high efficiency for consumer electronics. Scalable and reliable assembly of pixels is the key for commercialization, and I will discuss approaches for the integration and assembly.

Defect Thermodynamics and Engineering in Transferable Oxide Thin Films and Bilayer Heterostructures *Felix Gunkel, Marcus Wohlgemuth, Kapil Nayak, Anton Kaus, Lisa Heymann, Alex Sarantopoulos and Regina Dittmann; Forschungszentrum Jülich GmbH, Germany*

Free-standing oxides based on the delamination of atomically defined epitaxial thin films provide new opportunities to combine functional complex oxides with semiconductor (silicon) electronics. At the same time, the nanoscale confinement of these transferable lamellae enables to synthesize unique defect structures and functionalities, that follow from the structural boundary conditions and limited dimensions of the functional units. Here we discuss the synthesis of transferable perovskite oxide lamellae via the all-perovskite sacrificial-layer route as compared to the graphene-buffered remote epitaxy approach. Due to the generally high oxygen pressure and kinetics during oxide epitaxy by pulsed laser deposition (PLD), the latter approach bears a high potential for the damage of graphene-interlayers, which can be partially prevented by the use of inert gas atmospheres.

We then explore the defect structure of transferred lamellae based on the example of $SrTiO_3$, serving as a model system for ionic-electronic phenomena. As we elaborate, the confinement of the lamella facilitates the overall formation of oxygen vacancies as compared to the bulk oxide. Exploiting the ion-transfer between $SrTiO_3$ and $LaAlO_3$ (deposited under low oxygen pressure), we address the local redox-activity and demonstrate defect concentrations beyond the thermodynamic limit in the transferred lamella.

Finally, we demonstrate how the transferred $SrTiO_3$ lamellae can be used as a template for the growth of functional bilayer structures hosting ion-driven magnetic-electronic phase transitions and electrocatalytic properties. Achieving a layer-by-layer growth mode, we show that bilayer structures with sufficiently defined interfaces and morphology can be obtained on a non-epitaxial substrate, enabling a detailed analysis of magnetic and chemical depth profiles. Notably, despite the lack of an epitaxial relationship between substrate and bilayer, the lateral strain state of the bilayers depends on the expected bond-type (ionic vs. covalent) between the as-transferred lamella and substrate, allowing to achieve novel strain states that are inaccessible in standard epitaxy.

These examples showcase that the integration of complex transferable oxides heterostructures with semiconductors will come with new opportunities but also new challenges to tailor and design the properties of *functional oxides in their new environment.*

4:30 PM NM04.04.07
Spectral Phonon Analysis of Coherent and Incoherent Phonon Transport in Nanomeshes of 2D and 3D Materials *Haoran Cui, Theodore Maranets and Yan Wang; University of Nevada, Reno, United States*

Phononic crystals, particularly nanomeshes—porous thin films of 2D or 3D materials—have garnered significant interest due to their distinctive thermal, optical, and chemical properties. This study investigates the spectral thermal transport characteristics of silicon and graphene nanomeshes, featuring nanoholes of varied sizes arranged periodically and aperiodically. Our simulations demonstrate a pronounced reduction in thermal conductivity (k) for small-hole nanomeshes, attributable to aperiodic hole distributions along heat flow directions, in contrast to large-hole counterparts. Spectral phonon analysis reveals significant suppression of low-frequency phonons in small-hole nanomeshes, akin to behavior seen in 1D superlattices. Additionally, spectral energy density analysis identifies well-defined coherent phonon modes within the 0-3 THz range in small-hole silicon nanomeshes and, moreover, spectral thermal conductivity analysis reveals that these modes ballistically transport across the nanomesh. Furthermore, a comparative analysis of the phonon transport behaviors between silicon and graphene nanomeshes highlights distinct differences in phonon-boundary scattering and phonon coherence, influenced by their respective 3D film and 2D single-layer structures.

4:45 PM *NM04.04.08
From Epitaxy to Membranes: A Materials Science Approach to Functional Interfaces *Bharat Jalan; University of Minnesota Twin Cities, United States*

By leveraging advanced synthesis methods, such as hybrid molecular beam epitaxy (MBE), I will demonstrate an effective yet straightforward approach to creating high-quality oxide membranes and their bicrystals with precise structural and electronic properties. The presentation will focus on three key aspects: the synthesis of atomically-precise membranes, the challenges and solutions for producing membranes without or with controlled wrinkles and cracks, and the development of sensitive characterization techniques. Using SrTiO3 and BaTiO3 as examples, I will showcase our group's work in achieving thin membranes with excellent control over thickness, stoichiometry, and surface termination. Additionally, I will introduce the sacrificial layer approach, which yields oxide membranes with a room-temperature dielectric constant of approximately 300. This work offers a materials science perspective on how epitaxy can enhance membrane technology, unlocking new opportunities for applications in energy storage, sensors, and nanoelectronics.

SESSION NM04.05: Freestanding Membranes—From 2D to 3D I

8:45 AM *NM04.05.01
Advances in MOCVD for Wafer-Scale Synthesis of TMD Monolayers *Joan M. Redwing; The Pennsylvania State University, United States*

Metalorganic chemical vapor deposition (MOCVD) has emerged as a promising technique for wafer-scale *synthesis of transition metal dichalcogenides (TMDs) for device applications. Two general approaches have been pursued: direct growth on oxide-covered substrates at BEOL-compatible temperatures or high temperature epitaxy on single crystal substrates followed by layer transfer. Our work has focused on the later approach with the goal of achieving wafer-scale single crystal TMD films that can be transferred and integrated at BEOL conditions.*

It is challenging to reproducibly deposit TMD monolayer films over wafer-scale substrates without additional bilayer islands. Defects in the monolayer serve as nucleation sites for bilayer formation. Once bilayers nucleate, they grow rapidly aided by enhanced adatom diffusion on the monolayer surface. Our work has therefore focused on minimizing defects in the epitaxial TMD monolayers and developing in situ techniques to track and control the process for true layer-by-layer growth.

These efforts are illustrated for epitaxial growth of MoS_2 *and* WSe_2 *on 50 mm diameter c-plane sapphire using metal hexacarbonyls and hydride chalcogen sources in a* H_2 *carrier gas. The epitaxial orientation of the TMD is found to be strongly dependent on the pre-growth annealing ambient (*H_2 *vs* H_2S/H_2Se*) and the growth temperature which can be tuned to minimize inversion domains and high angle grain boundaries which negatively impact field-effect mobility. Spectroscopic ellipsometry is demonstrated as a promising in situ monitoring tool for TMD growth, enabling real time measurements of monolayer and bilayer surface coverage enabling improved control of layer number as well as insights into the epitaxial growth process.*

9:15 AM *NM04.05.02

Enhancing Photogating Gain in Scalable MoS_2 *Photodetectors Using Nitride-Based Plasmonic Metasurfaces*

Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Absorption of photons in atomically thin materials has become a challenge in the realization of ultrathin high-performance optoelectronics. While numerous schemes have been used to enhance absorption in two-dimensional semiconductors [1], such enhanced device performance in scalable monolayer [2] photodetectors remains unattained. Here, we demonstrate wafer-scale integration of monolayer single-crystal MoS_2 *photodetectors with a nitride-based resonant plasmonic metasurface to achieve a high detectivity of* 2.58×10^{12} *Jones with a record-low dark current of 8 pA and long-term stability over 40 days [3]. We observed an enhancement factor greater than 100 compared to control devices, which can be attributed to the local strong EM field's enhanced photogating effect by the resonant plasmonic metasurface. The combination of monolayer 2D materials with plasmonic metasurfaces opens new possibilities for boosting the performance of optoelectronic devices with design flexibility that accommodates various 2D materials. Given that 2D semiconductors and hafnium nitride (HfN) are not only Si CMOS process compatible but also achievable over wafer scales, our results pave the way for seamlessly integrating 2D semiconductor-based photodetectors into imaging, sensing, and optical communications applications. The detailed mechanisms and potential applications of this technology will be explored further in the presentation.*

9:45 AM BREAK

10:15 AM NM04.05.03

Synthesis of Quasi-2D NiO by Dip-Coating and Langmuir Methods *Diego J. Ramos[1], Stella M. Alicea[2], G. Cristian Vásquez[1], Eric Sandana[3], David Rogers[3] and David Maestre[1]; [1]Universidad Complutense de Madrid, Spain; [2]Inter American University, Puerto Rico; [3]Nanovation, France*

The synthesis of low dimensional structures based on p-type oxides with controlled composition and morphology, as well as their heterostructures with other p- or n-type oxides, are go-to topics that can broaden the field of applicability of these materials in modern technology. NiO is one of the very few p-type oxides which combines wide-bandgap with good stability and interesting physical properties [1]. However, contrary to other van der Waals materials, the fabrication of this oxide in 2D form, membranes and ultrathin films, is still scarce and in most cases requires of complex chemical reactions or high energy-consumption synthesis routes. In that sense, the advent of modern 2D-device technology requires of adequate and scalable synthesis methods to fabricate NiO, and other metal oxides, in the 2D range. In this work, low-cost and scalable methods based on dip-coating and Langmuir films and synthesis at the liquid-liquid interfaces are proposed. These methods are based on the self-assembly of nanoparticles or molecules previously dispersed in suitable solvents [2]. The ultra-thin films can be easily transferred to a target substrate, adding the possibility to fabricate heterostructures layer-by-layer. In order to assess the advantages of these methods, alternative NiO ultrathin films fabricated by Pulsed Laser Deposition (PLD) method will be analysed for comparison.
Owing to the optimization of the parameters involved in the synthesis of the dip-coating and Langmuir films, homogeneous films with variable thickness and properties were fabricated, using Si as substrate. The structural, compositional and physical properties of the NiO samples were analysed by means of diverse microscopy and spectroscopy techniques. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) confirm the formation of homogeneous films with low roughness and thickness in the range of few tens of nm, while Raman spectroscopy and energy dispersive x-ray spectroscopy (EDS) confirms the formation of rock-salt NiO. The optical and electrical properties of the samples were also analysed, and variations as a function of the thickness, doping or thermal treatments involved during the synthesis are discussed.

Using Langmuir Layers and Water-Soluble Dyes to Create Free-Standing van der Waals Membranes
Maximilian Hupfer, Sarah Jasmin Finkelmeyer and Martin Presselt; Leibniz Institute of Photonic Technology, Germany

We developed a thermodynamic model to link hysteresis regions of compression-expansion (CE) isotherms to intermolecular binding energies.[1] CE experiments were used to study the interactions between water-soluble dyes in the aqueous subphase of a Langmuir trough and Langmuir template layers. Our results show that these dyes either adsorb to or intercalate with specific Langmuir layers, as evidenced by the isotherm hysteresis. This interaction leads to the formation of stable H- or J-aggregates within the layers. The resulting heterolayer structures are remarkably stable, even spanning the meshes of copper lattices as free-standing bifacial heteromembranes.[2]

Our study highlights the potential of CE isotherms to characterize dye interactions and the structural stability of

Langmuir template layers, providing insights into the design of advanced material interfaces in free-standing membranes.

Towards Monolithic Integrated Quantum Photonics—Controlled Spin Defects in Hexagonal Boron Nitride Coupled to AlN Photonic Components *Xiuling Li; The University of Texas at Austin, United States*

Optically active spin defects in wide and ultrawide bandgap semiconductors offer a promising platform for the development of next-generation quantum sensing technologies. The well-known NV centers in diamond possess intrinsic limitations for quantum sensing, due to the conflicting requirements of proximity to surface and surface states due to the 3D nature of the material. On the other hand, the 2D layered structures allow for surface proximal spin defects, ensuring effective interaction with the external environment for sensing. In this talk, spin defects in hexagonal boron nitride (hBN) and various approaches of their integration with single crystal AlN based photonic components including resonators and waveguides will be presented.

11:15 AM NM04.05.06
Experimental Observation of Thermal Waves in Thin Graphite *Yeongcheol Park, Minyoung Lee and Jae Hun Seol; Gwangju Institute of Science and Technology, Korea (the Republic of)*

Phonon transport regimes are classified based on the relative occurrence of phonon scattering events. In bulks, heat is generally transferred in the diffusive mode through momentum-destroying resistive scattering. As mean free paths of phonons become larger than or comparable to the characteristic length with decreasing sample size and temperature, the phonon transport regime transitions into non-Fourier transport modes such as ballistic or hydrodynamic phonon transport, where the dominant phonon scattering mode is boundary or normal scattering, respectively. Particularly, the condition required for hydrodynamic phonon transport is rarely satisfied for most bulk materials. Recent calculations have demonstrated that graphitic materials are promising candidates for near-room temperature hydrodynamic thermal transport due to their large anharmonicity and high Debye temperature, which result in exceptional momentum-conserving normal scatterings. To support this, experimental attempts have been conducted, but they are still limited by sample preparation and technical measurement issues. In this study, we examined the signature phenomenon of phonon hydrodynamics, i.e., second sound, in graphite using an optical pump-probe experiment, which was configured with spatially offset beams to characterize basal-plane thermal wave propagations. Additionally, mechanically exfoliated thin graphite flakes with various thicknesses were measured to characterize the thickness effect on phonon hydrodynamic transport. These experimental results were analyzed by solving the viscous heat equations, which describe wave-like phonon hydrodynamic behavior, using first-principle calculation results

11:30 AM *NM04.05.07
Visualizing Strain, Stacking and Corrugations in Free-Standing Two-Dimensional Membranes with Advanced Electron Microscopy *Yimo Han; Rice University, United States*

Two-dimensional materials are not always uniform and flat, especially after being released from their original substrates. They often exhibit inhomogeneous nanoscale strain, varied stacking orders, and out-of-plane deformations that create corrugations. Despite increasingly advanced synthesis and transfer methods, *characterizing these structures in free-standing membranes remains challenging. In this presentation, I will introduce our advancements in state-of-the-art four-dimensional scanning transmission electron microscopy (4D-STEM) and electron ptychography techniques to map strain, stacking order, and out-of-plane morphology in 2D materials. These studies provide significant structural details of suspended 2D membranes, offering insights into their properties and potential applications.*

Overcoming the Limits of Silicon—Strain Engineering for Enhanced Optoelectronic Applications *Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)*

Silicon (Si) is an important material for microelectronics but limitations in its inherent optical absorption hinder its use in broader optoelectronic applications. This work explores how strain engineering can overcome this limitation. We present two approaches: (1) utilizing biaxial strain achieved through pneumatic pressure and (2) leveraging geometry-induced strain from crumpled Si nanomembranes (NMs). Both methods effectively reduce the Si bandgap, extending its light absorption range beyond its intrinsic limit. The first approach achieves a significant extension up to 1550 nm, crucial for LiDAR sensors in autonomous vehicles. These findings highlight the potential of strain engineering for developing advanced Si-based photodetectors and image sensors, paving the way for broader applications in optoelectronics.

2:00 PM NM04.06.02
Artificial Twisting of Freestanding Perovskite Heterostructures *Jeongkeun Song[1], Lin Shan[1], Yunkyu Park[1], Seounghun Kang[1], Amanda Roman Ashby[2], Trisha Musall[3] and Ho Nyung Lee[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Puerto Rico at Mayagüez, United States; [3]Tufts University, United States*

The integration of dissimilar materials in heterostructures has been pivotal in advancing modern materials science and technology. The advent of 2D van der Waals materials has expanded such concept to the mechanical assembly of layered materials such as graphene and transition metal dichalcogenide. Recently, applying the methodology of 2D heterostructures to ultra-thin complex oxides has opened new avenues to explore a rich spectrum of novel functionalities such as superconductivity, magnetism, and ferroelectricity. To deal with the strong 3D bonding oxides, ultra-thin perovskite membranes, including titanates, have been investigated to understand how to create wafer-scale membranes using a water-soluble sacrificial epitaxial layer, $Sr_3Al_2O_6$ *(SAO) and other related materials with different lattice constants. In this talk, we discuss the artificial twisting of perovskite membranes. High-quality perovskite membranes were fabricated by creating perovskite/SAO/substrate heterostructures using pulsed laser deposition. The perovskite membranes were then released by dissolving the heterostructure in the water and subsequently transferred. Moreover, we carried out a systematic characterization of twisted perovskite membranes and will report the details of reconstructed superstructures at the interface in twisted perovskite membranes.*

2:15 PM NM04.06.03

Chemical Vapor Deposition Substrate Attack Angle—Implications on Vertically Aligned Carbon Nanotubes Growth Efficiency *Lev Rovinsky and Noa Lachman; Tel Aviv University, Israel*

Vertically aligned carbon nanotubes (VACNT) offer three key benefits: an exceptionally high specific surface area, outstanding thermal and electrical conductivities, and adjustable directionality. Traditionally, yield optimization research on chemical vapor deposition (CVD) for synthesizing VACNT has focused on the chemical reactions between reactive gas and catalyst surfaces, yet the fluid dynamics within CVD reactors, which govern the transportation of reactive species to the catalyst, are equally crucial. Experiments show that during VACNT synthesis, the sample's center experiences 'growth starvation' due to less carbon feedstock reaching it compared to the periphery, resulting in inhomogeneous growth with a sunken middle. Extreme cases can even lead to the center collapsing. In this work, we combine computational fluid dynamics (CFD) and experimental data to investigate what causes the collapsing phenomenon, using pragmatic, first-order approximated simulations to depict a simple physical flow and its interaction with a solid object, revealing a deflection pattern. The simulations demonstrate that increasing sample height leads to a thicker flow boundary layer. In order to reduce the boundary layer thickness, the substrates were simulated to be at positive attack angles (10° through 30°) with respect to inbound gas flow. While all attack angles reduce boundary layer thickness across all sample heights, the simulations of 15°, 20°, and 25° showed an exceptionally thin boundary layer. Based on these simulations, jigs were manufactured to hold substrates at precise attack angles (15°, 20° and 25°) during CVD growth for various durations (4, 7, 10 and 13 minutes). While all experimented attack angles resulted in better growth performance compared to horizontally oriented non-jigged samples, samples mounted at 25° exhibited the most significant improvement—25% or 600-µm CNT. This research integrates CFD simulations and experimental data, investigating the impact of substrate attack angle on the growth behavior of VACNT samples and highlighting that yield optimization for nanomaterials extends beyond nano-scientific tools alone. On a broader scale, outside the specific application of VACNT growth, the research may indicate the catalysts are not exploited for their full potential, and efficiency enhancement is within reach.

3:30 PM *NM04.06.04
Freestanding Oxide Membranes for Electronic and Electro-Mechanical Devices *Thomas S. Jespersen; Technical University of Denmark, Denmark*

In this talk I will present our results on synthesizing, releasing, stacking, and transferring oxide membranes while keeping the structural and functional integrity of the crystals intact. While the oxide crystal define the overall functionality, the freestanding membrane geometry provides a new freedom in choice of target substrate which enables new applications and functionalities not possible with conventional thin film growth. I will present our results on the integration and manipulation of strain and strain gradients enabled by transferring membranes onto flexible substrates, substrates with predefined topography, or substrates with microfabricated cavities allowing access to electro-mechanical degrees of freedom in freely suspended membranes. Also, transferring onto silicon opens new possibilities for electronic devices exploiting the powerful tools of conventional nano and micro fabrication, and the integration of oxide electronics in integrated circuitry. The realization of silicon/oxide hybrid electronics based on freestanding membranes will be presented and I will discuss the potential impact and possibilities of this methodology for realizing new functionalities in quantum devices.

4:00 PM *NM04.06.05
Epitaxy Growth Of Bi-Layered 2D Semiconductors with Wafer-Scale Crystallinity on Non-Rigid Substrates *Kai Qi, Jui-Han Fu and Vincent Tung; The University of Tokyo, Japan*

Research in electronic nanomaterials has evolved remarkably over the decades. Traditionally dominated by studies of nanocrystals/fullerenes and nanowires/nanotubes, there is now a burgeoning interest in two-dimensional (2D) atomically thin films. Such materials present immense potential and practicality for unconventional soft electronics, i.e., foldable, bendable, and twistable to irregular surfaces. To this end, prevailing strategies typically hinge on transferring 2D thin films onto a pre-stretched elastomer substrate, tuning of material thickness, blending the 2D semiconductors with plasticizing agents, or the utilization of wavy or serpentine structures and patterning of elastomeric substrates of variable stiffness. While soft polymeric substrates often lead to polycrystalline or amorphous results due to their inherent limitations, crystalline substrates that are innately rigid offer the lattice alignment needed for epitaxy growth of single-crystal 2D materials. Thus, achieving direct epitaxy growth of single-crystal 2D materials on non-rigid substrates presents a dichotomy between desired electronic and mechanical properties. In this talk, we delve into the direct epitaxy growth of single crystalline 2D materials, particularly in their mono- and bilayer nanoribbon formats, on soft, insulating, or semiconducting substrates that are both bendable and twistable. This discovery significantly broadens the landscape of potential applications, enabling more robust and versatile electronic devices that can conform and adapt to varied form factors without compromising their performance. The synthesis techniques have also seen leaps and bounds in progression, creating twisted heterostructures with unparalleled properties.

4:30 PM NM04.06.06

Experimental Reexamination of Thickness-Dependent Phonon Transport in Graphite *Changho Kim, Minyoung Lee and Jae Hun Seol; Gwangju Institute of Science and Technology, Korea (the Republic of)*

In recent research, hydrodynamic phonon transport in graphitic materials has been demonstrated unexpectedly higher thermal conductivities compared to bulk materials through theoretical and experimental approaches. Phonon hydrodynamics, which considers the collective motion of phonons akin to a viscous fluid (Poiseuille flow), results in extremely high thermal conductivity. Graphitic materials are promising candidates for observing hydrodynamic phonon transport due to a large density of states of low-frequency flexural phonons, which results in the predominance of momentum-conserved scattering processes (normal scattering). In this study, a comprehensive experimental investigation was conducted to explore the thickness-dependent thermal conductivity of suspended graphite ribbons over a range of temperatures. The measurements, which utilized frequency-domain thermoreflectance (FDTR), were performed on samples varying from bulk to a few tens of nanometers in thickness. Taking into account the anisotropic nature and size, the measured results are fitted using finite element method. Additionally, a residue-free fabrication technique for graphite samples was employed to minimize undesirable defect scattering processes. The existence of phonon Poiseuille flow within a specific thickness range of the samples was confirmed through the calculations based on the phonon Boltzmann transport equation, incorporating Callaway's dual relaxation model and first-principles calculation results. This provides not only experimental validation of phonon hydrodynamics, but also a deeper understanding of the mechanisms underlying this behavior. Our findings highlight the crucial role of boundary and defect scattering processes in phonon hydrodynamics.

4:45 PM NM04.06.07

Alloying and Mechanical Characterization of 2D Transition Metal Dichalcogenides *Guy Alboteanu[1], Dan Mordehai[2] and Assaf Yaakobovitz[1]; [1]Ben-Gurion University of the Negev, Israel; [2]Technion–Israel Institute of Technology, Israel*

Transition-metal dichalcogenides (TMDs) are two-dimensional materials with attractive physical properties. Among them, two popular members are Molybdenum disulfide (MoS_2) and Tungsten disulfide (WS_2), which present

extraordinary mechanical, electrical and optical properties and thus, they attract immense attention for advanced applications in nanotechnology. Here we alloy the metal atoms of TMDs and thus, manipulating their properties. As a reference, we used a chemical vapor deposition (CVD) method to grow $Mo_{1-x}W_xS_2$ *alloys and we characterized their material properties. Importantly, we noticed that CVD based alloying is not scalable due to the clear thermodynamic dominance of* MoS_2 *growth over* WS_2 *growth. Accordingly, we developed a novel exfoliation-diffusion process that overcomes this issue. First, we mechanically exfoliated thin* WS_2 *nano-drumheads over prep-prepared cavities. Then, we controllably diffused Mo atoms into the nano-drumheads, thereby creating* $Mo_{1-x}W_xS_2$ *alloys.*
We applied several characterization methods to verify the atomic structure of the alloys, including Raman analysis and photoluminescence. Next, we applied topographic scans and indentation tests using atomic force microscope (AFM). We extracted the force-deflection curves of the alloy nano-drumheads, from which we got their Young's modulus and pretension. In parallel, we uncovered the atomic structure (i.e., the value of x) from energy-dispersive X-ray spectroscopy (EDS) measurements and we correlated the atomic composition to the mechanical properties. We found that high concentration of W atoms is associated with high Young's moduli. Furthermore, we found that due to weak interlayer interactions in the alloys, thick alloys are associated with low Young's moduli. We did not observe any trend relating the pretension to the values of x, although it increased as the nano-drumheads thickness increases. We also conducted atomistic molecular dynamics (MD) simulations of alloys, which demonstrated the stiffening effect of high values of x, as observed in the experimental results.
Therefore, our work exhibits a novel means for large-scale alloying of TMDs and reveals its mechanical properties tunability. Alongside the reported modulation of the optical and electrical properties of alloys, this work set the groundwork for their integration into advanced applications, such as flexible electronics and strain engineered devices.

5:00 PM *NM04.06.08
Atomic Lego for Future Computing Feng Miao*; Nanjing University, China*

Van der Waals (vdW) heterostructures, also known as "atomic Lego," are created by stacking different 2D materials, offering unprecedented opportunities to engineer atomic structures with diverse physics and functionalities beyond traditional materials. In this talk, I will demonstrate how these Lego-like structures open new avenues for exploring fundamental physics and developing practical applications in future computing. Specifically, I will showcase several atomic Lego-based neuromorphic computing devices, such as robust memristors utilizing a graphene/$MoS_{2-x}O_x$*/graphene vdW heterostructure [1], as well as 2D moiré synaptic transistors and ferroelectric topological devices based on graphene/hBN heterostructures [2-3]. Furthermore, I will discuss the applications of atomic Lego in retinomorphic computing, including a reconfigurable neural network vision sensor [4] and a visual perceptron [5], as well as broadband convolutional processing directly within sensors [6]. Additionally, I will highlight our work on using atomic Lego structures to construct a simple solid-state quantum simulator for the extended Hubbard model [7]. Finally, I will explore novel computing paradigms enabled by these devices [8-10] and provide insights into the future prospects of atomic Lego-based computing.*

Synthesis and Properties of Single Domain $BiFeO_3$ Thin Films and Free-Standing Membranes *Chang-Beom Eom; University of Wisconsin-Madison, United States*

$BiFeO_3$ (BFO) is positioned for success as a magnetoelectric material system, but its optimum usage in faster and more energy-efficient magneto-logic devices require advances. Most importantly, a ferroelastic and antiferromagnetic monodomain state with single-step deterministic switching is desirable for reliable low-power magnetoelectric devices with reproducibility and scaling using $BiFeO_3$. This would allow deterministic and robust control of both the internal magnetoelectric coupling in $BiFeO_3$ and the exchange coupling of its antiferromagnetic order to a ferromagnetic overlayer.

We have fabricated epitaxial (001) and (111) BFO thin films with both ferroelectric and antiferromagnetic monodomain states. Additionally, we have fabricated freestanding membranes of ferroelastic and ferroelectric monodomain $BiFeO_3$ using an $Sr_2CaAl_2O_6$ (SCAO) sacrificial layer. The membranes exhibit deterministic switching over a hundred thousand electric field cycles with lower voltage and faster switching dynamics than their thin-film counterpart. This progress is promising toward energy-efficient magnetoelectric memory devices. We will discuss additional multiferroic applications of these BFO membranes.

This work has been done in collaboration with P. Pal, J. L. Schad, K. J. Lee, Y. Yao, A. M. Vibhakar, R. D. Johnson, P. G. Radaelli M.S. Rzchowski.

CBE acknowledges support for this research through the Gordon and Betty Moore Foundation's EPiQS Initiative, Grant GBMF9065 and a Vannevar Bush Faculty Fellowship (ONR N00014-20-1-2844). Magnetic and transport measurement at the University of Wisconsin–Madison was supported by the US Department of Energy (DOE), Office of Science, Office of Basic Energy Sciences (BES), under award number DE-FG02-06ER46327.

9:15 AM NM04.07.02
Fabrication of Freestanding Polycrystalline Yttrium Iron Garnet Thin Films Using a Sacrificial Layer *Jorge M. Marquez Chavez, Sangho Lee, Miela Gross, Doyoon Lee, Jeehwan Kim and Caroline A. Ross; Massachusetts Institute of Technology, United States*

The emergence of epitaxial lift-off techniques as a novel method for layer transfer and hetero-integration has enabled the synthesis of freestanding oxide membranes with distinctive functional properties and promising *practical applications. Freestanding yttrium iron garnet ($Y_3Fe_5O_{12}$, YIG) films, in particular, have garnered increased attention within the spintronics community due to their diverse range of magnetic and magnonic phenomena—such as low damping, spin pumping, spin orbit torque and spin wave propagation—that not only hold potential for enhancement compared to their bulk counterparts but also for integration into advanced devices and new technologies.*

Despite their significant promise, there remains a gap in exploring reliable techniques for producing YIG membranes. While single-crystalline freestanding garnets have been previously fabricated using graphene-based remote epitaxy [1], the use of 2D materials for membrane fabrication in general is not well developed for garnet-based structures. The challenges arise due to the difficulty in achieving high-quality graphene and other 2D material transfer onto garnet substrates, the sensitivity of the 2D materials to the high temperatures and oxygen required for complex oxide growth, and the variety of other competing phases such as orthoferrites or iron oxides that can form from the constituents of the garnet.

In this work, we demonstrate an alternative method for the fabrication and transfer of freestanding garnet membranes using high-quality water-soluble $Sr_3Al_2O_6$ (SAO), which is commonly used for making freestanding epitaxial perovskite films. An $SrTiO_3$ (STO)/SAO (30 nm)/STO (8 nm) heterostructure is first grown using pulsed laser deposition in which the upper STO protects the SAO during subsequent steps, followed by the deposition of 5 nm silica using sputtering. The silica forms an amorphous layer upon which a 150 nm layer is grown from a YIG target by PLD without heating. The as-grown YIG-composition layer is amorphous, but it is then rapid thermal annealed at 900°C for 5 min in oxygen to obtain polycrystalline garnet without secondary phases according to x-ray diffraction, and with grain diameters of several μm. Use of the silica layer is necessary to prevent a Fe-rich $YFeO_3$ orthoferrite forming epitaxially on the STO layer [2]. The stack is then immersed into deionized water for one day to dissolve the SAO sacrificial layer, releasing the STO/silica/YIG, and hydrochloric acid is used to dissolve the STO. The as-grown and transferred YIG films exhibit magnetic hysteresis loops characteristic of polycrystalline garnet with an in-plane easy axis resulting from the dominant shape anisotropy. This method aims at inspiring alternative methods to remote epitaxy in garnet systems as means of exploring exotic physics, and developing innovative spintronic and magnetooptical applications.

9:30 AM NM04.07.03

Correlative Study of the Luminescence Properties of Gallium Oxide Nanomembranes Bianchi Mendez[1], Paula Perez-Peinado[1], Daniel Carrasco[1], Pedro Alcazar[1], Jaime Dolado[2], Ruth Martínez-Casado[1], Gema Martinez-Criado[2], Jani Jesenovec[3], John S. McCloy[3], Francisco Dominguez-Adame[1], Jorge Quereda[4] and Emilio Nogales[1]; [1]Universidad Complutense de Madrid, Spain; [2]European Synchrotron Radiation Facility, France; [3]Washington State University, United States; [4]ICMM-CSIC, Spain

Nanomembranes have appeared as attracting building blocks in future devices, which could ease the integration of a wide range of materials in low dimensional structures, such as van der Waals heterostructures. One of key materials family in the development of optical and electronic devices is the ultra-wide bandgap semiconductors, of which gallium oxide is the most representative material. The stable monoclinic phase of Ga_2O_3 possess a bandgap of 4.9 eV, and a lot of work has been done recently in the synthesis if bulk and thin films materials. In this work, we tackle the fabrication of nanomembranes by mechanical exfoliation of undoped Ga_2O_3 single crystals grown by Czochralski technique. The thickness of the membranes is in the 200 - 700 nm range, as results from optical interferometry and atomic force microscopy measurements.

The correlative study of X-ray absorption (XAS) and X-ray excited optical luminescence (XEOL) was used to study the optical properties of the Ga_2O_3 nanomembranes. The particular morphology of the nanomembranes allows for orientation-dependent study of the absorption and luminescence, shedding light into the relationship between the *local microstructure and defects involved in the luminescence bands. This understanding will be of paramount importance in the development of optoelectronic devices based on gallium oxide membranes.*

10:15 AM *NM04.07.04

Heterogeneous Integration of SrTiO3 on GaN HEMTs *Hyunseong Kum; Yonsei University, Korea (the Republic of)*

Heterogeneous integration of dissimilar crystalline materials has recently attracted considerable attention due to its potential for high-performance multifunctional electronic and photonic devices. The conventional method for fabricating heterostructures is by heteroepitaxy, in which epitaxy is performed on crystallographically different materials. However, epitaxial limitations in monolithic growth of dissimilar materials prevent implementation of high quality heterostructures, such as complex-oxides on conventional semiconductor platforms (Si, III-V and III-N). In this work, we demonstrate gallium nitride (GaN) high-electron-mobility transistors with crystalline complex-oxide material enabled by heterogeneous integration through epitaxial lift-off and direct stacking. We successfully integrate high-κ complex-oxide SrTiO3 in freestanding membrane form with GaN heterostructure via a simple transfer process as the gate oxide. The fabricated device shows steep subthreshold swing close to the Boltzmann limit, along with negligible hysteresis and low dynamic on-resistance, indicating very low defect density between the SrTiO3 gate oxide and GaN heterostructure. Our results show that heterogeneous integration through direct material stacking is a promising route towards fabricating functional heterostructures not possible by conventional epitaxy.

10:45 AM *NM04.07.05

Phase Transitions in Free-Standing (K,Na)NbO3 Membranes *Jutta Schwarzkopf, Jeremy Maltitz, Martin Schmidbauer, Saud Bin Anooz and Jens Martin; Leibniz Institute for Crystal Growth, Germany*

Ferroelectric perovskite oxides with the chemical formula ABO3 typically pass through a series of structural phase transitions upon cooling from a paraelectric, cubic high temperature phase to various ferroelectric phases with lower crystal symmetry. However, phase transitions in ferroelectric thin films could exhibit significantly different characteristics than their corresponding bulk material depending on effects like boundary conditions, (hetero-) epitaxial strain or growth-related defects. Phase formation and phase transitions can be specifically tuned by strain and defect engineering, although this is restricted to specific film-substrate combinations. In contrast, free-standing membranes which are released from a stiff substrate provide higher flexibility. This is of particular interest because in perovskite oxides the functional properties (e.g. dielectric permittivity or piezoelectric coefficients) are often strongly enhanced in the vicinity of the phase transitions.

In this contribution, we have investigated the phase transitions of heteroepitaxially grown films and free-standing (K,Na)NbO3 membranes. (K,Na)NbO3 is regarded as one of the most promising lead-free piezoelectric materials in respect to its electromechanical, electrooptical and piezoelectric properties. In order to gain fundamental understanding of phase formation, stability and transitions, films with high structural quality and chemical homogeneity are essential. For that purpose, we have applied metal-organic vapor phase epitaxy (MOVPE) as an ideal growth method since it works nearby thermodynamic equilibrium and provides well-ordered films with smooth surfaces and interfaces. Furthermore, it enables the growth of intentionally stoichiometric as well as off-stoichiometric films. For the preparation of (K,Na)NbO3 free-standing membranes (K,Na)NbO3 films have been grown on rare-earth scandate substrates with SrRuO3 as intermediate layer serving as sacrificial layer for the subsequent detachment process. Significant differences in phase transition behavior have been observed for free-standing and epitaxially strained films.

11:15 AM NM04.07.06

***Simulating Bulge Test of Wrinkled Diamond Membranes** Paulius Pobedinskas[1,2], Sara Salera[1,2] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]IMEC vzw, Belgium*

Nanomembranes (NMs) are very thin (≤ 500 nm) and have very high aspect ratios of thickness to lateral dimension ($\geq 10^4$). This makes them extremely flexible due to the linear decrease of bending strain with thickness. At the extreme thinness, materials fold much easier. When nanocrystalline diamond (NCD) thin films are grown on substrates, which have a higher thermal expansion coefficient than diamond, unavoidably, compressive stress is generated. When a NCD NM is released from such substrate a pattern of wrinkles evolves. The out-of-plane deformation is associated with the onset of an elastic instability, where the total energy is best minimized by the film bending rather than straining in-plane. Membranes are used to determine the mechanical properties of thin film materials by performing the bulge test experiment. The bulge test technique and existing models associated with it are well-known and widly used. However, the existing analytical models cannot accurately predict the behaviour of membranes that are wrinkled due to compressive in-plane stress. The formation of wrinkles affects the membrane's response to the load, and thus, one cannot disregard their presence and use the existing models. In this work, we present finite element simulations of compressive stress relaxation in a diamond NM as it is released from a supporting substrate. After the relaxation, the bulge test experiment simulation is performed on wrinkled diamond NM of various thickness (50 to 500 nm) and dimensions (0.1 to 10 mm). The results are compared with available experimental data. To study the impact of elastic constants on the bulge test, the calculations were made with different Young's moduli (150 – 1200 GPa) and Poisson's ratios (0.00 – 0.21). The compressive stress within the membranes was varied in the range from −10 kPa up to −5 GPa, and the bulging pressure was varied from 0 to 50 mbar. The simulation results indicate that the sensitivity of the membrane to the load increases with increasing size of a membrane or decreasing the in-plane stress, Young's modulus, Poisson's ratio or membrane thickness. The same behaviour is observed experimentally. We demonstrate that the bulge test is not valid for Young's modulus determination on large membranes if they are buckled and wrinkled due to compressive stress. The Young's modulus is underestimated, the higher the stress, the larger the discrepancy. Finally, we derive an empirical equation that relates the wrinkled membrane response to the load as a function of elastic constants, membrane dimensions and compressive stress.

*11:30 AM *NM04.07.07*

***Selective Etching and Micro-Transfer Printing of GaSb-Based Infrared Devices** Margaret Stevens[1], Alex J. Grede[1], Shawn Mack[1], Kenneth J. Schmieder[2] and Jill A. Nolde[1]; [1]U.S. Naval Research Laboratory, United States; [2]Formerly with the U.S. Naval Research Laboratory, United States*

III-V-Antimonide (Sb) compounds are useful for many different infrared device applications, ranging from full spectrum photovoltaics, to eye-safe photonic power converters, to light-emitting diodes for biomedical applications. The ability to remove the III-V-Sb device from its native substrate and heterogeneously integrate it with different materials would further support these technologies. For GaSb-based devices, heterogeneous integration is typically achieved by inverting the device, bonding the epitaxial surface to a new handle, and etching through the substrate. However, this method is not compatible with substrate reuse or additive manufacturing capabilities that could be provided with micro-transfer printing. Though complete substrate removal is undesirable in some aspects, it is typically the most successful method of separating a sample from its substrate due to the low etch selectivity between 6.1 Å semiconductors.

Our group has characterized etch selectivity between AlGaAsSb/InAsSb lattice matched to GaSb when using citric acid-based etches as well as hydrofluoric acid (HF) based etches [1]. Using 1:5 ratios of citric acid ($C_6H_8O_7$) and hydrogen peroxide (H_2O_2), an etch selectivity ratio of 852 was found between InAsSb/Al0.33GaAsSb, with InAsSb

etching vertically at a rate of 554 nm/min. Alternatively, using an etch mixture of 1:1:100 HF:H_2O_2:H_2O cooled to 10 °C yielded a vertical etch rate of >8000 nm/min for AlGaAsSb, but only resulted in an etch selectivity ratio of 171.5 for AlGaAsSb/InAsSb. To investigate how these vertical etch rates translated into lateral undercut rates, we grew 2 μm of AlGaAsSb membranes on top of InAsSb sacrificial and AlGaAsSb etch-stop layers, monitored progression of the lateral etch by infrared microscopy. While vertical etch tests demonstrated etch rates of InAsSb at ~554 nm/min, lateral etch rates were found to be significantly slower. To decrease the overall time required to undercut the device, the temperature of the solution can be increased without negatively impacting the etch selectivity. Using these findings, photovoltaic cells and quantum-well LEDs were grown by molecular beam epitaxy on GaSb substrates. Devices were fabricated on-substrate and immersed in a solution of 1:5 $C_6H_8O_7$:H_2O_2 for selective release. The importance of the thickness of the sacrificial etch layer, the tethering scheme, and the composition of the dielectric protection layer were explored to improve the etch-release yield and device performance.

Interaction-Induced Gap and Gate Tunable Magnetism in Suspended Rhombohedral Few-Layer Graphene
Chun Ning (Jeanie) Lau; The Ohio State University, United States

The flat dispersion in rhombohedral stacked N-layer graphene, where $E \sim k^N$, gives rise to diverging (for N>2) density of states that are unstable to enormous electronic interactions, leading to the formation of electronic states with spontaneous broken symmetries. In free-standing samples, the electronic interactions are further strengthened due to the absence of screening. Using transport measurements on suspended dual-gated devices, we observe an insulating ground state with a large interaction-induced gap up to 80 meV at half filling. This gapped state can be enhanced by a perpendicular magnetic field, and suppressed by an interlayer potential, carrier density, or a critical temperature of ~40 K, and is most likely a layer antiferromagnet. Upon small doping, we observe prominent conductance hysteresis and giant magnetoconductance that exceeds 1000% as a function of magnetic fields. Both phenomena are tunable by density and temperature, and disappear at $n>10^{12}$ cm^{-2} or T>5K. These results are confirmed by first principles calculations, which indicate the formation of a half-metallic state in doped r-FLG, in which the magnetization is tunable by electric field. Our results demonstrate that magnetism and spin polarization, arising from the strong electronic interactions in flat bands, emerge in a system composed entirely of carbon atoms. In the future, different ground states are expected to be stabilized by substrate engineering. Finally I will discuss a technique to make more robust suspended gates.

Tuning Ion Transport in 2D Phyllosilicate Membranes *Yining Liu[1,2], Yuqin Wang[1,2], Vepa Rozyyev[2], Zijing Xia[1], Jeffrey Elam[2] and Seth Darling[2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States*

Membranes incorporating two-dimensional (2D) materials have shown great potential for water purification and *energy storage and conversion applications to overcome the challenges of traditional polymetric membranes. A variety of 2D materials such as graphene oxide, transitional metal dichalcogenides, and MXenes have been investigated for membrane applications. Phyllosilicate minerals are naturally occurring layered materials that are earth-abundant and low-cost. These materials are composed of negatively charged 2D aluminosilicate layers and interlayer cations, which can be easily exfoliated by replacing the cations and subsequently restacked as 2D laminar membranes. However, as formed, these membranes exhibit poor water stability and limited ion transport selectivity. The transport properties of phyllosilicate membranes are determined by the chemical and structural properties of the 2D interlayer galleries. We report systematic approaches to tuning the ion transport properties of phyllosilicate membranes through molecular crosslinking and surface functionalization. The channel height of the 2D interlayer gallery can be tuned by controlling the crosslinker size, leading to enhanced stability and tunable water and ion transport [1]. Furthermore, the chemical environment of the 2D interlayer can be altered through surface functionalization, resulting in boosted ion transport selectivity. The prepared phyllosilicate membranes with enhanced water stability and tunable ion transport properties have great potential in separation applications such as water purification and resource recovery [2].*

Ratchet-Based Ion Pumps for Selective Ion Separations *Gideon Segev[1], Alon Herman[1], Dafna Meltser[1], Eden Grossman[1], Karen Shushan Alshochat[1], Baruch Hirsch[1], Brian Rosen[1], Rylan Kautz[2], Shane Ardo[2,2,2], Joel W. Ager[3,3,4] and Francesca M. Toma[3,5]; [1]Tel Aviv University, Israel; [2]University of California, Irvine, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]University of California, Berkeley, United States; [5]Helmholtz-Zentrum Hereon, Germany*

Even though highly selective ion pumps are found in the membrane of every living cell, artificial ion selective separation is a longstanding unmet challenge in science and engineering. The development of a membrane-based ion separation technology can drive a dramatic progress in a wide range of applications such as: water treatment, bio-medical devices, extraction of precious metals from sea water, chemical sensors, solar fuels and more. In this contribution we report on the experimental demonstration of ion pumps based on an electronic flashing ratchet mechanism and their theoretical ion sorting performance.

Electronic flashing ratchets are devices that utilize a temporal modulation of a spatially asymmetric electric field to drive steady state current. Like peristaltic pumps, where the pump mechanism is not in direct contact with the pumped fluid, electronic ratchets induce a net current with no direct charge transport between the power source and the pumped charge carriers. Thus, electronic ratchets can be used to pump ions in steady state with no electrochemical reactions between the power source and the pumped ions resulting in an 'all-electric' ion pump.

Ratchet-based ion pumps (RBIPs) were fabricated by coating the two surfaces of nano-porous alumina wafers with gold, thus forming nano-porous capacitor-like devices. The electric field within the nano-pores is modulated by oscillating the capacitor voltage. Thus, when immersed in a solution, ions within the pores experience a modulating electric field resulting in ratchet-based ion pumping. The RBIPs performance was studied for various input signals, geometries, and solutions. RBIPs were shown to drive ionic current densities of several μA/cm^2 even when opposed by an electrostatic force. A significant ratchet action was observed with input signal amplitudes as low as 0.1 V thus demonstrating that RBIPs can drive an ionic current with no associated redox reactions.

An important hallmark of ratchets is the ability to invert the direction of particle flow with a change in the input signal frequency. The stopping frequency, which is the frequency at which the particle flux changes its direction, is determined by the potential distribution and particles transport properties. As a result, for a given ratchet, there can be a frequency at which particles with the same charge, but different diffusion coefficients, are transported in opposite directions. This concept, that was never applied to ion separations, can enable the extraction of ions with

extremely low relative concentrations if their diffusion coefficient is even slightly different from the diffusion coefficient of other ions in the solution. We show by simulation, that for the prevalent ions in water, ions with a relative diffusion coefficient difference as small as 1% can be driven to opposite directions with a velocity difference as high as 1.2 mm/s. Since the direction of ion transport is determined by the input signal frequency, the sorting properties can be tuned in real time providing a simple fit-to-purpose solution for a variety of ion separations applications.
The development of ratchet driven selective ion pumping membranes requires new materials and fabrication processes. Specifically, the use of lift-off, film transfer, and stacking methods can provide new opportunities to realize these devices.

Binder Free Enhancement of Long-Term Stability of 3D-MXene Thin Film Structures for Supercapacitor Applications Using Initiated Chemical Vapor Deposition *Jan-Ole Stern[1,2], Till Keunecke[1,2], Helge Krüger[1,2], Dahnan Spurling[3], Torge Hartig[4], Stefan Schröder[1,4], Fabian Schütt[1,2], Valeria Nicolosi[3], Franz Faupel[1,4] and Rainer Adelung[1,2]; [1]Kiel University, Germany; [2]Functional Nanomaterials, Germany; [3]Trinity College Dublin, The University of Dublin, Ireland; [4]Multicomponent Materials, Germany*

MXenes have been found to be promising electrode materials for supercapacitor applications. They achieve high power output and fast charging/discharging by fast faradaic redox reactions at the surface, which has made them the focus of supercapacitor research in recent years [1].
The titanium carbide MXene ($Ti_3C_2T_x$), has been shown to hold significant interest, as it offers great pseudocapacitive properties combined with a high electronic conductivity. Thin film electrodes made up of $Ti_3C_2T_x$ have shown exceptional capacitance of up to 450 F/g and a good rate performance even up to 100 V/s [2].
Herein we advance the previously developed method for the fabrication of interconnected MXene ($Ti_3C_2T_x$) 2D thin films in a 3D macroscopic assembly [3][4][5], by coating the electrode structures with the co-polymer, poly(2-hydroxyethyl methacrylate-co-ethylene glycol dimethacrylate), (p(HEMA-co-EGDMA)) using initiated chemical vapour deposition (iCVD) [6]. The iCVD process, where a polymer thin film is polymerized directly on the substrate surface from the gas phase, enables the conformal coating of complex 3D structures, which would be difficult by other means [6][7]. The applied co-polymer p(HEMA-co-EGDMA) is a hydrogel with minimal swelling and great long-term stability in an aqueous environment, which makes it a promising material for supercapacitor applications.
At a thickness of 50 µm and areal loadings of more than 5 mg/cm^2, the uncoated electrode networks demonstrated volumetric and specific capacitances of up 140 F/cm^3 and 240 F/g respectively, at a scan rate of up to 200 mV/s [5]. At the same scan rate an areal capacitance of ~1.4 F/cm^2 is recorded, outperforming that of state-of-the-art MXene based electrodes by a factor of ~2 [5]. However, during long term cycling (>10000 cycles) MXene based electrodes decrease in performance due to delamination and oxidation of the individual flakes. This negatively influences the overall conductivity and capacitance of the structure. To address this problem, the p(HEMA-co-EGDMA) hydrogel thin film is applied to the 3D MXene thin film structures., where it is supposed to act as a supportive outer layer, fixing the MXene flakes in place and inhibiting the performance loss during cycling, without the need for a binder in between the flakes.
First experiments revealed, that with the hydrogel coatings, the cycling stability at 10 A g^{-1} of these network electrodes showed a full capacitance retention of 100% across 30000 cycles (C_1 = 156 F g^{-1}, C_{30000} = 237 F g^{-1}), whereas the uncoated electrode lost ~30% of its maximum capacitance (C_1 = 245 F g^{-1} , C_{30000} = 189 F g^{-1}).

Interaction of CdS QDs with the PS/PMMA Polymer Blend Thin Film and Their Influences on Morphology

Hemant Kumar, Rabibrata Mukherjee and Pallab Banerji; Indian Institute of Technology Kharagpur, India

Two polymers that are immiscible when dissolved in a mutual solvent undergo phase separation during spin coating on a non-wettable surface. Rapid evaporation of the solvent creates Marangoni stresses leading to instability between the two polymer interfaces. Phase separated morphology is influenced by several factors such as type of solvent, respective solubility of polymers, relative molecular weight, ratio of the polymers, type of the substrate and also its favored affinity towards the constituents. In this article surface morphology of as cast thin films of PS/PMMA polymer blend of composition 1:1 (ratio of PS & PMMA in solution, v/v) has been modulated by addition of CdS quantum dots. While presence of nano particles in a homo-polymer film makes the film stable against dewetting, in a blend it can also alter film morphology. To understand the influence of quantum dots in polymer blends, the morphology of spin coated PS/PMMA blend films was studied first. Upon addition of QDs, changes in morphology of the polymer blend film was studied with an Atomic Force Microscope. The Quantum dot concentration (C_{QDs}) was varied between 0% to 10%. As the concentration of QDs increases, size of PS domain is found to increase. In contrast, annealing above glass transition of PS/PMMA suppresses the PMMA domains in the particle free film. Blends containing QDs show a similar change in morphology, upon annealing, as QD free films. Photoluminescence (PL) spectra of the QD containing blend is similar to the particle free blend film, revealing that upon addition of QDs in a blend, optical properties remain unaltered. Moreover, the slight narrowing of PL spectra on addition of QDs in the blend has been observed which is attributed to the scattering effect in the blend. RAMAN spectra indicate the presence of particles in the PS as well as PMMA domains.

Fully Healable, Liquid-free Osmotic Power Generator Using Nanofluidic Membrane of 2D Vanadium Pentoxide Nanosheet

Kundan Saha and Sameer Sonkusale; Tufts University, United States

Osmotic power generators or salinity gradient-powered generators rely on the fundamental principle of reverse osmosis, coupled with electrochemical processes, to produce electricity. The power generator consists of two chambers, one containing a high concentration (HC) of ions and the other containing a low concentration (LC) of ions, separated by a permselective membrane (anion selective membrane, AEM or cationic selective membranes, CEM), which allows passage of co-ions and restricts the counter ions. This selective movement of ions through the perm-selective membrane results in electric power generation which is harnessed at the electrodes placed in the chambers. Despite decades of improvement in harnessing energy from salinity gradients, its practical application remains rare. This is primarily due to the lack of high-throughput fabrication techniques for nanopores and the need for expensive techniques. More importantly, the use of liquid electrolytes limits its use in portable devices. We report an osmotic power generator (OPG) utilizing a restacked membrane of vanadium pentoxide (V_2O_5) nanosheets and ion-infused gelatin hydrogel. V_2O_5 nanosheet membrane is the choice owing to its high cation transport property and easy fabrication process. While gelatin hydrogel is used owing to its exceptional biocompatibility, low cost of synthesis, easy availability, and high-water retention. Moreover, gelatin hydrogel *allows for efficient diffusion of ions across its matrix to facilitate osmosis and ensure a steady ionic flow. This gel-based osmotic power generator (GOPG) offers significant advantages over traditional liquid-based OPGs, including enhanced portability, higher power output, and improved spillage safety. The highly cation-selective nanofluidic membrane was fabricated by vacuum-assisted assembly of 2D V_2O_5 nanosheets which was in turn obtained by exfoliation of bulk V_2O_5 crystals with hydrogen peroxide (H_2O_2). To prepare the hydrogel, 1 gram of gelatin was stirred with 10 ml of the aqueous KCl solution of desired molarity at 80 °C for 2 hours. As the gelatin is completely dissolved, 400 µl of the solution is poured on cylindrical molds of diameter 1 cm and depth 0.3 cm to be cooled at 4 °C for 30 minutes for gelation. Gels of two different KCl concentrations (1M and 0.001M) was placed on two individual Ag/AgCl coated PET, which is used as the current collector. For the fabrication of the GOPG, a circular piece of the V_2O_5 membrane was sandwiched between the gels of higher and lower concentrations. As the gels of two different concentrations come in contact with the perm-selective V_2O_5 membrane, the positive ion from the high-concentration gel migrates toward the low concentration and electron flows through the external electrode. This gives rise to a stable open circuit voltage of 0.27 V and a short circuit current of 0.35 milliamperes, accounting for a power density of 0.13 Wm^{-2}. We have systematically investigated the effects of various ions, concentration gradients, and membrane thicknesses to optimize power output. On comparing with power produced using KCl, NaCl, and LiCl-infused hydrogels, KCl shows the highest power density due to its smaller hydration radius and higher mobility through V_2O_5 nanochannels. Furthermore, it was observed that thinner V_2O_5 membranes give high power density owing to the reduced ionic resistance through the membrane. Remarkably, physical damage to theV_2O_5 membrane can be easily repaired with a drop of water, while cracks in the gelatin gel can be healed by reheating and cooling the gel, making it a fully restorable osmotic power generator. The GOPGs can be connected in series or parallel to increase voltage and current, facilitating practical applications. We demonstrated the capability of the GOPG to power an LED and a humidity meter, highlighting its potential for real-world applications.*

3:45 PM NM04.08.07

Methods for Achieving Ultracleanness to Enable Freestanding Nanno-Membrane Research *Gong Gu, Gerd Duscher, Hao Wang, Milinda Randeniya and Austin Houston; The University of Tennessee, Knoxville, United States*

Even sub-monolayer, low-coverage contaminants, on both surfaces, obscure intrinsic properties of a freestanding atomically thin membrane or 2D material, and their ultimate thinness precludes the effective conventional cleaning methods that are almost always sacrificial. In this regard, suspended single-layer graphene and carbonaceous contaminants represent the most salient challenge.
We have achieved ultraclean suspended graphene, attested by electron energy loss (EEL) spectra, for the first time, as clearly resolved as the best data of graphite, with fine-structure features corresponding to the bonding characters and band structure of graphene. The notorious electron beam induced carbon deposition in electron microscopy has been eradicated, as demonstrated for the first time by dwelling an intense focused electron beam for one minute and continuously raster scanning the beam for a full work day at intensities ~ 6 × 10^8 $e^-/(Å^2$ s) without inducing carbon deposition in a transmission electron microscope. It is this level of cleanness that allowed for unprecedentedly high accumulated dose (10^{12} e^- in a 1 nm^2 scanned area) and long acquisition time (5 min) to achieve the high-quality spectra mentioned above.
The methods, while involving ex situ transfer and pre-cleaning and in situ cleaning, are readily adaptable to other experimental settings and other materials, to enable previously inhibited undertakings that aim at revealing or exploiting intrinsic properties of 2D materials or ultrathin membranes, especially those using graphene as an encapsulator for other membranes or as a supporting or buffer layer (e.g. in remote epitaxy). Importantly, the surprisingly simple and robust methods are easily implementable with common lab equipment.

4:00 PM NM04.08.08

Ambient Printing of Native Oxides for Ultrathin Transparent Flexible Circuit Boards *Minsik Kong[1,2], Man Hou Vong[3], Unyong Jeong[2] and Michael Dickey[3]; [1]Massachusetts Institute of Technology, United States; [2]Pohang University of Science and Technology, Korea (the Republic of); [3]North Carolina State University, United States*

Metal oxide films are essential in most electronic devices, yet they are typically deposited at elevated temperatures by using slow, vacuum-based processes. We printed native oxide films over large areas at ambient conditions by moving a molten metal meniscus across a target substrate. The oxide gently separates from the metal through fluid instabilities that occur in the meniscus, leading to uniform films free of liquid residue. The printed oxide has a metallic interlayer that renders the films highly conductive. The metallic character of the printed films promotes wetting of trace amounts of evaporated gold that would otherwise form disconnected islands on conventional oxide surfaces. The resulting ultrathin (<10 nanometers) conductors can be patterned into flexible circuits that are transparent, mechanically robust, and electrically stable, even at elevated temperatures.

Next-Generation Bioelectronics Enabled by Inorganic Single-Crystalline Semiconductor Membranes *Jiho Shin; Texas A&M University, United States*

Inorganic single-crystalline semiconductors such as Si, GaN, and GaAs form the basis of essentially all modern electronic devices, including various implantable and wearable systems that directly interface with the human body for clinical and fundamental neuroscience applications. However, the bulkiness, rigidity, and non-resorbable nature of conventional semiconductor materials have long been associated with various medical complications. In this talk, I will introduce layer transfer technologies that allow the production of inorganic single-crystalline semiconductor membranes that are peeled off from their epitaxial wafers, thereby enabling new classes of bioelectronic systems that are significantly less invasive and more bio-friendly.
More specifically, I will talk about my research on developing electronic systems that can: (i) completely dissolve in biofluids at physiological pH/temperatures [1,2], (ii) conformally adhere on skin to enable convenient, nearly imperceptible human-computer interface [3], and (iii) achieve ultrahigh device density through 3D integration of disparate functional layers for near-eye display [4] and neuroscience applications.

Spontaneous Assembly of Graphite Auto-Kirigami *Luc N. Capaldi, Li Yuan, Cangyu Qu, Daniel Sanchez, Robert W. Carpick and Ottman Tertuliano; University of Pennsylvania, United States*

We show, for the first time, the formation of graphite auto-kirigami (AK) structures using in-situ SEM nanoindentation. The low energetic requirements for out-of-plane bending of 2D materials have enabled the formation of a range of nanostructures that are readily coupled with fracture processes. Specifically, graphene AK are three folded nanoribbons that form up to 5 μm in length due to graphene-graphene adhesion during spontaneous folding, peeling and tearing after nanoindentation. This process offers a route towards mechanical self-assembly of 2D heterostructures. The initial nanoribbon must first overcome the bending energy required to fold onto the adjacent 2D material; the formation rate should then decrease dramatically as the bending stiffness increases with the number of layers. However, we report graphite AK structures with 2, 3, or 4 leaflets that are 1-3 μm long and an order of magnitude thicker than graphene AK. They assemble spontaneously after nanoindentation of substrate-supported graphite and, as shown by in-situ SEM experiments, initiate via localized elastic buckling coupled to a fracture event beneath the tip. Using molecular dynamics simulations of few-layer graphene, we demonstrate an equivalent indentation-triggered film delamination process as we approach the 2D limit. Accordingly, we discuss how the initial graphene AK state is a limiting case of graphite AK for which membrane strain dominates over bending strain.

NM04.09.02

Flexible BaTiO3-Au Vertically Aligned Nanocomposite for Multifunctional Sensing Platform *Tsai Tsai, Jialong Huang, Jiawei Song, Jianan Shen, Ya Ching Yu, Meng Hao Lee, Benjamin T. Stegman, Emiliano J. Flores, Patrick Tong, Ke Xu, Shiyou Zhou, Yizhi Zhang, Lia Stanciu, Wenzhou Wu, Xinghang Zhang and Haiyan Wang; Purdue University, United States*

Flexible and wearable sensors hold great promise for personalized healthcare through real-time health monitoring. Recently, vertically aligned nanocomposites (VANs) have enabled various material combinations to achieve multifunctionalities, such as multiphase multiferroics, magneto-optic coupling, and strong magnetic and optical anisotropy, which are challenging to achieve with single-phase materials. Incorporating these VANs into wearable sensors offers significant potential for detecting multiple components through different properties. This study shows the growth and transfer of BaTiO3-Au VAN with Sr3Al2O6 as a buffer layer to achieve a multifunctional sensor. After dissolving the sacrificial layer, the VAN thin film is transferred onto polydimethylsiloxane to create a novel flexible chemical and pressure sensor. The piezoelectric output detecting the pressure change and the detection of 4-mercaptobenzoic acid via surface-enhanced Raman spectroscopy demonstrate the potential of VANs in wearable multifunctional sensing platforms.

NM04.09.03

Epitaxy with a Twist—Magnetotransport Phenomena in Oxide Heterostructure Interfaces *Katja I. Wurster, Andrea D'Alessio, Charline K. Kirchert, Carlos Nunez, Felix Trier, Thomas S. Jespersen and Nini Pryds; Technical University of Denmark, Denmark*

Complex metal oxides are an exciting class of electronic materials which share key properties with conventional semiconductors but also bring new intrinsic functionalities to the world of electronics: high-temperature superconductivity, insulator transitions, ferromagnetism, ferroelectricity, piezoelectricity, and multiferroic properties. This richness arises from a strong correlation between the electrons in the d orbitals, which gives rise *to a complex interplay between the charge, spin, orbital, and lattice degrees of freedom. Traditionally, complex metal oxides can only be grown epitaxially on a lattice-matched substrate. However, the advent of lattice-matched sacrificial layers for complex metal oxides has overcome this limitation, allowing for the fabrication of freestanding complex oxide membranes. By reassembling complex oxide freestanding membranes with different materials and orientations into artificial stacks, it is possible to bypass the epitaxial roadblocks. An additional degree of freedom is introduced in such artificial stacks: by twisting the layers one can synthesize moiré superlattices.*

In this work, we present our approach to prepare novel interfaces between two controlled twisted and stacked freestanding membranes using SrTiO3-based materials. We start with a SrTiO3-based thin film epitaxially grown on a Sr3Al2O6 sacrificial layer that dissolves in water. After dissolving the layer, we transfer the released membrane onto a new substrate. Next, we stack a second membrane at an angle to the first, creating a unique, twisted interface between the two membranes. This method results in defect-free heterostructures of freestanding oxide membranes at the interface. This approach facilitates the direct integration of complex oxides at any desired twist angle, which we utilized to conduct low-temperature transport studies across a twisted bilayer freestanding oxide junction device.

NM04.09.04

***Effect of Growth Conditions on SiC Remote Epitaxy** Takayasu Oka[1], Keiju Sato[1], Takuji Maekawa[1], Yoshiaki Oku[1], Ken Nakahara[1] and Tsunenobu Kimoto[2]; [1]ROHM Co., Ltd., Japan; [2]Kyoto University, Japan*

Remote epitaxy is a promising growth technique for preparing freestanding epitaxial films [1]. Ultra-thin Graphene films formed on SiC substrates by Si sublimation or chemical vapor deposition using hydrocarbon is an attractive method for SiC remote epitaxy because there is no graphene transfer step. However, a problem in SiC remote epitaxy is that SiC homoepitaxial growth typically uses hydrogen carrier gas above 1500°C by chemical vapor deposition, which can damage or remove graphene. In this study, we used argon as a carrier gas to suppress graphene etching by hydrogen and investigated effects of the C/Si ratio in the supplied growth gas and pressure on SiC remote epitaxy. Epitaxial graphene was grown on n-type 4-degree off-axis 4H-SiC(0001) substrates by the Si sublimation method. SiC remote epitaxial growth was performed at 1500°C in a hot-wall CVD reactor. By depositing a highly stressed Ni stressor layer on the SiC film, the SiC-graphene interface was strained, and the SiC film was peeled off from the graphene surface by applying a thermal release tape. When SiC was grown by using typical supplied source gases with a C/Si ratio of 0.8, the graphene was etched out and could not be exfoliated. On the other hand, when SiC was grown on graphene with a high C/Si ratio above 10, SiC was successfully exfoliated from the graphene. The exfoliated SiC film was determined to be 4H polytype of SiC in the epitaxial relationship with the SiC substrate by cross-sectional transmission electron microscopy. However, when the C/Si ratio exceeded 10, graphene was grown in majority areas and the SiC-grown areas were rarely observed. To expand the SiC growth area, the effect of growth pressure was investigated. The nucleation on the film and the SiC coved area were increased with increasing pressure. These results indicate that it is important to select the appropriate C/Si ratio and pressure for SiC remote epitaxy.

NM04.09.05

***Growth Control of Epitaxial Graphene and SiC Film for Remote Epitaxy** Keiju Sato[1], Makoto Takamura[1], Takuji Maekawa[1], Yoshiaki Oku[1], Ken Nakahara[1], Ji Shi-yang[2], Kazutoshi Kojima[2] and Wataru Norimatsu[3]; [1]ROHM Co., Ltd., Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Waseda University, Japan*

In remote epitaxy, epitaxial films can grow on compound semiconductor substrates through 2D materials and be *transferred from the substrates to others [1]. This technique is effective for cost reduction of wafer process because it enables the reuse of the expensive substrates. SiC is one of the most promising materials for next generation of power transistors [2], and application of remote epitaxy to SiC is needed for the development of semiconductor industry. Graphene can be grown on SiC directly by thermal decomposition of SiC substrates (generally in atmospheric pressure or vacuum) [3], and these composite substrates are ideal for SiC remote epitaxy. However, step-bunching arises during annealing SiC substrates in graphene growth processes. This phenomenon leads to rough surface of the substrates, and these are not suitable as epi-ready substrates.*

In this study, we show an effective technique to suppress the step-bunching during graphene growth. We prepared 4-degree off-cut (in the [11-20] direction) 4H-SiC (0001) substrates. The growth process is divided into two steps: step-bunching suppression (step1) and graphene growth (step2). In the first step, the SiC substrates are annealed in vacuum atmosphere to grow only graphene buffer layer (so-called zero-layer graphene). Since decomposition of SiC occurs from low temperature in this condition, the buffer layer can grow with almost no step-bunching. In the second step, the substrates are annealed in Ar atmospheric pressure at higher temperature than step1. The pre-covered buffer layer effectively suppressed the step-bunching, and graphene grown in the atmospheric pressure has good controllability of the number of layers.

Next, we investigated the SiC growth on graphene/SiC substrates. Propane and silane are used as gas sources to produce SiC. To understand the effects of the gases on graphene, single gas of each source was flowed on graphene at 1300°C and more. These experiments revealed that silane can react with graphene to be SiC in high temperature though propane has little effect on etching of graphene. SiC growth experiments were carried out after these investigations, and we confirmed Si poor condition is needed for survival of graphene especially at the beginning of SiC growth. Our simulation of vapor phase reaction also supports the experiment results. Although complete balance of growth and etching of graphene in SiC growth process have not been achieved, these results will be a great help for future SiC remote epitaxy studies. This work was partly implemented under a joint research project of Tsukuba Power Electrics Constellations (TPEC).

Enhancing Energy Storage—A Novel Approach Using 2D/3D/2D Heterostructures *Sangmoon Han, Justin Kim, Yuan Meng, Zhihao Xu, Sunok Kim, Ji-Yun Moon, Seung-Il Kim, Sanggeun Bae and Sanghoon Bae; Washington University in St. Louis, United States*

Managing high energy density is increasingly critical for applications ranging from electric power systems to portable electronic devices. Electrostatic capacitors, renowned for their ultrafast charge and discharge rates, are pivotal in these applications. However, their performance is constrained by the low maximum polarization of conventional dielectric materials. In contrast, ferroelectric materials like HfO_2, ZrO_2, and $BaTiO_3$ (BTO) exhibit higher maximum polarization due to their higher electric susceptibilities, related to dielectric constants. Unfortunately, their high remnant polarization hampers effective energy storage and release during the discharging process.

We propose a strategy to precisely control the relaxation time of polarization with minimal energy loss, utilizing monolayer two-dimensional (2D) materials produced through the layer-splitting technique. This is achieved by creating 2D/single-crystalline 3D/2D (2D/C-3D/2D) heterostructures using a layer-transfer technique to produce freestanding single-crystalline BTO (C-BTO), allowing for manipulation at both interfaces. Unlike previous methods that degrade ferroelectric materials via structural changes, our approach preserves the single-crystal nature of BTO. In our design, a C-BTO layer is sandwiched between 2D materials in a freestanding membrane configuration.

This setup leverages the Maxwell-Wagner effect—relaxation by charge accumulation at heterogeneous interfaces—to modulate the relaxation time. By controlling the thickness of 2D materials with atomic precision through layer-resolved splitting, we achieve minimal energy loss and dielectric loss while managing relaxation time. This innovative approach effectively suppresses the remnant polarization of ferroelectric materials while maintaining maximum polarization. Consequently, we achieved an energy density of 191.7 J/cm^3 *with an efficiency exceeding 90%. Our method has the potential to significantly enhance the performance of dielectric materials, making it suitable for a variety of applications requiring high-energy storage systems.*

NM04.09.07
Tuning Instability in Suspended Monolayer 2D Materials *Jingzhuo Zhou[1], Yuan Hou[2], Juzheng Chen[1] and Yang Lu[2]; [1]City University of Hong Kong, Hong Kong; [2]The University of Hong Kong, Hong Kong*

Monolayer two-dimensional (2D) materials possess excellent in-plane mechanical strength yet extremely low bending stiffness, making them particularly susceptible to instability, which is anticipated to have a substantial impact on their physical functionalities such as 2D-based Micro/Nanoelectromechanical systems (M/NEMS), nanochannels, and proton transport membrane. In this work, we achieve quantitatively tuning instability in suspended 2D materials including monolayer graphene and MoS_2 *by employing a push-to-shear strategy. We comprehensively examine the dynamic wrinkling-splitting-smoothing process and find that monolayer 2D materials experience stepwise instabilities along with different recovery processes. These stepwise instabilities are governed by the materials' geometry, pretension, and the elastic nonlinearity. We attribute the different instability and recovery paths to the local stress redistribution in monolayer 2D materials. The tunable instability behavior of suspended monolayer 2D materials not only allows measuring their bending stiffness but also opens up new opportunities for programming the nanoscale instability pattern and even physical properties of atomically thin films.*

NM04.09.08
Can We Control the Release Dynamics of Rreestanding Oxide Membranes? *Christina Høgfeldt Christoffersen; Technical University of Denmark, Denmark*

Over the past few years, sacrificial layer techniques have become a mainstream method for fabricating freestanding oxides [1,2]. One of the drawbacks of this technique is the quality control of the epitaxial growth of oxide heterostructures, which is time-consuming and can usually take several hours. Recently, research has focused on minimizing release times by identifying suitable water-soluble sacrificial layers [3,4]. In this work, we demonstrate the effect of oxygen vacancies on the releasing dynamics of water-soluble $Sr_3Al_2O_6$ *(SAO) layer in the* $SrTiO_3$ *(STO) /SAO heterostructures. The STO (~20 nm thick)/SAO (~10 nm thick) films were grown on* TiO_2*-termianted STO(001) single crystals by using pulsed laser deposition. To clarify the effect of oxygen-stoichiometric of upper STO films on the underlying SAO layer, various oxygen partial pressure (*$P_O = 1 \times 10^{-4}$ *to* 1×10^{-1} *mbar) were employed during the STO film growth while keeping the consistent SAO film growth at* $P_O = 5 \times 10^{-4}$ *mbar. High-resolution x-ray diffraction (HRXRD) and atomic force microscopy (AFM) were used to examine the crystallinity and surface morphology of the grown films. The water dissolution rate of SAO was determined as a function of* P_O*, revealing a direct correlation between the dissolution time and* P_O*. This study offers valuable insights into how oxygen vacancies influence the release time and structure of SAO, aiding the development of more efficient techniques for fabricating free-standing oxide membranes.*

Optical Properties in Freestanding Thin Films—MXene Nanosheets Assembly in 1D Cellulose *Valeriia Poliukhova[1], Justin Brackenridge[1], Botyo Dimitrov[1], Laura Mae Killingsworth[1], Jisoo Jeon[1], Mykhailo Yelipashev[1], Iryna Roslyk[2], James Fitzpatrick[2], Yury Gogotsi[2] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Drexel University, United States*

In this study, we delve into investigating freestanding thin films combining 2D material, $Ti_3C_2T_x$ MXene, within 1D natural polymer network. Cellulose nanofibers (CNFs) derived from renewable resources, offering a sustainable alternative to synthetic polymers, create a unique environment for interactions at the interface with 2D MXene nanosheets. Our focus is centered on a distinct blend of two media where CNFs predominate, forming flexible, self-supporting thin films through hydrogen bonding and layered structure is obtained via vacuum-assisted filtration. Our approach utilizes minimal MXene content < 1% volume fraction within cellulose media to highlight the influence of MXene organization on the optical characteristics and photonic behavior. The obtained flexible films of 3-4 μm thickness exhibit up to 85% transparency, which are also flexible and mechanically strong with a modulus of 8.5 ± 1 GPa and tensile strength of 220 ± 28 MPa. Furthermore, the unique advancement of this work is the color variations of MXene within polymeric medium due to multiple reflections and scattering events, that we investigated with hyperspectral high-resolution imaging. Prompted by the disordered arrangement of the nanosheets within the cellulose matrix and their interactions, this work not only broadens our understanding of MXene in natural polymer composites, but also underscores their potential in emerging freestanding films and advanced photonic applications for innovative device architectures.

NM04.09.10
Step-Edge-Induced Structure Modulation in Freestanding $BaTiO_3$ Membranes *Shinhee Yun[1], Huaiyu Chen[2], Megan Hill[2], Changming Liu[3], Dan Zhou[3], Martin Albrecht[3], Edwin Dollekamp[1], Jesper Wallentin[2] and Nini Pryds[1]; [1]Technical University of Denmark, Denmark; [2]Lund University, Sweden; [3]Leibniz Institute for Solid State and Materials Research Dresden, Germany*

Freestanding oxide membranes offer a promising pathway for integrating devices on silicon and flexible platforms. Freestanding barium titanate ($BaTiO_3$, BTO) membranes, in particular, hold significant potential for miniaturized field-effect devices integrated on silicon substrates [1,2]. In this study, we investigate the structural modulations in freestanding BTO membranes caused by strain from one-unit-cell step-edges when these membranes adhere to substrates. Using X-ray nanobeam analysis, we examine the (020) Bragg peak with a spatial resolution of 50 nm across varying temperatures. As anticipated, these structural stripes remain rigid above the Curie temperature (120°C for bulk BTO). Our findings highlight that even subtle step-edges, previously overlooked in the study of freestanding membranes, might significantly impact the physical properties of these membranes. Furthermore, the various orientations of the step edges may introduce an additional degree of freedom, potentially leading to the emergence of new properties.

NM04.09.11
Development of High Selectivity Membrane for Effective Chemical Warfare Agent Protection Using

Graphene Oxide *Kim Hyung Jun; Chung-Ang University, Korea (the Republic of)*

The escalating global threat posed by chemical warfare agents (CWAs) has emphasized the need for advanced protective materials. In this study, we introduce a novel membrane that effectively blocks CWAs while maintaining high water vapor permeability. This innovative membrane is created by integrating graphene oxide (GO) with ethylenediamine (EDA) and polyethyleneimine (PEI). While adjusting the ratio of EDA to PEI, we control pH and efficiently modulate film thickness. This thickness control and amine functionalization enable physical blocking of CWAs and restriction of their movement through hydrogen bonding sites. We utilized p-nitrophenyl diphenylphosphinate (pnpdpp) as a simulant for nerve agents and 2-chloroethyl ethyl sulfide (2CEES) as a simulant for blister agents. The GO-EDA-PEI composite membrane effectively blocked pNPDPP permeation for over 5 days. Additionally, the vapor transmission rate of 2CEES decreased approximately 50% compared to the GO membrane. These results demonstrate the potential of graphene oxide-based membranes for preventing CWA diffusion with simple pretreatment

NM04.09.12

Computational Design of Stacking Oxide Freestanding Membranes into Artificial Heterostructures

William S. Hansen, Juan Maria García Lastra, Arghya Bhowmik and Ivano Eligio Castelli; Technical University of Denmark, Denmark

Oxide materials have shown a wide range of properties attractive for energy device applications. Novel phenomena occur especially at the interface [1], for example 2D electron gas [2], 2D hole gas [3], and ferromagnetism [4]. Previous approaches have utilized epitaxial growth to enable atomic-level control of the interface. However, this limits the interface to material systems with a good lattice match between the film and substrate.

New methods have produced ultra-thin freestanding oxide membranes [5]. In the NEXUS ERC project, we aim to produce artificial heterostructures by stacking these membranes allowing complete control of the interface, without the limitations of epitaxy.

This methodology opens several degrees of freedom for building the heterostructure, such as the materials stacked and the twist angle of the membranes, providing a way to tune the properties of the materials [6]. By engineering the device, we aim to find fast ionic paths through dislocation networks, potentially breaking the fundamental limits of existing energy devices.

In this pursuit, an in-depth theoretical understanding of the interfacial reconstruction and stability of the artificial heterostructures is required. A theoretical understanding will provide both insight to what enables or hinders fast ionic conductivity and will allow inverse design of the heterostructures to optimize the conductivity.

The complex heterostructures that can be engineered may require several thousand atoms to describe theoretically, due to the Moiré patterns that occur when twisting, making it nearly impossible to describe with density functional theory. Therefore, we will use message passing neural networks that have shown excellent accuracy as interatomic potentials, when trained on a high-quality data set [7].

Furthermore, it's been shown that traditional generalized gradient approximation functionals do not accurately describe the complex electronic structure in transition metal oxides [8], thereby not accurately capturing the transition states involved in the ionic diffusion. To alleviate this issue, we will construct a data set of hybrid-level calculations.

The sizable task of creating a data set of hybrid-level calculations sufficient for training an accurate machine learning interatomic potential is made possible by employing the batch active learning workflow CURATOR [9]. By utilizing molecular dynamics exploration and active learning, CURATOR efficiently explores the potential energy surface, reducing the computational cost of data generation.

Furthermore, we aim to go beyond state-of-the-art MLIPs and additionally train new models such as DeepDFT [10] that can predict the electronic structure. Thereby, we will significantly enhance the theoretical knowledge elicited from predictions of the model, to better explain the complex correlation phenomena occurring in the transition metal oxide.

The value of an accurate machine learning interatomic potential based on hybrid-level DFT is not limited to engineering fast ionic oxide heterostructures. In the rapidly developing field of freestanding oxide membranes, a wide range of properties can prove groundbreaking. The MLIP can provide valuable theoretical insight to understand these phenomena as the field develops.

A Novel Method for Bonding of Dielectric in 3D Integration Packaging Using Area-Selective Self-Assembled Monolayer

Wonbin Kim[1], Byoung-Joon Kim[2] and Young-chang Joo[1]; [1]Seoul National University, Korea (the Republic of); [2]Tech University of Korea, Korea (the Republic of)

Recently, due to the limitation of scaling down technology in semiconductor devices, advanced packaging technology for 3D stacking using hybrid bonding, which enables heterogeneous device packaging, is becoming increasingly important. One of the representative hybrid bonding technologies is surface activation bonding using plasma. This method facilitates bonding by rendering the dielectric surface hydrophilic through plasma treatment. However, surface plasma treatment may cause oxidation of the copper(Cu) metal pad, degrading bonding reliability. Moreover, as the Cu pad becomes increasingly sub-μm fine pitch, the transfer of Cu particles generated by re-sputtering to the dielectric raises concerns about potential short circuits failure issues. Therefore, a method to activate the dielectric surface without plasma was devised, and we found that surface activation bonding between dielectrics without plasma is possible using self-assembled monolayers(SAMs), which can be selectively aligned in a specific region to obtain the desired surface characteristics.
In this study, among the silane-based SAMs that can be deposited on the surface of silicon dioxide(SiO2), which is a representative dielectric material, APTES(3-aminopropyltriethoxysilane) with an amine group(NH2), a hydrophilic functional group that can activate the surface, was deposited through the solution dipping method. The

spontaneous alignment of SAMs on the SiO2 surface was confirmed through FT-IR, AFM, and XPS analysis, and an increase in the surface energy of SiO2 was verified through Contact Angle analysis. Interestingly, we observed that the interfacial adhesion strength increased by subsequent heat treatment after bonding. This appears to be due to the formation of an amorphous Si layer at the interface by subsequent heat treatment after bonding at room temperature through hydrogen bonding. Consequently, this SAM bonding technology, which can selectively activate the insulator surface in specific regions, is expected to be applicable to fine-pitch hybrid bonding technology in the near future.

Two-Dimensional Electron Gasses in Freestanding SrTiO3 Membranes—Device Fabrication And Transport Measurements *Charline K. Kirchert, Andrea D'Alessio, Felix Trier, Amit Chanda, Katja I. Wurster, Thomas S. Jespersen, Nini Pryds, Damon J. Carrad, Dags Olsteins and Eric Brand; Technical University of Denmark, Denmark*

The development of sacrificial liftoff methods for oxide materials has enabled a route for realizing free-standing STO membranes, which can be transferred from the parent growth substrate to virtually any substrate of choice. This enables easy integration of STO materials in silicon-based electronic devices and new possibilities for device fabrication and functionality. STO-based two-dimensional gasses exhibit an exciting palette of properties, including gate-tunable spin-orbit coupling, metal-insulator transitions, and gate-tunable superconducting transitions. We present an experimental study of the electronic properties of STO membranes of different thicknesses transferred on silicon. Methods are developed for achieving electrical contact to the STO electron systems, and devices are characterized as a function of temperature, gate, and magnetic field.

NM04.09.15

Atomistic Engineering of Anisotropic 2D vdW Magnets *Eugene Park[1], John Philbin[2], Hang Chi[3], Georgios Varnavides[4], Jonathan Curtis[2], Zdenek Sofer[5], Prineha Narang[2] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]University of California, Los Angeles, United States; [3]University of Ottawa, Canada; [4]University of California, Berkeley, United States; [5]University of Chemistry and Technology, Prague, Czechia*

The exploration of 1D magnetism, frequently portrayed as spin chains, constitutes an actively pursued research field that illuminates fundamental principles in many-body problems and applications in magnonics and spintronics. The inherent reduction in dimensionality often leads to robust spin fluctuations, impacting magnetic ordering and resulting in novel magnetic phenomena. Here, structural, magnetic, and optical properties of highly anisotropic 2D van der Waals antiferromagnets that uniquely host spin chains are explored. First-principle calculations reveal that the weakest interaction is interchain, leading to essentially 1D magnetic behavior in each layer. With the additional degree of freedom arising from its anisotropic structure, the structure is engineered by alloying, varying the 1D spin chain lengths using electron beam irradiation, or twisting for localized patterning, and spin textures are calculated, predicting robust stability of the antiferromagnetic ordering. Comparing with other spin chain magnets, these materials are anticipated to bring fresh perspectives on harvesting low-dimensional magnetism.[1]

Here, we examine the structural properties of two kinds of 2D magnets hosting 1D chains of magnetic atoms. Using scanning transmission electron microscopy (STEM), we characterize structural properties such as the alignment of magnetic chains between layers with atomic resolution. We also explore the nature of defects and the possibility of controlling defect location using the STEM electron beam.[2,3] By parametrizing a model spin-Hamiltonian based on density functional theory calculations, we predict the spin structure that develops from the chain arrangement of the magnetic atoms in this material. We discuss measurements to verify theoretical calculations using instruments such as vibrating sample magnetometry. Lastly, we engineer the 2D magnet via *electron beam irradiation to modify the structure of 1D spin chains and predict magnetic properties and spin structure using atomistic magnetic simulation.*

Ordered Orientation of the Droplets of a Spin-Dewetted Polymeric Thin Film on a Patterned Substrate with Variable Surface Energy

Sushree Ritu Ritanjali and Rabibrata Mukherjee; Indian Institute of Technology Kharagpur, India

Ultra-thin polymer films exhibit spontaneous instability and dewetting, leading to nearly equal-sized isotropic structures. These dewetted features can be aligned and created by dewetting the film over a topographically patterned substrate. A simple way of creating a topographically patterned substrate is by placing a Transmission Electron Microscopy (TEM) grid over Polydimethylsiloxane (PDMS) film, and then exposing it to a UV Ozone chamber, which results in physico-chemical patterns. Interestingly, no one has studied how the positioning of the grid pattern with respect to the rotation center during spin coating can influence the morphology and ordering of the polymer droplets. We have studied the ordering of spin-dewetted droplets to the continuous film of Polystyrene on a patterned PDMS surface. For patterning, we have used TEM grids of square shape and 400 mesh size. After UVO, the grids were removed from the PDMS surface. Polystyrene in toluene of various concentrations were then coated on the substrate spun for a fixed duration and revolutions per minute (RPM). During spin coating, when the concentration of the Polystyrene, is low (Cn ≤ 1%), the layer ruptures and dewets, and the polymer is aligned in the outward edges and corners of the grooves of the pattern depending upon the location of the patterns. With further increase in concentration, C_n, ($C_n \approx 1.5\%$) the polymer had already started to deposit, hence there is low extent of influence of the direction of the flow with respect to the patterns occur. Because of this, partial deposition of the polymer as well as the retraction of the polymer due to centrifugal force occurs thus eventually forming a continuous film. In the case of $C_n \approx 2\%$ deposition dominates over spin dewetting, i.e., it completely fills in the grooves and the polymer settles down along the boundary of the grooves. The spin dewetting is suppressed and continuous films start to form at Cn ≈ 3%. In this case, the morphology changes as the solvophilic grooves start filling in first followed by the partial spin dewetting over the solvophobic walls. At higher concentrations, i.e., Cn ≥ 5%, a completely continuous film forms. The variation of the morphology of the final dewetted droplets was then observed by annealing the above films at 160 °C. Upon annealing, the shallower threads of polymer on the lines of the pattern start to undulate first due to the onset of the well-known Rayleigh−Plateau instability engendered by the cross-sectional curvature of the long liquid threads. The amplitude of these undulations grows with time, and the ruptures appear due to the disintegration of the threads.

NM04.09.17
Revisiting Self-Discharge of Nanoporous Electrodes—Insights from Multilayered Graphene Membrane-Based Electrodes

Xiaoyang Du[1], Qinghua Liang[2], Wen-jie Jiang[1], Desheng Feng[3], Mengran Li[1], Xiao Wang[1], Lianhai Zu[1], Yang Cao[4] and Dan Li[1]; [1]The University of Melbourne, Australia; [2]Chinese Academy of Sciences, China; [3]The University of Queensland, Australia; [4]Australian Nuclear Science and Technology Organisation, Australia

Self-discharge (SD) of nanoporous electrodes is a phenomenon of spontaneous voltage drop when an electrode is placed in the open circuit state. It is not only a persistent challenge for the community of electric double-layer capacitors but also has plagued the development of other electrochemical systems owing to the dissipation of both electronic and ionic charges at the electrode/electrolyte interface. However, the intricate interplay of diverse interfacial electrochemical processes, involving ions, solvents, and host nanoporous materials, complicates the elucidation of the SD mechanism of nanoporous electrodes. The complex nanostructure and surface chemistry of typically used carbon-based nanoporous materials, such as activated carbon, add further complexity to the mechanism analysis. In this work, taking a series of additive-free and highly conductive multilayered graphene-based membranes with varied slit sizes as a platform, we revisit the SD of nanoporous electrodes. By leveraging a widely-used hybrid SD model, our fitting results suggest a predominant role of the kinetic process of activation-controlled Faradaic reactions during the SD of multilayered graphene membrane-based electrodes even under different testing conditions, encompassing varied slit sizes and different aqueous electrolytes. However, subsequent experiments on charging voltage-dependent SD and chemical characterization exclude the commonly deemed activation-controlled reactions, including carbon oxidation and water electrolysis, implying the involvement of previously unidentified activation-controlled processes. Our findings shed new light on the SD at the electrode/electrolyte interface and underscore the need to refine the existing hybrid SD model to accommodate these novel observations in nanoporous material.

NM04.09.18

Energy-Efficient Synthesis of Organic-Inorganic Hybrids Through Polymer Complexation

Shaghayegh Abtahi, Jiashan Mi, Kaitlyn Hillery, Nayanathara Hendeniya, Caden Chittick, Gabriel O. Mogbojuri, Aaron Rossini and Boyce Chang; Iowa State University of Science and Technology, United States

Vapor phase infiltration (VPI) processing is an emerging gas-phase method for producing organic–inorganic hybrid materials. This method involves the diffusion of vapor phase metalorganic precursors into organic polymers, leading to their transformation into versatile organic-inorganic hybrids. These materials have a broad range of applications such as lithography patterning, freestanding film modification, and the manufacturing of foams and textiles. Nonetheless, a notable challenge in this method is the requirement for highly pyrophoric and expensive precursors such as trimethylaluminum (TMA) to diffuse into the polymer chains and the bulk of material. These constraints necessitate a transition towards more environmentally friendly and economically viable alternatives for VPI precursors. To address these limitations, we introduce a novel approach for depositing metalorganics into polymer films. By utilizing elements with accessible d-blocks, such as silicon, which can readily form dative bonds with electron-donating polymers like poly(4-vinylpyridine) (P4VP), we achieve effective infiltration of metalorganic precursors into polymer chains to create organic–inorganic hybrid complexes at ambient room temperature, while minimizing the use of toxic gases. The formation of the polymer complexes is verified using Solid-State Nuclear Resonance Magnetic (SSNMR) technique and X-ray Photoelectron Spectroscopy (XPS). Spectral reflectance of P4VP films post reaction showed 30-35% film growth for different silane precursors including tetrachlorosilane, trichlorosilane and dichlorosilane, consistent with thermogravimetric analysis (TGA). We observed film growth in high molecular weight precursors, albeit with a slower growth rate.

NM04.09.19

Interpenetrating Network Polymer Electrolyte Membranes for Durable Fuel Cells

Minju Kim[1], Guogao Zhang[2], Zhigang Suo[2] and Sang Moon Kim[1]; [1]Incheon National University, Korea (the Republic of); [2]Harvard University, United States

Hydrogen fuel cells utilize polymer electrolyte membranes (PEMs) to conduct protons while blocking electrons, hydrogen, and oxygen molecules. However, the cyclic swelling and contraction due to fluctuating water production *during fuel cell operation can lead to fatigue crack growth in the membranes, limiting their lifespan. This study introduces an innovative approach to enhancing the fatigue resistance of electrolyte membranes by forming an interpenetrating network of Nafion, a plastic electrolyte, and perfluoropolyether (PFPE), a rubbery polymer. The Nafion-PFPE composite membranes were prepared by absorbing the PFPE precursor into the pristine Nafion membrane and then curing it to form a robust interpenetrating network.*

The introduction of the PFPE network modestly reduces the electrochemical performance of the membrane but significantly enhances its fatigue resistance. Compared to the pristine Nafion, the Nafion-PFPE composite membrane showed a 20% reduction in maximum power density but an impressive 175% increase in fatigue threshold. Under the wet/dry accelerated stress test, the lifespan of the Nafion-PFPE membrane was 410 hours, which is 1.7 times longer than that of the Nafion membrane.

The study details the preparation process, where Nafion is submerged in a PFPE precursor, followed by UV curing to form an interpenetrating network. Mechanical characterization showed that Nafion-PFPE membranes have significantly higher fatigue threshold compared to pristine Nafion. For instance, the Nafion-PFPE-50 (50% saturation with PFPE) exhibited a fatigue threshold of 275 J m^{-2}*, compared to pristine Nafion's 100 J* m^{-2}*. Electrochemical tests demonstrated that Nafion-PFPE-50 maintained a current density of 0.574 A* cm^{-2} *at 0.6 V, which is slightly lower than Nafion's 0.892 A* cm^{-2} *but still functional. The membrane also showed a moderate increase in hydrogen crossover, attributed to the increased permeability of the PFPE component. Despite this, the Nafion-PFPE-50 membrane displayed a comparable ohmic resistance to Nafion, indicating that the interpenetrating network does not significantly impede proton conduction. Further in situ wet/dry accelerated stress tests, which mimic real fuel cell operations with cyclic relative humidity changes, confirmed the enhanced durability of the Nafion-PFPE membranes. The open circuit voltage and hydrogen crossover indicated a 69% extension in operational lifespan for Nafion-PFPE-50 compared to Nafion. These findings suggest that the interpenetrating network of PFPE and Nafion significantly enhances the fatigue resistance and overall durability of PEMs in fuel cells.*

In conclusion, the development of Nafion-PFPE composite membranes offers a promising solution to the fatigue issues in PEMs, providing a balance between maintaining electrochemical performance and enhancing mechanical durability. This approach could lead to more durable and reliable fuel cells, contributing to the advancement of sustainable energy technologies.

NM04.09.20

Electrosorption-Enabled Fast Ion Diffusion Along the Graphene-Electrolyte Interfaces *Xiao Wang, Wen-jie Jiang, Xiaoyang Du and Dan Li; The University of Melbourne, Australia*

Modulating electronic charge transport at the interfaces of electroactive materials via external voltages is pivotal for advancing electronic transistor technology, crucial for modern information processing and intelligence systems. Inspired by the achievements in microelectronics and the vital role of ionic charge signalling in biological systems, there is an increasing interest in using external voltages to manipulate ion transport at electronic/ionic interfaces or within nanoconfined environment. However, experimentally probing ion transport along electrified electronic conductor interfaces presents significant challenges. Here, we propose an interface amplification strategy to investigate the effects of external voltage on lateral ion transport, specifically focusing on ambipolar ion permeation across electrified interfaces using reduced graphene oxide (rGO) membranes. These electronically conductive multilayered graphene membranes (MGMs), based on rGO sheets, are reconceptualized as an ensemble of numerous atomically thin sheet/electrolyte interfaces when immersed in an electrolyte solution. Our findings indicate that while the negatively charged chemical groups on rGO generally hinder ion permeation compared to bulk solutions, the application of a negative external voltage allows for unexpectedly rapid and collective permeation of both cations and anions through the membranes. We observed ion permeation rates exceeding those in bulk solutions by over three orders of magnitude for the negatively electrified membranes. By *combining Poisson-Nernst-Planck simulations with various electrochemical and nanofluidic characterizations, we underscore the critical roles of ion electrosorption and ion-ion interactions in shaping ion transport dynamics at highly charged interfaces. Our research also uncovers several fundamental, unresolved questions about electrochemical interfaces, providing new insights that could drive the development of advanced electrochemical and iontronic technologies.*

Selective Separation of Thiophene Derivatives Using MOF-Based Membranes *Aigerim Ospanova[1,2], Dana Kanzhigitova[1] and Nurxat Nuraje[1]; [1]Nazarbayev University, Kazakhstan; [2]National Laboratory Astana, Kazakhstan*

Effective oil desulfurization is critical for refining fossil fuels to meet stringent environmental standards and reduce the emission of harmful sulfur oxides. Traditional desulfurization methods struggle with the selective removal of thiophene derivatives, key sulfur-containing compounds in fuels. This study introduces an innovative approach utilizing metal-organic framework (MOF-5) based composite membranes to enhance the selective adsorption of thiophene over dibenzothiophene in octane solutions.
The research focuses on leveraging the unique properties of MOF-5, which is modified with different transition metals to achieve selective adsorption. MOF-5, chosen for its optimal microporous structure, was doped with copper (Cu), silver (Ag), and nickel (Ni) and integrated into a polyvinylidene fluoride (PVDF) matrix, resulting in three distinct composite membranes. Adsorption experiments were conducted using model system – a thiophene/dibenzothiophene/octane mixture.
Remarkably, the MOF-5/Ag composite membrane demonstrated the highest thiophene removal efficiency at 86.8%, significantly outperforming the MOF-5/Ni and MOF-5/Cu membranes, which achieved 71.96% and 45.24% efficiency, respectively. The exceptional performance of the MOF-5/Ag membrane is attributed to the strong interaction between silver ions and sulfur in thiophene, a mechanism less effective with Cu and Ni dopants. The efficiency of these membranes was double confirmed using a pervaporation system, in addition to the initial adsorption system tests. The results were consistent, confirming the reliability of the findings. Furthermore, the adsorption of thiophene by the membranes was verified using a CHNS elemental analyzer, providing definitive proof of thiophene capture.
All three membranes showed low DBT removal efficiency, confirming the selective nature of the adsorption process. This study highlights the substantial potential of MOF-5 based composite membranes for targeted desulfurization. It emphasizes the critical role of metal dopants in enhancing adsorption performance. These findings represent a significant advancement in polymer nanocomposite membrane design, offering a promising strategy to improve fuel quality by efficiently removing thiophene derivatives.

NM04.09.22

Ni- Assisted Growth of Nanowires and Nanoplates Based on Mn-Oxides *Javier Garcia-Alonso[1], Janghyun Jo[2], David Maestre[1] and Ana Cremades[1]; [1]Universidad Complutense de Madrid, Spain; [2]Forschungszentrum Jülich GmbH, Germany*

In this work, Mn-based oxides, mainly Mn_3O_4 and MnO, micro- and nanostructures in form of wires, rods, nanoplates and brush-like structures have been grown following a one-step vapor-solid process [1] using a controlled mix of Mn and Ni powders as precursors. These precursor powders have been treated at 1000 – 1500 °C under a controlled Ar flow using a NiO pellet as a substrate. Following this method, a high yield of elongated micro- and nanostructures have been fabricated, with variable morphology, dimensions and properties as a function of the parameters used during the thermal treatment. These structures have been analyzed by means of x-ray diffraction (XRD), electron microscopy (SEM, TEM, HRTEM), energy dispersive x-ray spectroscopy (EDS), Raman spectroscopy and x-ray photoelectron spectroscopy (XPS). When necessary, the elongated structures have been

detached from the pellet for their individual analysis. The microwires and rods present a terraced appearance with lengths up to hundreds of microns and widths of few microns. Moreover, most of them exhibit secondary growth in forms of nanowires hundreds of nm lengths and tens of nm width, occasionally decorated with nanoplates and 2D structures. Electron microscopy confirms the morphology and dimensions of the structures, while EDS indicates that the presence of Ni assisted the growth of secondary growths and nanoplates. XRD and Raman spectroscopy, confirms that these wires mainly consist of Mn_3O_4*, while HAADF images confirm the presence of metallic Ni acting as nucleation areas for the growth of the* Mn_3O_4 *nanowires, 2D structures and plates. XPS spectra confirm variations mainly in the Mn(2p) and O(1s) core levels as a function of the probed regions along the elongated structures. Based on this analysis, the properties of the micro- and nanostructures were studied and the Ni-assisted growth process has been discussed.*
The achievement of low dimensional structures, including 2D and quasi 2D forms, based on Mn- oxides will improve the applicability of these materials in diverse fields of technological research [2].

Preparation of Free-Standing Inorganic Nanosheet Membranes and Their Application as Proton-Conducting Electrolytes for Fuel Cells

Shintaro Ida, Keisuke Awaya and Kazuto Hatakeyama; Kumamoto University, Japan

We have fabricated several types of 3D free-standing membranes using suction filtration and spin coating methods with inorganic 2D nanosheet dispersions. These include a 200 nm thick titanium oxide nanosheet membrane, an oxynitride Ca2Ta3O9N nanosheet membrane capable of bending with a 1 mm curvature, perovskite-type oxide nanosheet membranes, and Bi-MOF nanosheet membranes (1-5). These membranes are oriented structures with perfectly stacked nanosheets in face-to-face junctions. In transmission XRD patterns, only the (hk0) in-plane diffraction of the nanosheets was observed, while in reflection XRD patterns, only the (00l) out-of-plane diffraction was detected. The proton conductivity of these free-standing nanosheet membranes exhibited remarkable anisotropy, with differences of 10 to over 1000 times between the in-plane and out-of-plane directions. Furthermore, these inorganic nanosheet membranes demonstrated high hydrogen gas barrier properties and functioned effectively as proton-conducting electrolytes in hydrogen/oxygen fuel cells. In this presentation, we will report on the fabrication methods and proton conductivity of these free-standing inorganic nanosheet membranes and discuss the performance of fuel cells using these membranes as proton-conducting electrolytes.
Fuel cells are key devices for a sustainable future society, producing only water during power generation and emitting no carbon dioxide. A major target is to develop fuel cells for heavy-duty vehicles such as trucks, buses, and ships. Two types of fuel cells are used in automotive applications: PEFCs (Polymer Electrolyte Fuel Cells) and SOFCs (Solid Oxide Fuel Cells). Both types face significant challenges in meeting the targets set for 2030. For PEFCs, the target operating temperature is 105°C or higher. However, operating at temperatures exceeding 100°C accelerates power loss and cell degradation due to the limited thermal stability of Nafion, a polymer material. For SOFCs, the target is to achieve low operating temperatures, specifically 200°C or lower, compared to the current operating temperature of around 800°C. To overcome these challenges, research on new electrolytes beyond conventional materials is needed. We have been focusing on 2D nanosheet proton-conducting materials, which exhibit high ionic conductivity due to special hydrogen bonding on their two-dimensional surfaces. To use nanosheets as electrolytes for fuel cells, it is necessary to ensure high proton conductivity, hydrogen barrier properties, and mechanical strength. Additionally, precise manufacturing technology for freestanding nanosheet membranes and advanced battery assembly technology are required. Typically, for fuel cell electrolytes, dense membranes are prepared using powder systems, which require high-temperature sintering to obtain a dense

electrolyte from powder pellets. In contrast, dense membranes in nanosheet systems can be fabricated at room temperature using suction filtration and spin coating methods.

NM04.09.24
Controlled Graphitization for GaN Remote Epitaxy *Jekyung Kim[1], Seokje Lee[1], Bo-In Park[1], Kyusang Lee[2], Hyunseok Kim[3] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Virginia, United States; [3]University of Illinois at Urbana-Champaign, United States*

Although remote epitaxy offers a promising solution for growing freestanding single crystalline membrance delicate control of 2D materials lead to the successful demonstration of remote epitaxial membrane with a high material quality. In this study, we demonstrated a controlled graphitization technique to directly grow a pristine graphene buffer layer (GBL) directly on 4H-SiC substrates on which GaN was grown by remote epitaxy. The clean surface of GBL prepared by this method, free of any contamination, enables the formation of high-quality GaN epilayers with facile exfoliation. This study reveals that this approach poses an important platform for wafer-scale fabrication of high-quality freestanding GaN.

NM04.09.25
Amorphous 2D Materials—A Novel Platform for Remote Epitaxy and Nanopatterned Epitaxy of III-V Semiconductors *Kuangye Lu, Ne Myo Han, Hyunseok Kim, Sangho Lee, Jin Feng and Jeehwan Kim; Massachusetts Institute of Technology, United States*

III-V semiconductor materials such as indium phosphide (InP) offer outstanding photonic properties that outperform silicon. However, the cost of InP wafers is considerably higher compared to commonly used semiconductor wafers like gallium arsenide (GaAs). While reusing original wafers can effectively reduce costs, traditional techniques for wafer recycling, such as chemical or mechanical lift-off, introduce significant expenses during fabrication, negating the cost savings achieved through wafer reuse. Besides, unlike other III-V materials such as GaAs, the epitaxial lift-off method for wafer recycling has not been extensively investigated for InP due to the lack of lattice-matched sacrificial layers with sufficient etching selectivity. Consequently, the reuse of InP wafers becomes more challenging.

Remote epitaxy and nanopatterned epitaxy have emerged as novel methods capable of facilitating the growth of III-V semiconductor membranes with single-crystal quality, as well as enabling easy exfoliation of these films. These breakthroughs offer a promising avenue for cost-effective wafer reuse. However, traditional approaches for transferring two-dimensional (2D) materials, utilizing polymethyl methacrylate (PMMA) or metal stressor layers to transfer materials grown on foreign substrates like copper (Cu) or silicon carbide (SiC), have been found to introduce defects and damages to both the 2D layer and the substrates during the transfer process. As a result, remote epitaxial and nanopatterned epitaxial films grown on these damaged 2D layers or substrates exhibit lower crystal quality and imperfect exfoliation, hampering wafer reusability and device performance. Additionally, the method of using grown thin amorphous carbon (TAC) for AlGaAs/GaAs is not suitable for InP, since the *decomposition temperature of InP (< 600* ***°C****) is significantly lower than the growth temperature of TAC (700* ***°C****).*

Here we report the MBE growth of amorphous boron nitride (a-BN) on InP wafers at low temperature that enabled improved quality of remote epitaxial and nanopatterned epitaxial films and their perfect exfoliation. We show fully covered a-BN on InP and InGaAs substrates despite their low decomposition temperatures. The surface of a-BN coated InGaAs/InP substrate remains smooth with RMS roughness of around 3Å. We also demonstrate 100% coverage of single-crystal InP thin films grown on a-BN, with the film's quality comparable to InP grown directly on wafers. In addition, the growth and exfoliation were successfully repeated multiple times, proving the feasibility for InP wafer recycling. Through this low temperature MBE growth approach with remote epitaxy and nanopatterned epitaxy, we successfully demonstrate large-scale flexible thin film exfoliation and recycling of InP substrates, which will lead to new opportunities in InP thin film-based photonics and novel heterostructures with significantly reduced cost.

NM04.09.26

Selective Area Epitaxy of Defect-Free III-V Layers on Silicon Via Graphene Nanoholes *Ne Myo Han, Kuangye Lu, Do A Kwon and Jeehwan Kim; Massachusetts Institute of Technology, United States*

The integration of III-V semiconductors on silicon is critical for advancing high-performance electronic and optoelectronic devices due to their high electron mobilities and direct bandgaps. However, the large lattice mismatch between III-V materials and silicon typically results in high dislocation densities, which severely degrade device performance. Techniques like graded-buffer layers (GBL), epitaxial lateral overgrowth (ELOG), and aspect ratio trapping (ART) have been proposed to mitigate these issues, but with limited success. While pseudomorphic growth can create dislocation-free III-V layers, it leads to interface roughening and mobility degradation in ultrathin channels. Therefore, it is critical to explore new relaxation mechanisms that avoid the formation of dislocations.

I will describe a graphene-assisted epitaxy technique to achieve strain-relaxed, dislocation-free III-V growth on silicon. Graphene, a two-dimensional material with a sp^2*-bonded structure, is directly grown on the silicon substrate to act as a buffer layer that mediates strain relaxation through selective area epitaxy (SAE) at engineered nanoholes. These nanoholes expose the silicon substrate which provides nucleation sites where the III-V material can grow, while the surrounding graphene prevents nucleation elsewhere due to its lower sticking coefficient. As the III-V material grows laterally over the graphene, the strain that typically arises from lattice mismatch is relaxed due to the flexible and slippery nature of graphene, which accommodates misfit strain through lateral overgrowth.* SiO_2 *trenches that confine the laterally grown III-V material further reduce defects by limiting the number of distinct nuclei that form the merged films. The interplay between graphene's strain-relaxing properties and the controlled nucleation process enables the direct growth of thin III-V layers on silicon without the formation of dislocations.*

This graphene-assisted epitaxy method offers a scalable and CMOS-compatible (transfer-free and monolithic) solution for integrating high-quality III-V materials on silicon, paving the way for future high-performance electronic and optoelectronic applications.

A Metastable Pentagonal 2D Material Synthesized by Symmetry-Driven Epitaxy *Lina Liu[1,2], Yujin Ji[3], Marco Bianchi[2], Saban Hus[4], Zheshen Li[2], Richard Balog[2], Jill Miwa[2], Philip Hoffman[2], An-Ping Li[4], Dmitry Zemlyanov[1], Youyong Li[3] and Yong Chen[1,2]; [1]Purdue University, United States; [2]Aarhus University, Denmark; [3]Soochow University, China; [4]Oak Ridge National Laboratory, United States*

Most two-dimensional (2D) materials experimentally studied so far have hexagons as their building blocks. Only a few exceptions, such as $PdSe_2$, are lower in energy in pentagonal phases and exhibit pentagons as building blocks. Although theory has predicted a large number of pentagonal 2D materials, many of these are metastable and their experimental realization is difficult. Here we report the successful synthesis of a metastable pentagonal 2D material, monolayer pentagonal $PdTe_2$, by symmetry-driven epitaxy. Scanning tunnelling microscopy and complementary spectroscopy measurements are used to characterize this material, which demonstrates well-ordered low-symmetry atomic arrangements and is stabilized by lattice matching with the underlying Pd(100) substrate. Theoretical calculations, along with angle-resolved photoemission spectroscopy, reveal monolayer pentagonal $PdTe_2$ to be a semiconductor with an indirect bandgap of 1.05 eV. Our work opens an avenue for the synthesis of pentagon-based 2D materials and gives opportunities to explore their applications such as multifunctional nanoelectronics.

8:15 AM NM05.01.02
Two-Dimensional Electronic Band Structure of a Pb Monolayer Confined Under Epitaxial Graphene on SiC
Bharti Matta[1], Philipp Rosenzweig[1], Kathrin Küster[1], Craig Polley[2] and Ulrich Starke[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]Lund University, Sweden

Stacking two-dimensional (2D) layers is a promising path towards materials with novel electronic properties beyond conventional bulk systems. Epitaxial graphene on silicon carbide (SiC), also known as epigraphene, is a versatile platform for stabilizing 2D forms of elements at its interface via intercalation, which allows for modifying *the properties of graphene [1,2]. Moreover, it is an elegant way of studying the intriguing properties of quantum-confined intercalant elements at the graphene/SiC interface [3,4]. In recent years, lead (Pb), a heavy element superconductor, has gained significant interest as an intercalant for epigraphene [5-9], due to the possible proximity effects, such as superconductivity and spin-orbit coupling [10,11]. In addition, theory calculations for a monolayer Pb on SiC show a non-trivial momentum-space spin texture, making the Pb-intercalated epigraphene a potentially interesting material for spintronics applications [12]. Here we present a detailed electronic band structure study of the interlayer Pb at the graphene/SiC interface using angle-resolved photoelectron spectroscopy (ARPES). The interlayer Pb bands cross the Fermi energy, showing its metallic nature. To a first order approximation, the interlayer bands can be fit with a free-electron-like model. The bands in the repeated Brillouin zone confirm the (1×1) alignment of the Pb layer relative to SiC. The 2D nature of the intercalated Pb is validated using constant initial state mapping, showing no dispersion of interlayer bands with photon energy, hence no bulk origin. Light polarization dependent ARPES measurements additionally shed light on the orbital character associated with various Pb band features along all the high-symmetry directions of its Brillouin zone. Density functional theory calculations for a (1×1) Pb monolayer on SiC show a good qualitative agreement with the experimentally observed interlayer bands, exhibiting a dominant p-orbital character. Furthermore, we demonstrate that the Pb-intercalated quasi-freestanding monolayer graphene on SiC is nearly charge neutral and involves charge transfer from both Pb and SiC. Finally, we discuss how an electron dopant, potassium (K) adsorbed on top of the Pb-intercalated epigraphene influences the band structure of graphene and the interlayer Pb. Apart from that, the Fermi surface illustrates that the K-adlayer orders itself in a (2×2) superstructure relative to the graphene unit cell.*

This work is supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) through the research unit FOR5242. MAX IV Laboratory (Lund, Sweden) is acknowledged for time at the BLOCH beamline. We are grateful to the beamline scientists at BLOCH for their support.

Thickness Dependent Magnetic Ordering in Two-Dimensional Magnetic Insulator *Muhammad Z. Khan[1], Andriani Vervelaki Vervelaki[2], Daniel Jetter[2], Kousik Bagani[2], Sergio Valencia[3], Florian Kronast[3], Andreas Ney[4], Martino Poggio[2] and Aleksandar Matković[1]; [1]Montanuniversität Leoben, Austria; [2]Universität Basel, Switzerland; [3]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [4]Johannes Kepler Universität Linz, Austria*

Magnetic domain formation in two-dimensional magnetic insulators offers insight into the fundamentals of magnetism and serve as a catalyst for the advancement of spintronics device technology. One such example is magneto-resistive random-access memory (MRAM). In case of 2D magnetic insulators in MRAMs, ultra-thin *antiferromagnetic barriers in combination with regular (non-magnetic) metals could lead to the development of future memory elements, computing in memory concepts, and self-reconfiguring circuits.[3,4] In order to propel these developments, its crucial to acquire understanding of the evolution of magnetic ordering at nanometer scale, as a function of number of atomic layers and applied magnetic field.*

From an implementation prospective, 2D van der Waal magnets present significant challenges related to stability, size, and critical temperature. One primary issue is the degradation of 2D magnets when exposed to ambient conditions. We propose to overcome this by exploiting naturally occurring iron-rich phyllosilicates. Phyllosilicates offer a unique opportunity to explore complex air-stable layered systems with high concentration of magnetic ions. These naturally occurring layered materials are inherently magnetic and are wide band gap insulators (i.e. 5-6 eV). In this study, we visualize few-layer annite (mica) ($KFe_3^{2+}AlSi_3O_{10}(OH)_2$) by employing a hybrid approach involving a scanning superconducting quantum interference device (SQUID) and an atomic force microscopy (AFM) probe. Annite is a naturally occurring van der Waals (vdW) magnetic insulators which incorporate local moment baring ions of iron (Fe) via in their octahedral sites.[1,2] The simultaneous imaging capability of the SQUID-on-tip microscope, capturing both the surface features and its stray magnetic field, enabled us to establish correlations between layer thickness and magnetic ordering. External field dependent maps of annite's stray magnetic field reveal coercivity of 70 mT for the 2D flakes, and capture the domain formation and flipping in the external field. We demonstrate correlations between the iron concentration, layer structure, iron oxidation states, and their magnetic response, indicating a path to design materials with higher critical temperatures via tuning the concenteration of magnetic species and oxidation state engineering.

8:45 AM NM05.01.04

Nano-Achiral Complex Composites for Extreme Polarization Optics *Jun Lu[1,2,3], Wenbing Wu[1,2,3], Felippe M. Colombari[4], Ali Jawaid[5], Bryan Seymour[5], Richard A. Vaia[5], André F. de Moura[6], Dhriti Nepal[5] and Nicholas A. Kotov[1,2,3]; [1]University of Michigan, United States; [2]Biointerfaces Institute, University of Michigan, United States; [3]Center for Complex Particle Systems (COMPASS), University of Michigan, United States; [4]Brazilian Center for Research in Energy and Materials, Brazil; [5]Air Force Research Laboratory, United States; [6]Universidade Federal de São Paulo, Brazil*

Composites made from 2D nanomaterials exhibit exceptional electrical, thermal, and mechanical properties. Their robustness, combined with the ability to control polarization rotation, is crucial for developing hyperspectral optics suitable for extreme conditions. However, the inherent random and achiral shapes of rigid nanoplatelets often disrupt the circular polarization of photons with similar wavelengths.

In this study, we demonstrate that multilayer nanocomposites derived from 2D nanomaterials with intricately textured surfaces can significantly and predictably rotate light polarization, even though they are nano-achiral and partially disordered. The pronounced circular dichroism (CD) observed in these nanocomposite films is attributed to the diagonal patterns of wrinkles, grooves, or ridges, which create an angular offset between the axes of linear birefringence (LB) and linear dichroism (LD). The layer-by-layer (LBL) assembly method allows for precise engineering of polarization-active materials from imprecise nanoplatelets, achieving an optical asymmetry g-factor of 1.0—approximately 500 times greater than typical nanomaterials. These composites also exhibit high thermal resilience, enabling operation at temperatures up to 250 degrees Celsius and facilitating the imaging of hot *emitters in the near-infrared (NIR) spectrum. When combined with achiral dyes, LBL-engineered nanocomposites achieve anisotropic factors for circularly polarized emission that approach theoretical limits.*

The versatility of this phenomenon is demonstrated through the use of various nanomaterials, such as molybdenum sulfide (MoS2), MXene, and graphene oxide (GO), along with two different manufacturing techniques. This capability paves the way for the computational design and additive engineering of a wide range of LBL optical nanocomponents for ruggedized optics applications.

9:00 AM NM05.01.05

Process-Induced Strain Engineering in Two Dimensional Electronic Materials *Yue Zhang, Helin Zhao, Siyuan Huang, Mohammad A. Hossain, Kelly Hwang, Elif Ertekin and Arend M. van der Zande; University of Illinois at Urbana-Champaign, United States*

Atomically thin, two-dimensional (2D) electronic materials such as transition metal dichalcogenides (TMDs) represent the ultimate thickness limit in scaling down integrated circuits. This paradigm shift facilitates the heterogeneous integration of 2D electronic devices into current silicon-based CMOS technology library [1]. A key challenge is understanding CMOS process compatibility with 2D materials, and what new fabrication capabilities are enabled by applying common CMOS processes on 2D devices. In particular, there is a knowledge gap in how thin film stress, commonly found across thin film deposition processes, interacts with 2D few-layers and how the van der Waals interface affects strain transfer during CMOS processes [2].

Here, we use thin film evaporation as an example, showing that CMOS process-induced stress applies a controllable strain when evaporating thin films on 2D monolayers and heterobilayers. We selectively deposit lithographically-patterned thin film magnesium oxide (MgO), known as stressors, onto 2D monolayers and heterobilayers with e-beam evaporation. By tracking the changes in Raman signature modes in monolayer MoS_2 *and* WSe_2*, we qualitatively estimate the strain, and the result is independently verified with the photoluminescence emission peak mode. Importantly, engineering the mechanical boundary condition enables the application of complex, spatially heterogeneous strain and strain gradients that are designable. This new ability has two impacts. In the monolayer, we demonstrate inducing up to 0.8% complex strain distribution that is challenging for polymer-based strain engineering methods. In the artificially stacked* MoS_2/WS_2 *heterobilayer, for the top layer, the MgO stressor applies a uniform, ~1% strain while the bottom layer is unaffected, creating layer-dependent strain, or heterostrain [3].*

The patterned stressor strategy allows direct device integration for strained 2D materials. As a demonstration, we start with a monolayer MoS_2 *transistor, and repeatedly deposit the MgO stressor while measuring the carrier transport at different stressor thicknesses. While the stressor is below the critical thickness (~150 nm), the device conductivity linearly improves due to the enhancement of electron carrier mobility: at ~0.4% strain, we observe a 62 +- 23% electron mobility enhancement. Compared to similar studies with polymer-based strain engineering methods, our strategy has a similar enhancement strength, while manifesting the integration of highly strained 2D systems into other solid devices [4].*

Overall, engineering process-induced stress provides opportunities to fine-tune the electronic properties of 2D materials with strain, and directly incorporate strained 2D systems into the current CMOS architecture. More broadly, highly localized strain and strain gradients enable unprecedented quantum functional devices made of 2D monolayers and heterostructures. Deterministically designing and applying strain with thin film stressors accelerates the integration of diverse strain-enabled multifunctional 2D devices into CMOS circuits, defined as "more than Moore" in technology road-maps [5].

Phase Transition in Two-Dimensional Monolayer (1L)-Molybdenum Disulfide Via Synchrotron X-Ray Monochromatic Beam Radiation for Superior Electronic Performance *Mayur Chaudhary[1,1], Aswin K. Anbalagan[2], Peter V. Sushko[3], Li-Chyong Chen[4], Kuei-Hsien Chen[4], Ya-Ping Chiu[5] and Yu-Lun Chueh[1,1]; [1]National Tsing Hua University, Taiwan; [2]Brookhaven National Laboratory, United States; [3]Pacific Northwest National Laboratory, United States; [4]National Taiwan University, Taiwan; [5]Academia Sinica, Taiwan*

Here, we report a novel approach to reduce the channel resistance by inducing a phase transition behavior from 2H to 1T in a monolayer MoS_2 (1L-MoS_2) by a synchrotron X-ray monochromatic beam (moon-beam) radiation. The effects of the biphase structure by the mono-beam on the 1L-MoS_2 film were investigated using Raman spectra, photoluminescence (PL) spectra, scanning tunneling microscopy, and scanning tunneling spectroscopy, respectively. Through material characterization, we identified that the lateral sliding of S-vacancies along the S-plane in the 1L-MoS_2 is the key reason for the origin of unidirectional phase transition. The precise phase engineering triggered by the mono-beam radiation process allows the realization of field-effect transistors (FET) with 2X improvement in mobility toward a high on/off ratio (~10^8) and a near-ideal subthreshold swing of ~88 mV per decade. The validity of the phase engineering could be further extended for its application as a memory device, exhibiting a gate tunable conduction modulation behavior and a high resistance ratio of ~10^2 at a gate bias of 5 V with endurance of ~100 cycles. Furthermore, an artificial neural network using the synaptic weight update with accuracy of ~93 % was achieved.

Electrochemical Lithium Intercalation and Exfoliation in 2D TMDs and Its In Situ Studies *Zhiyuan Zeng; City University of Hong Kong, Hong Kong*

We developed a lithium ion battery intercalation & exfoliation method with detailed experimental procedures for the mass production of 11 two dimensional TMDs and inorganic nanosheets, such as MoS_2, WS_2, TiS_2, TaS_2, ZrS_2, graphene, h-BN, $NbSe_2$, WSe_2, Sb_2Se_3 and Bi_2Te_3, among them 3 TMDs achieved mono- or double layer yield > 90%. This method involves the electrochemical intercalation of lithium ions into layered inorganic materials and a mild sonication process. The Li insertion can be monitored and finely controlled in the battery testing system, so that the galvanostatic discharge process is stopped at a proper Li content to avoid decomposition of the intercalated compounds. The intercalation strategy can also be used to tune 2D TMDs' physical and chemical properties for various applications. For example, we developed an one-step covalent functionalization method on MoS_2 nanosheets for membrane fabrication, which exhibited excellent water desalination performance. For lithium intercalation mechanism, the state-of-the-art In-Situ Liquid Phase TEM is an ideal technique for identifying the phase changes during intercalation process. With self-designed electrochemical liquid cell utilized, we can directly vapture the dynamic electrochemical lithiation and delithiation of electrode in a commercial $LiPF_6$/EC/DEC electrolyte, such as LiF nanocrystal formation, lithium metal dendritic growth, electrolyte decomposition, and solid-electrolyte interface (SEI) formation. Combining with other in-situ techniques, such as in-situ XAS, XRD and Raman, etc, the underlying lithium intercalation mechanism in TMDs were further investigated, which render us a comprehensive understanding of the intrinsic correlation between the intercalation process and TMDs layered structures.

Electrochemical Driven Synthesis of 2D Nanospace-Confined Metal-Based Catalytic Platforms for Silica Microenvironment-Assisted Catalysis *Sampathkumar Jeevanandham and In Su Lee; Pohang University of Science and Technology, Korea (the Republic of)*

Developing sustainable inexpensive alternatives like copper (Cu) based nanostructures in place of rare noble metals is crucial for industrial-scale fine-chemical synthesis, particularly in heterogeneous catalysis. However, controlling and understanding the intricate surface chemistry of Cu at the nanoscale remains highly challenging due to its kinetic instability, susceptibility to oxidation, and restructuring that leads to structural disproportionation during catalysis. Furthermore, establishing control over the reaction selectivity in heterogeneous catalysis remains a formidable challenge due to unguided molecular access to metal sites. Hence, designing model catalyst platforms, especially by synthesizing ultrathin 2D nanostructures can afford geometrically favorable co-planar exposed catalytic metal sites. Herein, by utilizing the nanospace-confined electrochemical (eChem) atomic layer deposition (NC-EAD) technique, ultrathin 2D Cu(0)-layer within (< 2 nm thickness) bilayer silica sandwiched envelope was synthesized. This model catalyst platform can also be extended towards the echem alloying of diverse 2D mixed metal islands within confined nanospace, creating an intimate 2D/2D interfacial contact between porous silica and metal/mixed metal sites. Ultrathin 2D-Cu layer sandwiched inside bilayer silica template provides a platform to decipher the critical cooperative role of Lewis basic amino-silica *microenvironment for [Cu]-catalyzed selective hydrogenation of unsaturated C-C bonds in diverse alkynes, ene-ynes, and α,β-unsaturated (alkene) Michael acceptors. Additionally, the confined microenvironment of 2D mixed metal catalytic systems enables reliable control over molecular orientation with ligand-shell cooperativity, offering switchable reaction selectivity in hydrogenation catalysis. These 2D model catalyst platforms provide detailed mechanistic insights into the concept of reactive metal surface-microenvironment, establishing a new paradigm for controlling complex molecular interactions in heterogeneous catalysts.*

Research on the Coherent Interface Design and Surface Microstructure Tailoring of Cu Matrix Materials
Jiamiao Ni and Yue Liu; Shanghai Jiao Tong University, China

Surface microstructures, including surface orientation and step structures, play a critical role in determining the electrical conductivity and stability of copper (Cu)-based materials, owing to their electron scattering effect and anisotropic surface energy levels. Previous works have demonstrated that achieving close-packed surface orientation and atomic flat surface can greatly enhance the surface properties of Cu. However, the intrinsic surface kinetics and thermodynamics of face centered cubic metals always result in non-close packed surfaces with large surface steps during heat treatment, raising challenges in the optimization of surface microstructures. In this work, we propose to tailor the surface microstructures of Cu by changing the intrinsic surface thermodynamic and kinetic conditions through the construction of coherent interfaces. Using cobalt (Co) and single layer graphene (SLG) as model materials, we constructed Cu/Co and Cu/SLG interfaces on Cu and found that the atomic flat {111} Cu surface can be achieved in Cu/SLG interfaces. Further microstructure characterizations and molecular dynamic simulations revealed that the formation of {111} reconstructed Cu surface was dominated by melting and re-solidification of Cu surface under the assisted from Cu/SLG interface energy. Meanwhile, the formation of atomic flat surface can be ascribed to the minimization of Gr strain energy and high-temperature assisted surface diffusion. Based on these mechanisms, two important criteria that can achieve atomic flat {111} Cu surface are proposed: (i) an appropriate processing temperature that can trigger the surface melting/surface diffusion and (ii) a crystalline surface coated layer with high modulus that can modify the Cu surface energy. The present results not only elucidate our designing concept but also provide a feasible strategy for tailoring the surface properties of Cu-based materials.

Topological Modifications of Layered Materials Beyond 2D Morphology *Wenhao Shao and Letian Dou; Purdue University, United States*

Morphological control of layered materials has crucial implications on modern electronics and photonics. However, layered materials do not naturally grow beyond 2D morphologies due to their inherent in-plane symmetry. Organic-inorganic hybrid lattice, however, presents unique crystal structure to tackle this challenge. For insance, layered perovskites readily synergize chemical tunability and solution processability of organics with optical and electronic properties of traditional inorganic crystals. Using layered perovskite as a structural template, I'll present a few molecular templating approaches to manipulate the network topology in the organic sublattice and achieve exciting morphological control on layered materials beyond 2D morphologies.

The first approach creates an 1D organic network in layered perovskites using robust and directional hydrogen bonding from aromatic carboxylic acids. This molecular templating method restricted the crystal growth along all directions except for a designed primary axis.
and promoted 1D growth (1). Our approach is widely applicable to synthesize a range of high-quality layered perovskite nanowires with large aspect ratios and tunable chemical compositions, including the deterministic

synthesis of longitudinal heterostructures. These nanowires form exceptionally well-defined and flexible cavities that exhibited a wide range of unusual optical properties beyond those of conventional perovskite nanowires. We observed anisotropic emission polarization, low-loss waveguiding and efficient low-threshold light amplification.

The second approach exploits the asymmetric strain built in such an 1D network topology, which created a primary bending axis in layered materials to allow for the automatic generation of morphological chirality during crystal growth. Helicoids or helical ribbons can be synthesis in a scalable fashion. The underlying mechanism is proposed to be a type of "incompatible elasticity" in well resonance with the chiral opening of seed pods (2). Our ongoing efforts to elucidate this mechanism via molecular dynamics modeling and experimental single crystal analysis will be discussed.

11:00 AM NM05.02.05
Investigating the CVD Growth Kinetics of 2D Crystals Through In Situ Optical Microscopy and Automated Image Processing *Faizal Arifurrahman, Tianshu Zhai, Yuguo Wang, Jing Zhang, Andrew Hitt, Jun Lou and Ming Tang; Rice University, United States*

Two-dimensional (2D) materials have gained significant attention for their unique physical and chemical properties with promising applications. Numerous efforts have been dedicated to synthesizing large-area, highly crystalline 2D materials using various techniques. Among these methods, chemical vapor deposition (CVD) stands out for its ability to enable wafer-scale growth with precise thickness control. However, comprehending the intricate relationship between the intrinsic thermodynamic parameters and the nucleation and growth of 2D crystals to achieve precise control over crystal orientation and grain size during CVD synthesis remains a formidable challenge.
This work uses a custom-built miniature CVD system with in-situ optical microscopy to investigate the real-time formation of individual molybdenum disulfide (MoS2) crystals during CVD growth. An automated image processing pipeline, which extensively employs machine learning algorithms, is developed to quantitatively analyze the microscopic video footage. Using this pipeline, we were able to extract the growth trajectory of each and every MoS_2 crystal before and after coalescence. Such information offers valuable insight into the growth behavior of 2D crystals. We observe that MoS_2 crystals that nucleated earlier also have larger growth rates. The crystal growth speed decreases monotonically with the crystal size but is independent of the crystal orientation. Interestingly, the in-situ observation reveals that neighboring MoS_2 crystals do not interfere with each other's growth and exhibit weak pair correlation when the reactor temperature is above 800 °C. This supports a ground-feeding growth mechanism in which nanoparticulate Mo precursors are deposited onto the sapphire substrate and supply Mo feedstocks to the surrounding MoS_2 crystals via surface diffusion.

11:15 AM NM05.02.06
Scalable Integration of Crystalline Oxide Dielectrics with 2D Semiconductors Through Epitaxial Metal Deposition and Controlled Oxidation *Zhenjing Liu[1], Qian Mao[2], Varun Kamboj[1], Paul Miller[1], Kate Reidy[1], Rishabh Kothari[1], Adri van Duin[2], Rafael Jaramillo[1] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]The Pennsylvania State University, United States*

Atomic layer deposition (ALD) is the established process to grow oxide dielectrics on semiconductors. ALD requires abundant nucleation sites on the substrate to enable fine control of deposition, and this creates challenges when depositing on 2D materials due to their dangling-bond-free surfaces. In prior work, we *demonstrated that quasi-van der Waals (q-vdW) epitaxial growth of 3D metals on 2D materials is possible, provided that the 2D materials surfaces are sufficiently clean [1]. Here, we leverage these results to develop synthesis of epitaxial HfO_2 on 2D materials by q-vdW epitaxial growth of ultra-thin Hf metal films, followed by controlled oxidation.*

To control oxide phase purity and achieve a high-quality, atomically-sharp 3D/2D interface requires atomic-level understanding of the process. We use in situ transmission electron microscopy (TEM), reactive molecular dynamics (RMD) with ReaxFF method, and scanning near-field optical microscopy (SNOM) to study the deposition and oxidation of ultra-thin Hf on graphene. Evaporated Hf metal forms epitaxial hcp-Hf crystals on sufficiently clean graphene substrates. Subsequent oxidation proceeds through two intermediate, metastable sub-oxides - an amorphous phase (a-HfO_x) and a crystalline hexagonal phase (h-HfO_x) - before terminating at the equilibrium monoclinic phase (m-HfO_2). All crystalline phases form in epitaxial relationships with the underlying graphene, including m-HfO_2 which forms in three equivalent orientations. The h-HfO_x phase has not been described previously. We identify its crystal structure, and describe the martensitic transformation by which it converts to m-HfO_2. We use SNOM to map electrical properties on the nanoscale, yielding a quantitative comparison of the conductivity of the h-HfO_x and m-HfO_2 phases. RMD simulations using ReaxFF validate our model of oxide phase sequencing, and illustrate the role of graphene in templating the h-HfO_x intermediate phase. Simulations reveal distinct phases of Hf, HfO_x, and HfO_2 that evolve differently depending on the O_2 concentration.

We then extend our work to other 2D materials, h-BN and MoS_2. Deposition of Hf on h-BN with substrate heating, followed by oxidation, results in a cubic structure that may be a boron-stabilized oxide. Similarly, deposition of Hf on MoS_2 with substrate heating results in HfS_2 that forms epitaxially on the substrate. These results highlight considerations when depositing functional layers on compound semiconductors, which may react by anion exchange mechanisms, especially when heated. In preliminary results, we also demonstrate that Hf metal can grow epitaxially on MoS_2 without formation of HfS_2, provided that the 2D material surface is sufficiently clean and cold.

Our results suggest a way to integrate high-performance dielectrics with 2D materials, by deposition of Hf metal followed by controlled oxidation, achieving epitaxy at each step. By illustrating Hf oxidation sequences in atomic detail we also suggest opportunities in hafnia phase engineering.

11:30 AM NM05.02.07

Phase Engineering of Confined Heteroepitaxial (CHet) 2D Silver and Its Use in Fano Resonance-Based Sensing *Arpit Jain[1], Kunyan Zhang[2], Matthew W. Liu[1], Alexander Vera[1], Li-Syuan Lu[1], Rinu A. Maniyara[1], Yuanxi Wang[3], Chengye Dong[1], Nader Sawtarie[4], Maxwell T. Wetherington[1], Vincent Crespi[1], Shengxi Huang[5] and Joshua A. Robinson[1]; [1]The Pennsylvania State University, United States; [2]University of California, Berkeley, United States; [3]University of North Texas, United States; [4]University of Pittsburgh, United States; [5]Rice University, United States*

Two-dimensional (2D) metals, distinct from their three-dimensional counterparts, exhibit remarkable electronic, optical, and quantum characteristics due to their reduced dimensionality. However, their inherent instability and susceptibility to oxidation pose challenges. Leveraging the Confinement Heteroepitaxy technique, we achieve the growth of centimeter-scale, air-stable 2D metals with gradient bonding, non-centrosymmetric structures, and unique features, including superconductivity. These metal films intercalate at the graphene/silicon carbide interface, where graphene protects against oxidation. Specifically, 2D silver displays semiconducting behavior and manifests in two distinct phases—3:3 (Ag_1) and 4:3 (Ag_2)—relative to the silicon carbide lattice. Our research demonstrates that tailoring the defects in the starting epitaxial graphene layer allows preferential intercalation of phases. By starting with buffer-layer graphene rich in sp^3 defects, we achieve Ag_2 phase localization in buffer regions and Ag_1 phase dominance in monolayer graphene regions, resulting in a large-area Ag_2 sample.

Additionally, controlled He plasma treatment induces line defects, facilitating selective Ag_1 phase growth post-intercalation. Notably, 2D Ag exhibits a pronounced asymmetric Fano resonance, which can be modulated by molecules, making it promising for sensitive single-molecule detection sensors. Despite minimal structural differences, these phases exhibit distinct optical absorption and saturation, suggesting potential applications in chemical sensors and optoelectronic devices.

SESSION NM05.03: Structure-Property Relation in 2D Materials and Heterostructures—Thermal, Optical, Mechanical and Magnetic II

Thermal Transport Across Slippery Interfaces in Twisted Graphite *Fuwei Yang[1], Wenjiang Zhou[2], Zhibin Zhang[2], Xuanyu Huang[1], Jingwen Zhang[3], Nianjie Liang[2], Wujuan Yan[2], Yuxi Wang[2], Mingchao Ding[4], Quanlin Guo[2], Yu Han[1], Te-Huan Liu[3], Kaihui Liu[2], Quanshui Zheng[1,1] and Bai Song[2]; [1]Tsinghua University, China; [2]Peking University, China; [3]Huazhong University of Science & Technology, China; [4]Chinese Academy of Sciences, China*

Interlayer rotation in van der Waals (vdW) materials offers a unique degree of freedom for manipulating phonon dynamics and heat flow in advanced electronics. However, precise measurement of single-crystalline twisted interfaces presents a great challenge, and the underlying physical mechanisms thus remain elusive. Here, we develop micro-mesa-based experimental schemes and achieve simultaneous mechanical and thermal characterizations of the intrinsic interfaces in graphite. Remarkably, we observe over 30-fold suppression of thermal conductance for the slippery interfaces with low sliding resistance compared to locked interfaces. Nonetheless, the conductance remains ~600 $MWm^{-2}K^{-1}$, approaching the highest values ever measured for any interface. Atomic simulations reveal the predominant role of transverse acoustic phonons. Together, our findings directly highlight a general force-heat correlation and lay the foundation for twist-enabled thermal management which are particularly beneficial to twistronics and slidetronics.

10:45 AM NM05.03.02
Strain-Induced Work Function Shifts in 2D Materials *Hyunchul Kim, Shahriar Muhammad Nahid and Arend M. van der Zande; University of Illinois at Urbana-Champaign, United States*

Two-dimensional (2D) materials are increasingly recognized as promising candidates for beyond-silicon electronics owing to their favorable size scaling of electronic performance. The heterogeneous integration of 2D materials with CMOS technologies often introduces the process-induced strain arising from mechanical mismatches, necessitating a comprehensive understanding of how strain impacts their electrical characteristics. Numerous studies have explored the effects of strain on the band gap alterations in 2D materials, such as WSe_2 and MoS_2, and consequent changes in the electrical performance of devices. For instance, strain tunes the optical band gap of WSe_2 at a rate of -54 meV/%,[1] and enhances the field effect mobility of MoS_2 transistors, 1.3 times/%.[2] However, one of the lesser understood yet crucial parameters that strain affects is the work function, which is crucial for understanding metal-semiconductor Schottky barriers, contact resistance and threshold voltage in transistors. Understanding the interplay between strain and work function in 2D materials is pivotal determining the ultimate performance of strain engineered transistors, and the behavior of stretchable electronics *from 2D heterostructures.[3]*

Here, we analyzed the strain induced tuning of the work function in wrinkled monolayer WSe_2. We fabricated 2D materials with periodically modulated strain by transferring WSe_2 with a 15 nm thick ALD grown HfO_2 support layer onto 2.5% pre-stretched elastomers. After releasing the pre-stretch, the 2D material-ALD heterostructure self-assembles into quasi-periodic micrometer wrinkles, which show periodic modulations in the strain of up to 0.67%.[4] We then used Kelvin Probe Force Microscopy (KPFM) to simultaneously measure the local topography and change in potential energy across the wrinkles. We then correlated the results to the optical properties through hyperspectral mapping of both Photoluminescence and Raman modes. There are two advantages of this approach. First, all strain conditions can be measured in a single acquisition, avoiding challenges of sample-to-sample variation or changes in tip measurements between samples. Second, we can directly correlate the topography and resulting strain state to the local work function.

From the topography, we found that the maximum strain occurred on the wrinkle peak of monolayer WSe_2, at a value of 0.39%, and the minimum strain occurred on the wrinkle valley at a value of -0.43%. Between the wrinkle peak and valley, the work function shifted at a rate of -79 ± 26 meV/%, while the band gap shifted at a rate of -58.6 ± 3.4 meV/%. The tuning of the work function is new, but bandgap shift is consistent with what is observed in uniaxial tension of WSe_2, where shifts of -54 meV/% have been observed.[1] These results suggest that tensile (compressive) strain decreases (increases) both the band gap and work function of WSe_2. Further, our approach is materials agnostic and can be applied to measure the strain relationships in many 2D materials.

This work elucidates the relationship between strain, work function, and optical band gap in 2D materials, which is important across device applications in the emerging field of 2D straintronics.

11:00 AM NM05.03.03

Probing Local Structural Phase Transition at the Surface of $(BA)_2PbI_4$ via Interlayer Exciton Emission Zeyi Liu[1] *and Dehui Li[1,2]; [1]Huazhong University of Science & Technology, China; [2]Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, China*

Two-dimensional (2D) halide perovskites have been extensively studied for optoelectronic applications owing to their outstanding excitonic performance. Studies have revealed high-temperature phase and low-temperature phase in 2D perovskite $(BA)_2PbI_4$ flakes and the correlation with the thickness; nevertheless, structural phase transition at surface still remains elusive. Here, we propose to use interlayer excitons in $(BA)_2PbI_4/WSe_2$ heterojunctions to characterize their structural phase transitions at surface in $(BA)_2PbI_4$. Two types of interlayer exciton emission caused by the phase transition of $(BA)_2PbI_4$ can be observed, which can be attributed to the low-temperature and high-temperature phases of $(BA)_2PbI_4$, respectively. Importantly, the spatially resolved PL mapping suggests that two phases in the coexisted region distribute rather uniformly and the degree of phase transition at the surface and interior of crystal remains largely same. Our results provide a novel and non-

destructive approach to explore the phase transition of $(BA)_2PbI_4$ and offer new route to further regulate its phase transition.

11:15 AM NM05.03.04

Nanosized Boron Nitride/Alumina Hybrid Filler-Incorporated PVA Composites as Thermal Interface Materials Enabling Tunable Isotropic/Anisotropic Thermal Conductivity *Sohyung Jiong, Donghyun Lee, Sooyeon Ji, Myounggi Hong and Wonjoon Choi; Korea University, Korea (the Republic of)*

(Thermal Management Challenges in Electronics)

Effective thermal management in miniaturized, densely packed electronics necessitates the development of thermal interface materials (TIMs) possessing a multifunctionality in limited form factors. Hexagonal boron nitride (h-BN) has attracted a lot of attention as functional fillers for next-generation TIMs owing to its exceptional thermal conductivity (185–300 W/mK), excellent electrical insulation (wide band gap of 5.5 eV), and low dielectric constant. However, incorporating high-aspect-ratio, platelet-like h-BN in polymeric backbones significantly increases viscosity, limiting usable amounts and hindering achievable thermal conductivity. Additionally, the intrinsic layered structure of BN causes it to align horizontally under film processing (e.g., shear forces during mixing or casting), leading to a significant reduction in through-plane thermal conductivity.

(A Simpler Approach to Isotropic Thermal Conductivity)

A common approach to improve the isotropy of BN involves creating spherical shapes derived from the platelet morphology of hexagonal boron nitride (h-BN). This is typically achieved through a complex process involving high-temperature heat treatment followed by grinding/sieving or spray-drying granulation and then vacuum sintering. However, these methods often involve high temperatures, multiple processing steps, and increased costs, limiting their practicality.

In this study, we present novel thermal interface materials (TIMs) utilizing a polyvinyl alcohol (PVA) matrix filled with nanosized boron nitride/alumina hybrid filler to address aforementioned challenges.

We employed a hydroxide-assisted ball milling process to synthesize nano-sized BN with an average lateral size of less than 100 nm, a thickness of 3-4 nm, and an aspect ratio of around 25. We subsequently achieved selective deposition of the nanomaterial onto the surface of micrometer-sized Al2O3 particles through controlled electrostatic interactions in solution. This approach yielded core-shell structures with a uniform, spherical morphology.

(Hybrid Fillers and Enhanced Isotropy)

Then, we investigated the impact of BN-coated Al2O3 particles on the isotropy of thermal conductivity in TIM films. Hybrid particles with weight ratios of BN to Al2O3 of 1:4 and 4:1 were used as fillers. The particles were mixed with PVA (1:1 weight ratio) and solvent-cast into films.

Compared to films made solely of bare BN (fabricated under the same conditions), the hybrid particle-based samples exhibited a remarkable 180% enhancement in the isotropic ratio (through-plane vs. in-plane thermal conductivity).

(Understanding the Mechanism)

To elucidate the underlying mechanism, the intensity ratio of the (002) and (100) miller indices of BN in the X-ray diffraction (XRD) profiles of the films was analyzed.

The analysis revealed that the BN particles on the Al2O3 surface were arranged more randomly compared to the bare BN films. This random arrangement allows for better heat flow in all directions, leading to preserved thermal conductivity through the thickness of the film (through-plane direction). This implies that optimizing hybridized fillers consisting of spherical Al2O3 particles with highly conductive BN particles can achieve a directional control of thermal conductivity, even though using a low-cost yet highly feasible process.

(Beyond Thermal Performance: Promising Applications)

Beyond their impressive thermal conductivity, these films exhibit remarkable bending durability, flexibility, and efficient heat dissipation. This unique combination of properties suggests broad applicability in various fields requiring both in-plane and through-plane thermal conduction, making them highly promising candidates for use as heat spreaders and heat sinks.

11:30 AM NM05.03.05

Selective Spin-Triplet and Spin-Singlet Interlayer Exciton Emission in WS_2/WSe_2 Heterostructure for All-Optical Valley Switch *Yue Hu, Xinglin Wen and Dehui Li; Huazhong University of Science & Technology, China*

Spin-splitting in transition metal dichalcogenides (TMDs) heterostructure generate spin-singlet and spin-triplet interlayer exciton (IX) with unique spin-valley physics. Although selective singlet and triplet IX emission can be achieved by applying electric and magnetic field, the device structure is complex and low-temperature condition is demanding. Here, by selectively coupling singlet or triplet IX dipole of WS_2/WSe_2 heterostructure to a SiO_2 sphere cavity, we can actively control the emissive IX species at room temperature in an all-optical route. We find the triplet IX dipole is almost along the out-of-plane orientation, whereas, only 69% of the singlet IX dipole is out-of-plane. Consequently, triplet IX emission is enhanced more greatly in TMDs/SiO_2 cavity hybrid structure due to that out-of-plane dipole presents higher Purcell factor for SiO_2 cavity. By utilizing the selective enhancement of singlet and triplet IX emission, we demonstrated an all-optical valley switch. Our finding provides a convenient approach to control the fine structure of IX and develop their applications in valleytronics.

11:45 AM NM05.03.06

Designing Phonon Coherency in Two-Dimensional Lead Organic Chalcogenides *Hanjun Yang[1], Sagarmoy Mandal[1], Bowen Li[2], Tushar Kanti Ghosh[1], Jonas M. Mark[1], Peijun Guo[2], Letian Dou[1] and Libai Huang[1]; [1]Purdue University, United States; [2]Yale University, United States*

Hybrid organic-inorganic semiconductors with strong electron-phonon interactions provide a programmable platform for realizing a variety of electronic, optoelectronic and quantum materials by controlling these interactions. However, in current hybrid semiconductors, such as halide perovskites, anharmonic vibrations with rapid dephasing hinder the ability to coherently manipulate phonons.

In this report, we report the observation of long-lived coherent phonons in lead organic chalcogenides (LOCs), a family of new hybrid two-dimensional semiconductors. These materials feature harmonic phonon dynamics despite distorted lattices, combining long phonon dephasing times with tunable semiconducting properties. Coherent optical phonon with dephasing time as long as 75 ps was observed at 10 K. The phonon dephasing time is significantly influenced by anharmonicity and centrosymmetry, both of which can be tunes through the design of the organic ligands due to the direct bonding between the organic and inorganic motifs. We further on explored the anisotropic phonon transport in LOCs and the optical-acoustic phonon interaction using transient reflection microscopy method. Our finding revealed the delicate interplay between the structural and phononic properties in this strongly coupled organic-inorganic hybrid materials.

Electrical Control and Long-Range Transport of Interlayer Excitons *You Zhou; University of Maryland, United States*

The control of interlayer excitons presents significant potential for the exploration of quantum phases such as Bose-Einstein condensates and the development of future optoelectronic applications. Here, we report the formation and electrical control of momentum-direct interlayer excitons in van der Waals heterostructures. These excitons are characterized by bright photoluminescence emission with a high quantum yield and a narrow linewidth of less than four meV. We demonstrate tightly bound interlayer excitons and the tuning of their emission energy over a wide range via the Stark effect. The high-quality sample allows us to demonstrate the long-range transport of interlayer excitons with a diffusion length exceeding ten μm. The electrical control of exciton energy and transport opens new avenues for investigating quantum many-body physics, including excitonic condensates and superfluidity, and developing novel optoelectronic devices like exciton and photon routers.

Excitons in Linear/Nonlinear and Time-Resolved Photo Responses of 2D Materials and Heterostructures
Steven G. Louie[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Recent studies revealed spectroscopic signatures of novel photo-excited states and intriguing pump-probe responses in 2D van der Waals structures. The nature of many of these phenomena remains to be fully understood. Here, we present some recent theoretical results in their understanding and predictions. We show that there is a rich diversity of excitons in transition metal dichalcogenide (TMD) moiré superlattices, including unforeseen novel intralayer charge-transfer moiré excitons.[1, 2] In pump-probe calculations, we discovered a self-driven exciton-Floquet effect in the time-resolved ARPES of 2D materials, wherein prominent satellite bands and renormalization of the quasiparticle bands are induced by excitons, analogously to the optical Floquet effect driven by photons.[3] We demonstrated a new exciton mechanism (direct coupling of intralayer with interlayer excitons) in the ultrafast optical response of TMD heterobilayers.[4] Moreover, we showed that strong excitonic physics in 2D materials can greatly enhances their nonlinear optical responses (e.g., shift currents and second harmonic generation).[5,6] This has led to the discovery of a striking phenomenon of formation of light-induced shift current vortex crystals in TMD moiré systems – i.e., 2D periodic arrays of moiré-scale current vortices and associated magnetic fields with remarkable intensity under laboratory laser setup.[7] Our studies are made possible with the development of new methods (based on the GW-BSE and time-dependent GW approaches) that allow for the ab initio calculations of excitonic physics and photo responses of systems with thousands of atoms in the unit cell and in the time domain.

***Mechanical Resonance Detection of 2D Spin Textures** Xiao-Xiao Zhang; University of Florida, United States*

The recently discovered atomically thin magnetic crystals provide a unique playground for understanding magnetization in 2D confinement and developing new approaches to manipulating magnetism for novel spintronic devices. In particular, antiferromagnets (AFMs) are promising for realizing high-speed information processing given their THz magnetic resonance frequency. However, they are also less sensitive to optical and electrical detection due to their net zero magnetization. In this talk, I will discuss our recent results on 2D AFM transition-metal trichalcogenides, where we couple the magnetic transitions into the mechanical degree of freedom. We observed the expected steady-state spin transitions based on magnetostriction effects and also saw signatures of additional transition points related to the spin texture dynamics.

Renormalization of Phonons and Excitons in Twisted Transition Metal Dichalcogenide Heterostructures
Hyeonsik Cheong; Sogang University, Korea (the Republic of)

Heterostructures of two-dimensional transition metal dichalcogenides have been extensively studied as the alignment of the bands in the constituent materials allows for manipulation of optoelectronic and transport properties. Several factors such as the band offset between the bands of the two constituent materials and the twist angle between the crystallographic directions of the two layers determine the physical properties of these structures. It has been demonstrated that the phonon spectrum as well as the electronic band structure and optoelectronic properties change systematically as the twist angle between two layers of a given set of materials is varied. Furthermore, at very small twist angles, atomic-scale lattice reconstruction [1] is observed and should be accounted for in describing the physical properties of heterostructures. Furthermore, we recently found that the lattice mismatch between the two constituent materials leads to a pair of torsional distortions with opposite chirality irrespective of the twist angle [2]. The periodic moiré potential also induce a series of moiré phonons, and the low-frequency Raman spectra show a rich array of interlayer shear and breathing modes that evolve with the twist angle [3]. The interlayer excitons in $MoSe_2/WSe_2$ that appear strong in the twisted heterostructures with the twist angles near 0° or 60° have different energies and photoluminescence excitation spectra for the two cases, which results from different electronic structures and carrier relaxation dynamics. These results demonstrate that the details of the lattice interactions as well as the twist angle should be considered in designing heterostructure-based devices.

High-Performance THz Sensing Based on Layered Topological Semimetals *Jun Xiao; University of Wisconsin-Madison, United States*

The emergent atomically thin layered materials enable the unique control of new phases of matter for high-performance electronics and optoelectronics. One remarkable example is the recent discovered nonlinear Hall effect (NLHE) in topological semimetals, which is mediated by their diverging quantum geometrical properties [1-3]. In this talk, I will report how we leverage this new notion for high-performance THz optoelectronics. Firstly, I will review how the certain polar stacking order and corresponding quantum geometrical properties of layered topological semimetals can substantially influence their electron transport and memory switching [3]. Along this line, I will show our recent demonstration on high-performance THz sensing devices based on those new discovered effects [4]. In particular, we investigate the NLHE response in THz regime on a layered type-II Weyl semimetal in both noninteracting state and correlated state. Leveraging a custom-designed and in-house fabricated plasmonic photosensing device, we attained ultralarge and tunable photoresponsivity in this atomically thin topological semimetal. Moreover, the intrinsic response time is down to picosecond level. Our findings illuminate a new mechanism for low-energy photon harvesting and transduction via quantum properties. The results also pave the way towards a wide range of THz applications in communication and imaging based on layered topological semimetals.

Ultrafast Dynamics of Chiral Phonons in Monolayer Semiconductors *Hanyu Zhu, Tong Lin, Xiaotong Chen, Rui Xu and Jiaming Luo; Rice University, United States*

The optical and valleytronic properties of monolayer transition metal dichalcogenide semiconductors strongly interact with phonons. Chiral phonons that break time-reversal symmetry are predicted to modify the excitons and spins in these materials. Here we measured the ultrafast dynamics of linearly and circularly polarized phonons at the Brillouin zone center in single-crystalline monolayer WS_2. The phonons were excited by intense, resonant, and polarization-tunable terahertz pulses, and probed by time-resolved anti-Stokes Raman spectroscopy. We separated the coherent phonons, which emit coherent sum-frequency generation, from the incoherent phonon population, which are detected by incoherent scattering. We found the incoherent population lifetime is much longer than what was expected from coherence lifetime, indicating that inhomogeneous broadening and momentum scattering play important roles in phonon decoherence at room temperature. Meanwhile, we found a *faster depolarization rate in circular bases than in linear bases, suggesting that lattice anisotropy makes linearly polarized modes the phonon eigenstates. Our results provide crucial information for improving the lifetime of chiral phonons and potentially facilitate dynamic magnetic control in two-dimensional materials .*

Achieving Large and Anisotropic Spinon Thermal Transport in Textured Spin-Chain Compound Ca_2CuO_3

Shucheng Guo[1], Xue Bai[2], Rafal Dunin-Borkowski[2] and Xi Chen[1]; [1]University of California, Riverside, United States; [2]Forschungszentrum Jülich GmbH, Germany

Spinons, as spin excitations in antiferromagnetic Heisenberg spin-chain systems, are crucial for exploring novel physical phenomena and practical applications in thermal management. However, current research is limited to single crystals, and research on polycrystals is lacking, which affects its widespread application. This work reports large and anisotropic spinon thermal transport in highly textured spin chain compound Ca_2CuO_3, fabricated by pressing nanosheets using the developed solvent-cast cold pressing (SCCP) method. The SCCP method effectively aligned the spin chains and inhibited spinon thermal transport in the plane parallel to the press direction, as confirmed by X-ray diffraction and Raman spectroscopy. As a result, a high thermal conductivity (κ) for polycrystalline magnetic insulators, approximately 12 W/m K near 300 K, with an aspect ratio of κ approaching 4.5. Compared to the conventional cold-pressed sample, κ_s extracted from the textured pellet is increased by about 50%. Furthermore, the spinon thermal transport processes, including spinon-defect and spinon-phonon scattering, were analyzed using a kinetic model for 1D spinon transport. These results provide useful insights into enhancing spinon thermal transport in 2D magnetic structures, presenting a promising approach for developing advanced thermal management devices.

Two-Dimensional Material Facilitated Surface-Enhanced Raman Spectroscopy Measurements of SARS CoV-2 Receptor Binding Domain *Jeewan C. Ranasinghe[1], Stephen K. Sanders[1], Ziyang Wang[1], Wenjing Wu[1], Edgar Dimitrov[2], Mauricio Terrones[2], Alessandro Alabastri[1] and Shengxi Huang[1]; [1]Rice University, United States; [2]The Pennsylvania State University, United States*

Surface-enhanced Raman scattering (SERS) offers a powerful method for identifying biomolecules by enhancing Raman signals from molecules adsorbed on or near nanostructured metal surfaces. By exploiting the strong electromagnetic field enhancements generated by plasmonic nanostructures, SERS can amplify weak Raman signals, enabling the sensitive detection and identification of biomolecules in complex biological samples. Hybrid structures combining zero-dimensional (0D) and two-dimensional (2D) materials can provide additional benefits for biological sensing applications. Coupling 2D materials with SERS is particularly useful for detecting the SARS CoV-2 receptor binding domain (RBD) due to its high sensitivity and specificity. In this study, we developed a SERS platform for the ultrasensitive and rapid detection of SARS CoV-2 RBD. We fabricated four types of SERS *substrates: one with gold nanoparticles (AuNPs) only, and three based on different 2D material-gold nanoparticle hybrids (AuNPs/graphene, AuNPs/MoS_2, and AuNPs/WSe_2). The SERS spectra collected from these substrates provided spectroscopic signatures and revealed key Raman bands and detection mechanisms for RBD. The AuNPs/graphene substrate demonstrated excellent performance, with a high signal-to-noise (SNR) ratio allowing for the identification of molecular fingerprints and high sensitivity for detection. Here, the AuNP/graphene substrate increases the SNR by reducing noise rather than increasing the signal. A theoretical model explained the observed variations in SNR for different substrates. The AuNPs/graphene hybrid substrate exhibited a low detection limit of 10^{-9} M for the RBD. Understanding the mechanisms of light-matter interactions in 0D-2D hybrid structures is crucial for developing highly efficient, label-free biosensors. We envision that our label-free spectroscopic platform will offer a valuable tool for the detection of viruses and their variants.*

SESSION NM05.05: Defect, Polar, Ferroelectric 2D Materials and Heterostructure I

Nanoscale Mapping of Surface Modulations and Inhomogeneities in Ferroelectric AlN/2D-TMDC Heterostructures *Bogdan Dryzhakov[1], Yueh-Chun Wu[1], Chloe Skidmore[2], Jon-Paul Maria[2], Benjamin J. Lawrie[1] and Kyle P. Kelley[1]; [1]Oak Ridge National Laboratory, United States; [2]The Pennsylvania State University, United States*

The optoelectronic interactions at nanoscale material interfaces have heightened sensitivity to surface modulations and inhomogeneities. This invokes this study's correlative nanometric analysis effort, to understand the tunability of multi-functional heterostructures of light-emitting 2D transition metal dichalcogenides (TMDCs) in distinct interface configurations: hexagonal boron nitride (hBN) encapsulated WSe_2 and MoS_2 on ferroelectric Aluminum Nitride (AlN) thin films. Spatially correlated spectroscopic measurements, including cathodoluminescence, photoluminescence, and Raman mapping, revealed collective and gradual red-shifting emission energies of WSe_2 excitonic complexes, correlating with variations in intrinsic and defect hBN emission intensity. Through Gaussian fitting and decomposition of spectral features across high-resolution maps, fitted spectral features reveal how nanoscale variations tune excitonic light emission behavior. Leveraging these insights, we then demonstrate multi-functional co-engineering of 2D-TMDC flakes as visible light absorbers impacting ferroelectric interfaces, and the light-emitting 2D-TMDC flakes across a strongly polarized ferroelectric AlScN thin film surface. By doping of AlN thin films, such as with Sc, the coercive field reduces to 3 MV/cm, allowing for ferroelectric switching to occur non-destructively through monolayer to few layer 2D-TMDC flakes. We employ functional atomic force microscopy to spatially resolve the ferroelectric switching dynamics through heterogeneous 2D-TDMC flakes. The AlScN thin film's large remanent polarization of 120 $\mu C/cm^2$ bolster the interfacial charge transfer and band structure modifications in the heterostructured 2D-layers, where by Kelvin probe force microscopy we resolve the surface potential between oppositely polarized domains in the heterostructure and observe a strong dependence on encapsulation to modify interfacial charge. This study combines several spatially-resolved correlative analyses to provide insights for designing multi-functional and tunable 2D TMDC-based optoelectronic devices through ferroelectric interfaces.

8:15 AM NM05.05.02

Conductive Atomic Force Microscopy for Defect Exploration of the 2D Magnetic Semiconductor CrSBr *Sara*

R. Tulchinsky[1,2], Rami Dana[2], Zdenek Sofer[3], Frances M. Ross[2] and Julian Klein[2]; [1]Wellesley College, United States; [2]Massachusetts Institute of Technology, United States; [3]University of Chemistry and Technology, Prague, Czechia

Defects in two-dimensional (2D) layered materials underpin important materials properties, affect behavior, and drive performance for a wide range of desirable applications. Chromium sulfide bromide, CrSBr, an air-stable magnetic semiconductor, is a van der Waals (vdW) layered material with exceptional potential for use in spintronics and quantum technologies [1, 2]. While its optical, electronic and magnetic properties have been widely studied, there is limited information on the types and densities of defects, as well as how they influence the properties of CrSBr [3, 4, 5].

Here, we investigate defects in CrSBr grown by chemical vapor transport (CVT) using conductive atomic force microscopy (cAFM). This microscopy technique has recently been demonstrated to be highly effective in assessing defects over large areas in layered materials [6]. Employing cAFM yielded results previously only trusted to be achievable with more tedious, complex, and costly microscopy methods, such as scanning tunneling microscopy (STM) or transmission electron microscopy (TEM). In this talk, we reinforce the advantages and accuracy of cAFM for a statistics-driven approach to defect characterization. We extend our studies to compare cAFM measurements made on CrSBr formed in different growth environments (Br-rich, S-rich), after annealing at high temperature, and grown with the addition of transition-metal dopants (V, Mn, Mo, and Fe). We offer analysis of how crystal growth, post-processing, or doping influences the defect properties (densities, size, origin) in each sample. Our results are supported by experimental STM data and theoretical calculations. Finally, we provide discussion of the expected effects of the defects on sample properties and subsequent potential for applications and functionalities.

In Situ Transmission Electron Microscopy on Two-Dimensional Ferroic Chalcogenides *Jiong Zhao; The Hong Kong Polytechnic University, Hong Kong*

Current electronic devices have encountered grand challenges, How to further scale down the device size, upgrade the integration of input/output, memory and computing units, and reduce the energy consumption. In particular, the massive communication between the computational unit and memory is hard to afford within current architecture of electronic devices and computers. New paradigm of in-memory-processing architecture has been put forward recently. Beyond current von Neumann systems, two-dimensional (2D) ferroelectrics (FE) with miniaturized dimension, high speed and high sensitivity, and robust ferroic order with memory functionalities, are superior candidates for next-generation in-memory computing devices. Moreover, the facile phase transition in 2D materials potentially offers another degree of freedom to manipulate the non-volatile memory states. Therefore, the 2D polymorphism and 2D ferroelectrics and ferroelastics indeed provide promising solutions to the aforementioned challenges.

In this presentation, we will clarify the ferroic ordering and their physical origin, and introduce how to *control/manipulate the phase transition and the ferroelectricity as well as ferroelasticity in 2D and build novel devices. We applied a variety of in situ transmission electron microscopy techniques, specifically employing in situ mechanical manipulation, in situ mechanical testing, in situ electrical testing, in situ heating, and in situ electron beam control, to conduct comprehensive investigations of ferroic phase transitions and ferroic ordering in two-dimensional (2D) chalcogenides. The diverse phases observed in these ferroic 2D materials showcase unique mechanical, electrical, and other captivating physical properties. Through our study, we successfully established a direct correlation between atomic-scale structures and device-level performance, thereby enhancing our understanding and enabling practical applications of 2D functional materials.*

Impact of Stacking Sequence on Multi-Layer Ferroelectrics—A Combined AFM and TEM Analysis

Ingyu Yoo, Jinwoo Kim, Gwan-Hyoung Lee and Miyoung Kim; Seoul National University, Korea (the Republic of)

Multi-Layer Ferroelectrics have garnered significant interest as rhombohedral stacked two-dimensional ferroelectrics exhibit unique sliding ferroelectricity due to lateral shifts between layers, generating out-of-plane electric polarization, termed 'slide-tronics'. Despite efforts to develop 2D ferroelectric devices, current strategies predominantly rely on indirect methods to correlate stacking sequence with ferroelectric properties, with limited experimental evidence directly linking stacking sequence to polarization and interlayer interactions. The comprehensive understanding of ferroelectricity in multi-layered materials remains incomplete, particularly regarding its relation to cyclic and acyclic stacking. Furthermore, while the use of polarized pulses for ultrafast ferroelectric switching is a growing field, experimental data on interlayer shear modes across different stacking sequences are still sparse.

In this study, we performed an in-depth combined analysis using Atomic Force Microscopy (AFM), Transmission Electron Microscopy (TEM), and Raman Spectroscopy on the same tungsten diselenide flakes, yielding comprehensive characterization through these cohesive techniques. This approach elucidates the correlations between stacking sequence, polarization, and interlayer shear mode, essential for applications in multi-layer ferroelectrics. First, using a 4D-STEM framework in TEM, we identified stacking sequences by obtaining diffraction patterns for each position and decomposing the diffraction stack into the overall intensity and diffraction polarity of the first-order peak. Next, we measured surface potential variations using Kelvin Probe Force Microscopy (KPFM), compiling a database to investigate differences in polarization among anti-parallel, cyclic, and acyclic stacks. Lastly, low-frequency Raman Spectroscopy was used to detail how the interlayer shear mode evolves with accumulating layers.

We explored a variety of stacking scenarios in tungsten diselenide, demonstrating how cyclic, acyclic, and anti-parallel stacking induce property changes in multi-layer situations when these various stacking configurations are *mixed. We have identified a trend in KPFM where surface potential increases or decreases based on cyclic and acyclic stacking. Building on this, the study progressed to complex cases where parallel and antiparallel stacking are mixed, investigating the impact of hexagonal stacking by focusing on surface potential changes in cyclic and acyclic stacking that occur after hexagonal stacking. Additionally, low-frequency Raman spectroscopy results indicated that the observed peaks are characteristic of each stacking sequence rather than the number of layers, providing insights into how the stacking sequence induces interlayer shear modes.*

9:00 AM NM05.05.05

Enhanced Ferroelectric Polarizations and Complex Switching Pathways with Small Barriers in In_2Se_3 and MXene Bilayers *Joshua Young; New Jersey Institute of Technology, United States*

Ferroelectric (FE)-based devices have long been investigated for their non-volatility, high speed, and low power consumption, but the need to scale down electronics has led to the search for new materials. 2D ferroelectrics (2DFEs), which exhibit spontaneous electric polarizations in only a monolayer or bilayer, represent the ultimate scaling limit. However, the magnitude of the spontaneous polarizations in 2DFEs is often small, especially in the technologically useful out-of-plane direction, and the polarization switching mechanisms can be complex. In this work, we used density functional theory calculations to investigate 2DFE bilayers consisting of monolayers of the non-centrosymmetric 2DFE In_2Se_3 and the centrosymmetric non-FE MXene Ti_2CO_2. First, we find that heterostructures of Ti_2CO_2/Ti_2CO_2 can be either polar or non-polar depending on the twisting angle between the two monolayers, leading to the presence of a small out-of-plane polarization. We then show that coupling two 2DFEs to form In_2Se_3/In_2Se_3 enhances the magnitude of the out-of-plane polarization from that of the monolayers, which can be further increased by changing the twisting angle. Finally, we interestingly find that the polarization reaches a maximum in In_2Se_3/Ti_2CO_2 bilayer heterostructures, despite being built from a centrosymmetric building unit. We show that these changes in the polarization are linked to an increase in the magnitude and asymmetry in charge transfer across the interface. Finally, we investigate the switching of the polarizations in these heterostructures. We find a complex interplay between sliding to switch the between-layer polarization, and atomic displacements to switch the in-layer polarization, with both displaying a bimodal switching pathway with ultralow barriers (< 0.1 eV). We also find that these two mechanisms can be coupled, leading to complex dynamics. Finally, we show that replacing the Ti_2CO_2 with the magnetic MXene V_2CO_2 to form In_2Se_3/V_2CO_2 leads to a polar metal. This work demonstrates that judicious selection of monolayers to form novel 2DFE bilayer heterostructures, including those which are centrosymmetric, can result in materials with unique properties and enhanced polarizations greater than the sum of their parts.

9:15 AM NM05.05.06

Cross-Correlated AFM and TERS Imaging Reveals Nanoscale Defects and Composition Misconceptions in MoSSe/MoSeS Janus Crystals *Tianyi Zhang[1], Andrey Krayev[2], Nannan Mao[1], Lauren Hoang[3], Eric Pop[3], Andrew J. Mannix[3] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]Horiba Scientific, United States; [3]Stanford University, United States*

Since the discovery of graphene, many more 2D materials have been identified and isolated in monolayer form. Transition metal dichalcogenides (TMDs) are probably the most researched 2D semiconductors due to their electrical properties and a plethora of fascinating optoelectronic phenomena in TMDs and their vertical and lateral heterostructures mediated by tightly bound excitons that survive at room or even elevated temperature. Recently, the naturally occurring TMDs have been complemented by a new, man-made class of monolayers, Janus TMDs, in which the layer of transition metal atoms is sandwiched between two layers of inequivalent chalcogen atoms. Due to the lack of inversion symmetry and the embedded vertical dipole moment, Janus TMDs possess several unique properties that are not observed in conventional TMDs, and which are promising for the future applications in non-

linear optics, energy harvesting, catalysis etc. Therefore, perfecting the synthesis of Janus TMDs and understanding and controlling defects in these man-made monolayers is of great importance for the 2D material community.

Using tip enhanced Raman spectroscopy (TERS) imaging cross-correlated with other AFM channels like topography, surface potential, and photocurrent, we identify the typical defects in Janus Mo-based TMDs produced by plasma-assisted selenization/sulfurization at room-temperature. We further demonstrate that the morphology and the specifics of TERS response of the end product such as the band splitting in A_1^1 *and* A_1^2 *modes, strongly depend on whether the conversion starts from a* MoS_2 *or* $MoSe_2$ *monolayer. Additionally, the high spatial resolution of TERS imaging (< 10 nm in air) reveals that the residual Raman signal of the precursor monolayer (*MoS_2 *or* $MoSe_2$*) is often related to the presence of bilayer islands that can be as small as a few tens- to a few hundreds of nanometers in width, rather than to the incomplete Janus conversion process.*

Through correlated TERS and AFM imaging, we demonstrate that excessive tensile strain in MoSeS Janus crystals converted from $MoSe_2$ *mechanically breaks these crystals into approximately 1 µm domains separated by 10-20 nm gaps. Conversely, MoSSe converted from* MoS_2 *experiences compressive strain which leads to the formation of wrinkles. From morphological characterization, these wrinkles have the appearance of cracks upon the gold- or silver-assisted transfer, but TERS confirms the continuity of the Janus crystal and reveals strong TERS enhancement over these inverted wrinkles. Moreover, we identified that MoSSe crystals synthesized on fused silica feature very smooth topography, mostly free from wrinkles and cracks, and very similar TERS/Raman response as compared to crystals grown on* Si/SiO_2 *substrates. This opens the possibilities for controlling the desired morphology of Janus monolayers which may be quite different for applications in optoelectronics (smooth topography) or catalysis (with increased number of wrinkles or edges).*

Bio-Realistic 2D Neuromorphic Computing Materials and Devices *Mark C. Hersam; Northwestern University, United States*

The exponentially improving performance of digital computers has recently slowed due to the speed and power consumption issues resulting from the von Neumann bottleneck. In contrast, neuromorphic computing aims to circumvent these limitations by spatially co-locating logic and memory in a manner analogous to biological neuronal networks [1]. Beyond reducing power consumption, neuromorphic devices provide efficient architectures for image recognition, machine learning, and artificial intelligence [2]. This talk will explore how 2D nanoelectronic materials enable gate-tunable neuromorphic devices [3]. For example, by utilizing self-aligned, atomically thin heterojunctions, dual-gated Gaussian transistors have been realized, which show tunable anti-ambipolarity for artificial neurons, competitive learning, spiking circuits, and mixed-kernel support vector machines [4,5]. In addition, field-driven defect motion in polycrystalline monolayer MoS_2 *enables gate-tunable memristive phenomena that serve as the basis of hybrid memristor/transistor devices (i.e., 'memtransistors') that concurrently provide logic and data storage functions [6]. The planar geometry of memtransistors further allows multiple contacts and dual gating that mimic the behavior of biological systems such as heterosynaptic responses [7]. Moreover, control over polycrystalline grain structure enhances the tunability of potentiation and depression, which enables unsupervised continuous learning in spiking neural networks [8]. Finally, the moiré potential in asymmetric twisted bilayer graphene/hexagonal boron nitride heterostructures gives rise to robust electronic ratchet states. The resulting hysteretic, non-volatile injection of charge carriers enables room-temperature operation of moiré synaptic transistors with diverse bio-realistic neuromorphic functionalities and efficient compute-in-memory designs for low-power artificial intelligence and machine learning hardware [9].*

***Sliding Ferroelectricity and Nonlinear Light-Matter Interaction in 2D Quantum Materials** Xiaofeng Qian; Texas A&M University, United States*

The ability to achieve noninvasive detection and efficient control of electric and magnetic orders as well as topology in 2D quantum materials is of great importance to the development of ultrathin quantum devices. In this talk, I will present our theoretical effort on understanding and predicting the sliding ferroelectricity and nonlinear response/memory effect in 2D quantum materials. I will first discuss sliding ferroelectricity in time-reversal invariant few-layer T_d-WTe_2. Although semimetallic it holds out-of-plane polarization which can be switched via interlayer sliding under vertical electric field. Moreover, ferroelectric nonlinear Hall effect can be achieved in few-layer WTe_2 by utilizing the intrinsic coupling among nonlinear susceptibility, crystalline symmetry, and quantum geometry of electronic states, paving a theoretical foundation for nonlinear quantum memory such as Berry curvature memory. Recent experimental demonstration of ferroelectric nonlinear Hall effect and Berry curvature memory in few-layer WTe_2 will also be discussed. Next, I will present our recent study of nonlinear photocurrent in PT-symmetric magnetic topological quantum materials where nonlinear probe could be particularly fruitful for probing and understanding magnetic topological quantum materials. Finally, I will briefly introduce our recently-developed unified quantum geometric approach based on generalized Wilson loop representation for computing general physical responses.

***Harnessing Moire Ferroelectricity to Modulate Semiconductor Monolayer Light Emission** Xiaoqin Elaine E. Li; The University of Texas at Austin, United States*

Ferroelectricity has been recently discovered in stacked or twisted van der Waals (vdW) layers. The versatility of producing a large array of size-tunable domains and integration with diverse functional materials make them an enticing platform for developing multifunctional devices. Here, we show that ferroelectric polar domains formed in a twisted hexagonal boron nitride (t-hBN) substrate can modulate light emission from an adjacent semiconductor monolayer. The abrupt change in electrostatic potential across the domains produces an in-plane electric field (E-field) and leads to a remarkably large exciton Stark shift in the adjacent $MoSe_2$ monolayer, previously only observable in p-n junctions created by the advanced e-beam lithography tools. Both the spectrum and spatial pattern of the light emission of the monolayer are periodically modulated by the remote moir\'e potential imposed by the t-hBN substrate. We further observe a characteristic hysteresis behavior in the light emission as an electric gate erases and restores the domains. Our findings chart an exciting pathway for combining the ferroelectric functionality of t-hBN substrates with diverse functional layers.

11:30 AM *NM05.05.10
***Updates from "SlideTronics"** Moshe Ben Shalom; Tel Aviv University, Israel*

The field of sliding ferroelectricity is gaining growing attention, in part, following our work on "interfacial ferroelectricity" back in 2021 [Science 372,1462-1466]. In that work, we have further introduced the term "Slide-Tronics" to point to wider multi-ferroic opportunities enabled by electric control of crystalline phases. Moreover, we extended the single-interface physics into multilayer multipolar TMDs, reporting a unique "Ladder-Ferroelectricity" [Nature 612, 465–469, 2022], with a pristine electronic response to the so-called "polar catastrophe" scenario, [Adv. Materials 202400750, 2024].
Beyond ferroelectric binary compounds, the polarizations extend to graphitic polytypes, which are raising much interest in the low-energy, correlated phases, community. As we have recently found, graphitic polytypes also host spontaneous internal polarization [Adv. Phys. Research 2300095, 2024], and hence can extend the multi-ferroic sliding response into non-volatile correlated transition.
The talk will discuss the stacking stability, vdW adhesions, planar deformations, electronic overlaps and band hybridization that governs the mechanical and electro-optical response of the polytypes. Moreover, by identifying the main structural switching mechanisms we suggest future directions to guide the specialized vdW community members that focus on unstable "twisted" moiré systems.

Structure and Electronic Property Correlation of 2D Platinum-Diselenide *Max C. Lemme[1,2]; [1]RWTH Aachen University, Germany; [2]AMO GmbH, Germany*

Platinum diselenide ($PtSe_2$) is a two-dimensional (2D) layered noble metal dichalcogenide (NMDC), a subgroup of the transition-metal dichalcogenides (TMDCs). Its high negative piezoresistive gauge factor (GF) [1] and high charge carrier mobilities of up to 210 cm^2/Vs. with stability in the air for many months [2], mechanical flexibility [3], and broadband optical absorption, [4] make it an interesting sensing, electronic and optoelectronic material.

$PtSe_2$ can be grown at CMOS-compatible temperatures below 400°C by thermally assisted conversion (TAC) [5]. In addition, it can be converted from a semiconductor to a semimetal by varying the number of layers [6–8]. Different device applications of PtS_2 have been demonstrated, both as piezoresistive nanoelectromechanical sensors (NMES) [1] and as isolated and waveguide-integrated photodetectors [4,9]. However, the experimental data shows significant variability that cannot simply be explained by the material thickness. Here, I will discuss how the nanocrystalline structure of TAC-grown $PtSe_2$ layers is related to the electronic properties of $PtSe_2$-based devices.

$PtSe_2$ layers grown with various parameters, thicknesses and methods were analyzed by Raman, X-ray photoelectron spectroscopy (XPS) and energy dispersive X-ray spectroscopy (EDX). Large differences in Raman spectra could not be correlated with XPS and EDX data, which showed no significant differences between the chemical composition of the different films. canning tunneling electron microscopy images of two samples showed nanocrystalline films with similar thicknesses but different sizes and arrangements of the nanocrystals. Also, while one sample had well-aligned crystals in a rather homogeneous film, another sample showed slightly tilted and randomly rotated crystals.

The different $PtSe_2$ films were then transferred onto oxidized silicon substrates and electrically characterized. Sheet and contact resistance (R_{sh} and R_c), four-point probe field effect, and AC Hall measurements were performed to determine the material's mobilities (μ). In addition, the $PtSe_2$ films were transferred onto flexible polyimide substrates to extract their piezoresistive GF using a bending beam configuration as described in [1].

We found large variations in R_{sh}, R_c, μ, and GF between the samples and clear correlations between the extracted quantities. The correlation between μ and GF was particularly evident. We also found both negative and positive GFs in our samples, depending on the material structures [10]. *The electronic properties of the $PtSe_2$-based devices correlate with the nanocrystalline structure of the 2D films. On the other hand, the electronic properties of the $PtSe_2$ films vary over several orders of magnitude despite similar film thicknesses and chemical composition.*

This work was financially supported by the German Ministry of Education and Research (BMBF) through the project NobleNEMS (16ES1121) and the German Research Foundation (DFG) through the project 2D-NEMS (LE 2440/11-1).

Point Defect Engineering of 2D MXenes at Ambient and Elevated Temperatures *Brian Wyatt and Babak Anasori; Purdue University, United States*

MXenes are a large family of 2D transition metal carbides, nitrides, and carbonitrides with more than fifty compositions synthesized to date. In addition to the compositional and structural tunability of MXenes, defects, specifically basal plane point defects (vacancies and substitutions) provide us with opportunities to control MXene stability and properties. In this talk, I will present how MXene synthesis conditions control the basal plane metal vacancy concentrations, ranging from less than 1 at.% vacancy to above 16 at.%. The optimized $Ti_3C_2T_x$ single flakes with < 1 at.% vacancies show remarkable stability in air up to 600 °C before oxidation and stability in an inert environment up to 1000 °C before transformation to 3D bulk carbide. Additionally, by controlling the vacancy concentration, it is possible to control cation interactions with MXenes, either cation decorating the surface or occupying the metal vacancy sites. When metal vacancies are occupied by alkali cations, defective MXene flakes can be stabilized and approach the stability of pristine MXene flakes. The concentration of vacancies and cation substitution also control the electrical conductivity of MXenes at ambient and elevated temperatures. Understanding and controlling defects demonstrate an important way to tune MXenes' and, in general, 2D materials' behavior and properties.

2D Materials for Electrically Driven Ion Transport and Energy Devices *Shanmukh Kutagulla and Deji*

Akinwande; *The University of Texas at Austin, United States*

Electrically driven ion transport is critical to many electrochemical technologies essential to decarbonization such as batteries, fuel cells and electrolyzers. These technologies, particularly fuel cells and electrolyzers, are still in their nascent stages and suffer from both membrane-related failures stemming from parasitic crossover as well as efficiency losses. 2D materials have been demonstrated to act as highly selective ionic conductors in previous work, but have yet to show sufficient performance, durability and scalability for commercial adoption. This talk will focus on 2D materials as optimal ion conductors for proton exchange membrane fuel cells (PEMFC) and electrolyzers while balancing performance with selectivity. In our current work, we demonstrate the power of defect engineering strategies and scalable deposition strategies in to improve fuel cell durability and scalability with limited to no negative impact to performance. These findings highlight the potential of defect-engineered 2D materials to advance the performance and durability of electrochemical energy devices.

Synthesis, Characterization and Application of Two-Dimensional Covalent Organic Framework Thin Films and Heterostructures *Jun Lou; Rice University, United States*

Two-dimensional (2D) covalent organic frameworks (COFs) are promising polymeric crystalline nanomaterials with broad applications. In order to realize the true potential of these thin film materials, precise control of thickness and morphology is necessary, and advanced synthetic techniques, including various forms of interfacial synthesis, have been widely explored. In this talk, we will highlight some of our recent efforts in the synthesis and engineering of 2D COFs. Corresponding nanomechanical characterizations of 2D COFs will be reported. Additionally, the heterogeneous integration of these thin films with other inorganic and organic materials will be discussed for applications in electronics, photocatalyst and energy storage applications, revealing exciting opportunities to integrate COF thin films with other state-of-the-art material and device systems.

4:00 PM *NM05.07.02
Epitaxial Growth of TMD Monolayers and In-Plane Nanodot Heterostructures for 2D Nanophotonics *Joan M. Redwing; The Pennsylvania State University, United States*

Epitaxial growth of transition metal dichalcogenides on sapphire has emerged as a promising approach for synthesis of wafer-scale single crystal monolayer films. Our work has focused on the use of metalorganic chemical vapor deposition (MOCVD) for TMD epitaxy on sapphire as it enables tight control over gas phase precursor concentration and the ability to form heterostructures via modulation of the transition metal and/or chalcogen precursor during growth. We previously developed a three-step process for TMD epitaxy on sapphire involving nucleation, ripening and lateral growth steps for synthesis of W-containing TMDs including WS_2 and WSe_2. Nucleation was observed to occur preferentially on the step edges on the sapphire substrate enabling *unidirectional orientation of domains and a significant reduction of inversion domains in coalesced monolayer films. This process was modified for the growth of in-plane $MoSe_2$-WSe_2 heterostructures by introducing a Mo precursor ($Mo(CO)_6$) during nucleation to form nanoscale $MoSe_2$ domains on step edges on sapphire and then switching the transition metal precursor to $W(CO)_6$ during the lateral growth step to embed the $MoSe_2$ domains in a continuous WSe_2 matrix. The $MoSe_2$ nanodots exhibit coherent interfaces with the surrounding WSe_2 and their size can be varied from 10-50 nm through control of the time for the nucleation step. Variable temperature photoluminescence measurements using a confocal microscope which samples a large ensemble of $MoSe_2$ nanodots within the WSe_2 layer reveals size-dependent confinement of excitons in samples where the dot size is intentionally varied as evidenced by a blue shift in the $MoSe_2$ exciton emission peak at low temperatures. Samples with the smallest average nanodot size (<10 nm) exhibit characteristics of single-photon emission at 1.6 K. Prospects for the development of large area films of 2D TMD quantum dots using this approach will be discussed.*

4:30 PM NM05.07.03

Star-Shaped WS_2 Monolayers with Twin Grain Boundaries Promoted by Molybdenum Doping *Na Zhang[1], Nadire Nayir[2], Yanzhou Ji[3], David Sanchez[1], Yueze Tan[1], Swarit Dwivedi[1], Mengyi Wang[1], Nannan Mao[4], Zhuohang Yu[1], Andres Fest Carreno[1], Da Zhou[1], Natalya Sheremetyeva[1], Tianyi Zhang[1], Ke Wang[1], Vincent Meunier[1], Adri van Duin[1] and Mauricio Terrones[1]; [1]The Pennsylvania State University, United States; [2]Istanbul Technical University, Turkey; [3]The Ohio State University, United States; [4]Massachusetts Institute of Technology, United States*

Monolayers of transition-metal dichalcogenides (TMDs) exhibit fascinating properties that make them attractive in optics, electronics[a], spintronics, and valleytronics[b], and it is of vital importance to understand and control their morphology and tune their physical properties[c]. However, understanding and controlling the morphologies of TMD monolayers grown by chemical vapor deposition (CVD) is challenging. . Here we report the controlled synthesis and formation mechanism of star-shaped WS_2 monolayers by adding trace concentrations of molybdenum when using a liquid-phase precursor-assisted CVD. Fluorescence imaging and photoluminescence (PL) mapping of six-arm stars revealed bright lines between adjacent arms. To correlate the morphology and optical properties with the microstructure, second harmonic generation (SHG) microscopy and dark-field transmission electron microscopy (DF-TEM) were used to confirm the presence of polycrystal domains with a 60° lattice misorientations and a mirror twin grain boundaries. Detailed analysis of the grain boundary and molybdenum atom distribution was assessed using high-resolution high angle annular dark-field scanning transmission electron microscopy (HAADF-STEM). The relationship of the growth morphology of WS_2 stars and the molybdenum to tungsten ratio of the precursor was also carefully investigated. In addition, we developed a multiscale model which combines density functional theory, the Wulff construction and a phase-field model, demonstrating that the anisotropy of grain boundary (GB) energies due to molybdenum doping can lead to the star-shaped morphologies. Our experimental-theory study provides further insights into controlling the morphology of crystalline TMD monolayers, with implications in the development of field-programmable semiconductor memristor devices.

Structural Control of 2H vs. 1T' polytypes in Single-Crystalline $MoTe_2$ Layers *Albert Davydov; National Institute of Standards and Technology, United States*

The ability to manipulate electronic, chemical, magnetic, and optical properties of layered van-der-Waals materials via controllable synthesis and processing enables their use for logic, memory, sensor, optoelectronic, and energy-related applications. This talk focuses on the chemical-vapor-transport (CVT) growth of MoTe2 single crystals to demonstrate the synthesis of specific crystal phases: a) semiconducting 2H-MoTe2 with tailored n- and p-type doping and b) semimetallic 1T'-MoTe2. The 2H vs. 1T' polytype formation was controlled by manipulating processing temperature during crystal growth or a follow-up annealing, while the doping of the 2H phase was controlled by utilizing relevant CVT transport agents, I_2 and $TeCL_4$ for p- and n-type, respectively. In addition, alloying $MoTe_2$ with W produced a composition-dependent array of $Mo_{1-x}W_xTe_2$ solid solutions of both 2H and 1T' polytypes. Reversibility of the 2H-1T' phase transition was achieved by repeatable annealing and quenching at the temperatures derived from the Mo-Te phase diagram. Such transformations, including a "frozen" co-existence of both polytypes in the same single-crystalline flake, were verified using TEM, SEM/EBSD, micro-XRD, and Raman spectroscopy.
Control of crystal phases in $MoTe_2$ and other van-der-Waals layered metal chalcogenides is important for device design and engineering [1-3].

NM05.08.01
Isotope and Heterostructure Engineering—Tuning Lattice and Optoelectronic Properties of 2D Materials

Vaibhav Varade[1], Jana Vejpravová[1], Martin Kalbáč[2], Golam Haider[3], Luka Pirker[2], Otakar Frank[2] and Jaganandha Panda[4]; [1]Charles University, Czechia; [2]J. Heyrovsky Institute of Physical Chemistry, Czechia; [3]Leibniz Institute for Solid State and Materials Research Dresden, Germany; [4]Central European Institute of Technology, Czechia

Isotope engineering allows researchers to tune the lattice and optoelectronic properties of two-dimensional (2D) materials by altering their isotopic composition, enabling systematic investigation and control of various physical properties and providing deeper insights into phonon dynamics and light-matter interactions. Moreover, heterostructure (HS) engineering of 2D materials combined with isotope engineering provides a platform to distinctly tune optoelectronic properties driven by interlayer interaction.
In this study, MoS_2 monolayers with four different isotopic compositions—natural sulfur (S), ^{32}S, ^{34}S and a 50-50% mixture of ^{32}S and ^{34}S -were synthesized using Chemical Vapor Deposition (CVD). Additionally, MoS_2 bilayers with ^{32}S and ^{34}S compositions, displaying both AA and AB stacking configurations, were fabricated, and a bilayer HS with a ^{32}S monolayer bottom layer and ^{34}S top layer was created using a 2-step CVD process.
Raman spectroscopy on monolayers revealed a redshift in A_1' and E' modes with heavier isotopes, consistent with

the effective mass variation. The Raman correlation plots between the A_1' and E' modes indicated irregular strain distribution within monolayers with heavier isotopes. Photoluminescence (PL) analysis showed the exciton-to-trion ratio remained consistent in isotopically pure MoS_2, whereas mixed isotope MoS_2 displayed higher levels of trions and B excitons. Temperature-dependent PL analysis demonstrated that exciton peaks for isotopically pure ^{32}S and ^{34}S MoS_2 followed Varshini's equation, while the 50-50 mixed case, due to its disorder, presented a complex scenario best described by the Manoogian model.

Tip-enhanced Raman spectroscopy (TERS) measurements confirmed the homogeneous distribution of isotopes in the mixed phase. Larger lattice inhomogeneity due to isotopic disorder in natural and mixed monolayers dramatically influenced phonon dynamics and light–matter interactions. Time-resolved photoluminescence (TRPL) measurements indicated nonradiative decay pathways were suppressed in lighter isotopes, while heavier isotopes induced lattice strain and electrostatic doping, supporting faster radiative decay and trion emission.

Further, we report strong interlayer coupling in isotopic HS of MoS_2 monolayers with different sulfur isotopes. The growth propagation revealed distinct triangular domains at separate nucleation centers on the underlying crystal, resulting in heterogeneity in stacking arrangements. The interlayer coupling was affirmed by low-frequency shear and breathing modes, with variability in the shear-to-breathing intensity ratio across different positions, suggesting potential for tuning interlayer coupling through heterogeneous stacking. Raman spectroscopy depicted the modification of fingerprint Raman spectra of individual isotope-modified MoS_2 MLs, indicating a coupling factor. PL spectra showed a significant decrease in A exciton intensity and a relative enhancement of B exciton intensity, corroborating the interlayer interaction. The minute variation in B exciton over the HS correlated with the heterogeneous stacking pattern. TRPL measurements revealed an additional slower decay channel due to interlayer recombination of carriers and faster lifetimes in the HS, highlighting the nuanced interplay of interlayer coupling dynamics.

These findings underscore the structural and optoelectronic modifications induced by isotopic labelling and heterostructuring in MoS_2 system. This approach opens up new avenues for optimizing the performance of 2D materials in various applications, including optoelectronics, superconductivity, exotic magnetism, and thermoelectricity. The controlled manipulation of isotopic composition and stacking configurations offers a versatile toolkit for advancing the functionality and integration of 2D materials in next-generation technologies.

NM05.08.02

Hetero-Stacking of MXenes and Metal Thin Films for Synergistic Enhancement of Electromagnetic Interference Shielding Performance *Geosan Kang[1], Guhyeon Kwon[1], Jiwoon Jeon[2], Young-chang Joo[1] and Hanwool Yeon[2]; [1]Seoul National University, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)*

An electronic packaging of small-form-factor devices requires a paradigm shift in electromagnetic interference (EMI) shielding layers from bulky metal cages to thin and conformal metal sheets. Unfortunately, thin-film shields exhibit inferior shielding performance compared to bulky shields. To address the thickness-limited performance, pores are intentionally formed in the shielding materials to drive internal multiple reflections/absorptions (MRA), surpassing conventional thin-film shielding performance. However, pore engineering induces processing costs, poor integration capability, and non-uniform passivation issues.

In this talk, I will present our material strategies for developing high-performance thin-film EMI shields without pore engineering. We have discovered that simply stacked metal/MXene/metal thin films exhibit a shielding performance of 70 dB at a 1-μm thickness, outperforming state-of-the-art shielding materials. This synergy is attributed to the formation of EM wave confinement walls by metal/MXene heterogeneous junctions, effectively driving MRA in the MXene layer. With the embedded-MXene-in-metal (EXIM) shields, we can conformably cover flexible Schottky diode arrays and portable USB 3.0 adapters, successfully protecting them from EM noises. Additionally, I will discuss details of the EXIM shields, including the MXene/metal stacking effect, as a *representative case of 2D/3D heterojunction-driven novel functionalities.*

NM05.08.03
Efficient Search for Stacking Patterns in van der Waals Heterostructures Using Bayesian Optimization

Beomgyu Choi, Tsuyohiko Fujigaya and Koichiro Kato; Kyushu University, Japan

Graphene, hexagonal boron nitride (hBN), and transition metal dichalcogenides (TMDC) are atomic layer materials that have garnered significant attention. These materials exhibit unique physical properties in both single and multiple layers. Recently, these materials have been studied more actively as materials that connect 2D and 3D, also known as 2.5D materials [1]. The fabrication of 2.5D materials is achieved through the stacking of various atomic layers, which allows for the design of an almost infinite number of structural patterns. This process results in the emergence of various physical properties. Extensive research has been conducted on these materials through experiment, theory, and simulation. In particular, density functional theory (DFT) has been heavily used for individual material analysis because of its compatibility with low-dimensional materials. Although there have been reports of building a DFT database of monolayer or homo-bilayer materials [2, 3], there is a limit to the conventional intuition-based search for promising materials because of the nearly infinite number of possibilities when hetero-stacking is taken into account. Therefore, due to the large number of candidates being researched, an inclusive approach using data science should be a powerful method.

In this study, we investigate an efficient method for searching optimal stacking structures of 2D materials using a combination of DFT and Bayesian optimization. This study verified the effectiveness of Bayesian optimization on 10 types of homo- or hetero-bilayer structures, including MoS_2, WS_2, $MoSe_2$, *and* WSe_2*, which are representative 2D materials. We set 420 structures as our search space. This incorporates 42 patterns of stacking displacement for each of the 10 different stacking bilayers, 42 multiplied by 10 yields 420 structures. After optimizing each initial structure, the band gap and Berry curvature at K point were calculated. The density functional theory (DFT) calculations were conducted using the Vienna Ab initio Simulation Package (VASP) code, with the Perdew-Burke-Ernzerhof (PBE) exchange-correlation functional and Grimme-D3 for van der Waals interaction correction. We compared the number of trials required to find a best stacking structure with the desired electronic properties using random search and Bayesian optimization. Three stacking pattern searches were conducted: (1) maximum band gap, (2) minimum band gap, and (3) maximum Berry curvature at K point. To ensure objectivity in the evaluation of effectiveness, each process was conducted 20 times independently to prevent the effects of randomness. The average number of searches was then counted.*

As a result, Bayesian optimization was found to be about three times more efficient than random search in the maximum and minimum bandgap search. The explanatory variables for Bayesian optimization are quite simple, consisting only of the material names of the first and second layers and the stacking displacement. The result that a model with a relatively simple set of explanatory variables achieved an efficiency improvement of approximately threefold is regarded as substantial evidence in support of the utility of Bayesian optimization. Furthermore, Bayesian optimization was about twice as efficient as random search in focusing on Berry curvature, a more sophisticated and complex physical quantity than the band gap. The outcomes of this study illustrate the efficacy of Bayesian optimization in the pursuit of optimal stacking patterns of 2D materials and suggest that highly efficient searches within multilayer structures are also feasible.

Modulating Energetic Characteristics of Multicomponent 1D Coordination Polymers—Interplay of Metal–Ligand Coordination Modes *Seunghee Kim and Kuktae Kwon; Agency for Defense Development, Korea (the Republic of)*

The energetic properties of multicomponent explosive materials can be altered for high detonation capabilities and minimized safety risk by changing their building components. We synthesized energetic coordination polymers (ECPs) using a 5,5'-bis(tetrazole)-1,1'-diolate linker and a N,N-dimethylacetamide (DMA) solvent, together with Cu and Mn metal cations. The new compounds, ***ECP-1*** *and* ***ECP-2****, contain two different types of 1D chain structures, straight and helical. We have conducted comprehensive studies on these ECP structures, energetic properties, and sensitivity and found excellent insensitivity owing to the long chain-to-chain distances created by the DMA solvent molecules. The results indicate that the metals as well as solvents used are crucial components influencing both the structure and energetic properties.*

NM05.08.05

Conductivity Gradient Carbon Materials Enable Dynamic Screening of Sharp Temperature Differences in Thin Films *Alexander Berger[1], Marius Schöttle[1], Flora Lebeda[1], Peter Bösecke[2], Sabine Rosenfeldt[1] and Markus Retsch[1]; [1]Universität Bayreuth, Germany; [2]European Synchrotron Radiation Facility, France*

Carbon materials offer a diverse range of microstructures, along with outstanding electrical and thermal properties, while also being cost-effective and widely accessible.[1] These materials can be produced through high-temperature carbothermal processes starting from biopolymers like cellulose. By using catalytically active compounds, such as iron salts, the required pyrolysis temperature can be lowered. These catalytic substances influence the carbon crystal structure during graphitization, allowing for varying degrees of structural order by adjusting the concentration of iron salts.[2]

We utilized an infusion withdrawal impregnation method to create an iron salt concentration gradient and, therefore, a monotonic increase in structural order along the sample. We verified the structural change with wide and small angle X-ray scattering and Raman spectroscopy. Consequently, we observe a similar change in the closely related electrical and thermal conduction properties, measured via four-point probe technique and lock-In thermography along the sample. Considering these insights, applying an electrical current to the material leads to a constant temperature gradient measured with an infrared camera. We achieve a maximum temperature difference of 80 K on the centimenter-scaled sample within seconds. Furthermore, finite element simulation verifies our experimental observation. We also show that the evolving thermal gradient can be transferred to another thin film material such as colloidal crystals. This opens the door towards characterization of temperature dependent structures and their kinetic evolution.[3] Since the temperature gradient evolves instantaneously, switching between the hot and cold state is simple, leading to possible applications such as continuous flow polymerase chain reaction[4], microfluidic[5], and battery research.[6]

2D Graphene Oxide and MXene Nanosheets at Carbon Fiber Surfaces

Katarina Adstedt[1], Madeline Buxton[1], Luke C. Henderson[2], David J. Hayne[2], Dhriti Nepal[3], Yury Gogotsi[4] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Deakin University, Australia; [3]Air Force Research Laboratory, United States; [4]Drexel University, United States

Carbon fibers, known for their high strength-to-weight ratio and thermal and chemical stability, are key components in advanced structural composites. The control of the fiber-matrix interface is key to achieving the required physical performance. Functional two-dimensional (2D) materials can conformally coat the fiber surface, facilitate interface and interphase engineering, enhance mechanical properties, and add functionalities. Understanding how 2D flakes bond, integrate, and perform at carbon fiber interfaces is critical to developing multifunctional high-strength composites. Using in-depth multimode scanning microscopy, our study focuses on the surface interactions of graphene oxide (GO) and $Ti_3C_2T_x$ MXene nanoflakes at the surface of low-tension carbon fibers with and without amine functionalization. Our findings suggest that beyond strengthening the interfaces, GO and MXene also provide efficient charge transfer. MXene, in particular, enhances the fiber surface's electrical conductivity, broadening potential applications of composites to broad areas, including structural supercapacitors and battery cooling/packaging materials. The modification of fibers with GO and MXene not only opens doors for increased interfacial adhesion in composites through enhanced surface roughness but also serves as anchors for bonding, energy dissipation, charge transport, and local interface stiffening, thereby significantly enhancing the properties of the carbon fiber interfaces.

NM05.08.07

Explicit Temperature Dependence of Thermionic and Field Emission Current in Graphene/n-Semiconductor Schottky Barrier Contacts

Argyrios Varonides; University of Scranton, United States

Fundamental understanding of carrier transport is needed for current graphene-based devices (e.g. graphene based Schottky diodes, FET geometries, solar cells) involving single layer graphene grown directly over n- or p- type semiconductors. In an intimate (ideal) G/n-Si junction under reverse bias, carriers may (a) tunnel through the junction and/or (b) thermionically overcome the junction barrier. Tunneling occurring at the junction is in essence thermionic field emission of carriers with energy levels below the junction barrier, with a less-than-one tunneling probability; thermal escape may occur if carriers have sufficient energy to overcome the barrier at the interface. The total current is expected to be the sum of two current components, thermionic emission (TE) and thermionic field emission (TFE) respectively, representing carriers surmounting and tunneling through the barrier, in the form $I = I_{TE} + I_{TFE}$, and is strongly dependent on temperature and doping. Specifically, we derive explicit results for both currents within the general Schottky diode current-voltage characteristic: $I = I_o (e^{qV/kT} - 1)$. The combined current prefactor includes strong dependencies on (a) temperature as $T^{3/2}$ and $T^{5/2}$ for TE and TFE components respectively (b) junction barrier qF_B (c) graphene layer thickness d and (c) different Richardson's constants for both components. We derive thermionic and thermionic field emission currents for reverse biased ideal Schottky barrier graphene/n-Si diodes by means of a modified Landauer formula. We calculate (a) thermionic currents above the max value of the junction barrier and (b) tunneling currents through the junction barrier. In either case we predict different temperature dependence of the reverse current when compared to the usual Schottky diode model ($\sim T^2$). We find that thermionic emission (TE) and thermionic field emission (TFE) currents depend on $T^{3/2}$ and on $T^{5/2}$ respectively, instead of the T^2-dependence that usually encompasses all Schottky diodes, along (inevitably) with different Richardson's constants. The total current through the junction (under reverse bias) is the sum of the TE and TFE components and follows the standard Schottky formula $j = j_o (e^{qV/kT}-1)$, with a different prefactor as shown

by expression (15). In dealing with ideal G/n-semiconductor diode modeling we did not include non-ideal effects (as image force effects at the SB junctions or carrier recombination at the depletion region of the G-semimetal junction). Probing to the next step, non-ideal effects at the G/SB junctions need to be addressed and additional carrier transport mechanisms such as generation/recombination and leakage currents will have to be included in the modeling.

NM05.08.08

Fabrication of Nanocomposite Thin Film Materials on Paper-Based Chemiresistor Surfaces for Detection of VOCs *Lidia G. Gebre[1], Guojun Shang[1], Zeqi Li[1], Dong Dinh[1], Madelyn Lee[1], Ielyzaveta Antonova[1], Seyed Danial Mousavi[1], Alfred Obaje[1], Jin Luo[1], Susan Lu[1], Cate Wisdom[2], Zakiya Skeete[3], Tony Yuan[2] and Chuan-Jian Zhong[1]; [1]Binghamton University, The State University of New York, United States; [2]Uniformed Services University, United States; [3]Pacific Northwest National Laboratory, United States*

The structural tunability of nanomaterials with 1D/2D/3D dimensionalities is important for the design of functional nanostructures. There is an increasing need of such tunable functional nanostructures for sensors to detect volatile organic compounds (VOCs) in air due to different processes and products used daily which are toxic and carcinogenic and pose a major risk to human health. We have been developing chemiresistive sensors for VOC detection with high sensitivity, selectivity, and fast response time. In this presentation, recent findings of our investigations of nanocomposite-structured sensing interfaces for chemiresistive sensors will be discussed. The nanocomposite structures incorporate different 2D graphene and 3D nanoparticles in 2D/3D thin films to allow optimal tunability of intermolecular interactions that occur between the targeted VOCs and the sensing structures. Chemiresistive sensor arrays with the tunable nanocomposite structures, integrated with electrical components for wireless data collection and portable applications, were evaluated with various types of VOCs. The nanostructure-function relationship in terms of the 2D and 3D components and its effect on the sensitivity and selectivity will be discussed.

NM05.08.09

Mechanistic Inquiry into TiO_2 Nanomaterial's Dye Degradation Ability *Grace M. Baumgartner and Ronald L. Grimm; Worcester Polytechnic Institute, United States*

The novel titanium dioxide one-dimensional lepidocrocite nanomaterial (henceforth referred to as '1DL') has demonstrated surprising morphologic, electronic, and catalytic properties. Specifically, 1DL has shown a remarkable capacity for the visible light-degradation of cationic dyes, which act as a proxy for organic industrial pollutants. However, the mechanism for this, especially as compared to the more widely-studied bulk P25 TiO_2, is not well-understood. Herein, we elucidate clues concerning the atom- and bond-level behavior of 1DL material to better optimize its photocatalytic performance. For instance, we demonstrate the varied effects of 1DL surface functionalizations, such as silanizations, alklyations, and others. Additionally, we investigate the hypsochromic reaction which occurs between cationic dyes and 1DL in the absence of light, something which is not observed in P25. These advances will aid in the continued development of 1DL's exciting practical applications.

NM05.08.10

Layer Dependence of Excitonic Properties in 2D Hybrid Metal Organic Chalcogenolates *Nicholas Samulewicz, Woo Seok Lee, Yeongsu Cho and William Tisdale; Massachusetts Institute of Technology, United States*

Rapidly expanding integration of semiconductors in consumer electronics up through large-scale supercomputers necessitates substantial quantum and production efficiency improvements to reduce global electricity consumption. 2D semiconductors, like transition metal dichalcogenides (TMDs) and 2D lead halide perovskites (LHPs), have emerged in recent years as strong contenders over silicon and other bulk semiconductors due to their strong exciton binding energies and highly tunable properties.

We investigate metal organic chalcogenolates (MOCs) as 2D semiconductors that can improve upon these existing structures—for example, the layer dependence of TMDs and instability of metal halide perovskites. MOCs are a novel class of van der Waals stacked hybrid organic-inorganic semiconductors with extreme 1D quantum confinement, in-plane anisotropy, and strong exciton-lattice interaction. Moreover, unlike TMDs and 2D LHPs, MOCs feature covalent bonding between organic and inorganic components, providing strong environmental stability while also allowing for bandgap tunability through organic functionalization. These properties are promising for applications as light emitting diodes (LEDs), excitonic switches, and a variety of other optoelectronic devices. Silver phenylselenolate, AgSePh, is a MOC of particular interest due to its narrow, natively blue emission (~467 nm). However, its excited state dynamics are still dominated by unknown nonradiative recombination mechanisms, limiting its potential to revolutionize future semiconductor frameworks. This work details layer dependence studies that determine the susceptibility of individual MOC layers to one another and their environment to elucidate the intrinsic light-matter interaction of this hybrid material class.

NM05.08.11

MoS_2 Monolayer Physical Properties—Engineering in Temperature-Controlled Environments *Emanuele Sangiorgi[1], Antonino Madonia[1], Francesca Migliore[1], Salvatore E. Panasci[2], Emanuela Schilirò[2], Filippo Giannazzo[2], Fiorenza Esposito[2,3], Luca Seravalli[2], György Z. Radnóczi[4], Viktoria Kovács Kis[4], Antal Koós[4], Béla Pécz[4], Gianpiero Buscarino[1,5], Franco M. Gelardi[1], Marco Cannas[1] and Simone Agnello[1,2,5]; [1]Università degli Studi di Palermo, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]University of Parma, Department of Chemical Science, Life, and Environmental Sustainability, Parco Area delle Scienze 17/A, 43124 Parma, (Italy), Italy; [4]HUN-REN Centre for Energy Research, Hungary; [5]ATEN Center, University of Palermo, Viale delle Scienze Ed. 18, 90128 Palermo, Italy, Italy*

The growing request for high-performance and low-power consumption devices[1] with nanoscale dimensions has led to consider Two-Dimensional (2D) materials as the new building bricks for nano-devices based on semiconductors. Thanks to the surprising new properties that matter shows at the nanoscale, they represent the best candidates to overcome the shrinking limit of electronic devices. Among the wide family of 2D materials, Transition Metal Dichalcogenides (TMDs) are one of the most studied and promising groups displaying semiconductive properties. In particular, Molybdenum Disulphide (MoS2) represents the most suitable TMD for optoelectronic and high-current applications[1], thanks to the interesting properties that the material has as a single-layer (1L-MoS2) structure. When the material is reduced to just one layer, it is possible to observe a rearrangement of the band structure which turns the 1L-MoS_2 into a direct band-gap semiconductor. In this configuration, direct exciton recombination occurs and a fluorescence emission of about 1.8 eV appears, which is useful for optoelectronic applications[2]. Despite the broad study of the physical properties of this material and some device applications, there is a lack of knowledge and a clear interpretation of how the substrate can influence the conduction and optical properties of 1L-MoS_2. In addition, the synthesis procedure has a significant role in defect formation, affecting the physical features of the flakes. Furthermore, applying external stress in controlled conditions gives a chance to tune the strain and doping[3], due to a re-arrangement of the interaction between the 1L-MoS_2 and the substrate.

To better understand all these aspects, we studied the interaction of a MoS_2 single-layer with different substrates (gold, silicon dioxide, gallium nitride) obtained via Gold-Assisted Transfer (GAT), Gold-Assisted Exfoliation[4] and Chemical Vapour Deposition (CVD)[5]. This approach allows us to compare the effects of several supporting

materials and the pros and cons of all the syntheses performed. To tailor the conduction and optical properties, we performed thermal treatments from 150 to 300 °C under controlled conditions, using 2 atm of Ar or O_2 gasses during two hours of treatment. The modification allows us to tune strain-doping conditions using a gentle process that significantly enhances the photoluminescence. In this work, we performed micro-Raman spectroscopy, Atomic Force Microscopy, Transmission Electron Microscopy, Scanning Tunneling Spectroscopy and micro-photoluminescence to investigate strain-doping modifications, characterize the morphology and have a wide overview of the defects that are present and the interaction of the substrates with 1L-MoS_2.
This study will help to determine the best conditions to use 1L-MoS_2 as the building blocks of the next generation of nano-devices based on semiconductors for electronic and optoelectronic applications.

Structure-Function Relationship of Highly Reactive CuO_x/Co_3O_4 Heterostructures Towards Superior Formaldehyde Sensing Performance

Matteo D'Andria[1], Frank Krumeich[1], Zhangyi Yao[2], Feng (Ryan) Wang[2] and Andreas Güntner[1]; [1]ETH Zürich, Switzerland; [2]University College London, United Kingdom

Structural control over nano-sized heterostructures enables selective molecular interactions in low-temperature catalysis and chemical sensing.[1] Yet, finding effective material combinations and identifying the reactive site remains challenging and an obstacle for rational catalyst/sensor design. Here,[2] the low-temperature oxidation of formaldehyde with CuO_x clusters on Co_3O_4 nanoparticles is demonstrated yielding an excellent sensor for this critical air pollutant. When fabricated by flame-aerosol technology,[3] such CuO_x clusters are finely dispersed, while some Cu ions are incorporated into the Co_3O_4 lattice enhancing thermal stability. Importantly, infrared spectroscopy of adsorbed CO, near edge X-ray absorption fine structure spectroscopy and temperature-programmed reduction in H_2 identified Cu^+ and Cu^{2+} species in these clusters as active sites. Remarkably, the Cu^+ surface concentration correlated with the apparent activation energy of formaldehyde oxidation (Spearman's $\rho = 0.89$) and sensor response (0.96), rendering it a performance descriptor. At optimal composition, such sensors detected even the lowest formaldehyde levels of 3 parts-per-billion (ppb) at 75°C, superior to state-of-the-art sensors. With selectivity against other aldehydes, ketones and alcohols, such CuO_x/Co_3O_4 heterostructures are promising for personal exposure tracking and occupational safety.

Probing In Situ Structure-Activity Relationship in 2D Nanoscale MoS_2 Catalysts for Methane-to-Methanol Under High Pressure *Steven L. Farrell[1], Juan D. Jiménez[1], Dominik Wierzbicki[1], Ayaskanta Sahu[2], Sanjaya D. Senanayake[1] and Eli Stavitski[1]; [1]Brookhaven National Laboratory, United States; [2]New York University, United States*

Ushering in carbon-neutral energy breakthroughs is critical to reduce greenhouse emissions and achieve clean energy targets. Catalyzing potent greenhouse gases like methane into useful chemicals, such as methanol, is a key reaction to achieve net-zero emissions and meet strict international carbon management goals. Methane-to-methanol (MtM) feed streams often contain contaminants, and MtM processes generally require elevated pressures and strong oxidants to be effective in converting methane. Therefore, resilient catalysts are imperative for creating sustainable processes. Molybdenum disulfide (MoS_2), a transition metal dichalcogenide commonly used in hydrogenation applications, is a low-cost catalyst material with superb durability under the intensive reaction conditions required for MtM. We have studied nanoscale 2D MoS_2 as an MtM catalyst, synthesized via a bottom-up colloidal synthesis approach to yield active edge sites and tight size control of ~5 nm. This colloidal approach affords a uniform distribution of size and morphology, which allows us to clearly relate observed physicochemical features with catalytic function and behavior. Using in situ synchrotron measurements, we probed the local and electronic structure of MoS_2 using pair distribution function and X-ray absorption spectroscopy under high-pressure reaction conditions, giving insight to how these catalysts behave when exposed to different pressures, temperatures, and in the presence of reactants. We observed excellent methane conversion activity in MoS_2 nanosheets, producing methane derivative oxygenates under mild conditions at competitive rates in comparison to precious metal catalysts while maintaining high selectivity. By elucidating these mechanisms through robust multimodal X-ray characterization and kinetic studies in real time, we can better design and optimize MoS_2 for peak methane conversion performance.

Spectroscopic Footprints of Hydrophobic and Hydrophilic Hydrogen Bonding Within 2D Coordination Polymers *Lucero Torres[1], Ana A. Lemus[1], Benjamín Portales-Martínez[1], Jesús Vega-Moreno[2] and Manuel Ávila-Santos[1]; [1]Instituto Politécnico Nacional, Mexico; [2]Consejo Nacional de Humanidades, Ciencias y Tecnologías, Mexico*

Aqueous solutions of dimethyl sulfoxide (DMSO) display hydrogen-bonding as the dominant molecular interaction. Physical chemistry properties vary upon the molar fraction and the liquid mixtures have short-live hydrogen bonding species difficult to isolate.
This solid-state study presents crystallographic, thermogravimetric, and spectroscopic data on structural and vibrational differentiation at atomic level of hydrogen bonding in the vicinity of amphiphilic DMSO molecule. Coordinatively unsaturated 2D $M[Ni(CN)_4]$ where (M= Mn, Fe, Co, Ni, Zn and Cd) coordination polymers form 1:1 hydrophilic : hydrophobic chemical environments where to glimpse strong and weak interactions separately as well as the influence of M nature on H_2O-DMSO linear association. The family of new compounds crystallizes in the tetragonal space group (81), with average unit-cell parameters of a=b=10.396(3), c= 7.980(4) and V=862.9(3) (Z=2) as determined by powder X ray diffraction. Hydrophobic hydration starts the dehydration process of these crystalline solids at 50 °C. Vibrational analysis by means of MIR, FIR and Raman spectra was performed in the range of 4000-70 cm^{-1} ^{13}C SSNMR spectrum analysis for Zn composition is provided. To the best of our knowledge this is the first report where the Hofmann-type layers extend their hosting behavior by means hydrogen bonds toward a second molecule beyond M coordination sphere.

NM05.08.16

Hexagonal Boron Nitride Functionalized AlGaN/GaN High Electron Mobility Transistor for Enhanced Carbon Dioxide Sensing *Vikas Pandey, Ankur Gupta and Mahesh Kumar; Indian Institute of Technology Jodhpur, India*

This study demonstrates design of a high-sensitivity carbon dioxide (CO_2) sensor utilizing an AlGaN/GaN High Electron Mobility Transistor (HEMT) functionalized with hexagonal boron nitride (hBN). The sensor leverages the unique electronic properties of III-nitride semiconductors, where a two-dimensional electron gas (2DEG) forms at the AlGaN/GaN interface, offering high electron mobility and enhanced sensing performance. The incorporation of hBN, known for its selective adsorption properties, significantly improves the sensor's CO_2 selectivity, resulting in a 56% response at 100 ppm CO_2, with a detection range spanning 1 ppm to 100 ppm and a rapid response time of 120 seconds. The material integration process involves epitaxial growth, metal deposition, photolithography, and hBN functionalization via mechanical exfoliation. This sensor is further integrated with an ESP32 IoT module for real-time environmental monitoring. The combination of advanced material engineering and IoT connectivity demonstrates the sensor's potential for precise CO_2 detection in environmental and industrial applications, overcoming limitations of conventional CO_2 sensors.

NM05.08.17

Earth-abundant Catalysts for the Oxygen-Evolution Reaction Supported on Zirconium Phosphate Layered Nanomaterials *Jorge L. Colón; University of Puerto Rico at Río Piedras, United States*

We are studying new applications of layered zirconium phosphate (ZrP) inorganic nanomaterials [1]. The θ phase of ZrP can be directly ion-exchanged with metal complexes and catalysts, producing intercalated phases useful for artificial photosynthesis schemes for water splitting, amperometric biosensors, and drug delivery applications. Recently, we have demonstrated improved electrocatalytic activity of ZrP nanomaterials loaded with metal ions suitable for the oxygen evolution reaction (OER) of water splitting. Electrocatalysts have been incorporated as intercalated species, surface bound, on exfoliated layers, and on nanoparticles of different morphologies (hexagonal platelets, cubes, rods, and spheres). Single and bimetallic electrocatalysts based on earth-abundant materials have been studied. Reduction in overpotentials and increases in mass activity have been achieved. Mixed metal NiFe-intercalated ZrP electrocatalysts at 90% Fe metal content proved to have superior OER electrocatalytic performance (decreased overpotentials, increased mass activities, reduced Tafel slopes) compared to adsorbed counterparts. We have recently prepared CoFe electrocatalysts systems and again the intercalated bimetallic system is more active than the surface-adsorbed one. We are starting to work also with Mn electrocatalysts. We are exploring OER activities of other mixed-metal catalysts on ZrP, bifunctional catalysts, and operando synchrotron X-ray absorption spectroscopy studies to elucidate the nature of the active species.

Low-Field Magnetoresistance in 2-2 Composites of $La_{0.7}Sr_{0.3}MnO_3$ and Metal Oxides *Nicholas Thiel-Hudson, Theodore Sauyet, Zachary Ritchey, Jacob Pfund and Menka Jain; University of Connecticut, United States*

Pure $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) exhibits colossal magnetoresistance, making it suitable for high-field applications. We find that the addition of insulating metal oxides in composite films results in low-field magnetoresistance (LFMR), thus expanding the application space for LSMO into the low-field regime. In this work, pure LSMO thin films are compared to composite layered heterostructures of LSMO and either SrO, TiO_2, or ZrO_2, grown on (001) oriented $LaAlO_3$ and $SrTiO_3$ substrates via chemical solution deposition. Structural, magnetoelectric, and magnetic *transport properties are presented. X-ray diffraction and Raman spectroscopy studies confirm chemical phase purity of all films, (001) oriented growth of pure LSMO, and polycrystalline LSMO heterostructures. Magnetic susceptibility measurements indicate a Curie temperature and metal-insulator transition temperature both near 370K for all samples. This work indicates that the inclusion of insulating metal oxides in heterostructural films is a relatively simple and scalable method for improving LSMO applications at low fields.*

InGaZnO/Graphene Cold Source Field Effect Transistors Enabling a Super-Steep Subthreshold Swing Below 60 mV/dec

Seyoung Oh, Ojun Kwon and Byungjin Cho; Chungbuk National University, Korea (the Republic of)

Reducing the operating power has been crucial in future electronics. Practically, generative artificial intelligent (AI) systems that require extremely high energy, such as the ChatGPT and DALL-E, keep pushing the limits of the power supply over what is practical for humans to utilize. Reducing drive voltage (V_{DD}) with steeper subthreshold swing (SS) allows switching field effect transistors (FETs) to minimize power consumption while enabling faster switching speeds. However, it is theoretically restricted to realize sub-60 mV/dec SS at room temperature in a conventional silicon semiconductor transistor switching device due to even high carrier concentration generated by a thermal energy, known as Boltzmann's tyranny. For a breakthrough to this performance limitation, the device structures with the new operation mechanism such as tunneling-, impact ionization-, and negative capacitance-FETs have been designed and demonstrated. Recently, a cold source FET (CSFET) is getting more attention due to its high on-current and reliable sub-60 mV/dec switching, which is based on the cold electron injection phenomenon triggered by low dimensional nanomaterials with super-exponentially decaying electron concentration at the channel/source interface. Although CSFETs based on single 1D carbon nanotube/2D graphene or 2D MoS_2/2D graphene achieved sub-60 mV/dec switching in recent works, their feasibility in large-scale electronic circuits remains challenging. Thus, we should explore practical strategies for producing an ultralow-powered switching device through large-scale fabrication.

Herein, we first demonstrated the InGaZnO (IGZO)/graphene cold-source transistor with sub-60 mV/dec switching characteristics at a relatively low V_{DD} of 0.5 V. We utilized an amorphous IGZO as an n-type semiconducting channel and p-type graphene as a cold-source electrode. A unique energy band structure of graphene, which is a linear density of states as a function of energy, leads to super-exponentially decaying electron concentration under a vertical gating field to the IGZO/graphene interface, providing ultralow off-current and super-steep slope switching. The delicate gate overlap structure with the gate electrode and graphene cold source qualifies dynamic Schottky barrier modulation at a channel/source interface, allowing high on-current at the same time. Particularly, the use of high-k HfO_2 gate dielectric exhibited lower sub-60 mV/dec SS due to fast surface potential change by gate voltage, compared to that with an Al_2O_3 dielectric. Diverse material characterizations such as transmission electron microscopy, atomic force microscopy, and kelvin probe force microscopy validated an IGZO/graphene cold-source device configuration. Output and transfer characteristics were characterized to analyze switching performance, and electrical device parameters such as field effect mobility (μ_{FE}), on/off ratio ($r_{on/off}$), and SS were statistically summarized. Compared to the control device, the effective Schottky barrier was further modulated in the IGZO CSFET. SS values in an 8 × 8 IGZO CSFET transistor array revealed low variation, showing uniform *switching parameters. The super-steep slope switching in the IGZO/graphene CSFET would pave the road toward next-generation ultralow-powered AI devices and electronic systems.*

8:15 AM NM05.09.02

Preparation of Silicon Nanosheet/Reduced Graphene Oxide Heterostructures and Their Application as Anodes for Li-Ion Batteries *Tomoki Tokudome[1], Kazuto Hatakeyama[2,1] and Shintaro Ida[2,1]; [1]Kumamoto University, Japan; [2]Institute of Industrial Nanomaterials, Japan*

Silicon (Si) is a promising material for Li-ion battery anodes due to its theoretical specific capacity, which is more than 10 times higher than that of carbon-based materials. However, the substantial volume change (up to 300%) during charge and discharge cycles necessitates the formation of a robust interface between the current collector and the silicon to accommodate this expansion and contraction. In this study, we fabricated silicon nanosheet (Si NS)/reduced graphene oxide (rGO) heterostructures and evaluated their performance as anodes in Li-ion batteries. The fabricated anodes demonstrated a discharge capacity of approximately 2400 mAh/g, corresponding to 60% of silicon's theoretical capacity, and operated stably for over 100 cycles. This high capacity is attributed to the formation of a robust interface where strong electronic and lithium interactions occur rapidly, not through point-to-point interactions between particles, but through face-to-face heterojunctions between the two-dimensional materials.
Among various anode materials for lithium-ion batteries, silicon is considered a next-generation material due to its high theoretical specific capacity (4200 mAh/g when fully lithiated to $Li_{4.4}Si$) and relatively low discharge potential (0.1 to 0.4 V vs. Li/Li^+). However, electrodes made from silicon materials face challenges in maintaining contact with conductive additives and current collectors due to volume expansion during lithiation. Therefore, an appropriate electrode design that enhances cycle stability and rate performance is essential for silicon-based batteries.
In this study, we prepared silicon nanosheets by exfoliating calcium silicide, which was then used to create heterojunctions with reduced graphene oxide. In this system, the reduced graphene oxide functions as the current collector. The heterostructures were prepared as follows: First, $CaSi_2$ was reacted with an excess amount of hydrochloric acid for two days to exchange the interlayer calcium with protons. Subsequently, the product was treated with sodium dodecyl sulfate solution to exfoliate the layered structure into monolayer silicon nanosheets. Atomic Force Microscopy (AFM) measurements revealed that the resultant silicon materials had a sheet-like structure with a lateral dimension of 1 μm and a thickness of 4 nm. To create the conductive carbon matrix, a GO dispersion was prepared and thoroughly mixed with the Si NS dispersion. The mixture was then freeze-dried and thermally reduced under a hydrogen atmosphere, resulting in a matrix with uniformly dispersed silicon nanosheets within the rGO nanosheets. To evaluate the electrochemical performance of the fabricated anode materials, half-cells were constructed using lithium foil as the counter electrode and subjected to charge-discharge tests.

8:30 AM NM05.09.03

2D Semiconductor Gate Stack and Implementation of Steep-Switching Impact Ionization Transistor *Taeho Kang[1], Joonho Park[2], Hanggyo Jung[3], Haeju Choi[1], Sang-Min Lee[1], Nayeong Lee[1], Ryong-Gyu Lee[2], Gahye Kim[3], Seung-Hwan Kim[4], Hyung-jun Kim[4], Cheol-Woong Yang[3], Jongwook Jeon[3], Yong-Hoon Kim[2] and Sungjoo Lee[1]; [1]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of); [4]Korea Institute of Science and Technology, Korea (the Republic of)*

Two-dimensional (2D) semiconductors are now considered a real possible replacement for Si channels, not only limited to academic society but also to serious efforts at the industry level. One of the serious remaining concerns is the integration of a high-κ dielectric on a 2D semiconductor to overcome the reported challenges of forming

high-quality interfaces with suppressed trap density and without degradation of device performance.

In this work, we report a high-quality gate stack (native HfO_2 formed on 2D $HfSe_2$) fabricated via plasma oxidation (unlike reported deposited or transferred dielectric structures where van der Waals gap exists), realizing an atomically sharp interface with a suppressed interface trap density ($D_{it} \sim 5\times10^{10}$ cm^{-2} eV^{-1}). The chemically converted HfO_2 exhibits dielectric constant, $\kappa \sim 23$, resulting in low gate leakage current ($\sim10^{-3}$ A/cm^2) even at scaled EOT ~0.5 nm. Density functional calculations elucidated that the atomistic mechanism for achieving a high-quality interface is the possibility of O atoms replacing the Se atoms of the interfacial $HfSe_2$ layer without a substitution energy barrier, allowing layer-by-layer oxidation to proceed. The field-effect-transistor-fabricated with $HfO_2/HfSe_2$ gate stack demonstrated an almost ideal subthreshold slope (SS) of ~ 61 mV/dec (over four orders of I_{DS}) at room temperature (300 K), along with a high I_{on}/I_{off} ratio of $\sim10^8$ and small hysteresis ~ 10 mV.

Furthermore, we report for the first time the successful fabrication of $HfO_2/HfSe_2$ based impact-ionization FET that exhibits n-type steep-switching characteristics at room temperature. Utilizing the separately controlled channel structure designed to concentrate the sufficient electric field to trigger impact ionization, further scaling of the SS to ~3.43 mV/dec, overcoming the fundamental Boltzmann limit was achieved. We strategically verified the potential for improving the reliability of impact ionization devices, a fundamental limitation, by achieving low gate injection efficiency through effective suppression of gate leakage current from high-quality gate stacks. The TCAD simulation supported the impact-ionization-induced steep switching behavior and scaling of the operating biases in the proposed devices. Our results provide a significant step toward the realization of post-Si semiconducting devices for future energy-efficient data-centric computing electronics.

Structural Design of 2D Materials for Future Computing *Feng Miao; Nanjing University, China*

The unique layered structures of 2D materials offer possibilities to design new atomic structures with rich physics and novel functions. In this talk, I will present our work on the well-controlled structural design of 2D materials and heterostructures, including on-chip phase engineering based on Pd-PdSe2 material system, and van der Waals (vdW) heterostructures (“atomic lego”) based on mechanical stacking of 2D materials, and show the corresponding device functionalities by design. First, I will introduce our work of in situ synthesizing 2D materials through on-device phase engineering [1]. Second, I will present our capability of accurate control of the twist angle in graphene moiré heterostructures. Such capability facilitates the observation of tunable quantum criticalities in an experimental simulator of the extended Hubbard model with spin–valley isospins arising in chiral-stacked twisted double bilayer graphene [2]. The results demonstrate a highly tunable solid-state simulator with intricate interplay of multiple degrees of freedom for exploring exotic quantum critical states and behaviors. Moreover, by fabricating double-aligned magic angle twisted bilayer graphene, we observed the coexistent ferroelectricity and Chern insulating states, and demonstrate the noise-immune neuromorphic computing technology based on the selective and quasi-continuous ferroelectric switching in such ferroelectric Chern insulators [3]. Finally, I will present our work based on vdW vertical heterostructures comprised of transition metal transition metal dichalcogenides, which can be exploited to realize neuromorphic computing devices, such as highly robust memristors based on graphene/$MoS_{2-x}O_x$/graphene vdW heterostructure [4]. Our experimental results on a prototype reconfigurable neural network vision sensor based on a WSe_2/BN heterostructure [5], and in-sensor broadband convolutional processing using a band-alignment-tunable $PdSe_2/MoTe_2$ heterostructure [6] will also be presented.

Competing Charge Density Wave States Above Room Temperature in 2D van der Waals Ta(Co,Ni)$_2$Te$_2$ Nanoflakes *Nitish Mathur[1], Guangming Cheng[1], Fang Yuan[1], Ratnadwip Singha[1,2], Scott B. Lee[1], Vincent M. Plisson[3], Francisco Ballester[4], Jiangchang Zheng[5], Caiyun Chen[5], Berthold Jäck[5], Kenneth Burch[3], Ion Errea[4], Maia Vergniory[4,6], Sanfeng Wu[1], Nan Yao[1] and Leslie Schoop[1]; [1]Princeton University, United States; [2]Indian Institute of Technology Guwahati, India; [3]Boston College, United States; [4]Donostia International Physics Center, Spain; [5]The Hong Kong University of Science and Technology, China; [6]Max Planck Institute for Chemical Physics of Solids, Germany*

Charge density waves (CDWs) are emergent phenomena in quantum materials, characterized by periodic modulations in charge ordering. Recently, novel functionalities of CDW phases in van der Waals (vdW) materials, such as 1T-Ta(S,Se)$_2$, have opened new prospects for engineering and exploring CDW-driven symmetry-breaking quantum phenomena near room temperature. However, there is a scarcity of two-dimensional (2D) materials that exhibit high-temperature CDW transitions and can be easily exfoliated to fabricate nanodevices. Here we report on TaCo$_2$Te$_2$ (space group Pmna), a 2D van der Waals Peierls-distorted metal that exhibits a one-dimensional commensurate CDW (1D-C-CDW) phase at room temperature and a reversible CDW transition (T_c) near 573 K. In-situ heating transmission electron microscopy (TEM) reveals irreversible hidden CDW ordering above T_c in exfoliated nanoflakes and focused ion beam (FIB) fabricated lamellae (<100 nm) of TaCo$_2$Te$_2$, manifesting as ordered incommensurate (O-IC) CDW superlattice peaks. Interestingly, we also observed O-IC CDW ordering in TaNi$_2$Te$_2$ (space group Pmna) nanoflakes, an undistorted version of TaCo$_2$Te$_2$, with a multi-q vector CDW ordering, in contrast to the 1D O-IC CDW ordering in TaCo$_2$Te$_2$. This irreversible O-IC CDW ordering is stable only in Ta(Co,Ni)$_2$Te$_2$ nanoflakes, not in the bulk crystal. The presence of internal residual strain and soft phonon modes facilitates the nucleation of competing charge orderings in Ta(Co,Ni)$_2$Te$_2$ nanoflakes at high temperatures and offers thermomechanical manipulation as a route to engineering CDW states at and above room temperature.

Self-Assembled Ti$_3$C$_2$T$_X$ MXene Thin Films for High-Performance Ammonia Sensors *Elmehdi Ould Maina; École polytechnique, France*

MXenes have emerged as a fascinating material for RT gas-sensing applications due to their outstanding properties. This work reports the design and fabrication of a high-performance ammonia sensor based on MXenes material. To improve its sensing performance, a MXenes nanosheets thin film with a thickness of ≈ 10 nm was prepared using a scalable self-assembled method. Specifically, we employed the controlled and enhanced interfacial self-assembled method to fabricate a continuous and conductive MXene ultra-thin film. The morphology and the structure of the produced MXene materials and their films were characterized by combining multi-characterization tools. Altogether, these highlight the uniform and continuous deposition of the MXene nanosheets film on the glass substrate. The electrical characterization indicates a sheet resistance value of 4.82×10^5 Ohm/sq. The fabricated devices present good RT sensing performances for NH$_3$ detection, ranging from 1 to 20 ppm. This demonstrates the outstanding sensitivity of MXene with a value of 1.92% for the lowest concentration (1 ppm), a fast response (179 s) and a recovery time of (612 s), which is related to the high quality of the ultra-thin MXene sensiting layer. Moreover, the sensors demonstrate high degree of stability and excellent reproducibility, make them suitable candidate for practical applications like environmental monitoring.

Design and Modeling of Scandium-Alloyed Wurtzite III-Nitrides Based Ferroelectric Heterostructure for Power Efficient Applications

Ruilin Wang, Siddhant Gangwal, Dragica Vasileska and Kexin Li; Arizona State University, United States

Introduction: *The transient negative capacitance (TNC) effect observed in ferroelectric materials offers a promising approach to reducing energy consumption in field-effect transistors by enabling a subthreshold slope (SS) below the conventional limit (e.g. 60 mV/dec at 300K) [1]. Scandium-alloyed wurtzite III-nitrides based ferroelectric high electron mobility transistor (FerroHEMT) which combines the high piezoelectric coefficients and low coercive field ferroelectricity in AlScN with the TNC effects, enables both high on-current and high-speed characteristics [2]. While the static charge-voltage (Q-V) characteristics of AlScN/AlN/GaN heterostructures has been carefully modeled in Ref. [3]. The TNC effects related to ferroelectricity in AlScN and related phenomena such as reverse DIBL and negative differential resistance (NDR) are not analyzed and included in the model [4]. To effectively utilize the advantages in the FerroHEMTs structure for circuit design, in this work, we identify the design constraints that must be met and develop model to capture the Q-V relation within AlScN/AlN/GaN heterostructures with TNC effects. We also extend the study and analysis from room temperature down to cryogenic level.*

Methodology: *The TNC origins from the difference between responding time of build-in polarization and screening charge at the materials interfaces. It can be observed when polarization switching current (dP/dt) exceeds free carrier displacement current (dQ/dt). When dP/dt largely increases, dQ/dt through a small depletion layer capacitance in the subthreshold region cannot fully balance. Then the voltage across the ferroelectric layer is reduced, which results in depolarization effect. We start with calibrating the static Q-V characteristics under different combinations of Sc composition, AlScN and AlN thicknesses in Sentaurus TCAD with 1D Schrodinger-Poisson solver at room temperature [5]. Then we carry out transient simulation in Sentaurus TCAD for the 1-D AlScN/AlN/GaN heterostructures. To observe the TNC effects, we carried out transient TCAD simulation on metal (M) / ferroelectric (F) / insulator (I) / semiconductor (S) structure, in which time dependent Landau-Khalatnikov (L-K) equation can be considered. To incorporate transient negative capacitance (TNC) effects into compact models for circuit design and simulation, we have modified the virtual source-based Q-V model for GaN HEMTs by integrating the dynamic L-K theory. This theory provides a time-dependent relationship between ferroelectric polarization and the electric field, as described in references [6, 7]. Additionally, we employed a 1D Schrödinger-Poisson solver to estimate the low-temperature characteristics.*

Summary: *We investigate and identify the optimal material and geometrical parameters of AlScN/AlN/GaN heterostructures that exhibit transient negative capacitance (TNC) effects, aiming to maximize carrier concentration at the heterointerface and achieve subthreshold slopes below the Boltzmann limit. We propose an analytical compact model that incorporates TNC effects to accurately describe the Q-V relationship within AlScN/AlN/GaN heterostructures.*

Giant Tunability of Electronic Properties of High Mobility Two-Dimensional Semiconductors *Chun Ning (Jeanie) Lau; The Ohio State University, United States*

Few-layer metal chalcogenides are promising material platforms for electronic, optoelectronic, and thermal applications, due to their high mobility, substantial band gap, and demonstrated synthesis in the wafer scale. Here I will present our recent work in two members of the material family with unprecedented mobility. In few-layer InSe quantum wells, we demonstrate electrostatic population and characterization of the second subband, with giant tunability of its energy, population, and spin-orbit coupling strength, via the control of not only layer thickness but also out-of-plane displacement field. A modulation of as much as 350% or over 250 meV is achievable, underscoring the promise of InSe for tunable infrared and THz sources, detectors and modulators. Moreover, for few-layer $PdSe_2$ *field effect transistors, we demonstratde large saturation current >350 mA/mm, and high field effect mobilities of ~ 700 and 10,000* cm^2/Vs *at 300K and 2K, respectively. At low temperatures, magnetotransport studies reveal unique octets in quantum oscillations that persist at all densities, arising from 2-fold spin and 4-fold valley degeneracies, which can be broken by in-plane and out-of-plane magnetic fields toward quantum Hall spin and orbital ferromagnetism.*

11:00 AM NM05.09.09
Mapping Domains and Domain Junctions in Mono- and Multi-Layer TMDs Using 4D-STEM—Toward Property Controlled 2D Device Materials *Hanako Okuno[1], Djordje Dosenovic[1], Arawinth Camatchy[1], Samuel Dechamps[1], Eva Desgue[2], Sergej Pasko[3], Pierre Legagneux[2], Nicola Vigano[1] and Alain Marty[1]; [1]CEA Grenoble, France; [2]Thales Research & Technology, France; [3]Aixtron, Germany*

Despite the increasing interest in 2D material-based devices, synthesized 2D layers generally contain inevitable intrinsic growth-related atomic defects, which are the cause of a discrepancy between the properties measured in synthesized materials and those theoretically predicted from a perfect model system. Among many atomic defects, a domain boundary is one of the dominant structural defects determining the intrinsic properties of 2D materials [1]. Identification of domains and quantitative localization of domain junctions on a large scale have become critical requirements for the development of high quality 2D materials and theoretically modeling 2D material-based device performance.
In this work, we demonstrate multi-scale analytical process using four-dimensional scanning transmission electron microscopy (4D-STEM); a new acquisition technique allowing to record a diffraction pattern at each pixel of the electron beam scanning position [2]. The generated 4D-datacubes provide local structural information with high precision and enable numerically reconstructing selected structural information as real space images. We present here the application of 4D-STEM techniques for the domain investigations in mono- and multi-layer 2D films.
First, orientation and polarity mapping is performed on wafer-scale highly oriented WS_2 *epitaxial layers. Typical domain junctions are identified and characterized using atomic resolution STEM imaging with the help of DFT calculations. Both rotational and polar inverted domains are then independently visualized at the micron scale by 4D-STEM mapping, using the position of 6-fold and 3-fold symmetry in diffraction patterns to extract quantitative local information. The distribution and density of different types of domain boundaries are quantitatively analyzed [3].*
Secondly, the lateral and vertical distribution of domains in 2D multilayer $PtSe_2$ *films is analyzed by combining 3-dimensionally resolved in-plane orientation maps. It has been previously reported that the electronic properties of*

$PtSe_2$ films vary with increasing number of layers, from semiconducting to semi-metallic in a single crystal [4]. The position and the in-plane and out-of-plane sizes of individual domains are analyzed by deconvoluting the multiple diffraction patterns resulting from the twisted domains superimposed within the 15ML films. The effects of the domain arrangement and the out-of-plane domain size on the conductivity and electronic properties of the $PtSe_2$ films are discussed by comparing samples with identical film thickness.
Finally, the results demonstrate the capability of the 4D-STEM multi-structural mapping method to characterize 2D films from the atomic to the micro-structures. This opens up possibilities for the construction of device scale structural models and further understanding of structure-property relationships in synthesized 2D device materials.

Magnetic Proximity Coupling to Defects In a Two-Dimensional Semiconductor *Muhammad Hassan Shaikh[1], Matthew Whalen[1], Dai Q. Ho[1], Aqiq Ishraq[1], Collin Maurtua[1], Kenji Watanabe[2], Takashi Taniguchi[2], Yafei Ren[1], Anderson Janotti[1], John Xiao[1] and Chitraleema Chakraborty[1]; [1]University of Delaware, United States; [2]National Institute for Materials Science, Japan*

The ultrathin structure and efficient spin dynamics of two-dimensional (2D) antiferromagnetic (AFM) materials hold unprecedented opportunities for ultrafast memory devices, artificial intelligence circuits, and novel computing technology. For example, chromium thiophosphate ($CrPS_4$) is one of the most promising 2D A-type AFM materials due to its robust stability in diverse environmental conditions and net out-of-plane magnetic moment in each layer, attributed to anisotropy in crystal axes (a and b). However, their net zero magnetic moment poses a challenge for detecting the Neel state that is used to encode information. In this study, we demonstrate the detection of the Neel vector by detecting the magnetic order of the surface layer by employing defects in tungsten diselenide (WSe_2). These defects are ideal candidates for optically active transducers to probe the magnetic order due to their narrow linewidth and high susceptibility to magnetic fields. We observed spin-polarized charge transfer in the heterostructure of bulk $CrPS_4$ and single-layer WSe_2 indicating type-II band alignment as supported by density functional theory (DFT) calculations. In the A-type AFM regime, the intensity of both right-handed and left-handed circularly polarized light emanating from the sample remains constant as a function of the applied magnetic field, indicating a constant polarized transition behavior. Our results showcase a new approach to optically characterizing the magnetic states of 2D bulk AFM material, highlighting avenues for future research and technological applications.

11:30 AM *NM05.09.11
Hexagonal and Amorphous Boron Nitride Thin Films for Next-Generation 2D Electronics and Battery Applications *Hyeon Suk Shin[1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)*

Hexagonal boron nitride (hBN) is a promising two-dimensional (2D) material owing to its unique optical properties in the deep-UV region, mechanical robustness, thermal stability, and chemical inertness. hBN thin films have gained significant attention for various applications, including nanoelectronics, photonics, single photon emission, anti-corrosion, and membranes. Thus, wafer-scale growth of hBN films is crucial to enable their industrial-scale applications. In this regard, chemical vapor deposition (CVD) is a promising method for scalable high-quality films. To date, considerable efforts have been made to develop continuous hBN thin films with high crystallinity, from *those with large grains to single-crystal ones, and to realize thickness control of hBN films by CVD. However, the growth of wafer-scale high crystalline hBN films with precise thickness control has not been reported yet. The hBN growth is significantly affected by substrate, in particular the type of metals, because the intrinsic solubilities of boron and nitrogen depend on the type of metal. In this talk, state-of-the-art strategies adopted for growing wafer-scale, highly crystalline hBN are summarized, followed by the proposed mechanisms of hBN growth on catalytic substrates. Furthermore, hBN on Cu foil can be used as a substrate for horizontal, uniform Li electrodeposition, where hBN plays a role in reducing the energy barrier for the surface diffusion of Li, thereby suppressing the formation of Li dendrites. The uniform Li film on hBN/Cu is very promising for Li metal anodes for next-generation batteries. In addition, amorphous BN (aBN) as a counterpart of crystalline hBN is introduced. Detailed structural characterisation indicates that a-BN is sp^2-hybridised, with no measurable crystallinity, and mechanically robust, with excellent diffusion-barrier characteristics. The aBN thin film shows ultra-low dielectric constant (< 2.5), indicating great potential for its applications in Cu interconnects of integrated circuits.*

Multifunctional MXene/Carbon Nanotube Janus Film for Infrared Shielding/Detection, Electromagnetic Shielding and Joule Heating in Harsh Environments *Chong Min Koo; Sungkyunkwan University, Korea (the Republic of)*

Multifunctional, flexible, and robust thin films capable of operating in demanding harsh temperature environments are crucial for various cutting-edge applications. This study presents a multifunctional bi-layer Janus film that integrates a highly crystalline Ti3C2Tx MXene and a robust carbon nanotube (CNT) film through strong hydrogen bonding. The hybrid film not only exhibits high electrical conductivity (4250 S cm-1), but also demonstrates robust mechanical strength and durability in both extremely low and high temperature environments, along with exceptional resistance to severe thermal shocks. This hybrid film reveals remarkable multifunctionality, including an outstanding electromagnetic shielding effectiveness (SE) of 72 dB at a thickness of 15 μm in X band and excellent IR shielding capability with an average emissivity of 0.09 (a minimal value of 0.02). Additionally, the Janus film demonstrates superior thermal camouflage performance over a wide temperature range (-1 to 300 oC), achieving a notable reduction in the radiated temperature by 243 oC against a background temperature of 300 oC. Furthermore, the Janus film exhibits outstanding IR detection capability, characterized by a 44% increase in resistance when exposed to 250 W IR radiation. The Janus film also exhibits superior joule heating performance compared to other nanomaterials. This multifunctional MXene/CNT Janus film offers a feasible solution for electromagnetic shielding, IR shielding/detection, and joule heating under challenging conditions.

1:45 PM NM05.10.02
Graphitic Polytypes in Penta-Layer Graphene *Nirmal Roy, Shaked Amitay, Simon Sallah Atri and Moshe Ben Shalom; Tel Aviv University, Israel*

Graphitic polytypes, with distinct meta-stable stacking arrangements of graphene layers, exhibit a diverse range of *electro-optical properties. Polytypes with flat dispersions can show electronic correlations such as orbital magnetism, unconventional superconductivity, and anomalous fractional quantum Hall states at low temperatures. Recently, we reported the emergence of spontaneous electric polarization and its intriguing doping dependence at room temperature for mixed-stacked tetra-layer polytypes. These phenomena extend to multilayer graphitic polytypes. For instance, the commensurate stacking of five graphene layers can result in six different periodic crystal structures, each with unique symmetries and responses, particularly under infrared/low energy excitations. Among these, two polytypes are expected to exhibit spontaneous electric polarization due to broken inversion and mirror symmetry. However, identifying specific polytype crystals and their orientations remains challenging. We address this by reporting distinct Raman, second harmonic, and electric surface potential measurements for the six polytypes in penta-layers, enabling their deterministic identification. Additionally, we report the relative abundances and stability of the polytypes and their in-plane and out-of-plane polar responses. These advancements are a crucial step towards the development of multi-ferroic, "slidetronic" devices that rely on structural transitions between polytypes through interlayer van der Waals sliding.*

2:00 PM NM05.10.03

Soft Vibration Sensor Based on Atomically Thin MoS_2 Nanoribbon Networks *Xufan Li[1], Chengyi Xu[2], Zhenan Bao[2] and Avetik Harutyunyan[1]; [1]Honda Research Institute USA, United States; [2]Stanford University, United States*

Soft, low-profile, and conformal vibration sensors that can simultaneously and continuously measure and differentiate weak, complex physiological activities from human body are highly desired. Most of the commercially available vibration sensors are bulky and rigid and have limited form factors, which largely limit the implementation in human-interfacing applications requiring seamless integration, safer interaction, improved signal quality, and continuous long-term recording. Low-dimensional materials such as carbon nanotubes, metal nanowires, and two-dimensional materials (e.g., graphene and transition metal dichalcogenides (TMDs)) have been emerging as potential candidates for soft vibration sensors. However, they still suffer the drawbacks of low sensitivities to small mechanical stimuli, structural non-uniformity, and poor mechanical robustness over repeated deformation. In this work, we present an ultrathin and soft vibration sensor made of directly grown single atomic layer MoS_2 nanoribbon networks (NRNT) as an active sensing material and styrene-ethylene-butylene-styrene (SEBS) thermoplastic elastomer. In contrast to the same MoS_2 NRNT on rigid polyethylene terephthalate (PET) that shows typical negative piezoresistive gauge factor (GF) upon bending, the MoS_2 NRNT/SEBS system is a crack-based sensor, which renders a positive GF with a much higher absolute value (~1500 at 1.5% strain) compared to the MoS_2/PET system (~200 at 1.5% strain) and other low-dimension materials based sensor under similar strain. Compared to continuous MoS_2 film, the NRNT shows much higher mechanical robustness, ideal for long-term sensing with bending-unbending cycles upon vibration. The MoS_2/SEBS is able to sense acoustic vibration up to 500 Hz with a signal-to-noise of up to 40 dB and differentiate frequencies of mixed vibration signals. The MoS_2/SEBS vibration sensor shows great potential for soft electronics in health monitoring, biomedical, and clinical applications.

2:15 PM NM05.10.04

Fabrication and Characterization of Ce:YIG Thin Films with Sub-Micron Magnetic Domains for Advanced Magnetooptical Devices *Taichi Goto[1], Yuki Yoshihara[1], Takumi Koguchi[1], Toshiaki Watanabe[2], Kanta Mori[1], Hibiki Miyashita[1], Caroline A. Ross[3] and Kazushi Ishiyama[1]; [1]Tohoku University, Japan; [2]Shin-Etsu Chemical Co., Ltd.,, Japan; [3]Massachusetts Institute of Technology, United States*

In the realm of magneto-optics and spin photonics, researchers are increasingly interested in optical devices that leverage magnetic materials, particularly those exhibiting nano to microscale magnetic domains. These innovative devices encompass a range of applications, from photonic integrated circuits and advanced 3D displays to *holographic storage systems, high-power Q-switched lasers, random number generators, and optical computing components. Central to these advancements are magnetooptical materials that can maintain nanoscale magnetic domains while demonstrating substantial magnetooptical effects and high transparency [1]. To tackle this challenge, our research centered on cerium-substituted yttrium iron garnet (Ce:YIG) films, aiming to create films with strong perpendicular magnetic anisotropy using ion beam sputtering techniques.*

We deposited a 130 nm thick film of Ce:YIG on a gadolinium gallium garnet (GGG) substrate using radio-frequency ion beam sputtering (RF-IBS). During deposition, the substrate was maintained at 810 °C and rotated to ensure uniform film growth [2]. We confirmed the film's high crystallinity and structural integrity through X-ray diffraction (XRD) and transmission electron microscopy (TEM) analyses.

Using a Faraday effect microscope with a 470 nm laser source, we observed maze-shaped magnetic domains. These domains measured about 300 nm in width, with domain walls estimated to be approximately 50 nm wide. Vibrating-sample magnetometry (VSM) verified perpendicular magnetic anisotropy with an anisotropy energy of roughly 13.7 kJ/m^3 and a saturation magnetization of 130 emu/cm^3. The film exhibited a Faraday rotation angle of -1.1 °/μm at 1064 nm. X-ray photoelectron spectroscopy (XPS) showed that the electronic state of cerium was predominantly Ce^{3+}.

We employed computational modeling using high-performance parallel computing to simulate the magnetic domain state in a 5 x 5 x 0.12 μm^3 volume with a 10 x 10 x 10 nm^3 cell size. The simulation produced domain sizes of about 150 nm and domain walls of approximately 50 nm. While the experimental and computational results differed in scale, both demonstrated maze-like patterns, validating the model's accuracy.

These findings underscore the potential of RF-IBS-created Ce:YIG thin films for applications such as magnetooptical recording, holographic media, and high-power Q-switched lasers. The combination of perpendicular magnetic anisotropy, sub-micron maze-shaped domains, and high Faraday rotation makes these films promising candidates for further magnetooptical applications.

Ultralow-Thermal-Budget Processing for Electronic-Grade Metal Chalcogenides and Elemental Chalcogen Films *Joonki Suh; Ulsan National Institute of Science and Technology, Korea (the Republic of)*

van der Waals coupled chalcogenides show a wealth of exotic physical phenomena when confined into the 2D lattice, and the relevant electronic devices thus far have defined themselves as a promising building block of nanoelectronics owing to the near-atom thickness, superior electrostatic control, and adaptable device architecture. This talk will highlight how such emerging materials can further benefit from ultralow-thermal-budget processing and new device configurations. I will mainly introduce vapor-phase synthetic strategy for wafer-scale, thickness-controlled, and low-temperature deposition techniques to bring such new electronic functionalities into device-level applications. To be specific, we demonstrate the wafer-scale growth of mono-elemental 2D tellurium

(Te) thin films using an annealing-free, low-temperature ALD process. As-deposited Te films exhibit exceptional homogeneity, precise layer controllability, and 100 % step coverage in high aspect ratio nanostructures. As a 2D building block with intrinsic p-type transport characteristics, ALD-grown Te films are employed for fabricating 2D/2D and mixed-dimensional 2D/3D vertical p-n heterojunction diodes exhibiting well-defined current rectification. Additionally, we showcase an ALD-Te-based selector device with fast switching time, selectivity and low V_{th}. As a second example, we also developed phase-tailored synthetic strategies where we achieve wafer-scale production of tin selenides (SnSe and $SnSe_2$) in the 2D limit by utilizing a low-temperature MOCVD process. Directly grown 2D $SnSe_2$ exhibits outstanding crystallinity and tunable thickness of nm-precision, and SnSe, which has intrinsic limitations for 2D film growth, can be prepared via a thermally driven phase transition, thereby retaining all of the advantages in the MOCVD-grown product. With those developed low-temperature processing, I will share more recent progress toward BEOL-compatible low-power steep-slope switch and cryogenic nonvolatile memory devices, all based on synthetic chalcogenide thin films.

4:00 PM NM05.11.02
High-Throughput Multi-Scale Computational Atomistic Materials and TCAD Device Study of UWBG-Metal Heterointerfaces and Heterojunctions *Ugonna C. Ohiri and Xiangyi Guo; Northrop Grumman Corporation, United States*

2D Ultrawide bandgap (UWBG) materials (e.g., diamond, gallium oxide, boron nitride, and aluminum nitride) are a new class of materials with a superior combination of electronic and thermal properties. However, UWBG materials still require further development that should help unlock new and unexplored physical regimes. For example, developing Schottky and ultralow resistance ohmic contacts to UWBG materials is still a work in progress, but is critical for minimizing power losses and maintaining operability at very high temperatures and harsh environments needed for developing high-performance UWBG-based devices.

Atomistic materials and Technology Computer-Aided Design (TCAD) device modeling and simulation are prime accelerators for understanding the formation and stability of various structure and guiding subsequent experimental device design. For example, modeling the UWBG-metal heterointerface can be useful for estimating and analyzing the Schottky barrier, which can aid the down-selection of contact metals needed for UWBG fabrication and device design. Here, we report on a deep dive investigation into various UWBG-metal heterointerfaces and UWBG nanoscale heterostructure devices using high-throughput, multi-scale Density Functional Theory (DFT) and Non-Equilibrium Green's Function (NEGF) atomistic simulation techniques. DFT and NEGF are used extract various atomistic materials (e.g., electronic band-structure, Raman, and Projected Density of States) and nanoscale device parameters (e.g., nanoscale current-voltage (I-V) characteristic curves, Schottky barrier, and ideality factor). Machine-Learned Force Fields (MLFF) were also briefly performed to ensure near ab-initio simulation accuracy of the UWBG heterostructures and to help accelerate the computationally expensive DFT simulations (i.e., 20-10,000 x speedup). UWBG TCAD device modeling and simulation were also performed and paired with the atomistic materials simulations to help guide systematic UWBG device design.

Overall, these results will help shed light into the various UWBG materials are within the physical design space and lay a general pathway for developing the next-generation of UWBG-based devices, UWBG-based circuits, and higher-level UWBG-based system architectures.

High-Throughput Computational Design of High-Performance High-K Dielectrics for 2D Electronics *Ming Yang; The Hong Kong Polytechnic University, Hong Kong*

Two-dimensional (2D) semiconductors such as molybdenum disulfide (MoS2) could potentially replace silicon in future electronic devices. However, the high-performance integration of high-k dielectrics on 2D semiconductors remains a grand challenge. In this talk, we show that for the interface between conventional high-k dielectrics and 2D MoS_2, hydrogenation is a desired approach to passivate the dangling bonds and improve the interface properties, in which the hydrogenation can selectively occur at high-k dielectrics such as Si_3N_4 and HfO_2, and do not affect the 2D semiconductor MoS_2. We further demonstrate the improved performance for hydrogenated interface of HfO_2/MoS_2, as evidenced by the increased carrier mobility, narrow hysteresis window, and much reduced interfere state density. We find that this selective hydrogenation strategy can be generalized to any interface of high-k dielectrics and 2D semiconductors, where there exists free energy difference for hydrogen adsorption between them. Finally, we report a data-driven approach to accelerate the development of various promising inorganic molecular crystals as the high-performance high-k dielectrics for 2D MoS_2 based electronic devices. These results deepen the understanding the interface of 2D semiconductors and high-k dielectrics, and could be useful for developing a broad range of high-performance 2D electronic and optoelectronic devices.

Structure Engineering of Fe-Doped MoS_2 by Oxygen Incorporation and Sulfur Source Control for Efficient and Accelerated Fenton-Like Reaction *Ziang Chang, Soliu O Ganiyu and Mohamed G. El-Din; University of Alberta, Canada*

Fe-based catalysts have been widely studied for PMS activation in Fenton-like reactions. Among them, atomically Fe-doped catalyst has attracted great interest because of its high atom utilization and tunable electronic structure of active sites. 2D molybdenum disulfide (MoS_2) has been developed as a potential cocatalyst/support for Fe-doped catalyst for its large surface area, tunable electronic structure and high chemical stability. However, the inert basal plane and limited edge site of 2H phase MoS_2 inhibited the co-catalytic/structure-modulating performance. In this work, we combine the strategies of atomic Fe doping and defect engineering to regulate the electronic structures of MoS_2-Fe and fabricated atomically Fe-doped edge-rich and high purity 1T phase oxygen-incorporated molybdenum disulfide (O-MoS_2-Fe_1) as a heterogeneous Fenton-like catalyst for the first time by controlling the sulfur source. SEM and TEM images of O-MoS_2-Fe_1 presented the flower-like morphology same as the structure of the MoS_2. The HRTEM image of O-MoS_2-Fe_1 showed a widened interlayer spacing of 0.68 nm compared to O-MoS_2-Fe_2 (0.64 nm). Element mapping images confirmed a homogeneous distribution of Fe-dopants on O-MoS_2-Fe_1. The XRD pattern of O-MoS_2-Fe_1 showed the characteristic peaks of MoS_2, indicating that O-MoS_2-Fe_1 retains the original structure of MoS_2. Additionally, the XRD pattern showed a lower (002) peak intensity, suggesting a higher number of edge planes in O-MoS_2-Fe_1. The higher intensity of J_1, J_2, and J_3 characteristic vibrational peaks and lower intensity of characteristic vibrational peaks of E^1_{2g} and A_{1g} shown in Raman spectra for O-MoS_2-Fe_1 proved the existence of higher proportion of 1T phase MoS_2. The deconvoluted XPS spectra of Mo 3d presented 65.2% 1T Phase Mo (IV) of O-MoS_2-Fe_1 while 47.7% 1T phase Mo (IV) in O-MoS_2-Fe_2, proving the higher purity of 1T phase Mo (IV) in O-MoS_2-Fe_1. The deconvoluted O 1s core-shell spectra and XPS-Fe 2p spectra showed that Fe (II)-S species present in O-MoS_2-Fe_1, while O-MoS_2-Fe_2 with Fe (III)-S species and Fe-O bond. Linear sweep voltammetry (LSV) demonstrated the superior electron transfer performance of O-MoS_2-Fe_1 and cyclic voltammetry (CV) showed excellent redox capacity. Excellent micropollutant degradation performance, ibuprofen (IBP) as a model compound, was achieved in 20 min. Other experimental parameters, such as pH effect, dosage influence, and water chemistry, were also explored. According to the results of quenching experiments and EPR tests, $SO_4^{\cdot-}$ and $O_2^{\cdot-}$ were confirmed as the direct species to decompose IBP molecule during the reaction. Electron-transfer pathway also played an important role. This study provides new insights into constructing atomically Fe-doped catalysts with Fe-Mo dual sites in Fenton-like processes.

Computational Insights into Phase Changes in Two-Dimensional Transition Metal Dichalcogenides *Katherine Inzani; University of Nottingham, United Kingdom*

Layered van der Waals crystals present an extensive structural phase space of polytype, dimensionality, twist and strain. In addition, charge density wave materials exhibit periodic lattice distortions associated with correlated electronic states. Across this materials class, enhanced coupling between structure and functional properties provides a rich parameter space of electronic, optical and magnetic behaviour. Leveraging phase transitions in these materials presents routes to devices based on controlled, multifunctional switching.

Here, I will discuss these diverse, controllable properties in transition metal dichalcogenides (TMDCs). We have recently exhibited hard ferromagnetism in an intercalated TMDC, with magnetic order persisting down to the two-dimensional limit [1]. We used first principles calculations to identify metastable spin states that are strongly dependent on interlayer separation, suggesting that thermal or strain-based mechanisms are available to control the magnetic properties. In addition, we showed the modulation of electronic properties with phase change in mixed polytype structures exhibiting charge density wave distortions [2].
